Section 4 of the questionnaire was adapted from a previously validated questionnaire on telemedicine in movement disorders [16]. This part was designed to compare remote programming with standard programming directly. Respondents were prompted to assess their perceptions of remote programming compared with standard programming, providing comparative insights that formed the basis of our analysis and discussion.

Data Analysis

Demographic characteristics were summarized using median values, IQR, and frequencies (percentage). Group comparisons were conducted using the Mantel-Haenszel chi-aquare test for categorical data and either the 2-tailed *t* test or Wilcoxon rank-sum test for continuous data, depending on their distribution.

Ordinal logistic regression was used to identify factors influencing the burden of each standard programming session, including caregiver needs, lost working time, and travel costs. Variable selection for the regression model followed a stepwise (both forward and backward) approach. Statistical significance was set at a 2-tailed *P* value of less than .50.

Data analysis was performed using SAS (version 9.4; SAS Institute Inc), with all data stored and managed in Excel (Microsoft). Responses to open-ended questions were categorized and analyzed using a web-based tool (Weiciyun). Detailed processes for logistic regression and the analysis of open-ended questions are provided in Multimedia Appendix 3.

Ethical Considerations

The study protocol was approved by the Ethics Committee of the Ruijin Hospital (Clinical Ethics Review [2023] No 231) and adhered to the principles of the Declaration of Helsinki. All patients were informed about the scientific purpose and their right to decline participation. Web-based informed consent was obtained at the beginning of the questionnaire.

Results

Overview of Participants

After excluding 7 records due to repeated submissions and 6 due to inaccurate names, 225 returned questionnaires were included in the analysis, resulting in a response rate of 49%. All patients had experienced standard programming, and 132 patients had also undergone remote programming (Table 1). Among those using remote programming, 54 (41%) had IPGs implanted by PINS, while the remaining 78 (59%) had devices from SceneRay.

The demographic profile was as follows: 105 (47%) were female, and the median distance from their residence to our center was 194 km, with an IQR of 91 - 513 km. The median age was 66 years (IQR 59 - 70), and the median disease duration was 11 years (IQR 8 - 15). Additionally, 51 (23%) patients had attained at least a junior college education, 195 (87%) were married, and only 18 (8%) were still employed.

Using the Unified Parkinson Disease Rating Scale III, we categorized 135 patients as having the tremor-dominant subtype. Additionally, 42 patients were classified under the postural instability/gait disorder subtype, 13 were deemed to have an indeterminate subtype, and scores were unavailable for the remaining 35 patients.

Table . Characteristics of the respondents.

Characteristics		All (n=225)	TD[a] (n=135)	PIGD[b] (n=42)	*P* value (TD versus PIGD)
Age (year), median (IQR)		66 (59 - 70)	66 (59 - 69)	68 (57 - 71)	.37
Sex (female), n (%)		105 (47)	63 (47)	19 (45)	.87
Disease duration (year), median (IQR)		11 (8 - 15)	11 (8 - 15)	11 (8 - 14)	.71
Follow-up period (year), median (IQR)		2 (0 - 3)	2 (0 - 2)	2 (1-3)	.20
Distance (km), median (IQR)		194 (91 - 513)	207 (98 - 567)	152 (34 - 367)	.09
Education, n (%)					.78
	Elementary school and below	61 (27)	37 (27)	12 (29)	
	High school and below	113 (50)	70 (51)	19 (45)	
	Junior college and above	51 (23)	29 (21)	11 (26)	
Marital status, n (%)					.56
	Married	195 (87)	114 (84)	37 (88)	
	Single, divorced, or widowed	30 (13)	21 (16)	5 (12)	
Employment status, n (%)					.36
	Employed	18 (8)	10 (7)	5 (11)	
	Unemployed, retired, or underage	207 (92)	125 (93)	37 (88)	

[a] TD: tremor-dominant.

[b] PIGD: postural instability/gait disorder.

Comparison of Programming Burdens Between 2 Methods

For standard programming sessions (n=225), 191 (85%) patients reported requiring more than 1 caregiver for accompaniment, 129 (57%) patients indicated that more than 2 days of work were lost for themselves or their caregivers, 98 (44%) patients stated that the cost for each session ranged from US $42 to US $146, and 14 (6%) patients incurred costs exceeding US $421. Furthermore, 159 (71%) patients experienced waiting times of over 60 minutes (Figure 1). No significant differences in these burdens were observed between the tremor-dominant and postural instability/gait disorder groups (not shown).

In remote programming sessions (n=115; Figure 2), 115 (87%) patients needed more than 1 caregiver, 38 (29%) patients reported more than 2 days of lost working time, and 93 (70%) patients perceived their costs of remote programming to be lower than standard programming. The lost working time was significantly reduced in remote programming compared with standard programming (*P*<.001), although no significant difference was noted in the number of required caregivers (*P*=.51).

Figure 1. Burden of programming in standard programming with deep brain stimulation (n=225). Data are presented as numbers (center of the bar) and percentages (vertical coordinate).

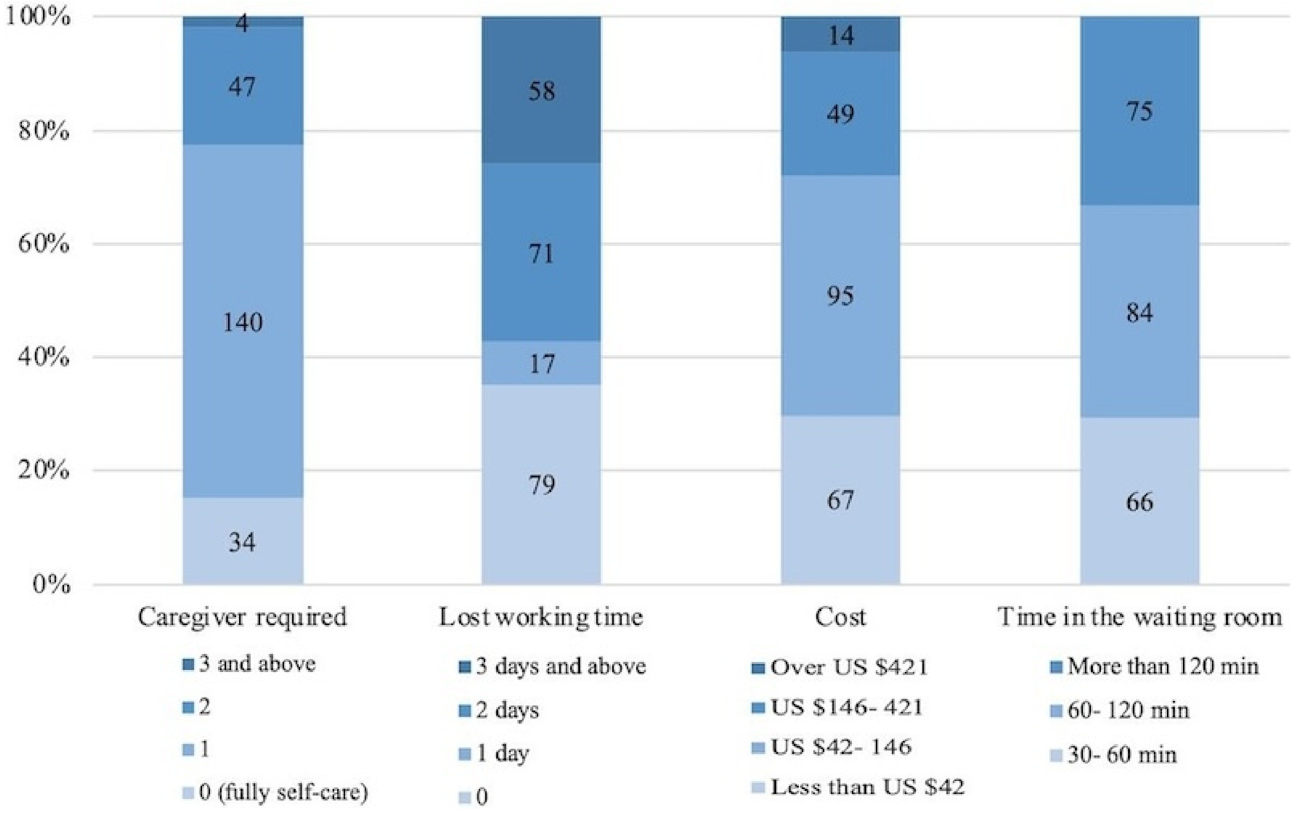

Figure 2. Burden between 2 programming methods (n=132). Data are presented as numbers (center of the bar) and percentages (vertical coordinate). *P*<.05 is considered statistically significant. RP: remote programming; SP: standard programming.

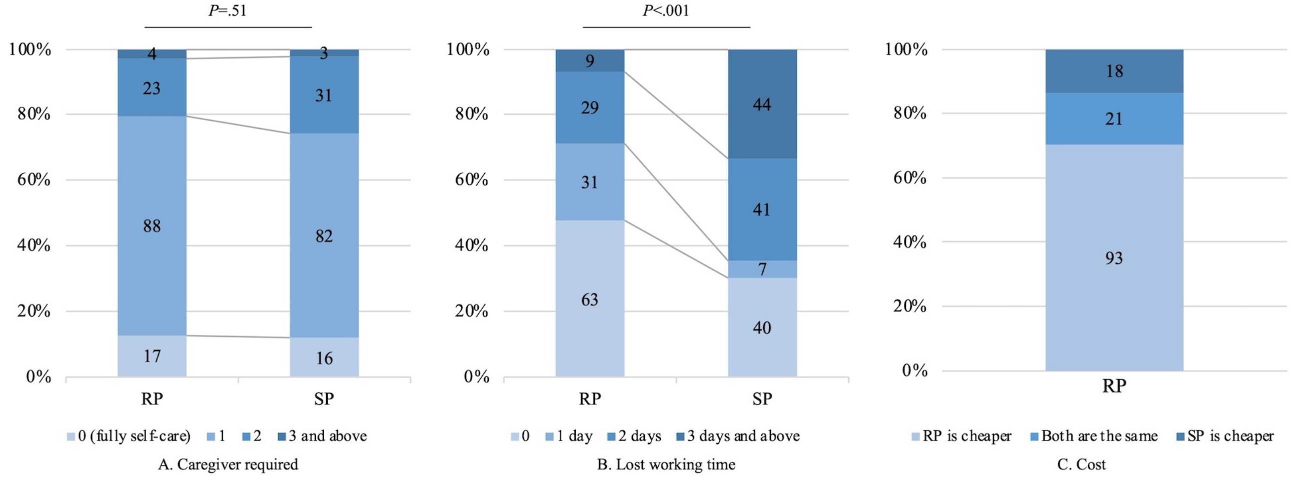

Factors Associated With Standard Programming Burdens

In the regression analysis, covariates of age, gender, distance, marital status, and education level were considered (Table 2). The requirement for caregivers was positively correlated with age (odds ratio [OR] 1.070, 95% CI 1.038 - 1.103, *P*<.001) and correlated with being female (OR 0.519, 95% CI 0.300 - 0.900, *P*=.02) as well as being single (OR 0.302, 95% CI 0.131 - 0.695, *P*=.005). Lost working time was positively correlated with distance (OR 1.001, 95% CI 1.000 - 1.001, *P*=.003) and negatively correlated with education level (high school and below: OR 0.312, 95% CI 0.153 - 0.636, *P*=.001; junior college and above: OR 0.446, 95% CI 0.250 - 0.796, *P*=.006). Additionally, the travel cost was also positively correlated with distance (OR 1.002, 95% CI 1.001 - 1.003, *P*<.001). No significant associations were observed between the preoperative Unified Parkinson Disease Rating Scale III score and any of the burden aspects (not shown).

Table . Factors associated with burdens of standard programming.

Factors	Caregiver required		Lost working time		Travel cost	
	OR[a] (95% CI)	*P* value	OR (95% CI)	*P* value	OR (95% CI)	*P* value
Age	1.070 (1.038 - 1.103)	<.001[b]	—[c]	—	—	—
Sex (reference=male)	0.519 (0.300 - 0.900)	.02[b]	—	—	—	—
Distance	—	—	1.001 (1.000 - 1.001)	.003[b]	1.002 (1.001 - 1.003)	<.001[b]
Marital status (reference=married)	0.302 (0.131 - 0.695)	.005[b]	—	—	—	—
Education: H[d] (reference=E[e])	—	—	0.312 (0.153 - 0.636)	.001[b]	—	—
Education: J[f] (reference=E)	—	—	0.446 (0.250 - 0.796)	.006[b]	—	—

[a] OR: odds ratio.

[b] *P*<.05 is considered statistically significant.

[c] Not applicable.

[d] H: High school and below.

[e] E: Elementary school and below.

[f] J: Junior college and above.

Attitude Toward 2 Programming Methods

Attitudes toward the 2 programming methods were reflected in the questionnaire results (satisfaction with remote programming section of the questionnaire). Among 132 patients with experience in remote programming (Figure 3), 53 (40%) patients disagreed (strongly) that using the remote programming system was difficult, and 75 (57%) patients disagreed (strongly) that communicating with doctors during remote sessions was challenging. A small percentage of respondents (8/132, 6%) viewed remote programming as an intrusion of their privacy, and a similar number (10/132, 7%) were (strongly) dissatisfied with the efficacy of remote programming. In addition, a significant majority appreciated the convenience (92/132, 69%) and the diagnostic accuracy (83/132, 63%) of remote programming.

When comparing remote to standard programming, 62 (47%) patients agreed (strongly) that doctors could better resolve their issues in standard programming, while 44 (33%) patients expressed a neutral opinion. Half of the patients (66/132, 50%) agreed (strongly) that the quality of remote programming matched that of standard programming. However, a substantial majority (102/132, 77%) believed their trust in doctors would increase with standard programming. Regarding their preferred method for future programming, 81 (62%) patients opted for remote programming. These results showed no significant differences between the 2 manufacturers (not shown).

Among 93 patients who had never used remote programming, those individuals typically lived closer to the medical center and had different educational levels compared with those who had used it. The top 3 reasons cited for not using remote programming were as follows: (1) a belief that remote programming might not be as convenient as hospital visits; (2) concerns about the effectiveness of remote programming; and (3) perceptions that remote programming was more expensive than hospital visits (Tables S1 and S2 in Multimedia Appendix 4).

The open-ended questions underscored the advantages and disadvantages of each programming method (Table 3). Remote programming was favored for its convenience and cost-effectiveness, though there were concerns about personal payment costs and the need for more scheduling resources. Conversely, standard programming was valued for direct doctor interaction and insurance coverage of fees, but issues like limited appointment availability and long waiting times were frequent complaints.

Figure 3. Perception of remote programming among patients (n=132). RP: remote programming; SP: standard programming.

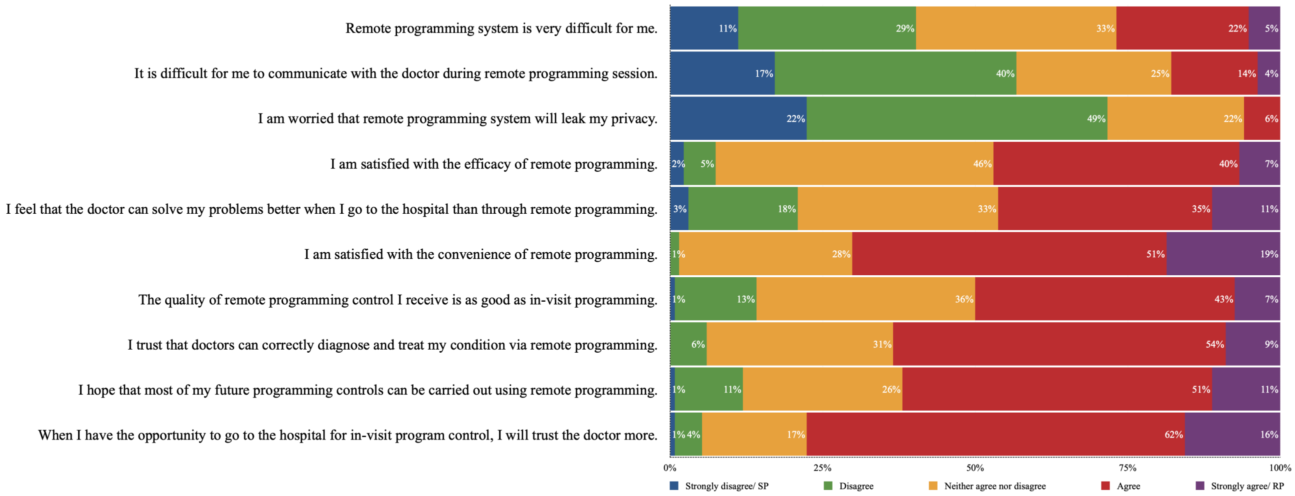

Table . Word frequency analysis of the pros and cons between 2 programming methods.

Programming method and category and comments ranked by frequency (top 3)			Count
Remote programming			
	Neg [a]		
		Hope the cost of personal payment can be reduced.	85
		Hope there are more appointment resources.	55
		Hope the remote programming system will be easier to use.	38
	Pos [b]		
		Remote programming is very convenient.	107
		Remote programming avoids long queue times for standard programming.	106
		Remote programming is cheaper.	40
Standard programming			
	Neg		
		It’s difficult to get an appointment for standard programming.	139
		Waiting too long in the waiting room.	117
		I hope the programming session can be longer at each time.	92
	Pos		
		I can communicate with the doctor face to face about my condition.	168
		The fee of programming could be paid through medical insurance.	40
		The doctor can give me a prescription directly for me to get the medication.	39

[a] Neg: negative comment.

[b] Pos: positive comment.

Discussion

Principal Findings

This survey study is the first to comprehensively examine the burdens associated with postoperative programming sessions of DBS from multiple perspectives. It also compares attitudes toward 2 different programming methods. Key findings include the following: (1) significant burdens were observed in terms of the number of required caregivers, lost working time, and travel costs, which heavily impacted patients and their caregivers; (2) patients facing higher risks of in-clinic programming burdens, such as those related to travel distance, age, and education level, might benefit more from remote programming; and (3) although remote programming has generally received positive feedback, there are specific areas where improvements are necessary.

As the coverage rate of DBS in standard programming increases annually [7], the associated costs are also expected to rise. A nationwide study from Hungary revealed that travel expenses could average €922.7 (≈US $1028) over 10 years following DBS [4]. Considering the median disposable income in China is US $4398 per year [17], the travel costs become significant for the 63 patients (28% of this study's cohort) who spend more than US $421 per standard programming session, especially assuming the need for 2 - 3 sessions annually post-surgery [18]. In this study, 93 (70%) patients confirmed that the costs of remote programming were lower than those of standard programming. Furthermore, a recent study indicated that, with the adoption of remote programming, 18 patients with Parkinson disease living farther from medical facilities received the same number of postoperative procedures as those residing nearby but at a lower average cost per programming session [15].

In addition to cost savings, the flexibility in time and space provided by remote programming is another substantial benefit. According to our survey, 159 (71%) patients reported needing to wait in the waiting room for more than an hour. Long waiting times coupled with short programming durations were common complaints about standard programming, as highlighted in the open-ended responses (Table 3). In China, the average waiting time for outpatient consultations in public hospitals is approximately 24.2 minutes [19]. The prolonged waiting times in DBS programming can be attributed to the time needed to observe symptom response to DBS stimulation [20], as well as the discrepancy between the high demand for postoperative programming and the limited availability of neurology specialists for programming. The web-based appointment system used in remote programming can eliminate excessive waiting times, and the home environment also provides a more comfortable and familiar setting for remote programming compared with a crowded hospital waiting room.

Patients at risk of high postoperative programming burdens are more likely to benefit from remote programming. In this study, for each standard programming session, factors such as longer distances and lower education levels were associated with increased lost working time as well as travel costs. An IPG capable of remote programming would be recommended for these patients. However, not all patients perceived remote programming to have these advantages. Ninety-three participants had never used remote programming; they believed that traditional in-person programming was a cheaper and more convenient option for them and expressed concerns about the effectiveness of remote programming. Living closer to our center may be the primary reason these individuals prefer standard programming, and varying education may also be caused by regional differences.

A previous British study highlighted that 174 (82%) patients with movement disorders preferred in-person medical treatment over telemedicine approaches once COVID-19 restrictions were lifted [16]. However, in our study, 81 (62%) patients expressed a willingness to continue using remote programming as their primary method. The contrast can be attributed to 2 factors. First, patients in this survey had undergone DBS surgery at our center and were familiar with the programming physicians, which could increase their trust in the doctor. In fact, 83 (63%) patients expressed trust in the doctor's diagnosis, compared with only 32 (15%) patients in the previous study. Second, telephone consultations were mostly used in the previous study, while during the remote programming sessions, patients and physicians communicated through real-time videoconferencing, which may have facilitated better communication compared with the telephone.

Highlighted in the open-ended responses, remote programming was favored for its convenience and cost-effectiveness, though concerns about out-of-pocket costs and the lack of appointment resources were noted. While remote programming reduces travel expenses and is especially beneficial for patients living far from medical facilities, some still perceive it as prohibitively expensive. In China, telemedicine fees are determined by doctors based on demand and their business volume. Although most outpatient procedures are covered by medical insurance, services provided by internet hospitals typically are not, leading many patients to view these as direct expenses. Conversely, standard programming was valued for its direct communication with doctors and coverage of programming fees by insurance, but it also drew complaints regarding the availability of appointments and long waiting times (Table 3). Clinicians need to carefully consider these factors to recommend the most suitable programming method for each patient, ensuring that both medical and personal needs are effectively met. This personalized approach will help maximize the benefits of DBS therapy while minimizing its burdens.

As DBS has been increasingly used among patients with Parkinson disease, labor-intensive postoperative management is increasingly burdensome for both clinicians and patients. To enhance the programming workflow, advanced technologies like closed-loop stimulation, which relies on various input signals [21], and image-guided programming based on visualization of DBS leads [22] are being developed. Patient feedback is still indispensable in these advancements. Although indirectly, remote programming offers a convenient method for clinicians to communicate with and gather feedback from patients. The integration of remote programming with these emerging technologies holds significant potential for improving post-DBS management.

Limitation

Several limitations of this study warrant consideration. The first is the single-center design with a low response rate. This survey was conducted at a single center and achieved a response rate of only 49%. This relatively low response rate could limit the generalizability of the findings and suggests caution when interpreting the applicability of the results to other settings. The variations in postoperative management strategies and the experience levels of programming physicians across different centers could influence the outcomes. The second limitation is the short follow-up duration. The median follow-up duration for participants in this study was 2 years. Considering that DBS has been shown to be cost-effective over a 15-year period for advanced standard programming in China [23], this limited follow-up may underestimate the long-term burdens faced by patients and their families. The third limitation is missing preoperative motor assessments. Preoperative motor assessment was not available for 32 patients, potentially compromising the validity of related conclusions. This missing data limits the strength of our findings concerning preoperative conditions and postoperative outcomes.

Conclusion

DBS postoperative programming places burdens on patients in standard programming and their caregivers in many aspects, and remote programming could alleviate such burdens in terms of the lost working time and total costs. Identifying patients at risk of such burdens before surgery and choosing IPGs with remote programming functions would help reduce the overall postoperative burden. Although the overall satisfaction of remote programming is high, a more complete and sounder system is still required to improve postoperative management.

Acknowledgments

We would like to thank all participants for partaking in the study. The authors declare financial support was received for the research, authorship, and publication of this article. This study was funded by the Shanghai Municipal Health Commission (grant number 202140181 to DL), the Shanghai Science and Technology Commission (grant number 22Y11903900 to DL), and Guangci Innovative Technology Launch Program (GCQH202205 to DL).

Abstract

Background: Cognitive impairment and dementia pose a significant challenge to the aging population, impacting the well-being, quality of life, and autonomy of affected individuals. As the population ages, this will place enormous strain on health care and economic systems. While computerized cognitive training programs have demonstrated some promise in addressing cognitive decline, adherence to these interventions can be challenging.

Objective: The objective of this study is to improve the accuracy of predicting adherence lapses to ultimately develop tailored adherence support systems to promote engagement with cognitive training among older adults.

Methods: Data from 2 previously conducted cognitive training intervention studies were used to forecast adherence levels among older participants. Deep convolutional neural networks were used to leverage their feature learning capabilities and predict adherence patterns based on past behavior. Domain adaptation (DA) was used to address the challenge of limited training data for each participant, by using data from other participants with similar playing patterns. Time series data were converted into image format using Gramian angular fields, to facilitate clustering of participants during DA. To the best of our knowledge, this is the first effort to use DA techniques to predict older adults' daily adherence to cognitive training programs.

Results: Our results demonstrated the promise and potential of deep neural networks and DA for predicting adherence lapses. In all 3 studies, using 2 independent datasets, DA consistently produced the best accuracy values.

Conclusions: Our findings highlight that deep learning and DA techniques can aid in the development of adherence support systems for computerized cognitive training, as well as for other interventions aimed at improving health, cognition, and well-being. These techniques can improve engagement and maximize the benefits of such interventions, ultimately enhancing the quality of life of individuals at risk for cognitive impairments. This research informs the development of more effective interventions, benefiting individuals and society by improving conditions associated with aging.

Introduction

Background

Cognitive decline in the aging population presents an unprecedented challenge for the United States and the world. The World Health Organization predicts that the global population of those 60 years and older will double from 1.4 billion in 2020 to 2.1 billion in 2050 and will triple for those 80 years and older reaching 426 million [1]. While some cognitive changes are normal with aging, impacting the performance of some everyday tasks, individuals experiencing nonnormative cognitive declines face even greater challenges. The risk of developing dementia and Alzheimer disease is substantial, with dementia being the seventh leading cause of death worldwide [1]. As the population continues to age, and despite declines in dementia prevalence [2] the number of people affected by dementia is projected to triple by 2050, along with the associated costs [3].

Addressing age-related cognitive changes is crucial for individuals' well-being and independence, and has broader societal impact. Cognitive training interventions, such as technology-based exercises targeting specific cognitive functions, have been widely used. However, research on their effectiveness has yielded both positive [4-6] and negative [7-9] results. Adherence to these training programs is essential for understanding and maximizing their benefits, but factors influencing adherence are not fully understood [10,11]. The ongoing Adherence Promotion with Person-Centered Technology project aims to understand adherence barriers, develop predictive algorithms, and support early detection of age-related cognitive decline. By predicting adherence, personalized reminders can be sent to encourage participants to adhere to the prescribed training schedule.

Our work differs from previous related research in 2 fundamental ways. Previous research efforts mostly used personality traits and metacognitive beliefs of each participant for predicting their adherence to training regimes [12-15]. These are static "distal" features, which quantify the personality and attitudes of a participant, and are unlikely to bear as much information about their continuing engagement to the training program as more proximal dynamic features such as aspects of current adherence behavior. Advances in computing technologies and computational approaches allow us to tailor interventions based on more objective, automatically collected data rather than on mostly subjective, self-reported measures, as well as to create highly adaptive, dynamic systems that can support different types of behavior change interventions [16,17]. We used relevant information about the engagement of a participant to the training schedule (eg, engagement time, number of tasks performed) for N consecutive days to predict their adherence for the (N+1)th day. These predictors contain richer and fine-grained contextual information about the participant's engagement and may thus be much more informative in predicting adherence. Further, while previous research mostly used naïve regression models for predicting the adherence of a participant [12-15], we used sophisticated deep learning models for the same purpose.

In our recent research, we demonstrated the potential of deep convolutional neural networks (CNNs) to predict adherence for a particular participant based on their past behavior, using data from previous computer-based cognitive intervention studies [18,19]. To capture the individualistic differences in participation, we developed a separate prediction model for each participant, rather than a single model for all participants. While our empirical results were promising, one challenge we faced was the limited amount of labeled training data per participant (30 days only) to train a reliable deep neural network. Our main objective in this research was to address this practical challenge by using relevant training data from other participants to train a prediction model for a given participant. This is a challenging task, as each participant has a unique pattern of engagement with the training schedule, and directly using the training data from other participants, without addressing the individualistic variabilities, may not produce the optimal model for a given participant.

Domain adaptation (DA) techniques are instrumental in leveraging ample training data from source domains to train a reliable model for a related target domain of interest, where labeled data are scarce, when the data of each domain are derived from a different probability distribution [20,21]. Through DA, the disparity between the source and target domains can be minimized, so that the training data from the source domains can also be used to train a model for the target domain, thereby addressing the challenge of limited labels. We used state-of-the-art adversarial DA techniques [22], together with advanced signal processing algorithms to overcome the challenge of limited training data for each participant.

Our study highlights the potential of using deep neural networks and DA techniques to predict adherence lapses and develop personalized support systems for cognitive training interventions. Such a prediction system can improve engagement and help maximize the benefits of such interventions, ultimately enhancing the quality of life for individuals with cognitive impairments. To the best of our knowledge, this research is the first of its kind to use advanced deep DA techniques to predict older adults' daily adherence to cognitive training programs.

Objectives

This study sought to (1) explore the potential of deep learning to predict a participant's adherence to cognitive training programs, based on their past behavior; (2) investigate if applying DA techniques can help improve the accuracy of predicting adherence for a given participant, by using relevant information from other participants in the same or different clinical trial; and (3) determine if time series data can be presented in a more meaningful and understandable way, and if it can be used to cluster the participants based on their adherence to a cognitive training program.

Methods

Research Design

We used the Mind Frontiers (Aptima Inc) cognitive training software package in this study. The video game application included 7 Wild West–themed mini-video games. These games were designed to improve memory, attention, spatial processing, task-switching, reasoning ability, and problem-solving, and were played on a Lenovo 10 tablet. Participants were trained on how to use the tablet and play each game; after each game, participants received feedback and the difficulty of the game was adjusted based on their previous performance.

Ethical Considerations

Florida State University Institutional Review Board approved this study's protocol (2017.20622) and informed consent form. Informed consent was obtained from all participants, and participants were given the opportunity to opt out at any time. This consent process included institutional review board–approved language that collected data could be made available for secondary analysis by other research teams and that any shared data would not include personal identifiers. Data were labeled with participant IDs, meaning that data were deidentified in this study. Participants were compensated a total of US $200 (study 1) or US $75 (study 2) for their participation, with the difference driven by the shorter commitment involved in study 2.

Datasets

In total, 2 datasets were used in this study, which we will refer to as the study 1 and study 2 datasets. Study 1 data [13] came from a cognitive training study that involved 2 phases. In phase 1, participants were asked to follow a prescribed schedule for 12 weeks, playing for 5 days each week, for at least 45 minutes per day. Phase 2 was unstructured, where participants were encouraged to play as frequently as they wanted to, for 6 weeks. In this study, only the data collected during the structured phase was analyzed, as adherence cannot be defined without the proposed game-playing instructions given in phase 1. This study had 118 participants, with an overall mean age of 72.6 years and an SD of 5.5 years. Further, 78 (66.2%) participants were female and 40 (33.8%) were male. The cognitive training program consisted of 7 different tasks with 5 possible outcomes (defeat, stalemate, victory, abandonment, or not yet completed). Participants were also given a custom user manual on how to operate the tablet and play each game within the intervention and were provided information on how to access technical support.

The study 2 dataset came from a similar but independent study [12]. Here, in phase 1, participants were asked to follow a prescribed schedule for 8 weeks, playing for 5 days each week, for at least 60 minutes per day. Phase 2 was unstructured and lasted for 4 weeks. A total of 120 adults aged 64 years and older were recruited from Leon County, Florida, and the surrounding area for this study. Among the participants, 116 completed the structured phase of this study. The average age of the participants was 72.6 (SD 5.5) years, with a range of 64 - 84 years. In total, 77 (64.2%) participants were female and 43 (35.8%) were male. The intervention also involved use of the tablet-based Mind Frontiers app (version 2.4.11), which included 7 gamified neuropsychological tasks targeting working memory, processing speed, executive control, and spatial reasoning. While the intent was for participants to complete both phases of this study, the second phase of this study did not require participants to engage with the gaming intervention for any predetermined length of time. Therefore, we only used the data from the first phase of this study. To increase the comparability of datasets, all analyses focus on the first 8 weeks of intervention engagement. Note that variations in study parameters make the datasets slightly different (eg, 45 min vs 60 min sessions).

Deep Neural Networks for Adherence Prediction

We used deep CNNs to predict adherence from the multivariate time series data. While CNNs are well-suited for image recognition tasks, they have also been successfully used for time series data classification [23-25]. The primary mechanism used by these models is convolution, which allows the network to extract essential features from the raw data. In 1D convolution, the kernel slides unidirectionally from the start of the time series to its end. If we have input vector f of length n and a kernel g of length m, the convolution $f \times g$ of f and g is defined as follows:

$$(1)(f\times g)(i)=\sum_{j=1}^{m} g(j)\cdot f(i-j+\frac{m}{2})$$

In this research, we used 2 convolution blocks consisting of a convolution layer and a maximum pooling layer for feature extraction. The maximum pooling layer moves a pool of predetermined size across the input and calculates the maximum of the region. These blocks are followed by a dense and an output layer. Figure 1 shows the architecture of the CNN used in this research.

Following the setup in our previous research [18,19], we used the first 30 days of data for each participant for training and the next 30 days for testing. We used 4 time-dependent variables obtained through game interface interactions as our predictors, namely, (1) duration for which a participant played, (2) number of sessions, (3) maximum level reached, and (4) the number of tasks performed. Session refers to daily session, the number of days on which gameplay occurred. Participants were asked to play 5 sessions (on different days) each week. A session, however, was comprised of the completion of a number of tasks (or games). The participants were said to be satisfying the minimal adherence criterion if they played for at least 10 minutes on a given day. This minimal adherence criterion was selected to ensure that the participants spent a reasonable amount of time playing the game and to avoid cases where they may have accidentally opened the app and then backed out. Hence, this was considered as the threshold to define the 2 classes (adherent and nonadherent) in our study. Based on the values of these predictors for a given participant for N days, our goal was to predict the adherence class of the participant for the (N+1)th day, N being the window size. This is depicted in Figure 2. Note that participants were asked to play on 5 out of 7 days per week. As such, nonengagement was permitted 2 days per week, and a participant could still be classified as adherent overall for the week by not playing for 2 days. The ability to predict whether participants engage or not on a specific day, however, is crucial for facilitating the early detection of adherence lapses so that our system under development can provide just-in-time adherence support. In this paper, we focus on the artificial intelligence aspect of the problem, predicting whether a participant will adhere to the training schedule on any given day, given their past N days of data (as shown in Figure 2). A separate, personalized deep neural network was trained for each participant to capture the individual playing patterns, rather than attempting to fit a single model for all participants.

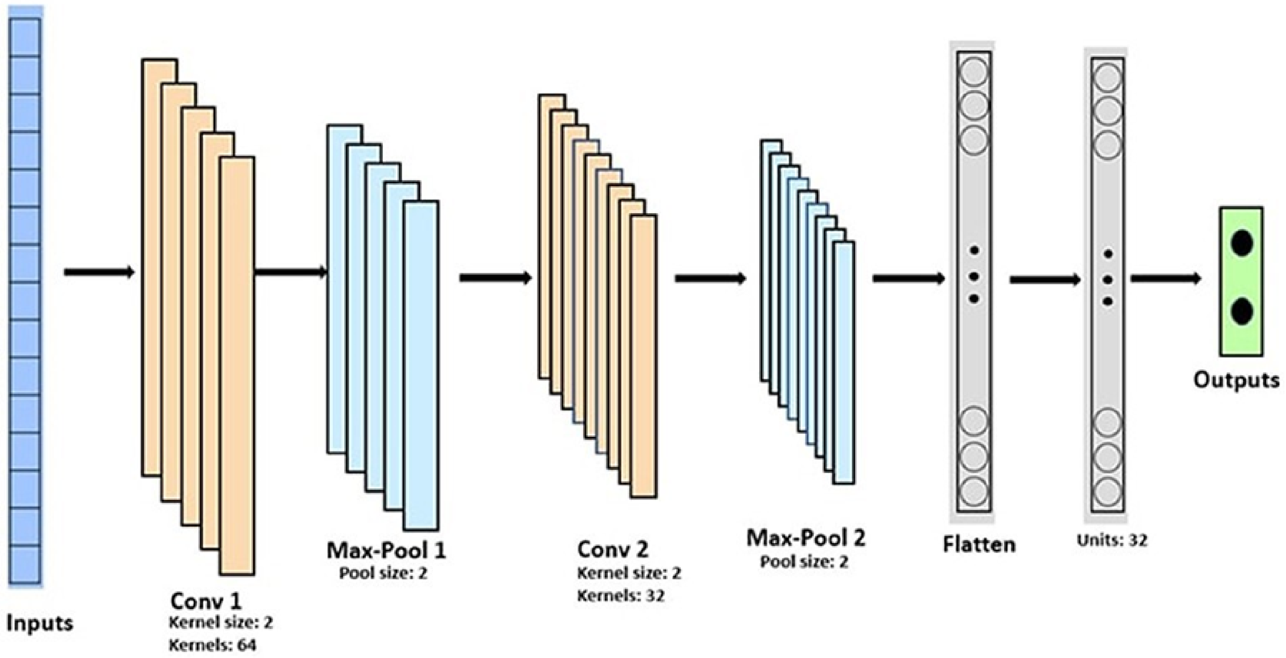

Figure 2. Given the play patterns of a participant for N consecutive days, our goal was to predict whether the participant will meet the minimal adherence criterion on the (N+1)th day (adapted from Singh et al [19], which is published under Creative Commons Attribution 4.0 International License [26]).

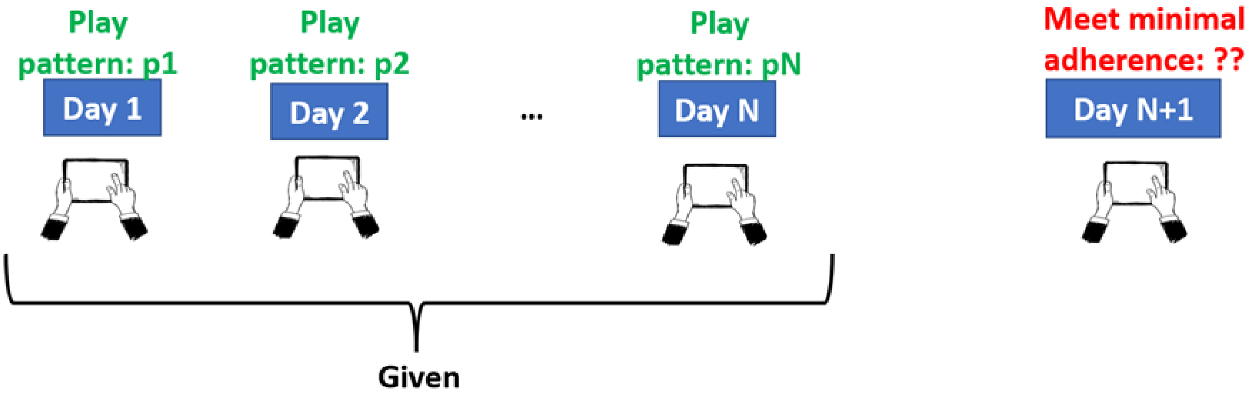


DA for Adherence Prediction

One of the main challenges in our problem setup was the limited amount of labeled data per participant (30 d) to train a reliable deep neural network. DA or transfer learning is a technique used in machine learning to address the challenge of model training with limited labeled data. The fundamental premise of DA is to leverage abundant labeled training data in one or more source domains to train a model for a target domain of interest, where labeled data are scarce [20-22]. The source and the target data are derived from different probability distributions and thus a model trained on the source domains may not generalize directly to the target domain. This necessitates a strategy to address the disparity between the probability distributions of the source and target domains so that the labeled source samples can be used to train a robust model for the target domain. While extensively used in computer vision, DA has also been successfully used with time series data [27,28].

DA techniques based on adversarial training have depicted promising empirical performance. We used the domain adversarial network in our study (please refer to [22] for further details). The architecture includes a deep feature extractor, together with 2 classification heads: one to classify the label y of a given sample (adherent or nonadherent in our case) and the other to classify the domain d from which a given sample is derived (source or target). During model training, the label classifier was trained to achieve high accuracy (so that the test samples are accurately classified), but the domain classifier was trained to achieve minimal accuracy. This ensures that the deep model learns domain invariant features and a classifier trained to distinguish between the source and target domain samples has high error. This also ensures that the disparity between the 2 domains is addressed, and the labeled source samples can be used to train a model for the target domain. The conventional cross-entropy loss is used to train the label classifier; the domain classifier is connected to the feature extractor via a gradient reversal layer that multiplies the gradient by a certain negative constant during the backpropagation-based training so that the domain classifier is trained to have a high error. Please refer to Ganin et al [22] for more details about this method.

In our problem setup, a particular participant constitutes the target domain and each of the other participants constitutes the source domain. Each participant had a unique playing pattern, which implies that the data for each participant is derived from a different probability distribution. Our objective was to use data from the source participants to augment the training data for the target participant and to train a better adherence prediction model for the target participant. To deal with the scale of the data, and to ensure that the source participants had similar playing patterns as the target participant (so that only relevant information is transferred), we exploited a clustering technique based on Gramian angular fields (GAFs), as described below. We clustered the participants based on their playing patterns and the DA scheme was applied cluster-wise; that is, a particular participant was considered as the target, and all the other participants in the same cluster (instead of the whole dataset) were considered as the source participants.

Clustering Time Series Data Using GAFs

Directly clustering temporal cognitive training data can be challenging due to its complex and dynamic nature. We hence used GAFs to transform the univariate time series data (time spent in playing games) into images [29-31]. GAF images provide a more intuitive representation of the data, making it easier to interpret and analyze. As mentioned before, the adherence classes were defined based on how long each participant engaged in the training schedule on a particular day. We therefore used the variable "time spent in playing games" to transform the (univariate) time series data into images and cluster them, instead of the other variables: "number of sessions," "maximum level reached," and "number of tasks performed." This ensured that participants with similar adherence patterns belonged to the same cluster; thus, during DA, only participants with similar playing patterns as the target participant can be used to transfer relevant knowledge.

The process of converting time series to GAFs involves several steps, as detailed below (the complete pipeline is depicted in Figure 3):

- Normalizing the time series data: The time series data are first normalized to have a mean of 0 and an SD of 1. This step is important to ensure that the resulting GAF images capture the underlying patterns and trends in the data.
- Conversion to polar coordinates: The time series data were then mapped to the polar coordinate system where each point on the plane is determined by its distance from a reference point and an angle from a reference direction. Assuming our time series is composed of T timestamps with corresponding values x_i, then the angles are computed as $arccos(x_i)$. They lie within $[0, \pi]$. The radius is computed using time stamp i, where $i \in T$ represents the timestamp of data point x_i.

Mathematically it translates to,

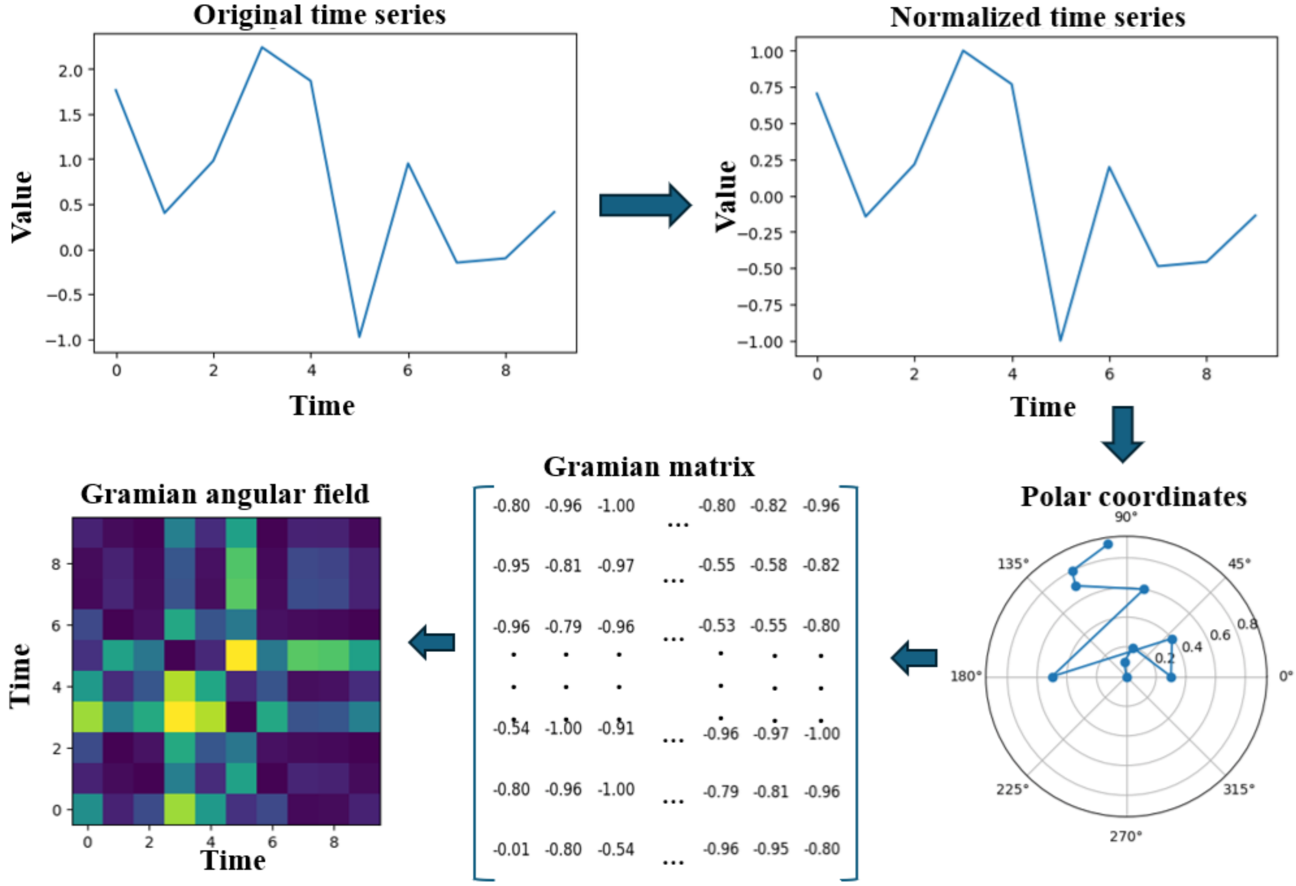
$$(2)\{r=i/T\ \theta_i=\arccos(x_i), -1\leq x_i\leq 1$$

- Generating a Gramian matrix: The normalized and converted time series data were then used to generate a Gramian matrix using a chosen mathematical function, such as the cosine or sine function. The Gramian matrix captures the pairwise inner products between the time series data points, which provides a measure of the similarity between different points in the time series.5

$$(3) GAF=[\cos(\theta_1+\theta_1)\ldots\cos(\theta_T+\theta_1)\cos(\theta_1+\theta_2)\ldots\cos(\theta_T+\theta_2)\cos(\theta_1+\theta_T)\ldots\cos(\theta_T+\theta_T)]$$

- Mapping the Gramian matrix to an image: The Gramian matrix was then mapped to a 2D image using a color mapping scheme, such as a grayscale or rainbow colormap as shown in Figure 3. The resulting image captures the underlying patterns and trends in the time series data.

Figure 3. Pipeline for converting time series data into GAF images. GAF: Gramian angular field.

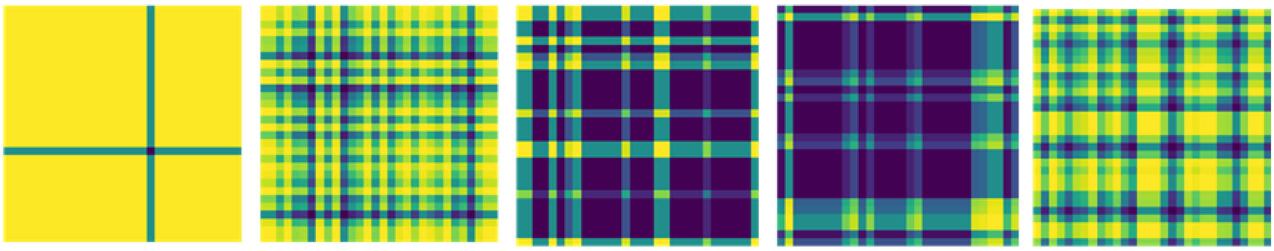


Clustering of Images

We converted the univariate time series data of the length of playtime for each participant into GAF images using the cosine function, to capture the underlying patterns in cognitive training performance [32,33]. We then used the pretrained Visual Geometry Group 16 deep neural network to extract features from the GAF images, which were fed into the K-means clustering algorithm to group the participants into distinct clusters based on their daily playing time. Sample images from different clusters are shown in Figure 4. The GAFs are symmetrical along the diagonal, and the colors vary from yellow to blue with green gradients in between. The yellow or lighter color means that the participant did not play or spent much less time playing, while the increase in the gradient from yellow to blue implies that the participant spent more time playing. The first image in Figure 4 comes from a participant who did not play at all (GAF image is mostly yellow). The third and fourth images come from participants who played more consistently; however, there were some days in between where they either did not play or played for a short duration, which explains the yellow regions in between. The second and fifth images come from participants who were erratic in their playing patterns.

The advantages of converting the time series data into images and clustering them were twofold: (1) the resulting clusters allowed for a more visually interpretable understanding of the data and enabled us to identify distinct trends in the playing patterns of the participants, which can be used to tailor cognitive training programs to specific groups of individuals; and (2) it enabled us to identify the relevant source participants (who have similar playing patterns) for a given target participant, while applying DA to train a model for the target participant.

Figure 4. Examples of generated GAF images. GAF: Gramian angular field.



Experimental Setup

For each participant, we used the first 30 days of data for training and the next 30 days for testing. This split was selected to strike a balance between the training and testing samples. Further, there is evidence in the psychology literature showing that the median time to develop different health-related habits asymptotes around 30 days [34]. The proposed split can thus be useful to assess long-term adherence. The input to the CNN was the multivariate time series data consisting of the maximum task level reached, number of sessions played, time spent playing, and number of tasks completed each day. A threshold of 10 minutes on the play time on a particular day was used to determine the classes (adherent or nonadherent); that is, if a participant played for more than 10 minutes on a given day, they were considered to adhere to the training program on that day; otherwise, they were considered to be nonadherent to the program on that day. Given the playing data of a particular participant over N days, our goal was to train deep neural networks to predict the adherence class on the (N+1)th day. As detailed in our previous research [19], we used the fast Fourier transform to detect the presence of any seasonality in the time series data. Fast Fourier transform was applied to transform the time series training data into the frequency domain and derive the corresponding amplitude and frequency. The highest amplitude frequencies represent seasonal patterns and the lowest amplitude frequencies represent noise. The inverse fast Fourier transform was then applied to the frequency with maximum amplitude to obtain the time interval for the most prominent cycle (periodic pattern). This cyclic period was used as the window size N, which was computed as *7* in our study. A separate deep model was trained for each participant to capture individualistic playing patterns. After every epoch, the error of the model on the validation set was noted to avoid overfitting.

The data from a particular clinical trial were first clustered using GAFs. We experimented with different numbers of clusters and manually inspected the GAFs within each cluster. With 4 clusters, the GAFs within each cluster visually appeared to be similar, denoting that participants with similar playing patterns were grouped in each cluster; with other values of *k*, each cluster had mixed GAFs, denoting that each cluster had participants with varied playing patterns. We therefore performed K-means clustering with (K=4) clusters in our empirical studies. Further, 1 participant from a given cluster was selected as the target participant, and all the other participants in the same cluster were designated as the source participants. A deep model was trained for the target participant and was evaluated on the test data for the same participant. The process was repeated for all participants across all the clusters and the final score was computed as the average score over all the participants. In total, 4 evaluation metrics were used: precision, recall, F_1-score, and accuracy. Precision, recall [35], and F_1-score [36] were used to measure the model's performance on positive predictions, while accuracy was used to evaluate the overall model performance. We conducted 3 different sets of experiments:

1. No source, no DA: In this setup, only the 30 days of training data for the target participant was used to train a model for that participant; the data from the other participants was not used at all.
2. With source, no DA: here, in addition to the training data of the target participant, the training data from the source participants (in the same cluster as the target participant) was also used to train a model for the target participant. However, the training data from the source participants was used directly, without applying any DA.
3. With source, with DA: In this setup, DA was used to address the domain disparity between the target and source participants, and the training data from the source participants (in the same cluster) was used to train a model for the target participant.

In all 3 setups, the trained model was tested on the test data of the target participant. For the experiments without DA, the CNN architecture in Figure 1 was used, while for experiments with DA, the layers before the flatten layer were used as the feature extractor as in .

Results

Experiments With a Single Dataset

The results on the study 1 and study 2 datasets are depicted in Tables 1 and 2, respectively. Note that all the evaluation metrics referred to in this section are the average values of all the participants across all clusters. For the study 1 dataset (Table 1), using training data only from the target participant, without any source or DA, resulted in an accuracy of 63% (the accuracy was computed as the percentage of times our model correctly predicted whether a given participant will meet the minimal adherence criterion on day N+1, as illustrated in Figure 2; this was averaged across all the participants). Using training data from the other participants (source) in the same cluster as the target participant, but without DA, resulted in an improved accuracy of 67.9%. Using training data from the source participants together with DA produced the best accuracy of 71.7%. The superior performance of DA is also reflected in all the other evaluation metrics. The same pattern is evident for the study 2 dataset (Table 2), where using the training data from the source participants (in the same cluster as the target participants) together with DA consistently furnished the best performance. Notably, using DA, both the accuracy and F_1-score improved by more than 8% compared to the "no source, no DA" experiment.

We also note that the "with source, no DA" experiment produced slightly better results than the "no source, no DA" experiment. This shows that using training data from the source participants can improve the adherence prediction performance; however, using the data directly without addressing the domain disparity may not produce optimal results. The best results were obtained when the training data from the source participants were used, and the difference in probability distribution between the source and the target participants was addressed through DA.

We also conducted statistical tests of significance on the F_1-score using the ANOVA repeated measures (the F_1-score may be a better indicator of the overall performance than accuracy, to address the presence of any class imbalance in the data). We compared the performance of the CNN models for the following two experimental setups: (1) with source, no DA, and (2) with source, with DA. A statistically significant difference (P=.004) was found between the results of using DA compared to not using DA for the study 2 dataset. A sign test was also conducted on the F_1-score of the individual participants to test for consistent differences in the results with and without using DA. A significant difference (P=.003) was found in the results for the study 2 dataset. These results corroborate the potential of DA algorithms to develop personalized deep learning models for predicting adherence to cognitive training programs in older adults.

Table . Results (in percentage) on the study 1 dataset. Italicized values represent the best performance. The scores are calculated by averaging the respective scores over all the participants.

Experiment type	Accuracy, mean (SD)	Precision, mean (SD)	Recall, mean (SD)	F_1-score (SD)
No source, no DA[a]	63 (0.2)	58.3 (0.2)	57.1 (0.2)	54.3 (0.3)
With source, no DA	67.9 (0.3)	61.1 (0.3)	60.2 (0.3)	58.7 (0.3)
With source, with DA	*71.7 (0.3)*	*63.2 (0.3)*	*62.3 (0.3)*	*59.4 (0.3)*

Table . Results (in percentage) on the study 2 dataset. Italicized values represent the best performance. The scores are calculated by averaging the respective scores over all the participants.

Experiment type	Accuracy, mean (SD)	Precision, mean (SD)	Recall, mean (SD)	F_1-score (SD)
No source, no DA[a]	57.3 (0.2)	54.1 (0.2)	52.4 (0.2)	49.6 (0.2)
With source, no DA	61.8 (0.2)	54.5 (0.2)	53.4 (0.2)	50.1 (0.2)
With source, with DA	*66.6 (0.2)*	*60 (0.2)*	*60.4 (0.2)*	*57.6 (0.2)*

[a] DA: domain adaptation.

Experiments With a Combination of the Two Datasets

Having validated the usefulness of DA on single trial datasets, we conducted an experiment to study whether data from participants from a different clinical trial can also help in training a predictive model for a target participant in a given clinical trial. To this end, we segregated all the participants in both datasets together, into 4 clusters using the GAF method. Within each cluster, for a given target participant, only participants from the other dataset (different from the target participant's dataset) were considered as source participants. This was accomplished to mimic the following challenging real-world scenario: a participant enrolls in a cognitive intervention program, and we desire to train a deep neural network to predict adherence for this participant; we have access to a limited amount of training data from this participant. However, we do not have any training data available from other participants in the same program; rather, we have access to data from other participants from a similar (previously conducted) intervention program. Our goal, therefore, was to leverage data from a similar intervention program, in addition to the limited labeled data for the target participant, to develop an adherence prediction model for the target participant. Note that, the only objective of clustering the participants in both datasets together, was to identify the source participants for a given target participant. Once the source participants were identified, the prediction model was trained for the target participant using data from the source participants; no prediction model was trained on the combination of the 2 datasets. The same 3 experiments were conducted, and the results are presented in Table 3.

The results depict a similar pattern, with DA comprehensively outperforming the other 2 experiments. The F_1-score increased by almost 8% compared to the scenario where the source data are used directly without applying DA. As before, a statistical test of significance was conducted on the F_1-score using the ANOVA repeated measures. A significant trend (P=.08) was found between the results of using DA compared to using the source data directly for training without DA. A sign test was also conducted on the F_1-score of the individual participants; a significant difference (P=.004) was found in the results with and without using DA. We also conducted a sign test on the combined results obtained from the 3 experiments (study 1, study 2, and study 1 and study 2 combined). A significant difference (P<.001) was found in the results of the individual participants with and without using DA. These findings suggest that incorporating other participants' data by using DA techniques can improve the generalization capability of a deep neural network trained to predict adherence of a particular participant, even when the other participants' data are derived from a different (but similar) intervention program.

Overall, the findings of this study suggest that DA has tremendous promise in improving the performance of a deep neural network trained to predict adherence to a cognitive training program of a given participant, by appropriately leveraging training data from other participants. Such a framework can be immensely useful in situations where only a limited amount of training data is available for the target participant. DA consistently produced better performance compared to baseline methods which did not incorporate data from other participants (source participants) at all or used the data directly without DA. Additionally, ANOVA repeated measures analyses demonstrated a statistical trend toward significance in the F_1-score between experiments with and without DA while using the source data, further corroborating the efficacy of DA on adherence prediction accuracy.

Table . Results (in percentage) on study 1 and study 2 datasets. In this experiment, for each cluster, a participant is selected as the target and all the participants, from the other dataset, in the same cluster are considered as source. Italicized values represent the best performance. The scores are calculated by averaging the respective scores over all the participants.

Experiment type	Accuracy, mean (SD)	Precision, mean (SD)	Recall, mean (SD)	F_1-score (SD)
No source, no DA[a]	64.2 (0.3)	57.1 (0.3)	58.2 (0.2)	54.2 (0.3)
With source, no DA	66.9 (0.3)	51.3 (0.3)	57.3 (0.2)	50.9 (0.3)
With source, with DA	*68.5 (0.2)*	*61.3 (0.2)*	*60.4 (0.2)*	*58.7 (0.2)*

Discussion

Principal Results

The results of this study have several important implications for the field of adherence prediction in the context of gamified cognitive intervention programs. Our findings suggest that CNNs can be a powerful tool for analyzing time series data and predicting adherence and can have important implications for the field of cognitive neuroscience. By using CNNs to predict adherence, we were able to identify patterns and trends in the data that could be used to improve cognitive training interventions, ultimately leading to enhanced quality of life for individuals with cognitive impairments. This research has implications for the development of more effective intervention approaches that can benefit individuals and society by improving conditions associated with aging and the life course.

More importantly, each participant has a unique playing pattern, and it is important to address the individualistic variabilities when developing adherence prediction models for cognitive gaming programs. Our study demonstrated that DA techniques can effectively reduce domain shift and improve the accuracy of CNN models in predicting adherence. The results of the experiments conducted on the study 1 and study 2 datasets demonstrated the effectiveness of DA in improving adherence prediction performance. This suggests that appropriately leveraging information from participants with similar playing patterns can enhance the accuracy of adherence pattern predictions. To the best of our knowledge, this is the first research effort to study the performance of advanced deep DA techniques to predict adherence to cognitive training programs for older adults.

Our study also suggests that GAFs can be a valuable tool for preprocessing time series data and clustering participants based on their playing patterns. The findings indicate that GAFs can aid in identifying participants with similar behaviors and interpret the patterns visually. They also enable us to identify source participants that have similar playing patterns as the target participant, so that relevant information can be transferred during DA.

Conclusions

In conclusion, this study highlights the potential of deep neural networks and DA techniques in predicting adherence lapses and developing personalized support systems for cognitive training interventions. The findings contribute to the advancement of the field and provide valuable insights for improving engagement and maximizing the benefits of such interventions for individuals with cognitive impairments. Future research will further explore the application of these techniques in other contexts and populations with the fundamental goal of improving the effectiveness of cognitive training interventions.

Abstract

Background: Cognitive stimulation of older people helps prevent, and even treat, age-related diseases, such as mild cognitive impairment. Playing games reduces the probability of experiencing this pathology, which is related to the loss of the ability to carry out some instrumental activities of daily living.

Objective: This work describes the design and development of a serious game for the cognitive stimulation of older people, with exercises related to the daily life task of shopping. A pilot study for its preliminary usability validation is also presented.

Methods: The designed serious game includes 4 exercises consisting of shopping in a hypermarket, ordering products, making payments, and organizing the purchase, thus dealing with the most frequent cognitive problems of older people associated with episodic declarative memory, naming, calculation, and organization, respectively.

Results: A total of 19 older people participated in the pilot study for the usability validation of the serious game. They indicated that they like the aesthetic and interesting topic of the game. They reported that it provides a high level of entertainment and could be useful in daily life for mental stimulation. The participants found the serious game to be intuitive, but the ease of use and readability of the instructions could be improved.

Conclusions: This study suggests that the innovative serious game developed could be accepted by older people for their cognitive stimulation to prevent or treat mild cognitive impairment, although a long-term intervention study should be performed as future work. Its ecological validity design, with everyday tasks, adaptable levels of difficulty, and motivational mechanisms, is a differentiating factor compared to similar serious games.

Introduction

The increase in life expectancy means that we can live with age-related pathologies, such as dementia. However, the prevalence of this pathology is clearly on the rise, and there are currently about 55 million people affected worldwide [1] and around 11 million for the broad European region [2]. This acquired syndrome is characterized by a progressive deterioration of cognitive functions, which influences activities of daily living (ADL) and decreases the level of independence of individuals. For this reason, dementia is classified into grades, where simple activities can be performed in the mild stage but the severity of symptoms increases as the impairment progresses [2-4]. Mild cognitive impairment (MCI) is the term used for individuals whose cognitive changes fall between those of aging and early dementia and is considered a precursor to early dementia in around 30% of cases; thus, those with MCI are much more likely to progress to this type or level of dementia, especially in older people [4]. Treatment usually includes drugs that aim to reduce or delay cognitive, psychological, and behavioral symptoms [5], but nonpharmacological treatments are also very important. These include reality orientation, reminiscence and validation therapies, or cognitive stimulation [6].

Cognitive stimulation includes techniques that focus on treating cognitive aspects through activities that allow them to be worked on globally and simultaneously [6,7]. Cognitive and reminiscence activities, multisensory activities, as well as those that work on social aspects are used, along with group activities that facilitate integration and social participation among users [8]. In fact, several studies confirm an improvement in different aspects of the cognitive sphere and in the quality of life of people with dementia who have participated in this type of therapies [9,10]. We also found improvements in mood and ADL maintenance [11].

Currently, information and communication technology (ICT) instruments and tools are incorporated into nonpharmacological treatments. These technological devices facilitate performance, which can lead to a greater sense of self-efficacy and improve one's own perception of functionality, as well as reduce the burden of caregivers. Some of the devices that are commonly used with people with dementia are tele-assistance, devices that improve cognitive functions, and robotics [12]. Among them, the most widely used are those that can be connected to the internet (tablets, mobile phones, computers, and video game consoles), which provides a wide variety of resources that allow the diversification of therapies and increase motivation and adherence to treatment [8,13]. The use of ICTs as therapeutic tools requires a previous study of the person's abilities and skills for their use and management, to avoid feelings of frustration that can lead to discouragement from therapy or rejection of the device [9]. Therefore, it is essential to gradually approach the device and its applications, looking for intuitive tasks that the user can easily carry out independently [9,13].

Serious games are ICT games whose main objective is to give a therapeutic or diagnosis value to the playful action of the games. They have been tested in different areas of intervention in pathologies with cognitive impairment [14,15], particularly dementia [16]. Through serious games, we can work to delay deficits, increase autonomy and relationships with their social environment, and improve the quality of life of people with dementia [17]. For this intervention, the occupational therapist may include in their individual intervention plans games to work on physical, cognitive, and social aspects. The literature reveals that there are already a number of well-established serious games that could improve older people's cognitive health. Some examples of these are focused on sport simulations, quizzes with text and images, music tools, arithmetic and reading calculations, etc [17]. Others instead use a fantasy world setting, minigames, puzzles, or scenarios to cope with stressful or negative situations [18]. However, few serious games have been developed that incorporate tasks focused on ADL, such as cooking [19]. Once cognitive impairment becomes perceptible in ADL, the disease has usually progressed, so the analysis of ADL performance would help to assess cognitive status during the course of cognitive impairment [19]. In this sense, serious games can be a valuable tool for achieving this in a motivating and enjoyable way for older people with ecological scenarios.

In this study, we describe the design and development process of a serious game developed for the cognitive stimulation of older people, with exercises related to the daily life task of shopping. We also present the results of a usability validation from a pilot study of the game.

Methods

Game Development Process and Design Requirements

In the process of designing and developing this serious game, researchers with a bioengineering profile, game designers and developers (computer and telecommunication engineers), and health care professionals (neuropsychologists, psychologists, and occupational therapists) participated to fulfill the essential collaboration of an interdisciplinary team [20].

First, 2 focus groups were performed with 11 psychologists and 6 occupational therapists from Extremadura, Spain, to identify the needs, limitations, and motivations of older people to use cognitive stimulation programs. The selection criteria of participants in both focus groups were the geographical location (working in rural and urban areas) and the kind of institutions in which they work (public and private). The focus groups were conducted by 2 engineers with extensive experience in conducting interviews. After the presentation of the study and the objectives, a previously created guide with topics of interest and questions was followed to conduct the session in a semistructured way. With the participants' consent, all conversations were recorded for subsequent transcription and analysis. NVivo 2017 (QSR International) software was used to carry out this analysis to facilitate the drawing of conclusions. Four thematic areas were identified: (1) the most frequent cognitive problems of older people are mainly focused on memory loss, disorientation, difficulty in performing executive tasks, or difficulty in concentrating; (2) motivation is the fundamental element for the success of new training exercises; (3) technological barriers are mainly related to interface design problems and cultural level; and (4) the low degree of awareness of older people regarding the importance of leading an active life. This served as a basis for designing the new tool to promote the cognitive training that directly stimulates memory and executive tasks, as well as orientation and concentration skills.

In the implementation of this serious game for Android OS, Unity 3D (C#, Visual Studio 2017) was used, following the design recommendations established in previous studies [21]. In this sense, the game interface was designed while taking into account that the target audience is older people and adapted to their needs, including the minimum necessary information in a clear and concise way, which allows the older people to understand the objective of the game. Regarding user interaction, the game was designed to be used on a tablet instead of the standard keyboard and mouse to provide a more natural interaction and facilitate the acceptance by older people [22].

Two fundamental characteristics were taken into account in the design of this serious game. First, a shopping task with high ecological validity was included, that is, a day-to-day activity of older people. In this way, a greater interest and acceptance by older people should be achieved, due to the high utility of this tool in their daily lives. The concept of ecological validity is determined by the degree of representativeness, that the game is represented in a form and context that correspond to its occurrence in everyday life, as well as by the level of generalization that the results are able to explain similar tasks in everyday life [23]. Second, the difficulty level of the game was customized by professionals according to the needs of each older person, as detailed in the description of each game in the following sections.

An additional characteristic included in the design of the game was that immediate feedback is provided to the user at the end of each game, showing the attempts, hits, and failures made after the user performance. Moreover, positive feedback with encouragement messages is showed to the user during the completion of the game, such as "Come on, you're about to get it," "You almost got it. Try again," "Surely you have the name on the tip of your tongue," and "Don't worry. Let's go with another product."

Game Description

First Exercise: Shopping in a Hypermarket

Episodic declarative memory is the neurocognitive function that is affected the earliest in Alzheimer disease due to the initial involvement of the hippocampal formation in the medial temporal lobe, so the stimulation of episodic declarative memory in people with MCI who are affected by mnesic impairment is of utmost importance.

This exercise is designed with the specific aim of stimulating verbal intentional episodic declarative memory at the level of the 3 mnesic processes of encoding or fixation, consolidation or storage, and recall or retrieval of information, thus consisting of 3 phases:

- *1.1 Learning Phase*: memorization of a shopping list
- *1.2 Interference Phase*: preparation of the money to pay for the purchase
- *1.3 Recall Phase*: purchase of products from the shopping list

The level of difficulty can be adjusted by the number of products on the shopping list, the number of product categories, the memorization and interference times, the number of attempts, or the total allowed time.

Second Exercise: Ordering Products in a Hypermarket

On the one hand, expressive language impairment manifests itself very frequently and early in the form of anomia, a naming deficit that consists of the difficulty to recall the names of objects. Due to the great frustration caused by this early expressive language difficulty for people with MCI, it is essential to include naming stimulation tasks within the global stimulation of expressive language in cognitive stimulation programs.

On the other hand, complex visual gnosias, in which the visual recognition and identification of objects is hindered by a modification of the characteristics of the objects' images, are one of the cognitive functions that are affected in the early stages of several primary cortical degenerative dementias, hence the importance of their stimulation.

This exercise is designed with the specific aim of stimulating language at the level of naming and complex visual gnosias in 2 phases:

- *2.1 Phase 1*: hypermarket product naming
- *2.2 Phase 2*: visual recognition and identification of hypermarket products

The difficulty can be customized by adjusting the product familiarity percentage, the number of products that appears, whether or not to provide help to recognize the products, or the allowed time.

Third Exercise: Making Payments

Executive attentional control processes are affected early in several types of primary and secondary dementias such as subcortical vascular dementia. Working memory, a key element of executive attentional control, is the ability to maintain and manipulate information in on-going cognitive activity, such as money management for shopping. It is therefore very important to place great emphasis on the stimulation of these cognitive processes to maintain the highest possible level of functional independence of each person.

This exercise consists of 3 phases and is designed with the specific aim of stimulating the working memory through calculation tasks by simulating purchase payments:

- *3.1 Phase 1*: payment of the purchase
- *3.2 Phase 2*: check the change (money returned)
- *3.3 Phase 3*: check the price of products on the purchase receipt with the catalog of offers

Professionals can adapt the difficulty by adjusting whether or not to include decimals in the amount to be paid or the change, the number of attempts, the allowed time, the number of correct banknotes or coins in the change, the number of products, pages and sections in the catalog of offers, or the rate of products with erroneous price.

Fourth Exercise: Organizing the Purchase

Executive functions, such as planning and organization, reasoning, cognitive flexibility, or monitoring when problem-solving, are crucial functions for a good performance of any adult in advanced and instrumental ADL. In the context of cognitive treatments for MCI, the stimulation of executive functions is a compulsory subject given their close interdependence with the maintenance of a high level of functional independence and personal autonomy in ADL.

This exercise is designed with the specific objective of stimulating this executive function of organization, as well as abstract reasoning, performance monitoring, visual gnosias, semantic memory, and visuospatial function.

The only phase of this exercise consists of the arrangement of the purchase products in the corresponding rooms of the house.

In this case, the adaptation of the difficulty can be achieved by adjusting the number of products on the list and the maximum time allowed to complete the task.

Acceptance and Usability Study

A preliminary validation of the serious game was carried out by 4 participants from the Association of Friends of the Minimally Invasive Surgery Centre in Cáceres, Spain; 5 participants from senior centers in Castelo Branco, Portugal; and 10 participants who attended the FEHISPOR fair held in Badajoz, Spain. The nonprobability intentional sampling technique was used to conduct the recruitment of participants, with inclusion criteria of older people aged 60-80 years with MCI. Through this method, older people from those attending various demonstrations of the game at the aforementioned events and venues were recruited to voluntarily participate in the study.

Participants tested the game until all exercises were completed and then filled in a questionnaire. The questionnaire consisted of questions scored on a 5-value Likert scale (1=lowest value, 5=highest value) about the acceptance and usability of the game, assessing (1) the user's perception and degree of satisfaction when using the game and (2) the design and layout of the game. A descriptive analysis with the average values of the answers provided by the participants was performed.

Ethical Considerations

Both ethical approval and written participants consent were waived for this study because they were not within the scope of Law 14/2007 of 3rd July on Biomedical Research, due to this study not involving any invasive procedure on the participants. Only verbal informed consent was considered sufficient. All data have been deidentified, and there was no compensation for participation.

Results

Game Implementation

First Exercise: Shopping in a Hypermarket

This exercise consists of 3 phases.

In *1.1 Learning Phase*, the user must learn a series of products from a shopping list in 3 subphases (Figure 1): (1) organization of the list by categorization, since the structure of the information facilitates its deep encoding; (2) identification of specific characteristics that differentiate the products, since better fixation of information with clues optimizes recall; and (3) intentional memorization of the list in a specific time frame.

Figure 1. The first exercise stimulates episodic declarative memory with 3 mnesic processes: encoding, consolidation, and recall. The user must learn a series of products from a shopping list.

In *1.2 Interference Phase*, the task simulates the preparation of the wallet with the money to pay for the purchase. It activates the processes of attentional control at the level of selective attention to choose the correct banknotes or coins, working memory to sum the money, and monitoring of the execution to avoid errors.

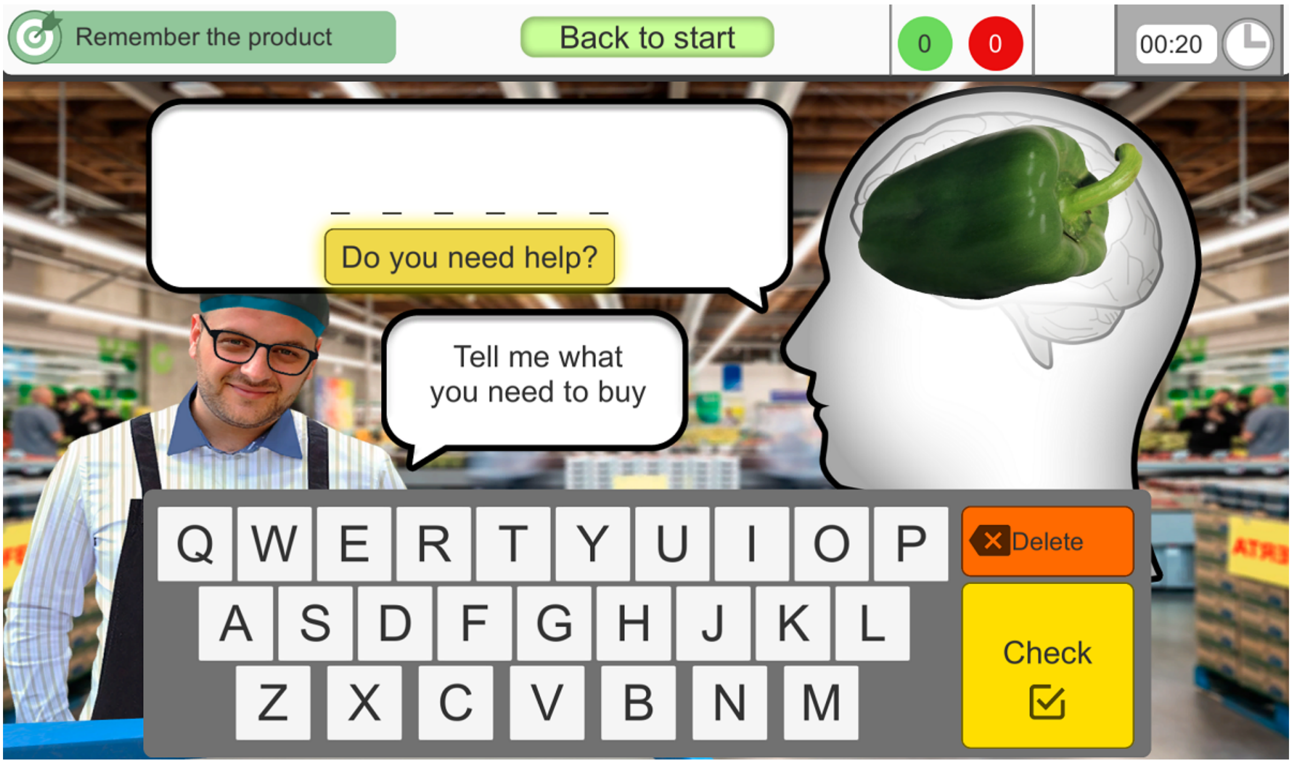
In *1.3 Recall Phase*, the user is presented with a map of a hypermarket where the sections are marked out, and the user has to fill a shopping basket with those products from the shopping list studied in the *1.1 Learning Phase* among distracting products. The aim is to stimulate the mnesic process of recalling short-term episodic declarative memory.

Second Exercise: Ordering Products in a Hypermarket

This exercise consists of 2 phases.

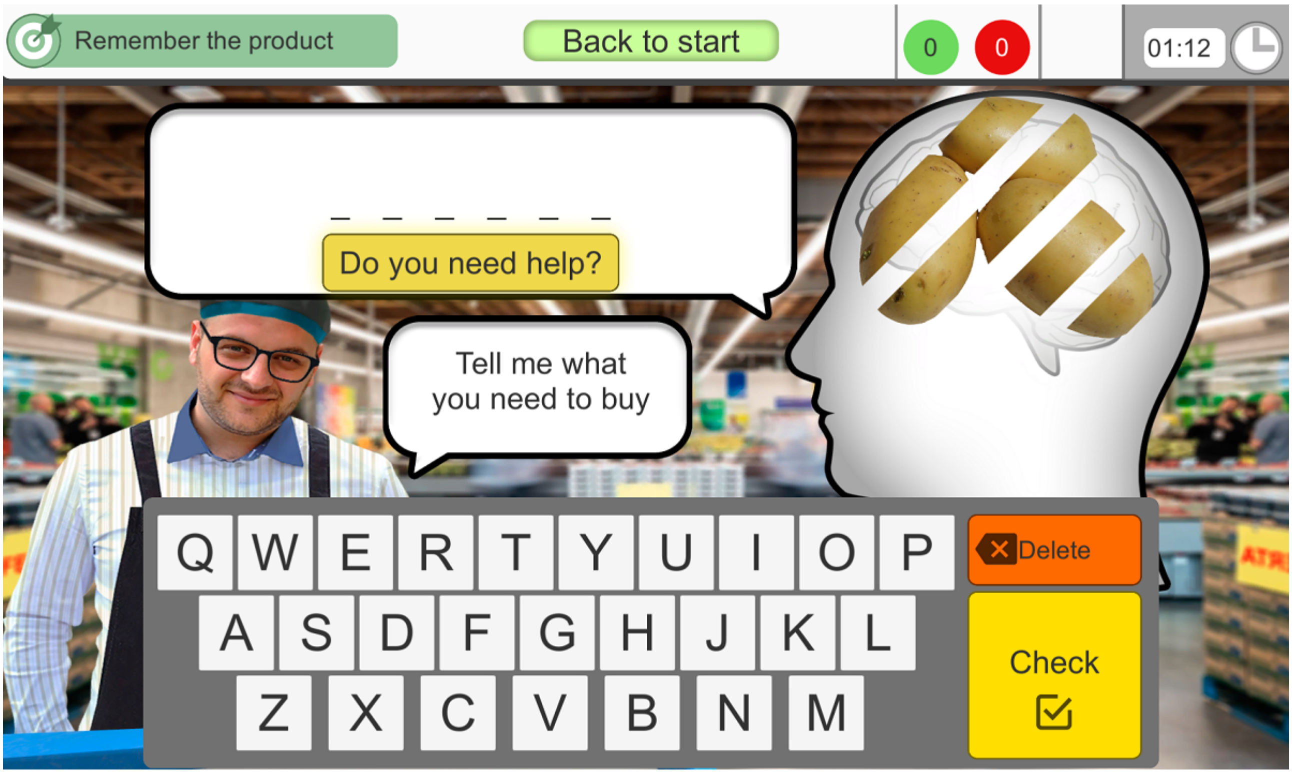
In *2.1 Phase 1*, the user has to write the names of the hypermarket products that appear in the images (Figure 2).

Figure 2. The second exercise (2.1) stimulates expressive language. The user has to write the names of the products that appear in the images.



In *2.2 Phase 2*, the user has to recognize and identify the hypermarket products through their distorted images and subsequently name these products (Figure 3). The emphasis is placed on the stimulation of complex visual gnosias, making it difficult to recognize and identify the objects to be named.

Figure 3. The second exercise (2.2) stimulates complex visual gnosias. The user has to recognize and write the names of the products through their distorted images.



Third Exercise: Making Payments

This exercise consists of 3 phases.

In *3.1 Phase 1*, the user has to use banknotes or coins to make the exact payment of the purchase (Figure 4).

Figure 4. The third exercise stimulates executive attentional control. The user has to use banknotes or coins to make the exact payment of the purchase.

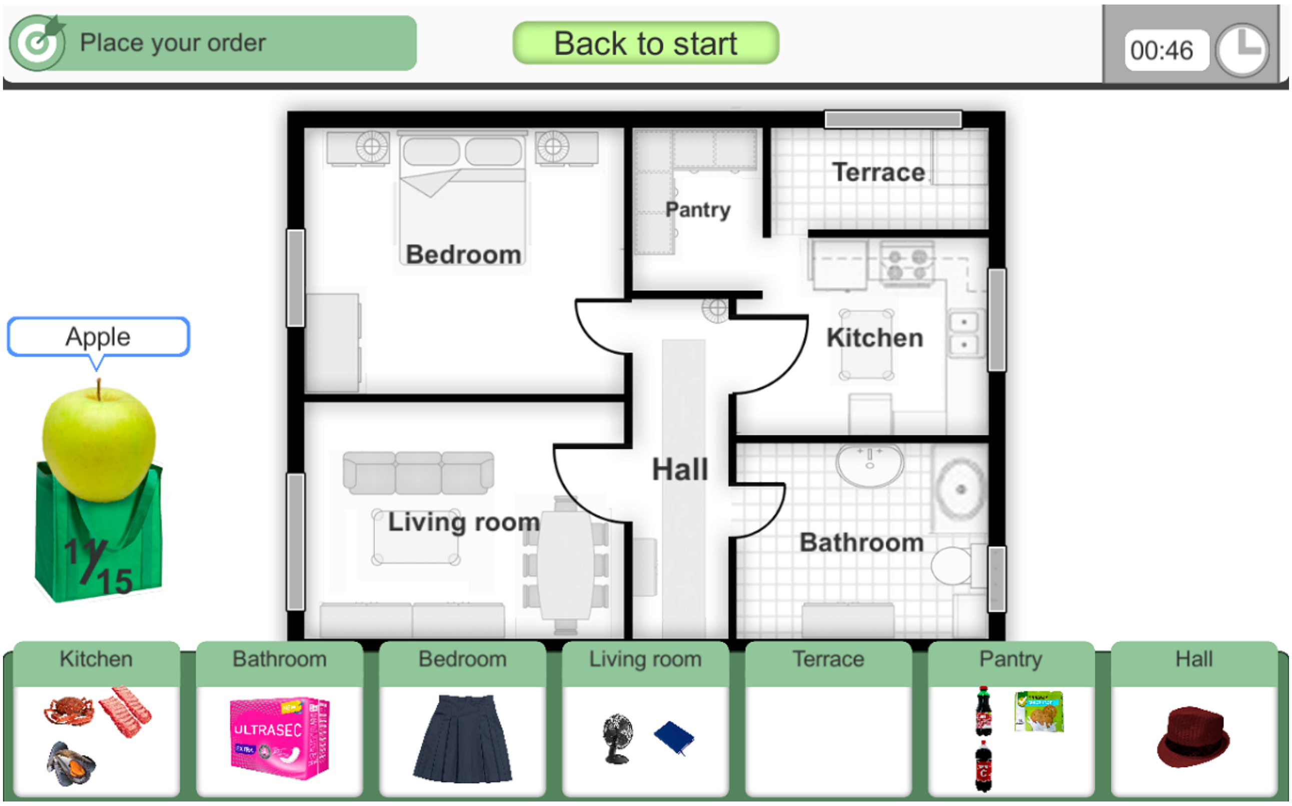
In *3.2 Phase 2*, the user must check whether the change (money returned) received is correct, and if not, he or she must select the banknotes or coins necessary to make the change amount correct.

In *3.3 Phase 3*, the user has to check the price charged for each product on the purchase receipt to verify whether it corresponds to the price for that product in the catalog, and in the case of error, to mark on the receipt the products for which the amount on the receipt is erroneous.

Fourth Exercise: Organizing the Purchase

In this exercise, the user must arrange the products of a purchase into the rooms of a house, whose floor plan appears on the screen and consists of the following spaces: kitchen, terrace, bathroom, pantry, living room, and bedroom (Figure 5). Within each of these house spaces, the correct storage location is flexible according to each product.

Figure 5. The fourth exercise stimulates executive functions. The user must arrange the products of a purchase into the rooms of a house.



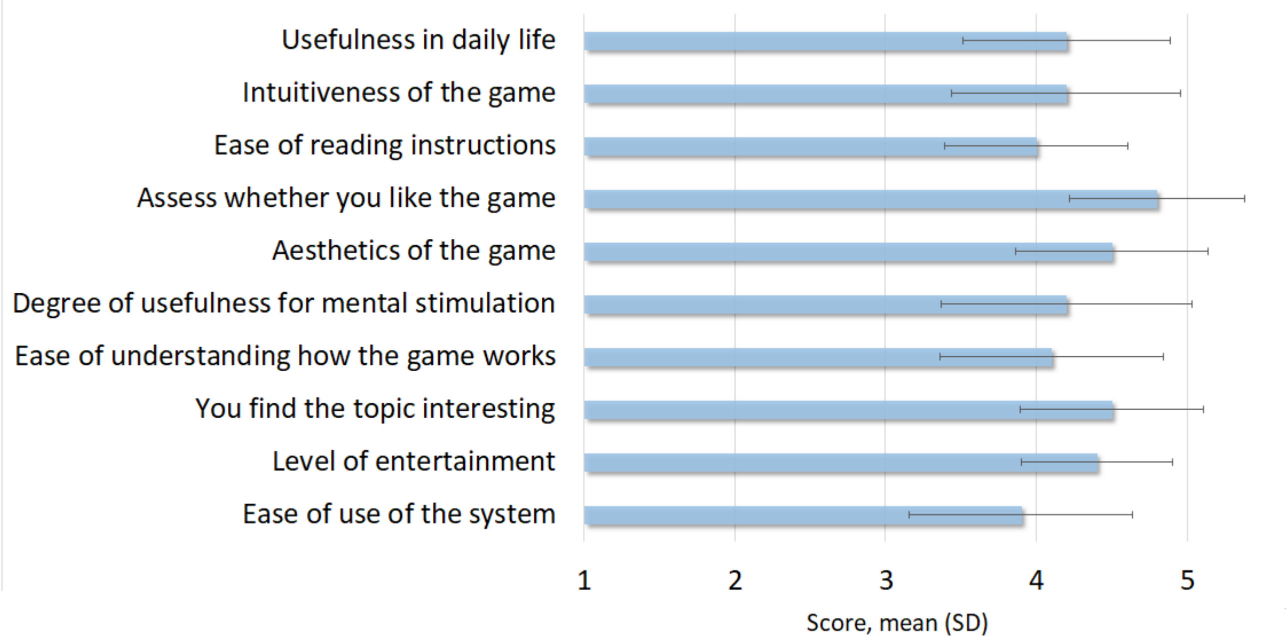
Acceptance and Usability

A total of 19 people participated in the study (Table 1) and provided their opinions regarding the serious game, which are shown in Figure 6.

Table . Demographic characteristics of participants.

Characteristics		Value (N=19)
Age (years), mean (SD)		75.3 (1.4)
Gender, n (%)		
	Woman	16 (84)
	Man	3 (16)
Level of education, n (%)		
	Secondary (high school)	19 (100)
Smartphone experience (frequency of use), n (%)		
	Once a week	19 (100)

Figure 6. Scores of older people who participated in the validation.



All items were highly valued with a score over 3.5 out of 5, which is the threshold for an item to be considered as positively validated, and the average value was 4.28 (SD 0.67). On the one hand, the most valued aspects were that participants like the game (mean 4.8, SD 0.58), both from the aesthetics point of view (mean 4.5, SD 0.64) and the interesting topic (mean 4.5, SD 0.61) of the game. On the other hand, the items that had the lowest score were the ease of use of the system (mean 3.9, SD 0.74) and the ease of reading the instructions (mean 4.0, SD 0.61).

Discussion

Principal Findings

From a cognitive point of view, the first effects of deterioration in older adults are directly related to the loss of the ability to carry out some instrumental ADL. However, there are multiple studies showing that people who read or play games are less likely to develop dementia or even Alzheimer disease [24,25]. In particular, the use of serious games has proven its value as a cognitive therapy for older people [26]. In the literature, different games have been designed and validated for cognitive stimulation [17,18], but it is not common for these games to use tasks focused on ADL. The aim of this work has been to describe how a serious game has been designed and implemented for cognitive stimulation of older adults by means of memory, naming, calculation, and organization exercises, which are key in ADL such as shopping. In this way, this serious game deals with the most frequent cognitive problems of older people indicated by health professionals.

According to the literature, it is not completely clear to what extent existing health care research explicitly distinguishes between gamification and serious games [27]. Serious games refer to the use of games and gaming technology for purposes other than just entertainment or fun, including health purposes. They can have direct or indirect positive physiological and psychological effects on people, which is precisely the objective of serious games in health and health care [28]. Our work applies to this definition because our serious game was designed for cognitive stimulation of older people with MCI and could have direct positive psychological effects on older people for the prevention or treatment of such cognitive impairment.

The preliminary pilot study carried out to validate the usability of the serious game showed that participants had a great opinion of this game and considered the theme interesting, entertaining, and useful for mental stimulation, so we can think a priori that the game could be well accepted among older people. Users found the serious game intuitive and aesthetically appealing; therefore, it meets the principles of simplicity and intuitiveness for the design of user interfaces for older people to avoid extracognitive load for the user [29].

Taking into account preferences of older people, game themes should meet their interest because they have a predilection for games related to real life [30]. In this sense, ecological validity was considered in the design of our serious game, since it is important for the validation of cognitive skills that influence functional tasks in real-world contexts [31]. Moreover, the fact that the difficulty of the game can be set by the professional to provide an achievable difficulty for each older adult user is important to motivate them to play and avoid frustration, anxiety, or negative emotions when playing [30].

Previous studies have described the benefits of using tablets for cognitive stimulation [32], but at the same time, rejection and barriers for older people in the use of these technologies have also been described [33]. In this regard, the results obtained in this study indicate that the game is easy to use and understand. However, these are preliminary findings as the study participants use smartphones in their daily live, which greatly reduces the rejection of this type of technology. Nevertheless, as future work, it is necessary to improve the interaction and facilitate the use of the game to avoid the rejection by older people, since results obtained from the questionnaires regarding the ease of use and instructions of the game were positive, but there was room for improvement.

In relation to the use of technologies by older adults and to digital health, the European Commission encourages improving the digitalization of health systems to fight health inequalities [34]. However, digital health services and devices are useless if consumers, in this case older people, do not have the skills or understanding to use them. For that, in the digital age, more than ever, literacy in digital health is a critical first step to improve the quality of life.

A feature of this serious game is that it provides feedback to the user at the end of each stage of the game, indicating whether the task was correctly completed or not and the type of mistake that was made. This agrees with Brox et al [35], who stated that when older people achieve their goal, feedback should be immediately provided. Moreover, to avoid frustration, which is another key aspect of the game, the system also provides encouraging messages during the completion of the game, so that the user can try again. This positive feedback for encouragement favors a successful experience of older user with the game [36], allowing them to achieve the goal with high motivation [30]. The use of narratives and the low complexity of the game are factors that motivate older people to play [37,38]. In this way, motivational mechanisms have been included in this serious game, which is the fundamental element for success of new training exercises.

According to the literature [39], game design features related to the game genre (GG), game nature (GN), and game development strategy (GDS) are necessary to develop a serious game. The GG covers sports, simulation, and strategy, among others. GN features include player perspective taking (first-person perspective vs third-person perspective), gameplay mode (multiplayer vs single player), type of scenery or in-game environment (realistic, fantasy themed, or simple), the presence or absence of playable characters, and the level of immersion applied to the use of immersive or nonimmersive virtual reality. GDS refers to custom-made serious games developed specifically for the study in question or direct-to-consumer approaches. In our work, regarding the GG, we can associate gender to the simulation of ADL, such as shopping, thus meeting this design criterion. In the case of GN, a first-person perspective, single-player experience, realistic scenario, the absence of playable characters, and no immersion was implemented. According to these design features, those of interest that have not been included in our serious game and could be implemented and tested in the future works are as follows: (1) a multiplayer gameplay mode: in this way, older people could simulate going shopping together with their loved one, family member, or friend, which is something they are probably used to in their life, thus increasing the feeling of sociability; and (2) changing the level of immersion to include the use of virtual reality: the use of virtual reality could be of interest, so that the older person is immersed in the game and can feel as if they are actually doing the shopping task, especially in the exercises that involve going to the supermarket, such as asking the shop assistant for the products, moving through the sections of the supermarket and filling the shopping basket with the products on the list, or even arriving home with the shopping basket and moving through the different sections of the house to place the products. All of these features would involve older people in a more realistic environment. However, the effort (human and material resources) involved in implementing these features, as well as the acceptance of older people to the use of this type of virtual reality technologies, either with glasses or simulating on a PC with a keyboard and mouse, would have to be carefully studied. Finally, regarding the third game design feature of GDS, our serious game has been implemented solely for our study, but it will be freely available for download and use by older people and health care institutions who wish to use it.

This serious game presents an alternative format to traditional interventions for older people, so we suggest defining a protocol to assess the effects on the cognitive function of older adults with a long-term intervention after a period of time to test the effectiveness of this serious game.

Limitations

The study has the limitation that the pilot study used a small sample size belonging to a limited geographical area, which may influence the generalizability of results. Therefore, it is necessary to extend these results with a larger sample size, including people of different cultural levels, with different experiences in the use of tactile devices, as well as people with different levels of cognitive impairment, to test the robustness of our findings.

Comparison With Prior Work

Ecological validity has been taken into account in the design of the serious game in this work, with tasks focused on ADL such as shopping. This is not common in the different games designed and validated for cognitive stimulation found in the literature, some of which focused on sport simulations, quizzes with text and images, music tools, arithmetic and reading calculations, etc [17], whereas others use a fantasy world setting, minigames, puzzles, or scenarios to cope with stressful or negative situations [18]. The innovative factor of including ecological scenarios of ADL tasks favors a greater interest and acceptance by older people and could help to assess the cognitive status to prevent or control the progress of the cognitive impairment.

Conclusions

In this work, an innovative serious game for cognitive stimulation of older people has been designed and developed, focusing on the ADL of shopping, incorporating motivational elements, and allowing for difficulty adaptability. The set of exercises included in the serious game have been described, including the theoretical basis on which each exercise has been implemented, which deal with the most frequent cognitive problems of older people associated with episodic declarative memory, naming, calculation, and organization. This study could serve as a basis for future serious games for cognitive stimulation of older people that may benefit from the knowledge obtained about the design strategies followed.

A pilot usability study carried out with older adults has shown that this serious game is intuitive, provides a high level of entertainment, and is useful for its application in daily life. In conclusion, according to the preliminary results obtained, we think that the serious game could be widely accepted by older people and, therefore, could become a tool that contributes to delaying their deterioration and increasing their independence. In this way, the serious game developed could contribute to increase the low degree of awareness of older people regarding the importance of leading an active life.

Acknowledgments

The authors would like to gratefully acknowledge all the people from Spain and Portugal who willingly participated in the study. Moreover, they would like to thank the Pixel Ratio SL company for the technical development of the serious game. This study was carried out under the EuroAGE+ Project (0124_EUROAGE_MAS_4_E), “Red Internacional de Investigación, Innovación y Transferencia de Tecnologías para la promoción del envejecimiento activo,” financed jointly by the European Regional Development Fund (ERDF) through the Operational Program of Cross-border Cooperation Spain - Portugal (POCTEP) 2021-2027. The paper was cofinanced by the Spanish Ministry of Science and Innovation TED2021-131739-C22, supported by MCIN/AEI/10.13039/501100011033 and the European Union “NextGenerationEU”/PRTR.

Abstract

Background: Asking questions is common in conversations, and while asking questions, we need to listen carefully to what others say and consider the perspective our questions adopt. However, difficulties persist in verifying the effect of asking questions on older adults' cognitive function due to the lack of a standardized system for conducting experiments at participants' homes.

Objective: This study examined the intervention effect of cognitive training moderated by robots on healthy older adults. A focus on the feasibility of the intervention at participants' homes was also maintained. Feasibility was evaluated by considering both the dropout rate during the intervention and the number of questions posed to each participant during the experiment.

Methods: We conducted a randomized controlled trial with 81 adults older than 65 years. Participants were recruited through postal invitations and then randomized into 2 groups. The intervention group (n=40) received sessions where participants listened to photo-integrated stories and posed questions to the robots. The control group (n=41) received sessions where participants listened to photo-integrated stories and only thanked the robots for confirming participation. The participants participated in 12 dialogue sessions for 2-3 weeks. Scores of global cognitive functioning tests, recall tests, and verbal fluency tasks measured before and after the intervention were compared between the 2 groups.

Results: There was no significant intervention effect on the Telephone Interview for Cognitive Status-Japanese scores, recall tests, and verbal fluency tasks. Additionally, our study successfully concluded with no participant dropouts at follow-up, confirming the feasibility of our approach.

Conclusions: There was no statistically significant evidence indicating intervention benefits for cognitive functioning. Although the feasibility of home-based interventions was demonstrated, we identified areas for improvement in the future, such as setting up more efficient session themes. Further research is required to identify the effectiveness of an improved cognitive intervention involving the act of asking questions.

Introduction

The aging of the world's population has led to a growing interest in maintaining a healthy lifestyle and enhancing the quality of life in later years. Previous studies have suggested that a healthy lifestyle can prevent or delay age-related cognitive decline [1,2].

Social interaction is a key component of a healthy lifestyle in later years. The social isolation attributed to social distancing during the COVID-19 pandemic may have particularly impacted older adults. For example, the impact of loneliness due to isolation on mental health is concerning [3].

Another concern is that reduced social participation can increase the risk of cognitive decline [4]. Conversations with a variety of people can be a trigger for understanding others' perspectives and acquiring new information, which plays an important role in maintaining and improving older adults' cognitive function

[5]. Sharifian et al [6] showed that older adults with a higher proportion of family members in their social networks have less contact with friends, which is negatively associated with their episodic memory. As the aforementioned study conjectured, contact with family members is usually restricted to obligatory tasks. In contrast, contact with friends is more likely to involve new conversations and information exchanges, which may be cognitively beneficial. Thus, cognitive maintenance and improvement mechanisms may be absent for older adults whose social participation is limited, such as those who only communicate with family members or caregivers or those who are completely isolated. The lives of older adults often involve factors that prevent social participation, such as the COVID-19 pandemic [7]. Therefore, methods to safely and remotely deliver cognitive training programs have been developed [8,9]. Dodge et al [8] have reported the effect of improving language-based executive function for older adults who have mild cognitive impairments through discussion intervention. However, previous studies still indicate a need for conversational human partners; hence, full automation of conversations needs further study.

Another issue in providing cognitive training for older adults is the limited available human resources for performance [10]. For example, a software agent that learns user characteristics, such as an intelligent assistant [11], could help older adults manage their health based on personal data collected automatically [12]. Furthermore, socially assistive robots may reduce the burden on caregivers to continuously monitor older adults who live alone with cognitive impairments and are at daily risk of various accidents [13].

Hence, our goal is to develop assistive robots that enable older adults' remote participation in conversational cognitive training with the same degree of effectiveness as in-person social interaction for cognitive function. Home-based cognitively assistive robots aim to conduct cognitive training for older adults at home. A previous study has suggested that cognitively assistive robots have the potential to benefit older adults and society [14,15]; however, few studies have rigorously evaluated their benefits [16]. The challenge to overcome in promoting such research is the difficulty in controlling users' characteristics related to speech. For example, depending on personality and familiarity with device use, the amount of conversation with the robot may differ from person to person. Therefore, the training effects provided by the robot cannot be accurately evaluated without controlling for such factors.

Similarly, we developed a conversational intervention program, Photo-Integrated Conversation Moderated by Robots (PICMOR), and examined its effect on healthy older adults' cognitive function [17]. Briefly, the PICMOR program is a group conversation that uses photos taken by the participants beforehand. The program consists of 2 parts. First, the participants elaborate on the photos. Second, the participants receive questions about the photos from other participants and answer them. Each part has a time limit and is controlled by a robot facilitator. Notably, the questioning time for each participant is controlled by the robot. It has the function of encouraging participants who talk too much or too little to reduce or promote their speech as needed.

In a randomized controlled trial (RCT), we observed the beneficial effects of PICMOR on performance in a letter fluency task [17]. A follow-up experiment using multimodal magnetic resonance imaging provided candidate brain metrics that could be associated with the intervention effects on phonemic verbal fluency [18-20]. For instance, resting-state functional connectivity between the left inferior frontal gyrus, one of the most important brain regions for verbal fluency, and the right temporal pole, a semantic-related brain region, positively correlated with enhanced verbal fluency performance [18]. Moreover, we conducted another RCT using PICMOR and examined whether the intervention effects on verbal fluency varied as a function of neuronal states estimated from blood-based biomarkers, such as plasma neurofilament light chain [21]. The results showed that individuals with lower neurofilament light chain, indicating a relatively intact neuronal state, performed better in a category fluency task.

Despite these observed benefits, we could not accurately identify the components of this intervention program that contribute to the enhancement of verbal fluency [18]. This is because the intervention methodology included a variety of cognitive and mental activities, such as preparing a short presentation within a certain length of time, flexibly asking and answering questions among participants, intentionally storing and manipulating information to ask questions, and refraining from interrupting other participants' utterances.

As merely developing methods to improve performance on specific tasks is not enough to improve cognitive function generally applicable to daily life, intervention strategies that bundle multiple components are being researched [22-25]. However, distinguishing these components to clarify the mechanisms underlying the intervention effects and develop more effective intervention methods is also important. In this study, we explored the effects of "asking questions" on cognitive functions among healthy older adults, assuming that it would be an important factor in verbal fluency enhancement.

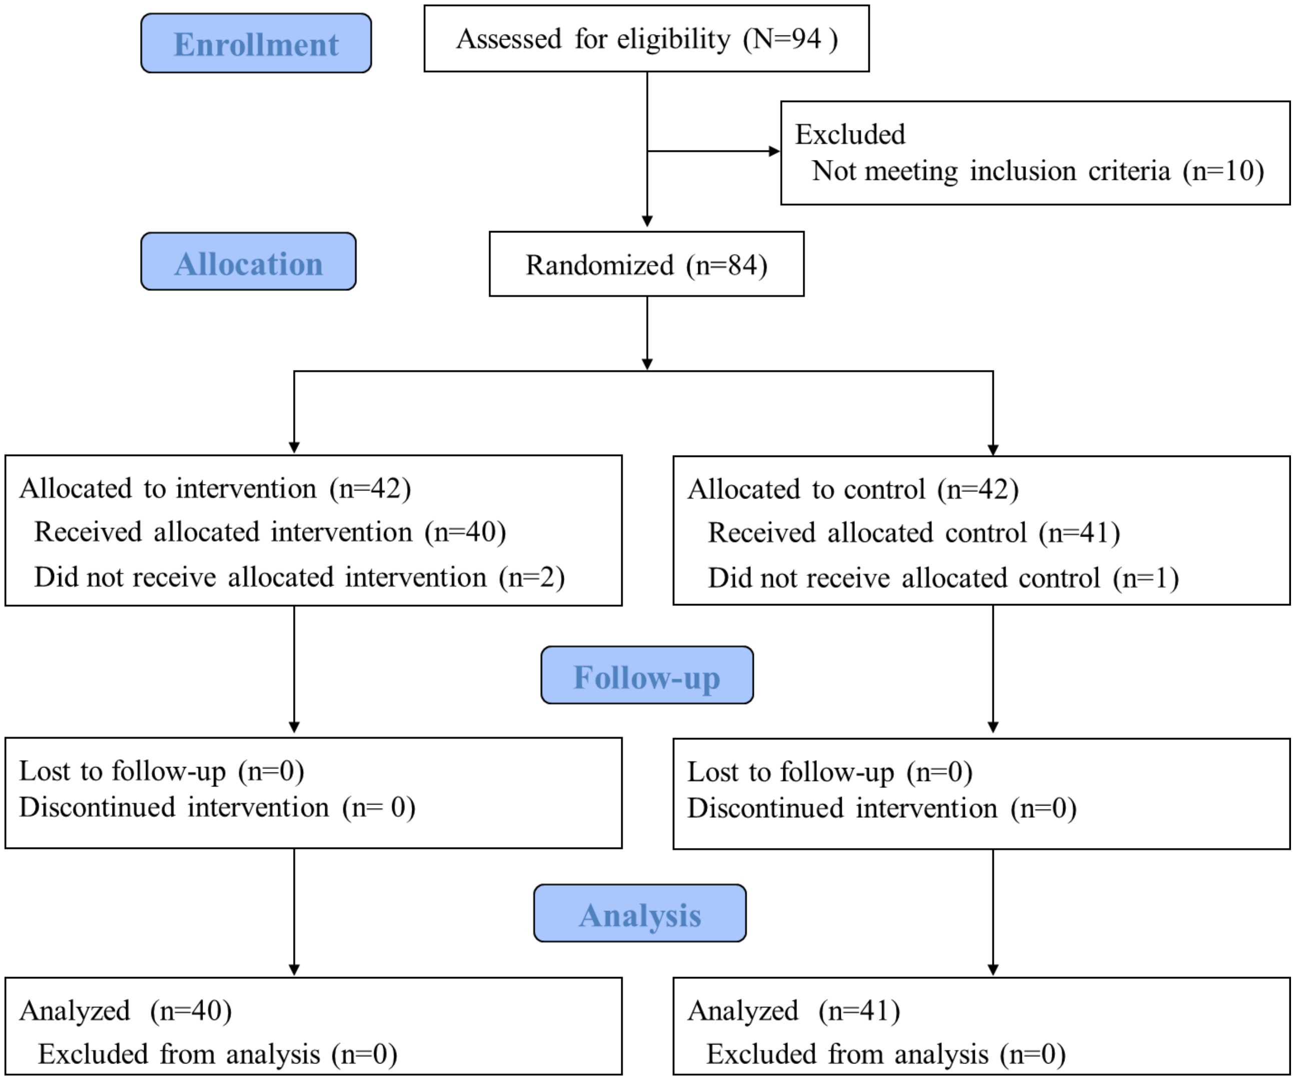
This study conducted an RCT to collect evidence on the feasibility of asking questions to robots at home and its effect on the cognitive functions of healthy older adults. Our hypothesis is that cognitive function will improve in the intervention group compared to the control group. Additionally, the effects and future improvements of the intervention program are discussed.

Methods

Trial Design

This study used an RCT with a two-parallel-arm design and 1:1 allocation. All RCT procedures were conducted from February to November 2021 at the participants' homes. Figure 1 presents the CONSORT (Consolidated Standards of Reporting Trials) flowchart of this trial. No participants dropped out of the intervention at follow-up.

Figure 1. The CONSORT (Consolidated Standards of Reporting Trials) diagram flowchart.



Ethical Considerations

The studies involving human participants were reviewed and approved by the RIKEN Ethical Committee. All participants provided written informed consent to participate in the study. The study is registered with ClinicalTrials.gov (UMIN000039489).

Participants

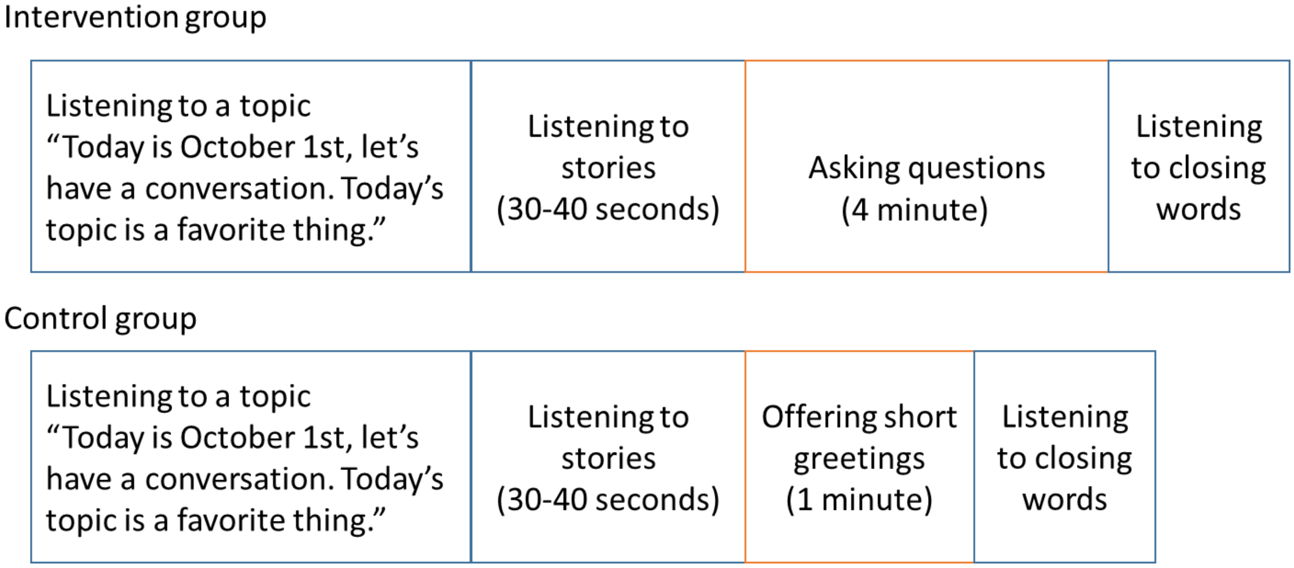
Participants were community-dwelling older adults with subjective memory concerns living in an urban city (Wako-shi) in Japan. They were recruited through postal invitations. In total, 92 participants were screened for eligibility. The eligibility criteria for the trial were as follows: (1) age ≥65 years, (2) Telephone Interview for Cognitive Status-Japanese (TICS-J) score ≥33, and (3) complaints of cognitive concern. The exclusion criteria were as follows: (1) any neurological impairment known to affect the central nervous system, (2) any serious complicating disorder, (3) any history of serious head injury, (4) any disease or medication known to affect the central nervous system, (5) medical history of stroke, and (6) need for care. We defined the term “need for care” as certification of care needs levels or “support need levels” in the Japanese public long-term care insurance system, and participants were screened based on their self-report.

Intervention Design

In the intervention group, participants listened to stories and subsequently asked the dialogue robots as many questions as possible during the experiment. In the control group, participants listened to the stories and subsequently offered short greetings to the robots as evidence of participation. Participants received 2-3 intervention sessions weekly; we arranged the schedules with participants individually to complete 12 dialogue sessions. The theme of each session was based on our previous studies [17,26]. The training and intervention procedure is described as follows: before the experiment, all the experimental devices were mailed to each participant. The system was preliminarily set up for each participant, eliminating the need for them to log in to the system. On the first day of the experiment, participants learned how to use the robot and tablets through Zoom. Then, a practice session was conducted via Zoom. In addition, 2 sessions were conducted with the administrator’s face hidden so that participants could become familiar with the devices. Finally, the participants were asked to answer questionnaires on the last day. For other experimental dates, participants received an intervention program.

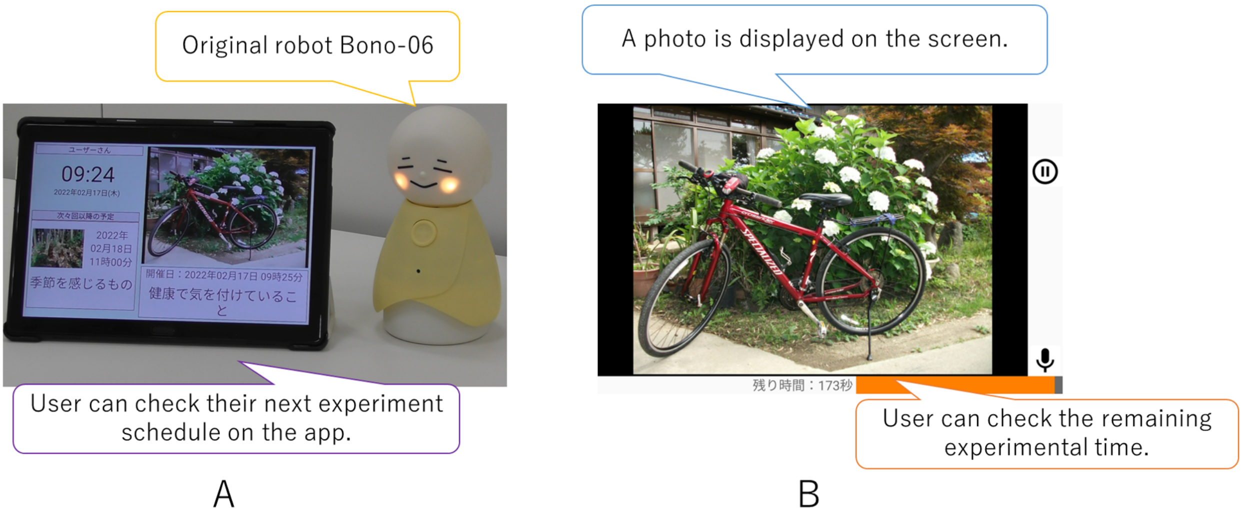
The experimental procedure for both groups included listening to a story and subsequently asking questions to robots while looking at a photo. Both the photos and a summary of the older adults' conversation (called a story) were preliminarily collected from 2 older adults [27]. For storytelling, the length of the story was adjusted to 30-40 seconds, referring to the logical memory task of the Wechsler Memory Scale-Revised (WMS-R) [28]. In the intervention group, participants posed as many questions as possible within 4 minutes. When the participants asked questions, the robots provided a plausible response from a list of approximately 550 responses collected beforehand. Contrastingly, in the control group, participants indicated their participation by simply saying "Thank you for the conversation" within 1 minute. Participants were required to push a switch before each utterance, as the pushing switch had a trigger function for the robots to activate question-answering mode. Further details are presented in Figure 2. Therefore, the difference between the intervention and control groups was whether questions were asked during the dialogue session.

Figure 2. Session timelines for the intervention and control groups.



For the experimental devices in our experimental setting, we used an original robot called Bono-06 [29] as a user interface for older adults (shown in Figure 3A). Bono-06 has 1 degree of freedom for nodding its head. Red, green, and blue full-color LEDs on its cheeks indicate the system's status, such as whether it has successfully connected to a tablet. Additionally, a push switch on the chest allows intuitive interaction with older adults. In this study, the robots were designed to enable older adults to ask them questions by only pushing a switch. We also developed an original app that manages participants' experimental schedules and displays photos and experimental time in dialogue sessions (shown in Figure 3B). The app was designed to display participants' experimental schedules and run them automatically so that participants could participate in the experiment by turning on their tablets and robots at home without cumbersome operations, such as taps and swipes.

Figure 3. Experimental devices for participants. (A) Android app and original dialogue with robot Bono-06. (B) App screen during the experiment.



Finally, the system's operation in home-based experiments was also considered [26]. A delivery and reporting function was implemented in our system so that the experiment administrator could remotely set up each experimental session as scheduled and observe the system report of each session, including the number of utterances and errors. In addition, the experiment report, including the transcribed audio, namely utterances for each dialogue session, was stored in a database on the cloud server. Thus, the experiment administrator could remotely monitor and download the results. In other words, the administrator monitored the experiment while the actual experiment was being conducted in the participants' homes.

Outcome

Our primary concern was to examine the extent to which our intervention program improved cognitive function. The TICS-J [30], recall tests, and verbal fluency tasks [31] were assessed before and after the intervention as primary outcomes by well-trained psychologists.

The TICS-J, an 11-item cognitive test, was used to assess global cognition [30]. TICS-J included the immediate recall test, in which the participants were asked to recall a 10-word list. In addition to that, we also conducted a delayed recall test 5 minutes after the immediate recall test. The numbers of words recalled were the scores of these tests. For comparison with a previous RCT [17], the results of the immediate recall test were also reported separately from the total TICS-J score.

Verbal fluency tests were conducted to assess verbal and executive control abilities. Two types of verbal fluency tasks were performed: letter and category [31]. In the letter fluency task, participants were required to produce as many words as possible, beginning with a given letter ("ka" in Japanese) within 1 minute. In the category fluency task, they were asked to produce as many words as possible belonging to a specific category (animals) within 1 minute. The number of words generated was the score for each task. All tests were conducted via telephone interviews.

As a secondary aim, we also investigated the intervention effect on the suboutcomes using questionnaires, including the World Health Organization's 26-item Quality of Life questionnaire [32], the Japanese version of the Geriatric Depression Scale (short form) [33], and the Tokyo Metropolitan Institute of Gerontology-Index of Competence [34], to assess quality of life, depression symptoms, and functional capacity.

We also examined the factors of our intervention program that should be improved in the future to increase its effectiveness, which will be mainly reported in the *Ancillary Analysis* section. First, we counted the total number of utterances to measure the extent to which our intervention prompted participants to speak. In this study, the number of turns taken by a participant in a conversation with the robot was defined as the number of utterances. Second, we related it to participants' cognitive test scores to examine how much the intervention worked differently, depending on their cognitive functions. Third, we investigated the extent to which participants's use of digital devices affected their total amount of utterances. This was achieved by asking participants to answer a 4-item questionnaire about the frequency of their use of PCs, emails, smartphones, and flip phones in their daily lives (1: usually; 2: sometimes; 3: rare; 4: never).

The reason for the distinction between smartphones and flip phones lies in the history of the cell phone market in Japan [35]. Although flip phones used to be popular in Japan, smartphone use began to exceed that of flip phones in 2013. The difference in the time of popularization between the two could result in different user demographics; in other words, those who still frequently use flip phones may be less likely to switch to a new device compared to those who use smartphones. This has particular implications among older adults, the target population of our study. In fact, in 2020, the percentage of Japanese people in their sixties using flip phones was about 26%, while that of Japanese people in their twenties was about 12%. Considering the possibility that these differences between both users might affect their attitude toward the device used in our intervention, we decided to ask them separately about their use.

Randomization Implementation

Stratified block randomization with a 1:1 allocation was implemented. Participants were stratified into male and female groups and then sorted based on total TICS-J scores. Subsequently, blocks of size 2 were created and randomized. The coding was performed in R 4.3.2 (R Foundation for Statistical Computing). This determined which participants belonged to the intervention or control group. The experimenter assigned participants to the 2 groups based on this result. The person who conducted the randomization was different from the experimenter and had no information other than IDs, TICS-J scores, and gender at the time of randomization. The assessors were blinded to the allocation results.

Statistical Analysis

As explained in the *Outcome and Estimation* section, we used linear mixed models with random intercepts to examine the effects of the intervention on cognitive function. The models included total TICS-J scores, immediate and delayed recall test scores, letter fluency test scores, and category fluency scores as outcome variables, with time (1: end point; 0: baseline), group (1: intervention group; 0: control group), and their interaction terms as independent variables. We interpreted the regression coefficients associated with the interaction terms as the degree of the intervention effects. We also reported the sizes of intervention effects measured by f^2 [36].

For the ancillary analysis, we applied linear mixed models with random intercepts to the intervention group, which included cognitive function scores as outcome variables; time, the number of utterances, and their interaction terms as explanatory variables; and gender, age, and education as control variables. For these models, we reported regression coefficients associated with the number of utterances to understand the relationship between cognitive function scores at baseline and the number of utterances; we also reported regression coefficients associated with the interaction term to understand the relationship between the number of utterances and change in scores before and after the intervention. In addition, we reported the relationship between participants' digital device use in the intervention group and their total number of utterances using 2-tailed t tests.

All analyses were performed using R. To implement the linear mixed models, the lmer function in the R package (lme4) was used [37].

Results

Baseline Data

A total of 40 participants in the intervention group and 41 in the control group underwent cognitive testing, both at baseline and end point, and were included in the analysis. Table 1 shows the baseline characteristics of the participants. For all demographic and cognitive variables (Table 1 and Table 2), there were no major differences between the intervention and control groups, namely, participant attributes were balanced at baseline.

Table . Baseline characteristics of the intervention and control groups (N=81).

Characteristics		Intervention (n=40)	Control (n=41)
Age (year), mean (SD)		73.9 (3.8)	74.0 (4.1)
Gender (female), n (%)		24 (60)	25 (61)
Education (≥13 years), n (%)		19 (48)	30 (73)
WHO[a] QOL26[b] questionnaire, mean (SD)		3.68 (0.38)	3.67 (0.41)
GDS-15[c], mean (SD)		2.17 (2.00)	2.05 (2.32)
TMIG-IC [d] , mean (SD)			
	Total score	11.93 (1.1)	11.73 (1.3)
	Instrumental activity of daily living	5.00 (0.0)	4.95 (0.2)
	Intellectual activity	3.62 (0.7)	3.73 (0.6)
	Social role	3.30 (0.9)	3.05 (1.0)

Outcome and Estimation

Table 3 shows the results of the linear mixed models used to examine the intervention effects on cognitive function. No significant intervention effects were found for the total TICS-J score, immediate and delayed recall, and verbal fluency. The regression coefficient associated with the time-group interaction term for the category fluency test score was the largest among the study outcomes (1.361), but the effect was not significant (P=.09; effect sizes of f^2<0.01 for all outcomes). We found no significant intervention effects on any of the secondary outcomes. Table 4 shows the conversation theme of each session and the descriptive statistics for the number of participants' utterances therein.

Table . Results of the linear mixed models used to examine the intervention effects on cognitive function.

Table . Descriptive statistics of the number of utterances per session. The participant count in the intervention group is 40. Mean, SD, minimum, and maximum are at the participant level.

Theme	Total, n	Mean (SD)	Minimum	Maximum
1. Favorite things	291	7.28 (2.20)	1	10
2. Neighborhood landmarks	344	8.60 (1.85)	2	11
3. I try to get off the train at a station that I seldom use	346	8.65 (2.05)	2	11
4. Favorite foods	346	8.65 (1.70)	4	12
5. For my health	335	8.38 (1.23)	5	10
6. Found on a 10-minute walk	363	9.07 (1.94)	4	11
7. Saving energy	317	7.92 (1.67)	4	11
8. Funny stories and mistakes	328	8.20 (1.92)	4	11
9. Things to get rid of	323	8.07 (1.83)	2	11
10. Tips for daily living	353	8.82 (1.80)	3	12
11. Feeling the season	359	8.97 (1.75)	5	12
12. Starting something new	366	9.15 (1.72)	5	12

Ancillary Analysis

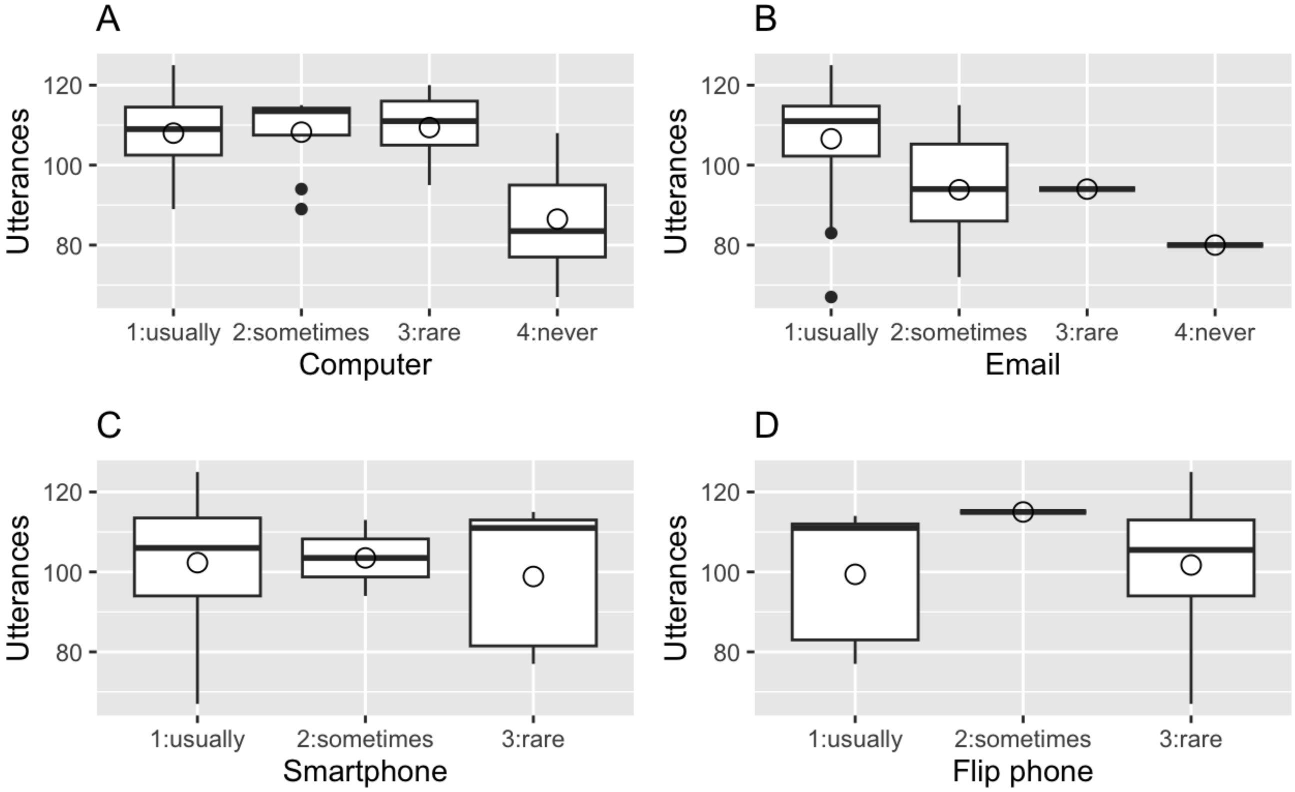
The average total number of utterances of the participants in the intervention group was 101.78 (SD 14.72). The number of utterances was positively correlated with a higher letter fluency score at baseline (letter fluency: B=0.11, SE 0.04; *P*=.01), while no significant associations were found for the other outcomes (TICS-J: B=0.03, SE 0.03; *P*=.30; category fluency: B=0.10, SE 0.06; *P*=.07; immediate recall: B=−0.01, SE 0.02; *P*=.64; delayed recall: B=0.01, SE 0.02; *P*=.55).

There was no significant association between the number of utterances and change in scores for any of the outcomes (TICS-J: B=−0.03, SE 0.03; *P*=.31; category fluency: B=−0.01, SE 0.04; *P*=.79; letter fluency: B=0.02, SE 0.03; *P*=.63; immediate recall: B=−0.003, SE 0.02; *P*=.85; delayed recall: B=−0.01, SE 0.02; *P*=.76).

Figure 4 shows the relationship between the digital device use of participants in the intervention group and their total number of utterances. In Figure 4A, we notice that participants who never used a computer had fewer utterances. In fact, the average number of utterances for participants who chose “4: never” was

86.50, compared to 108.32 for participants who chose options other than “4: never.” This difference was significant (*P*<.001). In Figure 4B, we observe that participants who usually used email had more utterances. In fact, the average number of utterances for participants who chose “1: usually” was 106.58, compared to 92.8 for participants who chose options other than “1: usually.” This difference was significant (*P*=.005). No significant associations were found between the frequency of smartphone use and flip phone use and the number of utterances (Figure 4C and 4D). This result persisted in regression analyses, even after controlling for age, gender, and education years. Associate regression coefficients were 19.69 (SE 4.15; *P*<.001) for computer use, 12.06 (SE 4.44; *P*=.01) for email use, 3.74 (SE 5.39; *P*=.49) for smartphone use, and −2.89 (SE 6.75; *P*=.67) for flip phone use.

Figure 4. Box plots for the relationship between the frequency of device use by participants in the intervention group (horizontal axis) and the total amount of their utterances (vertical axis). Boxes represent IQRs. White circles indicate the mean values. Black lines in boxes indicate the median values. Observations outside the first (third) quartile (i.e., outside of 1.5 × IQR) are indicated by black circles. No participant selected “4: never” for C and D.



Discussion

Overview of This Study

This paper presented the intervention effect of asking questions to improve cognitive function in healthy older adults. The intervention involved an RCT conducted at participants’ homes. There were no significant intervention effects on scores of TICS-J, recall tests, and verbal fluency tasks. Notably, the feasibility of the intervention was confirmed, as all participants were able to ask at least 1 question in every session, with no participants dropping out.

Principal Results

This study identified no significant intervention effect in category fluency task scores and letter fluency task scores. In both types of verbal fluency tasks, the number of words produced per unit of time is commonly used as a behavioral index. However, the mechanisms of word production are supposedly quite different. The category fluency test requires retrieval of content included in a given semantic category, which involves access to semantic memory. This mechanism helps one use existing links between related concepts, such as those between the categorical label and its contents and among associated category members [38]. In contrast, the letter fluency task demands retrieval from a phonemic category in which the association of semantically related words should be suppressed [38]. This strategy depends on an effortful exploration of lexical systems. To ask questions, one must understand the meanings of others’ utterances and identify what is unclear with reference to one’s knowledge. A series of these processes would inevitably involve access to semantic memory.Nonetheless, no intervention effect was found on category verbal fluency and letter fluency.

This result may have been influenced by the short duration of the intervention. Other studies have involved longer experimental periods, lasting 6 [8] and 12 weeks [17]. Therefore, further studies are needed to clarify the effectiveness of asking questions, for example, by setting up a program with a longer intervention period. Another reason why the results did not show any significant intervention effects may pertain to various elements included in the conversations. We solely focused on asking questions and did not incorporate other elements into the intervention. Older adults who are more inclined to compare opinions with others display higher cognitive function [5]. Therefore, thinking about things from the perspective of others during conversations and thinking about the similarities and differences between oneself and others may be important for improving or maintaining cognitive function. Considering this, simply asking questions is not an adequately strong intervention to affect cognitive function, and combining questions with other cognitive elements, such as thinking about questions from the other person's point of view or asking questions based on the similarities and differences between one's thoughts and those of others, may be effective in strengthening future interventions.

Another area of interest is the feasibility of home-based interventions and their improvement. As shown in Table 4, all participants asked at least 1 question in every session, and no participants dropped out. These results indicate the feasibility of this intervention method.

The result that the frequency of device use was positively correlated with the number of questions asked during the intervention, even after controlling for age, gender, and years of education, suggests that future improvements to the usability of our system may enhance intervention effectiveness. One could be optimistic about this point. As Table 4 further indicates, the average number of utterances increased slightly more in the latter half of the intervention period compared to the former. This may have occurred because participants became accustomed to the system through repeated session participation. A more extended intervention period may compensate for the disadvantage owing to the lower frequencies of device use.

However, in terms of the social implementation of intervention programs, such a view may be too optimistic. This is because users may want to discontinue use of the program before becoming accustomed to it. From this perspective, we need to continue improving usability and developing appropriate evaluation methods, keeping in mind that our target population is older adults [39]. For example, it would be helpful to investigate which individuals, among those who use less frequently digital devices at baseline, are more likely to experience higher intervention effectiveness.

Furthermore, it would be important to have a perspective on what kind of interface to provide and how to personalize it according to the user's preferences or personality as well as the characteristics of the user's daily conversations [40], to keep them motivated to continue with the intervention program. This could lead to an overall increase in the effectiveness of the intervention, benefiting even those who are already accustomed to using the device.

Strengths

This study has some strengths. One strength is that we presented a technical framework for examining the impact of "asking questions," an important factor for conversation-based interventions for cognitive function, which was lacking in our previous studies [17,21]

Another strength of this study is that we successfully conducted home-based interventions while most intervention studies, including our previous ones [17,21], have been conducted on-site. Notably, this study demonstrated that home-based interventions are feasible even though some participants were unfamiliar with digital devices.

Finally, a strength of our study is that the system is fully automated after human-assisted training, requiring fewer human resources compared to previous methods. The impact of automation on participants' satisfaction needs further investigation.

Limitations

This study has several limitations. First, this study is limited by the diversity and sample size of the participants. Currently, this program only supports Japanese people; therefore, this study was conducted in an urban city in Japan for feasibility. Second, this study was conducted during the COVID-19 pandemic; hence, the research was designed to reduce communication as much as possible to keep the participants safe. To achieve this, we did not collect magnetic resonance imaging data from participants, unlike our previous intervention study [17]. Therefore, from a neural perspective, this study could not obtain useful information about the impact of asking questions on improving the intervention effect on cognitive function. The importance of asking questions in conversation-based intervention programs should be reevaluated in future research after accounting for these issues.

Finally, we did not sufficiently examine the effects of session topics and their order on the number of participants' utterances. The topics suitable for improving cognitive function through conversation must be neither so challenging that participants cannot generate questions nor so easy that they do not train cognitive function. There has already been a study that identified the characteristics of utterances by older adults with higher cognitive functioning in group conversations, and then, identified conversation topics in which such utterances are likely to be observed [41]. However, this has not been examined in terms of encouraging participants to ask questions and enriching the conversation. Future studies should consider setting up efficient session themes for improving cognitive function.

Conclusions

This study evaluated the possible improvements associated with introducing a dialogue-based robot in cognitive interventions, aiming to verify the training effects of asking questions in healthy older adults.

We did not observe any significant differences in global cognition between the 2 groups. The feasibility of our study was identified by (1) no loss in the intervention and (2) all participants asking at least 1 question in every session. We also recommend improvements to the intervention program, such as setting up more efficient session themes for cognitive training. This study has provided future directions for cognitive training studies of older adults at home.

Acknowledgments

We are grateful to all the study participants and staff. We would especially like to thank Sachiko Iwata and Kumiko Umemoto for their support. This research was partially supported by Japan Society for the Promotion of Science (JSPS) KAKENHI (grants JP18KT0035, JP19H01138, JP20H05022, JP20H05574, JP20K19471, JP22H04872, and JP22H00544) and the Japan Science and Technology Agency (grants JPMJCR20G1, JPMJPF2101, and JPMJMS2237).

Abstract

Background: Markerless motion capture (MMC) uses video cameras or depth sensors for full body tracking and presents a promising approach for objectively and unobtrusively monitoring functional performance within community settings, to aid clinical decision-making in neurodegenerative diseases such as dementia.

Objective: The primary objective of this systematic review was to investigate the application of MMC using full-body tracking, to quantify functional performance in people with dementia, mild cognitive impairment, and Parkinson disease.

Methods: A systematic search of the Embase, MEDLINE, CINAHL, and Scopus databases was conducted between November 2022 and February 2023, which yielded a total of 1595 results. The inclusion criteria were MMC and full-body tracking. A total of 157 studies were included for full-text screening, out of which 26 eligible studies that met the selection criteria were included in the review.

Results: Primarily, the selected studies focused on gait analysis (n=24), while other functional tasks, such as sit to stand (n=5) and stepping in place (n=1), were also explored. However, activities of daily living were not evaluated in any of the included studies. MMC models varied across the studies, encompassing depth cameras (n=18) versus standard video cameras (n=5) or mobile phone cameras (n=2) with postprocessing using deep learning models. However, only 6 studies conducted rigorous comparisons with established gold-standard motion capture models.

Conclusions: Despite its potential as an effective tool for analyzing movement and posture in individuals with dementia, mild cognitive impairment, and Parkinson disease, further research is required to establish the clinical usefulness of MMC in quantifying mobility and functional performance in the real world.

Introduction

Markerless motion capture (MMC) technology uses sensors and advanced software algorithms to track and analyze human movement, without the attachment of physical markers to individuals or the use of external devices such as pressure sensors or wearables. There is growing use of MMC to provide highly accurate quantitative parameters of physical function including mobility [1,2], balance [3], upper extremity tasks [4], and activities of daily living (ADL) [5].

While 3D motion capture systems using markers are considered the gold standard for movement analysis, they have several limitations including their lack of portability, the need for trained staff, and the requirement for reflective markers to be placed precisely on participants' bodies [6]. In contrast, the use of MMC provides several advantages: being easier to operate, requiring less space, and being more economical than traditional marker-based systems [7]. Importantly, their ability to capture movement unobtrusively is a key benefit for user compliance [8], particularly when working with individuals with cognitive impairments.

MMC is attractive for health care and research use, such as monitoring functional performance loss or improvement in neurodegenerative diseases. While traditional movement analyses are based on subjective clinical assessments, MMC can be used to generate objective and quantifiable digital biomarkers that can help detect a decline in functional performance by capturing movement unobtrusively [9]. Variations in these digital biomarkers could indicate underlying impairment and enable earlier support. The fact that MMC can be deployed in home environments may avoid unnecessary hospital visits for patients, as well as detect subtle changes in functional ability that may only be apparent in everyday home-based settings rather than within a clinic.

Several MMC devices can provide cost-effective assessments of functional performance in research and clinical settings. Broadly, the 2 main types of MMC camera hardware are depth cameras and standard red-green-blue (RGB) video cameras, used in single or multicamera systems. Commonly used and widely accessible depth cameras are the Kinect (Microsoft) devices, which use standard RGB color video as well as depth estimation by recording the distance between the camera and each pixel through the emission of structured light patterns [10]. Machine learning algorithms can be used to reconstruct 3D skeletal models in real-time from the RBG+depth (RBG-D) image. Alternatively, deep learning can be used with standard video cameras or mobile phone cameras to record limb location and orientation. This method uses deep neural networks trained from large datasets to estimate body segment position and orientation (pose) and motion tracking, without explicit depth sensing. It requires specific body segment positions known as the 6 degrees of freedom: 3 rotational (flexion or extension, abduction or adduction, and rotation about the longitudinal axis) and 3 translational (sagittal, frontal, and transverse) [11]. Both forms of MMC have shown promising use thus far.

A scoping review of single-camera MMC models used in health care highlighted the significant potential for use in clinical applications but also noted the need to improve their tracking accuracy [12]. A previous systematic review of MMC-based training devices used in neurological rehabilitation found that these devices improve motivation and enable better functional performance potentially due to the gaming element [13]. Another systematic review of MMC-based devices in rehabilitation found that balance training with the support of MMC resulted in better outcomes potentially due to more dynamic training conditions [14]. While those systematic reviews explored the use of MMC specifically in rehabilitation training, this review focuses on the technology-based evaluation of functional tasks. The recent increase in the number of studies involving MMC-based movement analysis in neurodegenerative diseases offers a strong rationale for this review. This trend includes the use of MMC to track gait decline [9], assess fall risks [15,16], detect disease traits [17], estimate disease severity [18], and detect cognitive impairment from gait features [19].

Neurodegenerative diseases such as dementia and Parkinson disease (PD) lead to declining functional performance. Detecting problems in everyday functional tasks in these patient groups can help provide early, timely, and clinically appropriate interventions that may help maintain independence, decrease caregiver burden, and potentially slow the rate of functional decline [20,21]. MMC can provide digitally measured functional performance data that could be used to enhance clinical decision-making and remote monitoring; identify risks such as falls; and better capture the impact of rehabilitative, pharmacological, and surgical interventions. Although MMC technology could offer the potential for detecting functional changes in neurodegenerative diseases, a model that is comparable to established gold-standard motion capture systems is essential for deployment in real-world applications. This study aimed to complete a systematic review of published literature on the use of MMC with full-body tracking for quantifying functional performance in people with dementia, mild cognitive impairment (MCI), and PD.

Methods

Study Design

The web-based Covidence (Veritas Health Innovation) software platform was used in this review, and the titles and abstracts were screened by 2 independent reviewers. The full text of the relevant studies was reviewed, and the quality of the studies was assessed by 2 independent reviewers. Data extraction was also performed by 2 independent reviewers, and any conflicts were resolved through discussion.

Search Strategy

The search strategy was designed to include all types of studies that used MMC with full-body tracking in individuals with dementia, MCI, or PD. To identify relevant studies, a combination of both the Medical Subject Headings thesaurus and free-text terms related to the 3 conditions and MMC technology were used. The search included publications from all years in the CINAHL, Embase, MEDLINE, and Scopus databases using the terms "Motion Capture," "Motion Analysis," "Movement Analysis," and "Pose Estimation" in combination with "Dementia," "Mild cognitive impairment," and

"Parkinson's disease." The details of the search activity can be found in Multimedia Appendix 1.

Inclusion and Exclusion Criteria

The inclusion criteria for the systematic review were as follows: (1) markerless optical motion capture; (2) full-body tracking; (3) involving participants with dementia, MCI, or PD; (4) original research; and (5) English language studies. Studies with the following characteristics were excluded: (1) motion capture with markers, inertial measurement units, body-worn sensors, or pressure sensors; (2) movement analysis of specific parts of the body or symptoms such as tremor and rigidity; (3) evaluating interventions such as exercises, deep brain stimulation, medication, rehabilitation protocol, dance, and gaming; and (4) pose estimation of videos found on the internet.

Data Extraction

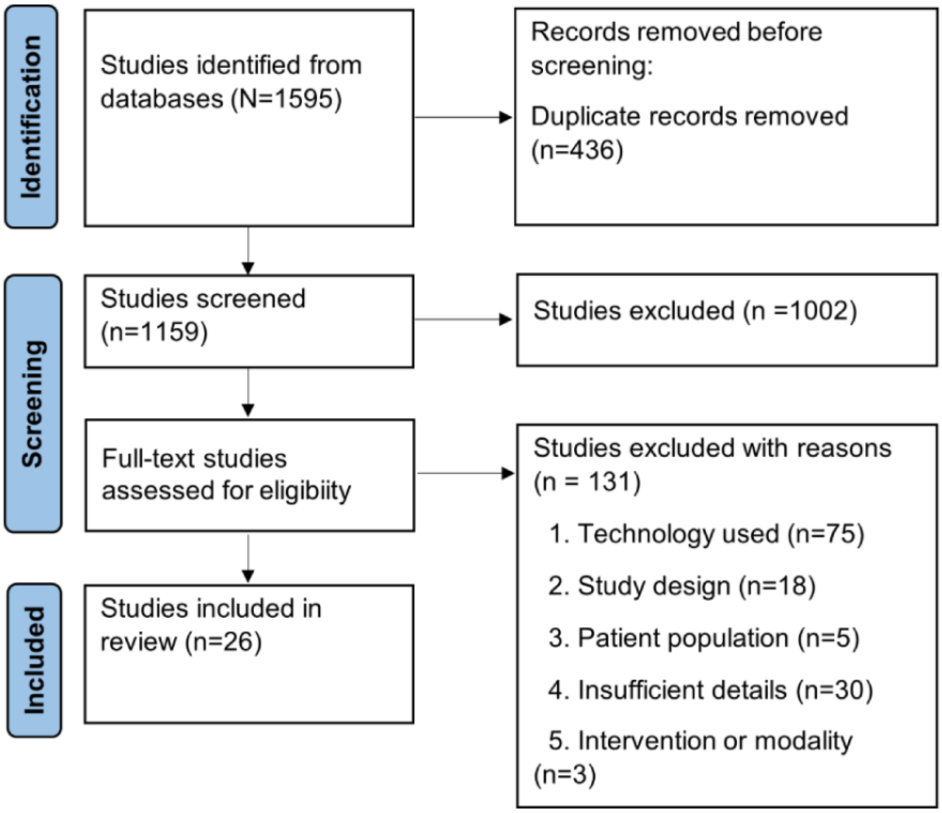
The general information extracted from the studies included: the center and country where the study took place; study characteristics; funding sources; age, sex, and number of participants; number and duration of visits; study aims; inclusion and exclusion criteria; and the main disease condition evaluated. Methodological information extracted included technical details of the MMC system used; functional performance area evaluated, for example, gait or sit to stand; software used for feature extraction; and the method of analysis. The results information extracted included the following: statistically significant movement features, whether they were measured under single or dual task (motor or cognitive) conditions, whether compared to established gold standard models or a relevant clinical measure, and key outcomes including the level of accuracy obtained.

Results

Study Selection

The literature search yielded 1595 results; after removing duplicates, 1159 studies remained for title or abstract screening. Subsequently, 131 studies were identified for full-text screening, of which 26 studies met the inclusion criteria and were included in the review. A PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart [22] outlining the selection process can be found in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram for new systematic reviews.



Quality Assessment

The 26 selected studies were assessed for quality using the Specialist Unit for Review Evidence questions to assist with the critical appraisal of the cross-sectional studies tool [23]. While no studies were excluded from the review based on this assessment, issues pertaining to quality were identified within several of the studies. Table 1 shows that all studies included in this review used appropriate outcome measures (n=26, 100%).

Most studies clearly stated the study design (n=20, 77%); provided information on the study setting, location, and dates (n=20, 77%); described the results well (n=19, 73%); and provided participant characteristics (n=16, 62%). However, few studies reported if participants were fairly selected (n=10, 38%) or provided information on participant eligibility (n=2, 8%) and handling of missing data and control of potential biases (n=1, 4%).

Table 1. Quality assessment summary.

Study	Is the study design clearly stated?	Are the setting, location, and relevant dates provided?	Were participants fairly selected?	Are participant characteristics provided?	Are the measures of exposures and outcomes appropriate?	Is there a description of how the study size was arrived at?	Is there information on how missing data was handled and whether sources of bias were controlled for?	Is information provided on participant eligibility?	Are the results well described?

Patient Groups

The 26 studies comprised 18 involving participants with PD, 6 involving participants with dementia, and 2 involving participants with MCI. Most (18/26, 69%) of the studies used Kinect sensors for MMC. All studies that included participants with dementia (n=6) used the Kinect sensor and were conducted in inpatient settings. The Kinect was used to quantify gait decline over 10 weeks [9], propose a prognostic model for fall risk [15], and demonstrate the association with clinical gait measures and future falls [16]. In inpatients with dementia and drug-induced Parkinsonism, the Kinect was used to capture Parkinsonian traits [17]; quantify Parkinsonian gait [38]; and along with pose estimation of recordings from a video camera, estimate Parkinsonian severity [18]. It was also used in the MCI studies reviewed (n=2), as a tool to detect MCI from gait features [19,39].

Of the 18 studies that included participants with PD, 10 (56%) reported the use of the Kinect sensor for analyzing gait, including its feasibility to extract relevant features [34,42], ability to detect PD [24,32,41,43], and ability to measure clinical disease severity [28,31,33]. Alternative MMC models that use image processing for pose estimation of videos from RGB cameras have also been used with participants with PD, demonstrating the feasibility of these models in quantifying gait impairment and disease severity [18,25-27,29,30,36,40].

Functional Performance Components

Most studies (24/26, 92%) evaluated aspects of gait, although there were significant variations in the features extracted and methods used for analysis, with some of them lacking statistical significance. Other functional performance components evaluated were sit to stand (n=5) and stepping in place (n=1). Table 2 shows functional performance components by study.

[a] PD: Parkinson disease.

[b] MCI: mild cognitive impairment.

[c] ROM: range of motion.

Feature Categories

Table 2 shows extraction feature categories by study. Spatiotemporal features of gait that were reported as having statistical significance included spatial parameters, such as step length (n=8), step width (n=5), and stride length (n=4), and temporal parameters, such as cadence (n=5), gait velocity (n=4), step time (n=4), stance duration (n=1), double support duration (n=1), stride time (n=1), turning time (n=1), turning speed (n=1), swing time (n=1), step velocity (n=1), and stride velocity (n=1). Other extracted feature categories included symmetry (n=9), stability (n=8), range of motion (n=2), and rhythmicity (n=1).

MMC Devices and Feature Extraction Methods

Table 3 shows that most studies (18/26, 69%) used Kinect depth cameras (4 used V1; 12 used V2; 1 used Kinect eMotion; and the latest version, the Azure Kinect, was used in 1 study), while the remainder used regular video or mobile phone cameras. Common camera positioning included frontal views (n=4), ceiling-mounted (n=4), and multiple cameras from different angles (n=3). However, camera position was not reported in 7 of the study papers. The majority of studies have developed their own custom programs (n=10, 38%) or have used open-source libraries (n=8, 31%) to identify bodies in frame and extract movements. The use of propriety software was less common (n=5).

Table 3. Markerless motion capture devices and feature extraction methods used.

Study	Device (camera or sensor)	Devices, n	Frames per second (fps or Hz)	Position of cameras	Extraction methods
Cimolin et al (2022) [24]	Kinect V2	1	30	Tripod in front	Custom algorithm

Ťupa et al (2015) [43]	Kinect V1	1	30	60 cm above floor	Custom algorithm

Key Findings

Tables 4-6 summarize the key findings of the 26 studies that used MMC to study movement features in people with dementia, MCI, and PD. Stride length, cadence, gait stability, step length, arm swing, and number of steps were the primary features investigated in these studies. Notably, several studies [26,28,33,37] found that stride length and cadence are commonly affected in those with PD. Other studies [15,31,38] highlighted the potential of MMC for predicting fall risk and discriminating between individuals with PD and controls.

Most studies (20/26, 77%) used some form of clinical validation for the assessment of disease, and patients were referred to or assessed within a clinical research facility by a clinician. The most common clinical measures used were the Unified Parkinson's Disease Rating Scale (UPDRS) for assessing Parkinsonism symptoms in those with PD and dementia and the Performance Oriented Mobility Assessment–gait and Performance Oriented Mobility Assessment–balance assessments for evaluating mobility characteristics. Many of the studies (23/26, 88%) used the MMC features to classify patients from control participants and to classify symptom severity (eg, UPDRS scores in PD) using various techniques, including support vector machines, random forest models, multivariate ordinal logistic regression, and adaptive neuro-fuzzy inference system classifiers. Several studies reported excellent classification accuracy, with some achieving 100% accuracy [26,27,41]. For instance, Seifallahi et al [39] achieved an accuracy of over 90% for differentiating between people with MCI and controls using an adaptive neuro-fuzzy inference system classifier. Khan et al [26] reported a 70.83% accuracy in predicting UPDRS-gait scores using a support vector machine model, with an area under the receiver operating characteristic curve of 80.88%.

Conversely, most studies included within this review (20/26, 77%) did not evaluate their MMC system or algorithms against an established gold-standard motion capture model, making it difficult to conclude whether their derived features for monitoring functional performance characteristics were comparable to an accepted measure of movement analysis. Some notable exceptions such as Cimolin et al [24] compared their Kinect setup to a Vicon system, which is an accepted and clinically validated method for assessing gait. Other studies used established and clinically validated spatiotemporal measures including the GAITRite system [34,40] and the Zeno Walkway system [37], although the study by Pedro et al [34] only had 2 participants. Li et al [29] had experts manually annotate videos, which, while subjective, proved effective for creating labels to train machine learning algorithms for task segmentation. They also used automated labeling to generate subtask segmentation, which could help automate larger-scale studies and clinical assessments.

MMC models showed moderate to strong positive correlations with Vicon [24], Zeno [37], and GAITRite [40]. However, some of the studies also identified limitations of MMC. For example, Pedro et al [34] found that Kinect cameras may overestimate step length variation in people with PD due to inherent smoothing, while Sabo et al [37] found that automated heel strike algorithms may struggle to identify short steps. Some studies [19,29] reported challenges with data processing and interpretation, highlighting the need for more standardized methods in this field.

Despite these limitations, the findings suggest that MMC is a promising tool for studying characteristics of functional performance in people with dementia, MCI, and PD. It is worth noting that specialized depth cameras may not be necessary for extracting suitable joint positions in camera space [37]. However, further research in this field is warranted to fully understand the potential of MMC.

Table 4. Key findings from studies that used the Kinect.

Study	Primary features	Main results
Cimolin et al (2022) [24]	• Gait cadence, mediolateral sway, and step width	• Strong positive correlation between Kinect and Vicon systems for gait cadence and mediolateral sway (ICC[a] 0.94-0.97) and a weak correlation for step width (ICC 0.44) in people with PD[b]
Kondragunta et al (2020) [19]	• Gait cycle (dynamic time warping)	• SVM[c] for classifying between controls, persons with possible MCI[d], and persons with MCI: 74.6%-87.3%
Lai et al (2022) [28]	• Stride length, straight walking speed, and turning speed	• Mediation analysis demonstrates decreased stride length, walking speed, and turning speed are associated with increased falls prediction model score (*r*=–0.58, *r*=–0.52, and *r*=–0.46, respectively; *P*<.001) • UPDRS[e] negatively correlated with features (*r*=–0.65, *r*=–0.56, and *r*=–0.37, respectively; *P*<.001) but positively with fall prediction model score (*r*=.53, *P*<.001) • UPDRS serves as a mediator for features and higher fall prediction model scores

Mehdizadeh et al (2021) [9]	• Gait stability, step time, step length, step time variability, and step length variability	• Mixed effects models over 10 weeks show:
		  • Decrease in primary features and an increase in variability over time for people with dementia
		  • Gait stability decreased more in men
		  • Mediolateral range of motion decreased in those with mild neuropsychiatric symptoms but increased in those with more severe symptoms

Mehdizadeh et al (2021) [15]	• Gait stability.	• Cox proportional hazard regressions show gait stability predicts time to fall in people with dementia (ROC[f] 0.80 at 7 days, 0.67 at 30 days)
Muñoz-Ospina et al (2022) [31]	• Left and right arm and ankle swing (magnitude and speed), stance time, gait speed, total time, and number of steps	• Random forest model was most accurate for discriminating between people with PD and controls (85% using all gait features)
Ng et al (2020) [16]	• Gait: cadence, symmetry, CV[g] of step time, step width (average and CV), and eMOS[h]	• Univariate linear regression: cadence associated with POMA[i]-gait scores (*P*<.001) • Poisson regression: cadence, eMOS, average step width associated with the number of future falls (*P*<.001)
Ospina et al (2021) [32]	• Arm swing: magnitude, time, and arm swing asymmetry	• Age influenced arm movement • People with PD showed significant reductions in arm swing magnitude (left, *P*=.002; right, *P*=.006) and speed (left, *P*=.002; right, *P*=.004) • Arm swing asymmetry differentiated people living with PD from controls (ROC: 78%)
Otte et al (2020) [33]	• Cadence, knee amplitude, asymmetry, average step time, longest step time, arrhythmicity, average stance time, and longest stance time	• Knee amplitude and longest stance time correlated with UPDRS (–0.51, *P*=.003 and 0.52, *P*=.002, respectively) • Postural instability (pull test) correlated with longest stance time (0.47, *P*=.008) • Knee amplitude, asymmetry, and average step time differed between on- and off-medication states (*P*=.002, *P*=.007, and *P*=.007, respectively)
Pedro et al (2020) [34]	• Step length	• In comparison with the GAITRite (CIR Systems, Inc) system, the Kinect camera overestimated the average variation in step length for the 2 people with PD potentially due to inherent smoothing
Procházka et al (2015) [35]	• Average step length	• In total, 91.7% classification accuracy for determining between controls and those with people with PD. Decrease in step length (regression coefficient=–0.0082 m/year)
Sabo et al (2022) [18]	• Number of steps, cadence, velocity, step length, CV of stride width, and step and swing time	• Moderate or strong positive correlations between steps, cadence, step width from 2D pose-estimation, and Zeno in people with PD • Automated heel strike algorithm struggled to identify short steps

Study	Primary features	Main results
Sabo et al (2021) [17]	- Cadence, steps, average step width, average margin of stability, CV of step width and time, and symmetry	- ST-GCN[j] using 2D joint trajectories and gait features outperforms ST-GCN using only gait features - Regression models for predicting UPDRS-gait over 94% if off by 1 is allowed
Sabo et al (2020) [38]	- 2D: steps, cadence, symmetry, and CV of step time - 3D: walking speed, step length or width, step width, step length symmetry angle, RMS[k] of ML[l] velocity, margin of stability, and CV step width	- Multivariate ordinal logistic regression models achieved 61.4% and 62.1% for 2D and 3D features for predicting UPDRS-gait in people with dementia
Seifallahi et al (2022) [39]	- Steps and stride	- Adaptive neuro-fuzzy inference system classifier accuracy >90% for differentiating between MCI and controls
Soltaninejad et al (2018) [41]	- Stride and tremor	- Random forest classifier accuracy for differentiating controls and people with dementia: 93.33% stride and 81% tremor
Tan et al (2019) [42]	- Step length, step time, vertical pelvic displacement, and gait speed	- Multivariable regression: step length during TUG[m] and vertical pelvic displacement during the gait speed were associated with postural instability and gait disorder (*P*=.01 and *P*<.05, respectively) in people with PD
Ťupa et al (2015) [43]	- Step length and average speed	- Combining gait features improves classification accuracy relative to single features - 2-layer neural network achieved an accuracy of 97.2% in classifying people with PD from controls

[a] ICC: intraclass correlation coefficient.

[b] PD: Parkinson disease.

[c] SVM: support vector machine.

[d] MCI: mild cognitive impairment.

[e] UPDRS: Unified Parkinson’s Disease Rating Scale.

[f] ROC: receiver operating characteristic.

[g] CV: coefficient of variation.

[h] eMOS: estimated margin of stability.

[i] POMA: Tinetti Performance Oriented Mobility Assessment.

[j] ST-GCN: spatiotemporal graph convolutional networks.

[k] RMS: root mean squared.

[l] ML: mediolateral.

[m] TUG: Timed Up and Go.

Table 5. Key findings from studies that used video cameras.

Study	Primary features	Main results
Kaur et al (2023) [25]	Stride (91 derived features based on variation and asymmetry speed)	- Logistic regression, random forest, deep learning–based classifiers 75% (walking and talking) and 78.1% (walking) - Multi-scale residual neural network: 100% accuracy for classifying people with controls, multiple sclerosis, and people with PD[a] during walking and walking-while-talking, and 78% for new subjects walking - 1D convolutional neural network: 75% walking-while-talking and 79.3% when generalizing to new subjects in different tasks
Khan et al (2021) [26]	Slow walking short-shuffling steps gait festination	- SVM[b] classification predicts UPDRS[c]: gait scores with 70.83% accuracy and area under ROC[d] curve 80.88%
Khan et al (2013) [27]	Stride cycles and posture lean	- SVM classification of 100% for differentiating between people with PD and controls
Li et al (2018) [29]	Subtask segmentation based on selected body points: neck, R/L[e] shoulder, R/L hip, R/L knee, or R/L ankle	- Accuracies for subtask segmentation of TUGg: OpenPose+LSTM[f]=93.10% and OpenPose+LSTM=92.8% - Correlations between OpenPose+LSTM and experts on timed reduction rates: turn (0.93), walk-back (0.98), and sit-back (0.98)
Sabo et al (2022) [37]	Cadence, steps, average step width, average margin of stability, CV[g] of step width and time, symmetry, and stability	- ST-GCN[h] operating on 3D joint trajectories outperform 2D models - Best model prediction of UPDRS-gait and SAS[i]-gait scores are 53% and 40%, respectively.
Shin et al (2021) [40]	Step length, gait velocity, number of steps, and turning time	- Features correlated with Freezing of Gait Questionnaire, UPDRS part III total score, HY[j], and postural instability in people with PD - Features measured improvements following medication

[a] PD: Parkinson disease.

[b] SVM: support vector machine.

[c] UPDRS: Unified Parkinson’s Disease Rating Scale.

[d] ROC: receiver operating characteristic.

[e] R/L: right or left.

[f] LSTM: long short-term memory (machine learning model).

[g] CV: coefficient of variation.

[h] ST-GCN: spatiotemporal graph convolutional networks.

[i] SAS: Simpson-Angus Scale.

[j] HY: Hoehn and Yahr scale.

Table 6. Key findings from studies that used mobile phone cameras.

Study	Primary features	Main results

Morinan et al (2022) [30]	- D_{body}: distance between nose and 2 ankles
	- Standard of D_{body}, proportional increase in D_{body}, and percentage jerk of D_{body}
	- D_{hand}: distance between 2 wrists
	- U: hands used (Boolean)
		- Ordinal random forest classifiers:
		  - U=99.6% accuracy for hands used to push up from chair
		  - UPDRS[a] ratings estimated by models agree by 79.2% with clinicians’ ratings for people with PD[b]

Rupprechter et al (2021) [36]	- Steps, arm swing, postural control, and smoothness	- Step frequency highly correlated with labeled steps (*P*<.001) - Ordinal random forest: 50% prediction

[a] UPDRS: Unified Parkinson’s Disease Rating Scale.

[b] PD: Parkinson disease.

Discussion

Principal Findings

This systematic review has shown that there is a paucity of studies exploring the use of MMC in people with dementia and models exploring the performance of ADL. Moreover, there is a lack of standardization in the used MMC models and clinical validation in real-world applications. The absence of standardization among the models used posed a significant challenge, precluding the possibility of conducting a meta-analysis to compare and synthesize study results.

The review findings suggest that there is more evidence of the use of MMC with full-body tracking in patients with PD (n=18) compared to those with dementia (n=6) and MCI (n=2). This demonstrates a bias toward movement disorders, where the motor symptoms are more prominent, and highlights a significant knowledge gap in the feasibility and effectiveness of using MMC models in quantifying functional performance in people with dementia and MCI. Moreover, the studies that included patients with dementia [9,15-18,38] were all conducted in inpatient dementia units, indicating a lack of research involving this patient group in real-world settings. This underscores the need for further investigation in this area.

While MMC models based on gait features extracted mainly from straight-line walking may provide useful preliminary data for model development, they have less scope in quantifying functional performance in a real-world context, particularly in people with cognitive impairment. In contrast, the evaluation of ADL tasks could potentially provide more comprehensive insights into real-world functional performance from routine daily activities. Previous research suggests that dual-task tests of mobility are more effective in detecting cognitive decline as well as predicting cognitive impairment and falls [44-46], potentially due to the increased cognitive demand on the individual. However, just 1 study included in this review [19] used dual tasks for the classification of MCI from control, and it was not reported how the completion of dual tasks impacted the results. Feature extraction of ADL tasks that require planning and organization could potentially facilitate the measurement of dual-task performance. Therefore, analysis of ADL tasks could help provide a more accurate assessment of neurodegenerative impairment.

The findings of this review suggest a lack of consensus on the most effective features used. Some spatiotemporal features of mobility such as step length are commonly used, but other features vary widely between studies, making it difficult to determine which are most effective. Additionally, some unique features such as vertical pelvic displacement [42] and D_{body}, the distance between nose and 2 ankles [30], have been identified in individual studies, but their effectiveness is unknown without further evaluation. Moreover, it is important to note that the effectiveness of several of these feature extraction models has not been tested in real-world settings which therefore requires further evaluation.

Several studies included in the review (n=10) reported machine learning classifier outcomes for identifying people living with dementia, MCI, or PD from control [19,25-27,31,32,35,39,41,43], whereas several others (n=8) reported models that computed clinical assessment scores [17,18,29,30,33,36,38,40]. Although these are useful outcomes, it is important to note that models that help detect gait impairment and predict falls (n=5) [9,15,16,28,42] could potentially be more useful in practical applications for assessing functional performance. It must also be noted that these models were all based on the Kinect cameras demonstrating the potential of RGB-D cameras for detecting and predicting functional impairment.

Accurate feature extraction and classification are crucial for improving the quality of MMC-based functional assessment [47]. The accuracy rates of MMC models reported in the reviewed studies ranged from 40% for a model predicting a clinical assessment score [18] to 100% for machine learning classification of PD from control [27]. Those numbers cannot be compared directly due to the different number of classes and the resulting chance level, as well as the task difficulty between classifying patients from control participants to rating symptoms. However, it is important to ensure that any clinical applications of these models are consistent and accurate because inaccurate predictions could potentially have consequences for patient care. Further validation and refinement of the models may therefore be necessary before they can be safely used in practical applications.

It is important to note that the accuracy of a model does not only depend on its ability to correctly identify a condition but also on its capacity to detect features of functional performance consistently in various real-world settings. Potential real-world applications include the detection of problems in functional performance in clinical settings and functional deterioration in home settings. The effectiveness of several feature extraction models reviewed in this study has not been tested in such settings, and therefore, the accuracy in practical applications remains unclear. Moreover, devices used in clinical applications must be subjected to a rigorous clinical validation process to ensure safety and efficacy before use on patients [48]. Many of the studies reviewed seem to have primarily focused on the technical aspects of the MMC models, such as feature extraction and analysis, with less focus on their clinical utility. Therefore, further MMC research should objectively evaluate the practical clinical and real-world mobility applications of this technology. If a standard MMC movement analysis protocol could be established, functional performance could be compared across diagnoses.

Additionally, the cross-sectional nature of most of the included studies may limit their ability to evaluate and track functional performance over time. Longitudinal studies would be necessary to assess the performance of these models for tracking functional changes caused by factors such as disease progression, infections, and treatment effects or recovery. Despite these limitations, the effectiveness of MMC models using the Kinect [24] and 2D pose estimation [37] in comparison to established gold-standard motion capture systems within experimental settings suggests they may be suitable for testing in real-world applications such as remote monitoring. However, further research is required to explore and address ethical and privacy considerations when deploying MMC devices that capture video and movement within people's homes. Managing consent where patients lack mental capacity and safeguarding the privacy of patient data that is stored or shared with clinical teams will also need to be carefully addressed while deploying MMC in remote monitoring applications.

It is important to consider the overall quality of studies included in this review, as shown in Table 1, which summarizes key questions to consider when assessing quality. Most studies had a clear study design and focused research questions with appropriate measures of exposures and outcomes. However, only 1 of the studies reported if potential sources of bias from confounders such as musculoskeletal comorbidities, were controlled which could have significant implications for clinical applications. Moreover, few studies provided information on participant eligibility and whether they were selected fairly which could have implications for generalization of study results. The suboptimal quality observed in the included studies in key aspects such as bias control and participant selection suggests these MMC models need to be further evaluated potentially using more rigorous study designs before deployment in real-world applications. Studies that have attempted to create MMC models for fall prediction have primarily focused on retrospective analyses, for example, the number of falls in the past few months. While it is useful to examine historical patterns, future studies should aim to develop prospective studies. Testing the algorithms for MMC models in a prospective study would offer the capability to analyze more detailed information on fall events and contextual associated factors therefore making them more generalizable and valid for predicting falls.

The main findings of this review highlight the potential of MMC in assessing components of functional performance including gait and sit-to-stand characteristics in individuals with dementia, MCI, and PD. Notably, high classification accuracies in several studies demonstrate the potential for clinical applications, such as identifying, monitoring, and predicting outcomes in these populations. However, it is crucial to address the limitations and challenges, such as overestimation of step length variation and difficulty in identifying short steps, as well as the need for standardized methodologies and further research.

A segment of motion analysis research will likely continue to focus on simplified, discrete tasks executed within the controlled setting of a laboratory. However, advancements in technology are progressively enabling the expansion of movement analysis into real-world environments [49]. While the current body of literature predominantly centers on gait analysis, the potential applications of MMC extend far beyond this domain, particularly within the realm of ADL. The integration of knowledge gleaned from analyzing various types of functional tasks will empower clinicians to better assist individuals with neurodegeneration in enhancing their quality of life.

Limitations

It was not feasible to conduct a meta-analysis of the reviewed studies due to significant heterogeneity in the MMC models evaluated, the features extracted, and the analysis methods used. The use of search terms that are not specific to MMC such as motion capture and movement analysis may have introduced the possibility of inherent biases in the search results. However, the adoption of these broad search terms facilitated a more comprehensive screening of studies, encompassing a wider spectrum of the literature. Furthermore, it is important to acknowledge a potential constraint inherent in the search strategy, specifically about the inclusion criterion of full-body tracking MMC models. This led to the exclusion of studies that analyzed the movement of specific body parts. Another limitation of this review is that only a small number of studies met the inclusion criteria limiting the generalizability of this study's results.

Conclusion

The findings of this review illustrate that the use of MMC technology with full-body tracking has the potential to quantify functional performance in people living with dementia, MCI, and PD. However, the lack of consistency in evaluating these models presents a challenge. Standardization of the extracted features and analysis methods may help overcome the heterogeneity of the evaluation process and propose a framework for assessing future models. The findings further suggest that MMC models based on both RGB-D and standard video cameras are viable options for analyzing movement, yielding similar outcomes. Nonetheless, RGB-D cameras have been favored in models intended to detect gait impairment and predict instances of falling.

It is worth noting that the majority of the reviewed studies evaluated aspects of gait, with no evidence of ADL tasks being analyzed. Future studies should incorporate ADL tasks, as this would be more representative of real-world scenarios, particularly for individuals with cognitive impairment. Moreover, longitudinal studies are required to develop models that could track functional impairment over time and potentially predict decline.

Although accuracy is an important factor to consider when evaluating MMC models for clinical applications, other factors such as comparability to established gold-standard motion capture models and capability for analyzing routine tasks and reproducibility in the natural environment are also important. Therefore, a more holistic approach to model development and evaluation with a clear focus on real-world clinical utility may be necessary to ensure that the models are suitable for use in practical applications.

Acknowledgments

This study was supported by the UK Dementia Research Institute, Care Research & Technology Centre. JJ-J's research fellowship is funded by the Imperial Health Charity and the National Institute for Health and Care Research Imperial Biomedical Research Centre. SH is supported by the Edmond and Lily Safra Fellowship.

Data Availability

No new or unpublished data are included within this study and all data are freely available. All code relating to summary figure development is available on request to the corresponding authors.

Authors' Contributions

JJ-J and SH wrote the review protocol, JJ-J, MC-R, HS, and TJ conducted the literature searches and performed data extraction. JJ-J, MC-R, and SH wrote this paper. All authors read and critically commented on drafts of this study, including the latest version.

Conflicts of Interest

None declared.

Abstract

Background: Older adults with chronic or acute cognitive impairment, such as dementia or delirium, who are hospitalized face unique barriers to person-centered care and a higher risk for negative outcomes stemming from hospitalizations. There is a need for co-designed interventions adapted for these patients to the hospital setting to improve care and outcomes. Patient life storytelling interventions have demonstrated promise in enhancing person-centered care by improving patient–care team relationships and providing information to enable care tailored to individual needs and values.

Objective: This study aims to engage patients, care partners, and clinical stakeholders in a co-design process to adapt an existing life storytelling model for use with older adults with dementia and at risk of delirium in the acute care hospital setting.

Methods: We recruited patients with dementia or at risk of delirium who were hospitalized, their care partners, clinicians, and informaticists. A 3-stage co-design process that used a mixed methods data collection approach including in-depth interviews and surveys was completed. We used content analysis to analyze qualitative data and descriptive statistics to summarize quantitative data.

Results: In total, 27 stakeholder informants (ie, patients, care partners, and interdisciplinary care team [IDT] members) participated. Stakeholders were unanimously interested in using patient life stories as a tool for hospital care through electronic health record (EHR) integration. Stakeholders shared potential topics for life stories to cover, including social support, information on patients’ key life events, and favorite activities. Participants provided insights into the logistics of integrating life stories into acute care, including interview arrangement, story-sharing methods, and barriers and facilitators. IDT members shared preferences on EHR integration, resulting in 3 co-designed mock-ups of EHR integration options. Stakeholders shared ways to optimize future acceptability and uptake, including engaging with the care team and promoting awareness of life stories, ensuring suitability to the acute environment (eg, distilling information in an easily digestible way), and addressing concerns for patient capacity and privacy (eg, engaging care partners when appropriate). Thoughts on potential impacts of life stories were also elicited, including improving patient- and care partner–IDT member relationships; humanizing patients; increasing clinical team, patient, and caregiver satisfaction; and enabling more specific, tailored care for patients with dementia and at risk of delirium.

Conclusions: This study resulted in a co-designed life storytelling intervention for patients with dementia and at risk for delirium in an acute care hospital setting. Stakeholders provided valuable information to ensure future intervention acceptability and uptake, including potential benefits, facilitators, and challenges in the acute care setting.

Introduction

Background

Between 25% and 40% of patients aged ≥65 years have acute or chronic cognitive impairment during a hospitalization, which can greatly affect their experience, care, and ability to communicate [1]. This impairment can be a chronic deteriorating impairment as is seen in Alzheimer or other dementias, or it can be an acute and likely reversible impairment which happens in hospital-induced delirium. For older adults with dementia or at risk of delirium, hospitalizations are often dehumanizing and disorienting [2,3]. No matter if it is a chronic cognitive impairment or an acute delirium episode, it is often difficult for these patients to communicate their needs and preferences in a new environment such as the hospital.

These challenges, coupled with a hospital's limited set of resources, tools, and time to provide person-centered care can contribute to loss of patient dignity and autonomy [2,4] and result in negative quality and clinical outcomes, including increased restraint use, longer hospital stays, and higher hospital mortality compared to patients without cognitive impairment [1,5-7]. In addition, hospital interdisciplinary care team (IDT) members report feeling moral distress and low satisfaction when they are unable to provide high-quality, person-centered care for patients with dementia and delirium [8]. Care partners for older adults with dementia and delirium experience increased caregiver strain and negative health outcomes from the stress of caregiving [9-13].

Addressing the complexities associated with high-quality, person-centered care for patients with dementia or at risk of delirium requires co-designed solutions that accommodate the workplace demands of the hospital IDTs and prioritize the well-being and individual needs of patients and care partners. Co-design is a dynamic process, endorsed by leading health agencies [14], that involves active engagement of stakeholders in intervention development to produce sustainable, acceptable interventions [15,16].

By acknowledging the unique demands and requirements of multiple clinical roles within the IDT, we can develop interventions that fit into the existing resource-limited care context, resulting in more effective and efficient health care delivery. Engaging IDT members in intervention development can improve their satisfaction and ultimate uptake of the intervention [16]. Co-design has been used to improve the use of electronic information exchange tools (eg, patient portals) by eliciting patient, care partner, care team, and other stakeholders' perspectives on barriers and facilitators to engagement with these tools [17].

In addition, co-designing with older adults with dementia or at risk of delirium presents an opportunity to understand their needs and wishes [18] but comes with logistical and ethical challenges regarding capacity to consent and participate in research. There is a paucity of research including patients with dementia or at risk of delirium who were hospitalized, in co-design. A recent review identified only 8 published co-design studies in the acute care setting, and none focused specifically on patients with dementia or at risk of delirium [19]. Interviewing the older adults in the presence of their care partner can help with communication [18].

Given the unique barriers to providing person-centered care for older adults facing cognitive issues who were hospitalized, co-designed interventions adapted to this setting and population are sorely needed. Life stories and similar narratives have emerged as a powerful strategy to enhance person-centered care by improving patient–care team relationships and communication. Life stories include information about patients' values, preferences, and personal experiences that enable the delivery of personalized care aligned with patients' unique needs. Research on life stories and similar narratives has shown improvements in patient–care team relationships and communication, as well as patient well-being [20-24]. However, life stories have yet to be tailored to the acute care setting for older adult patients with dementia and at risk of delirium.

This Study

Because of negative hospital experiences (eg, experiencing confusion and disorientation), communication challenges, and barriers to person-centered care in the hospital, these populations may similarly stand to benefit from patient life storytelling. The aim of this study was to describe a stakeholder-engaged co-design process to adapt an existing life storytelling model for older adults with dementia or at risk of delirium in the acute care hospital setting.

Methods

Study Design

The co-design process involved using a mixed methods data collection approach including in-depth individual interviews and survey.

Setting

This study took place in the Acute Care for Elders (ACE) Unit at the University of California San Francisco (UCSF) Medical Center between May and December 2022. The UCSF ACE Unit provides a specialized acute care environment for older adult patients to promote independence and function and prevent complications such as delirium that are common for older adults who are hospitalized [25].

Ethical Considerations

This study was reviewed by the Advarra Institutional Review Board (Pro00056445) and deemed exempt in accordance with the US Department of Health and Human Services regulations at Title 45 Code of Federal Regulations Part 46. Participants provided written informed consent. Patients were able to participate if their legally authorized representative or surrogate provided written informed consent. Participants were remunerated with Visa gift cards for participating; US $20 for surveys and US $50 for qualitative interviews. All data were deidentified before analysis.

Intervention Development and Description

MemoryWell life stories, which have been used primarily in long-term care settings since 2017, were developed by expert interviewers (JN-S and MC) with backgrounds in journalism. They developed the life story questionnaire drawing from evidence-based, dementia-friendly interview strategies [26] as well as user experience at long-term care and palliative care settings at 45 sites in more than 20 states. MemoryWell's life stories have demonstrated improved experiences for patients, care partners, and care staff; in one 30-story pilot at a skilled nursing facility (SNF), patients and family members reported feeling better understood because of the life story, and family members reported improved relationships with care staff [27]. Staff reported increased satisfaction and ability to care for patients considering their needs and wishes after life story intervention [27].

Life stories include information about patients' life stages (eg, childhood and early adulthood), achievements, challenges, religion and spirituality, favorite activities, and social support. MemoryWell's life storytelling model consists of a 30- to 45-minute interview conducted by trained interviewers with a patient or their care partner, or both together. The life story interview format is dependent on the patient's cognitive capacity, care needs, and family preference and availability. When possible, patients participate in all or part of the life story interview independently, and the interviewer can contact their care partner to provide additional information if needed. Otherwise, the interview is conducted with the patient and a care partner present. Questions are addressed to the patient, and the care partner fills in and supports the interview as needed. For patients who are unable to recall or communicate their life stories or whose care needs interfere with the ability to give an interview, a care partner can provide the interview on their behalf. This interview is audio recorded and automatically transcribed. On the basis of this interview, a professional writer writes an approximately 500- to 700-word life story narrative, which takes approximately 1 to 2 hours. The story is then reviewed by an editor for clarity, which takes about half an hour, before being shared with the family and care team. The story is intended to inform care for this particular patient. This study's goal was to adapt MemoryWell's SNF life story intervention to the acute care setting for older adults with dementia or at risk of delirium, reflecting setting differences in patient continuity, workflow, and time constraints.

Participants and Recruitment

Patient and Care Partner Recruitment

We used purposeful sampling [28] to identify eligible patients and care partners to participate in in-depth interviews for the co-design process. Eligible patients were English-speaking adults aged ≥65 years, admitted to the ACE Unit, with a diagnosis of dementia documented in their medical chart or a positive AWOL score [29], a validated hospital admission-screening tool that determines the risk of acquiring hospital delirium. The AWOL score uses a person's age (A), ability to spell "world" backward (W), orientation to environment (O), and a nurse assessment of illness severity (L) to determine not only an increased risk of delirium during their hospitalization but also it gives the medical team general information about a patient's current cognitive status (whether it is acute delirium or a more chronic cognitive issue, although it does not distinguish the difference). A positive score indicates an increased risk for hospital delirium. English-speaking care partners aged ≥18 years of eligible patients were also invited to participate. If a care partner spoke English but the patient did not, care partners were invited to participate. Non-English speakers were not enrolled due to constraints in translation resources for consent and interviews.

Eligible patients and care partners were identified daily through the electronic health record (EHR). Eligible patients and care partners were then invited to participate in the study in person during their hospitalization or via telephone shortly after their hospital discharge.

IDT Members and EHR Informaticist Recruitment

Inpatient IDT members were eligible if they delivered care to an eligible patient in the ACE Unit. Using purposive sampling [28], inpatient IDT members were invited to participate via email. To address different clinical perspectives, IDT members from a variety of roles on the ACE Unit were invited, including geriatricians, hospitalists, physical therapists, chaplains, social workers, case managers, nurse practitioners, registered nurses, and pharmacists. To explore the potential utility of life stories in the patients' care transitions after hospitalization, eligible outpatient geriatric primary care and postacute care providers were invited by email. These participants included physicians, geriatricians, nurse practitioners, and a SNF medical director.

Eligible EHR informaticists and programmers from the UCSF APeX Enabled Research (AER) program were invited to participate. APeX is the name of the Epic EHR used at UCSF. The AER program supports the use of APeX for faculty-initiated research projects and provided consultation and technical services for this project [30].

Data Collection and Co-Design Process

Figure 1 demonstrates our 3-stage co-design process with stakeholders and methods used.

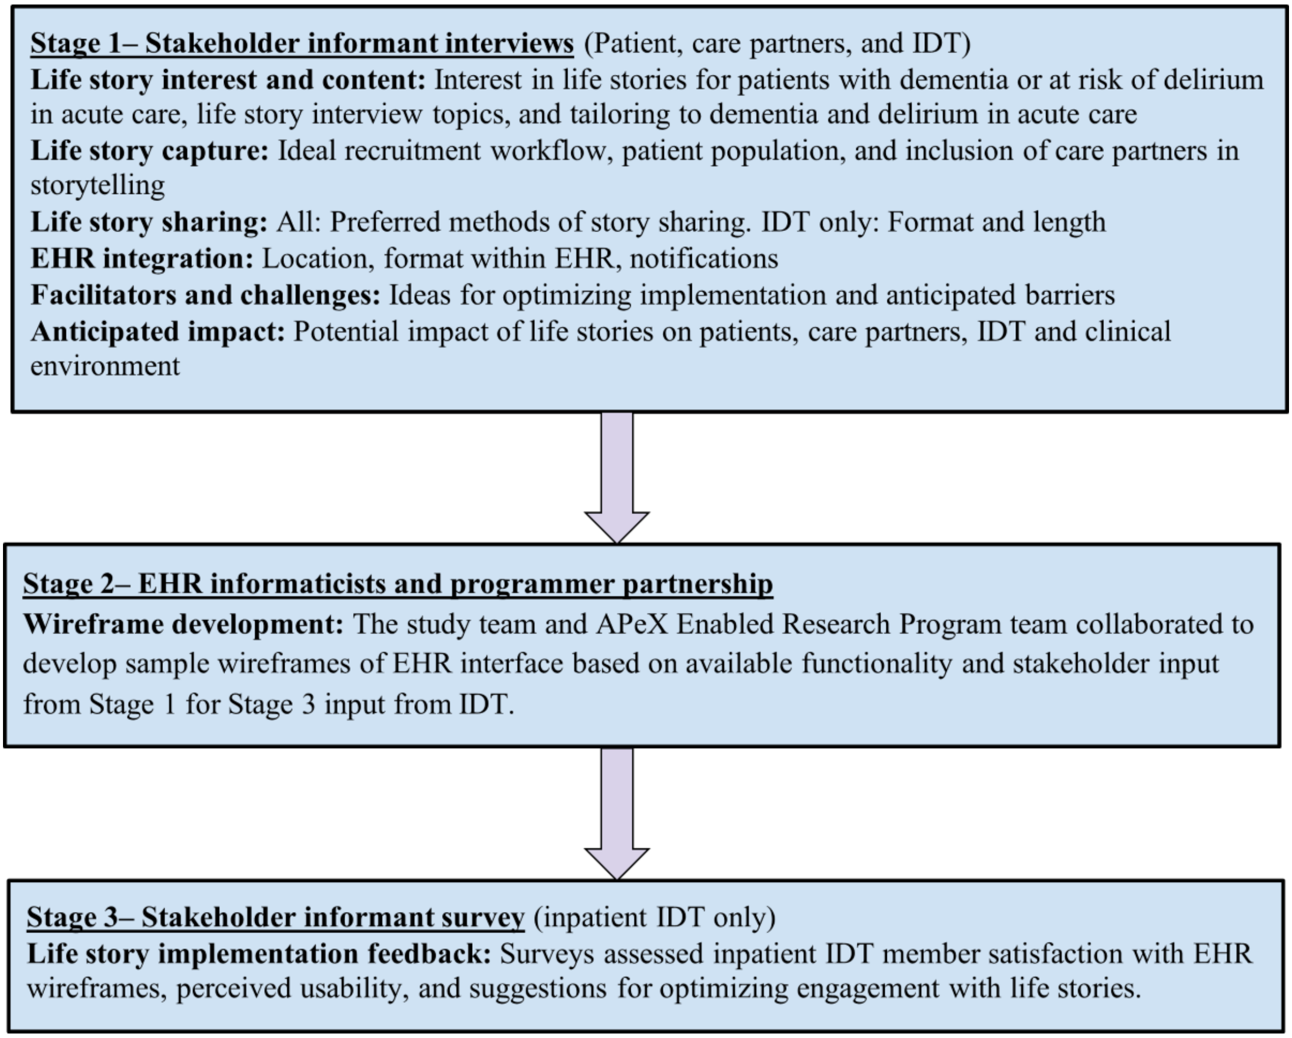

Figure 1. Co-design of life storytelling intervention for patients with dementia or at risk of delirium who were hospitalized, in acute care. EHR: electronic health record; IDT: interdisciplinary care team.

Stage 1– Stakeholder informant interviews (Patient, care partners, and IDT)

Life story interest and content: Interest in life stories for patients with dementia or at risk of delirium in acute care, life story interview topics, and tailoring to dementia and delirium in acute care

Life story capture: Ideal recruitment workflow, patient population, and inclusion of care partners in storytelling

Life story sharing: All: Preferred methods of story sharing. IDT only: Format and length

EHR integration: Location, format within EHR, notifications

Facilitators and challenges: Ideas for optimizing implementation and anticipated barriers

Anticipated impact: Potential impact of life stories on patients, care partners, IDT and clinical environment

Stage 2– EHR informaticists and programmer partnership

Wireframe development: The study team and APeX Enabled Research Program team collaborated to develop sample wireframes of EHR interface based on available functionality and stakeholder input from Stage 1 for Stage 3 input from IDT.

Stage 3– Stakeholder informant survey (inpatient IDT only)

Life story implementation feedback: Surveys assessed inpatient IDT member satisfaction with EHR wireframes, perceived usability, and suggestions for optimizing engagement with life stories.

Stage 1: Stakeholder Informant Interviews

Stage 1 involved in-depth qualitative interviews with stakeholder informants. We developed a study-specific interview guide, based on our previous experience interviewing patients with dementia in long-term care, to assess the feasibility and acceptability of integrating life stories into acute care for patients with dementia or at risk of delirium (Multimedia Appendix 1). At the beginning of each interview, stakeholders were given an overview of the purpose of the study which included the overarching goal of developing a life story intervention for implementation in the acute care setting. The questions explored the stakeholder's level of interest in life stories and anticipated impacts on care. Interviews elicited preferred topics for life stories as well as content that stakeholders did not want to be included in life story interviews. We also explored stakeholders' views on how life stories could be implemented into hospital clinical practice such as preferences on the life story interview process, including timing (eg, in relation to hospital stay and time of day) and method (eg, in-person vs remote and who participates in the interview). Barriers and facilitators to life story implementation and workflows were also assessed. Inpatient and outpatient IDT members were also asked about their preferences for integrating life stories into the EHR. Questions included life story format, preferred location within EHR, and strategies for integrating life stories into clinical workflows. All interviews were digitally recorded.

Stage 2: EHR Informaticists and Programmer Partnership

Data from stage 1 interviews were then used to inform the design of the life story intervention and implementation workflow in partnership with informaticists and EHR programmers. We identified opportunities for feasible and functional EHR integration. The AER team created sample wireframes (2D illustrations of the EHR interface) to demonstrate EHR integration options to stakeholders.

Stage 3: Stakeholder Informant Survey

Stage 3 involved asking stakeholder informants to provide additional feedback and insights on the intervention and implementation workflow using the wireframes as potential examples. We developed a survey for inpatient IDT members using study-created measures and measures adapted from the American Customer Satisfaction Index to assess their satisfaction with EHR wireframes, perceived usability, and suggestions for optimizing engagement. Measures were rated on a scale of 1 to 10, with 1 being the least desirable and 10 being the most desirable (eg, convenience of accessing: 1=very difficult and 10=very easy; satisfaction: 1=very dissatisfied and 10=very satisfied). Surveys were administered via email using SurveyMonkey (SurveyMonkey Inc) [31].

Analysis

Qualitative interviews (stage 1) were deidentified and professionally transcribed verbatim. We used a combination of qualitative and quantitative content analysis for interview data [32,33]. Transcripts were reviewed independently by 2 members of the research team (SJF and JDH). We first used qualitative content analysis to systematically examine the transcripts to obtain a condensed understanding and description of the content [33]. We used a data-driven (inductive) approach to analysis whereby open coding was performed to identify salient and elevated topics of importance within the data set. Reviewers (SJF and JDH) met to define and refine coding categories to ensure trustworthiness throughout the analysis. Negotiated consensus was used to resolve disparities and coding categories [34]. We then organized codes around key study questions: interest and content, story capture, story sharing and EHR integration, anticipated impact, and facilitators and challenges to implementation. Quantitative content analysis was then performed to count coding categories. This was conducted for the purpose of providing a more detailed assessment of how frequently certain codes or themes were mentioned. Data analysis was managed in Dedoose (SocioCultural Research Consultants, LLC) [35]. Stage 3 surveys were analyzed using descriptive statistics.

Results

Stage 1: Stakeholder Informant Interviews

Of the 27 individuals interviewed, 3 (11%) were patients, 6 (22%) were care partners, and 18 (67%) were IDT members. Table 1 shows stakeholder *interest* in life stories and potential *topics to include* in life stories for patients, care partners, and IDT members. All stakeholders were interested in implementing patient life stories in the acute care setting. Care partners and patients focused on wanting to share who the patient is as a person outside of their current state, including reviewing the patient's life stages (eg, education, former occupations, and places they have lived) and favorite activities. Several IDT members indicated that while they suspected certain preselected topics could be useful, they would want to know what patients and care partners prefer to share in each story. All IDT members wanted to know about the patient's social support, as this was deemed to be critical knowledge for tailoring care plans.

Table 1. Life story level of interest and potential topics to include[a].

	Total (N=27), n (%)	Patients (n=3), n (%)	Caregivers (n=6), n (%)	IDT[b] (n=18), n (%)
Interested in life stories for acute care	27 (100)	3 (100)	6 (100)	18 (100)
Topics[c]				
Life stages	23 (92)	1 (100)	6 (100)	16 (89)
Social support	23 (92)	1 (100)	4 (67)	18 (100)
Spirituality	6 (24)	0 (0)	2 (33)	4 (22)
Hobbies and activities	20 (80)	1 (100)	5 (83)	14 (78)
Preferred foods	5 (20)	0 (0)	3 (50)	2 (11)
Legacy and achievements	11 (44)	0 (0)	3 (50)	8 (44)
SDOH[d], mental health, and trauma	14 (56)	0 (0)	2 (33)	12 (67)
Care preferences	7 (28)	0 (0)	1 (17)	6 (33)
What brings joy	11 (44)	1 (100)	2 (33)	8 (44)

[a] Where data do not equal 100%, data are missing due to nonresponse.

[b] IDT: interdisciplinary care team.

[c] Only one patient answered about topics to include, so N=25 for these rows and n=1 for the patient.

[d] SDOH: social determinants of health.

Life Story Interview Process

Patient and Care Partner Perspectives on Life Story Interview Timing and Format

Timing of Life Story Interview

Most patients and care partners indicated they would be willing to complete a life story interview during hospitalization if the interview would not interrupt daily activities, including medical procedures or favorite television programs. In addition, 1 care partner said that there was too much going on while the patient was hospitalized, so it would be preferable to capture stories before hospitalization.

Life Story Interview Format

Patients and care partners responded that in-person or virtual interviews were preferred; 1 care partner noted that because internet connectivity was poor in some patient rooms, Wi-Fi hot spots would need to be provided to conduct Zoom (Zoom Video Communications, Inc) interviews.

IDT Member Perspectives on Life Story Interview Timing and Format

Timing of Life Story Interview

Themes from IDT members regarding life story interview scheduling include challenges navigating short lengths of stay, ensuring patients are medically stable, and finding a time of day that fits the hospital workflow and patient needs. To ensure the story is used within short lengths of stay, IDT members suggested collecting stories as soon as possible once the patient is out of the emergency department on the hospital floor. Life story interviews must fit the clinical workflow, in between medication administration, testing, specialist visits, procedures, and mealtimes. The optimal time between these tasks, when patients are most alert, was noted to be between 10 AM and 5 PM.

Life Story Interview Format

IDT members highlighted that life story interviews must be responsive to COVID-safety considerations as well as technology and visual and hearing needs of patients and families. They cautioned that Zoom interviews may be difficult for patients if they have issues with hearing or vision. For patients with cognitive impairment, they recommended care partners be involved in life story interviews. Care partners supported having an interviewer from outside of the care team conduct the life story interview and write the life story if they were made aware that the interviewer was from an outside organization, noting that professional writers would be “the right people for the job.” They felt MemoryWell conducting interviews would save time and resources for the care team while helping fill in information gaps; MemoryWell was described as a “bridge to patients for the care team.”

Life Story Sharing

Life Story Sharing With Patients and Care Partners

Patients and care partners suggested a variety of methods to personally receive their stories after they had been completed, including via email, paper copies, and UCSF’s patient portal, MyChart.

Life Story Sharing With IDT Members

Life Story Format

Most IDT members indicated that they would prefer a story format that includes both paragraphs and bullet points. Bullet points were perceived to skim information quickly when IDT members have limited time while paragraphs can offer more detailed context. IDT members prioritized ease of reading, and several suggested that communicating valuable information in a concise manner was more vital to ensuring use than the exact length of the story. IDT members emphasized the importance of keeping the stories brief to ensure that they would not get overwhelmed and avoid reading stories. Most suggested 1 to 2 pages and others preferred even briefer stories at just 2 to 3 paragraphs or 350 words.

EHR Integration

IDT members emphasized the importance of ease of access to life stories in the EHR to ensure they could incorporate life stories into their workflow. Most IDT members suggested integrating life stories into the social history section because the life story content intuitively aligns with this section and most clinicians would be able to find it. Further, the social history EHR section automatically pulls into notes and is a static location that can be viewed as an inpatient or outpatient IDT member. Others suggested locations that would be visible immediately upon opening the patient’s chart or integrating into the EHR’s Daily Rounds tab. IDT members stressed avoiding information overload in clinical notes or other important EHR pages and suggested potentially storing a summary in some sections (ie, social history) with an option to click to another location for the full life story.

IDT members said that making the story easy to find is the most significant priority, preferable to creating alerts or notifications that a story is available; several suggested an icon next to the patient’s name that would change colors to indicate that the story was available. Other suggestions included only flagging for especially critical information, such as trauma history, through a pop-up notification.

Anticipated Impact of Life Story Integration Into EHR and Patient Care

Overview

Themes and exemplary quotes about the anticipated impact of life stories can be found in Table 2.

Table 2. Anticipated impact of life story integration into EHR[a] and patient care.

Stakeholder, theme, and theme description	Quotes
Patients and care partners	
Theme 1: Life stories can help the care team see patient as a person beyond their medical issues.	• “One doctor came in and he was very kind of brusque and fast talking, didn’t even really look that much at us at the beginning...I felt like saying, hey...my mom is a person, not just a patient, she’s a person.”
Theme 2: Life stories may support patient and IDT[b] relationship building.	• “I think the best would be if the doctor can have the capacity to take on this patient,...and have that kind of personal time to get to know the patient. Because caring, the feeling is so complicated. There’s magic to it, and it can only come from like a true...kind of collaboration...when a doctor makes a connection with a patient.”
Theme 3: Life stories can provide context that could help prevent discrimination based on age and race.	• “Not enough credit is given to the elderly to be able to think and express themselves. That throws them into a depressed state of mind, thinking that it’s over for me. But if they are involved and respected, it’s a better transition.” • “I think they would treat her differently. It’s unfortunate that when people perceive you, the outside of you, they have a limited view of what you’re really like as a person...For example, people of other cultures tend to look at African Americans as not being knowledgeable, not being experienced with the other parts of the world.” • “I just think that... people have a really limited view of older people. I think especially with older people that if they know... she’s really sharp and she’s usually really active, I think that... it would make a difference—if they actually wanted to know. I just have a lot of doubt about them really actually wanting to know.”
IDT members	
Theme 1: Life stories could help improve person-centered care by (1) humanizing patients, (2) fostering patient- and care partner–IDT relationships and communication, and (3) enabling care tailored to what matters the most to patients.	• “I think that the humanizing element is really important. In the hospital specifically... there are many dangers of having a narrow track mind, and we want people to fit in the narrow track... and so the more ways that we can bring out the individuality, the intriguing parts of a person’s story, I think that can soften our approach and actually make it easier to do our jobs.” • “You have all the tests and you have all the medications available, but really don’t have the time to sit down and know them. So maybe working as a team would be helpful, where maybe the care team there could be a champion saying okay, this is a person who is going to make sure this person’s wishes are done, and inform everybody in the team. It could be an email, as you said, like where the case manager sends an email. Oh, just wanted to let you know this other thing is on the person’s life story, just for the team to know.” • “Our providers are working in an increasingly busy care environment. They want more support, because we’re being asked...to see more patients with less support...it is a moral distress as an inpatient provider. You want to spend time with patients, you want to get to know them. So the value proposition for this is like, this is a tool that allows your providers to get to know your patients, starting off instead of at first base on third base, with all this information about them in a very easy way that’s user friendly, that’s right in front of them, that’s readable, where you don’t have to spend time as a provider sifting through the chart.”
Theme 2: Life stories could be especially helpful for caring for patients with CI[c] or delirium.	• “It gives us things to talk about with the patients, and it’s helpful in cases of delirium or dementia to know what was important to that person so that we can kind of help ground them and give them more context, just make them feel less lost in the alien atmosphere of being in the hospital.” • “When you do medical interventions to this type of patient it can be very challenging sometimes because of their behavior. So I think it gives an in to the clinicians of how to soothe the patient and making sure oh, this patient can still make a little bit of decision with guidance. If we have that in the life story of the medical records, then we know already...the patient is not a stranger to us...we already know the patient’s background.” • “I think it’s extremely important to connect with your patient, especially because people with dementia are usually older and frail and scared in the hospital. And they do best, a lot of times they do best when they’re around familiar surroundings, which they can’t be around, so familiar conversation always helps provide some comfort.”
Theme 3: Life stories help improve stakeholder satisfaction.	• “And knowing more about who our patients are and what they’ve done with their lives and what was important to them really humanizes them and I think facilitates staff to have greater empathy for their situation. Frankly, I think it improves care for everybody. I think the staff feels more satisfied, feeling like they know who they’re taking care of.” • “I imagine that in general people like to feel known and seen for who they are.” • “I feel like families often feel more comfortable with their loved one being in the hospital if they feel like we know their loved one well, we care about trying to make them comfortable.”

[c] CI: cognitive impairment.

Patient and Care Partner Themes About the Anticipated Impact of Life Stories

Theme 1: Life Stories Can Help Care Team See Patient as a Person Beyond Their Medical Issues

Patients and care partners said that life stories could be helpful in encouraging the IDT to see the patient as a full person.

Theme 2: Life Stories May Support Patient and IDT Relationship Building

Care partners expressed the importance of care teams taking the time to build genuine relationships with patients and that life stories could help foster these relationships by helping IDT members get to know their patients.

Theme 3: Life Stories Can Provide Context That Could Help Prevent Discrimination Based on Age and Race

Care partners also shared that life stories could help prevent ageism and discrimination, arguing that if the IDT understood patients' life experiences and social context, they could be less quick to judge them based on their age or race. They also expressed that life stories could help with suboptimal care team communication and rapport.

IDT Member Themes About the Anticipated Impact of Life Stories

Theme 1: Life Stories Could Help Improve Person-Centered Care by (1) Humanizing Patients, (2) Fostering Patient- and Care Partner–IDT Member Relationships, and (3) Enabling Care Tailored to What Matters Most

IDT members said that knowing more about their patients as people could help humanize the patients. They expressed that in a setting with limited time and background information on patients, life stories could be a valuable *time-saver* in jump-starting the patient- and care partner–IDT relationship by providing context for building rapport and communication. Several IDT members also said that giving social and cultural context and knowing about trauma history and root causes of social needs can help "decrease bias and promote respect and cultural competency."

IDT members expressed that life stories could be beneficial for tailoring their care around "*what matters most* to the patient." Further, knowing about family dynamics and if there is a designated health care proxy can help the care team know whom to involve in decision-making. Knowing about previous functional status and current social support can help optimize care and discharge planning. IDT members expressed that providing better person-centered care could lead to better patient outcomes, such as reduced delirium and readmissions.

Theme 2: Life Stories Could Be Especially Helpful for Caring for Patients With Dementia and Delirium

IDT members said that information from life stories could be especially helpful for patients with dementia or at risk of delirium by helping orient patients in an unfamiliar, often scary environment. This could help prevent the use of physical and chemical restraints in response to challenging behaviors. Furthermore, when these patients are unable to speak for themselves, a life story could help document important information and give them a voice in the medical record.

Theme 3: Improved Satisfaction for Each Stakeholder

IDT members shared that building better relationships and providing optimized person-centered care could lead to satisfaction for patients, care partners, and IDT. The story can be given as a gift for the family, which offers a chance to reflect on the patient's life during a difficult time. IDT members anticipated that patients and care partners could feel seen and heard by someone in the medical setting taking the time to listen to and document their stories. IDT members explained that they often feel moral distress in not being able to provide the care that they want to and that life stories could help them take a step back and remind them of the meaning of their work.

Facilitators and Challenges to Implementation

Table 3 shows IDT member–reported potential barriers and facilitators to life story implementation. IDT members emphasized the importance of training the full IDT around life stories to ensure life story use by everyone who cares for the patient. They also raised concerns about the time constraints within acute care and the necessity for life stories to be easily accessible. IDT members said that while patients with dementia and delirium could be uniquely well-suited for a life story intervention, care must be taken to adapt to patient capacity, involve care partners when appropriate, and ensure understanding of how information is being shared and with whom.

Table 3. IDT[a]-reported potential implementation barriers and facilitators.

Barriers and facilitators	Description of barriers and facilitators
Engaging care team and awareness of life stories	
Potential barriers	• Need cultural buy-in to treat the whole person • Life stories must be available for enough patients to become a part of the regular workflow • Some specialties may be less likely to want to engage with life stories (eg, surgery and pharmacy) or see components as outside of the scope of their role (eg, social determinants of health)
Potential facilitators	• Providing training regarding (1) the existence of life stories, (2) how to access stories, and (3) the potential benefits of reading life stories • Some specialties may be more apt to see the benefit of life stories (eg, geriatricians well-versed in dementia and delirium care)
Suitability to acute environment	
Potential barriers	• Short length of stay • Story may not be a priority in comparison to acute needs • Resource intensive
Potential facilitators	• Distill information into an easily digestible format • Must be easily accessible in EHR[b]
Concerns for patient capacity and privacy	
Potential barriers	• Privacy concerns: some patients may not want to share personal information, especially for populations at risk of potential legal system involvement (eg, undocumented patients) • Ensuring patients are aware all IDT members can access life story in EHR • Patient capacity to consent and communicate is dependent on cognitive impairment and illness severity
Potential facilitators	• Engaging with care partners as appropriate • Working with patients to find an appropriate time to conduct life story interviews within day and stay • Patients with dementia and at risk of delirium stand to benefit the most

[b] EHR: electronic health record.

Stage 2: EHR Informaticists and Programmer Partnership

We partnered with 3 members of the UCSF AER team who provided insights into feasible EHR integration. Moreover, 3 sample wireframes focusing on available functionalities, intended behaviors, and space allocation with prioritization of content were created incorporating options of how the life story would look in the EHR. Figures 2-4 present these wireframes in 3 potential EHR locations, including the Daily Rounds tab (used to quickly collect basic clinical information before rounds), Advance Care Planning (ACP) tab (which summarizes all ACP discussions and documents), and Social History section (the section to input a patient’s social history).

Life Story

Life Story Summary

- Wife named Lois Jean, one daughter named Linda born in Sao Paulo, grandfather of two
- Former missionary in Brazil, helped found missionary organization called the Brazilian Evangelical Association
- Grew up on famous maple syrup farm in Ohio
- He also used to play music at senior communities, help widows with food and finances, and took in children in need.

Keith Britton, a child of the Great Depression, lives to help people. He grew up on a farm in Kinsman, Ohio that produced maple syrup so famous that folks would drive more than 90 minutes from Cleveland just to buy it. As a missionary in Brazil, he risked a lot to do his work, including an attempted kidnapping of his only daughter, Linda, who was born in Sao Paulo. He and his wife Lois Jean stayed in Brazil as long as they could, eventually they had to return to Ohio for financial reasons. Later, he helped found a missionary organization called the Brazilian Evangelical Association. Back in Dayton, Keith worked for a Christian radio station, WEEC. He was manning the news ticker on the day that President John F. Kennedy was shot. He also used to play music at senior communities, help widows with food and finances, and took in children in need.

Life Story Narrative

The Joys and Struggles of Growing up on a Farm

Keith Britton lives to help people. As a missionary in Brazil, he risked a lot to do his work, from an attempted kidnapping of his only daughter to losing children to a mudslide on a field trip he was leading. Nothing deterred him from bringing food and clothes to the needy in Rio de Janeiro's and Sao Paolo's favelas, or the word of God to those with spiritual needs.

That kind of tenacity came from his parents, who owned a farm in Kinsman, Ohio. Herbert Kline Britton and his wife Elsie Jane Fonnor, along with their three sons, Lyle, Darl and Keith produced maple syrup so famous that folks from Cleveland would drive more than 90 minutes to Kinsman just to buy it.

Keith, the youngest, was born July 24, 1930, a child of the Great Depression. One day when Keith was about six, he was helping his father plough a field. Keith sat atop one of a pair of horses, who'd been pulling the plow. Herbert had just unhooked the plough when the horses spooked. Little Keith had no idea as he laughed and clung to the horses as they galloped off while his father was dragged along, holding onto the reins for dear life. Ultimately, everyone was fine, even if Herbert's overalls were stuffed with mud.

Keith would always remember those horses, how when it was time to tap the trees, his father had them so well-trained that they would stand and wait at each tree patiently and only advance when his father gave the
word. But all that hard work couldn't overcome the economic realities of the Depression, and soon they lost the farm.

Keith's older brothers both served in World War II and he grew up listening to President Franklin Roosevelt's fireside chats. Nicknamed "Windy" because he liked to talk a lot, Keith was always very devout. He went to Bible college and then planned to become a missionary in Brazil. He was drafted, but was excused when he said he planned to be a missionary.

Keith met his wife Lois Jean on a street corner. They were taking part in a youth festival with their church. Lois Jean was the sister of the pastor's wife and an avid musician. She'd taught herself to play piano at the age of 3 and she also played the accordion and the church organ. The couple went to Brazil together and their only child, Linda, was born in Sao Paolo.

Keith never did learn Portuguese fluently, but despite the danger - Linda's attempted kidnapping and the floods that took out one of the church's campers, killing two young girls who were with their group - Keith and Lois Jean tried hard to stay in Brazil.

They went back and forth until Linda was 9. That year, there were political riots, and they got caught up in them. After that, Brazil started to require that missionaries pay a $10,000 deposit, and the family couldn't afford it.

Life Story

Summary:

- Wife named Lois Jean, one daughter named Linda born in Sao Paulo, grandfather of two
- Former missionary in Brazil, helped found missionary organization called the Brazilian Evangelical Association
- Grew up on famous maple syrup farm in Ohio
- He also used to play music at senior communities, help widows with food and finances, and took in children in need.

Keith Britton, a child of the Great Depression, lives to help people. He grew up on a farm in Kinsman, Ohio that produced maple syrup so famous that folks would drive more than 90 minutes from Cleveland just to buy it. As a missionary in Brazil, he risked a lot to do his work, including an attempted kidnapping of his only daughter, Linda, who was born in Sao Paulo. He and his wife Lois Jean stayed in Brazil as long as they could, eventually they had to return to Ohio for financial reasons. Later, he helped found a missionary organization called the Brazilian Evangelical Association. Back in Dayton, Keith worked for a Christian radio station, WEEC. He was manning the news ticker on the day that President John F. Kennedy was shot. He also used to play music at senior communities, help widows with food and finances, and took in children in need.

Narrative:

The Joys and Struggles of Growing up on a Farm

Keith Britton lives to help people. As a missionary in Brazil, he risked a lot to do his work, from an attempted kidnapping of his only daughter to losing children to a mudslide on a field trip he was leading. Nothing deterred him from bringing food and clothes to the needy in Rio de Janeiro's and Sao Paolo's favelas, or the word of God to those with spiritual needs.

That kind of tenacity came from his parents, who owned a farm in Kinsman, Ohio. Herbert Kline Britton and his wife Elsie Jane Fonnor, along with their three sons, Lyle, Darl and Keith produced maple syrup so famous that folks from Cleveland would drive more than 90 minutes to Kinsman just to buy it.

Keith, the youngest, was born July 24, 1930, a child of the Great Depression. One day when Keith was about six, he was helping his father plough a field. Keith sat atop one of a pair of horses, who'd been pulling the plow. Herbert had just unhooked the plough when the horses spooked. Little Keith had no idea as he laughed and clung to the horses as they galloped off while his father was dragged along, holding onto the reins for dear life. Ultimately, everyone was fine, even if Herbert's overalls were stuffed with mud.

Keith would always remember those horses, how when it was time to tap the trees, his father had them so well-trained that they would stand and wait at each tree patiently and only advance when his father gave the
word. But all that hard work couldn't overcome the economic realities of the Depression, and soon they lost the farm.

Keith's older brothers both served in World War II and he grew up listening to President Franklin Roosevelt's fireside chats. Nicknamed "Windy" because he liked to talk a lot, Keith was always very devout. He went to Bible college and then planned to become a missionary in Brazil. He was drafted, but was excused when he said he planned to be a missionary.

Keith met his wife Lois Jean on a street corner. They were taking part in a youth festival with their church. Lois Jean was the sister of the pastor's wife and an avid musician. She'd taught herself to play piano at the age of 3 and she also played the accordion and the church organ. The couple went to Brazil together and their only child, Linda, was born in Sao Paolo.

Keith never did learn Portuguese fluently, but despite the danger - Linda's attempted kidnapping and the floods that took out one of the church's campers, killing two young girls who were with their group - Keith and Lois Jean tried hard to stay in Brazil.

They went back and forth until Linda was 9. That year, there were political riots, and they got caught up in them. After that, Brazil started to require that missionaries pay a $10,000 deposit, and the family couldn't afford it.

Stage 3: Stakeholder Informant Survey

Stage 3 involved asking inpatient IDT stakeholder informants to provide feedback on EHR wireframes and life story implementation, including perceived usability and suggestions for optimizing engagement. Table 4 presents findings from the stakeholder informant survey, where 10 inpatient IDT members were surveyed with a 100% response rate. The Daily Rounds tab was rated highest on convenience of access and satisfaction (out of 10), followed by the Social History and ACP sections, respectively. The Daily Rounds tab was the most common top choice, followed by Social History. The majority (7/10, 70%) of IDT members responded they would review the story for all patients.

Table 4. Stakeholder informant survey of 3 sample EHR[a] wireframe examples (N=10).

Location	Daily Rounds tab	Advance Care Planning tab	Social History section
Convenience, mean (SD)	8.3 (1.6)	5.5 (1.7)	5.5 (2.1)
Satisfaction, mean (SD)	7.7 (1.8)	5.7 (1.8)	6 (1.9)
Respondents who ranked top choice, n (%)	7 (70)	1 (10)	2 (20)
Respondents who ranked second choice, n (%)	1 (10)	2 (20)	7 (70)

Outputs of Co-Design Process: Co-Designed Life Story and EHR Wireframe Selection

Co-Designed Life Story for Acute Care

On the basis of the feedback from stages 1 to 3, the resulting Life Story section of the wireframe was divided into 2 sections: Life Story Short-Form and Life Story Narrative. The Life Story Short Form is intended to provide concise information about the patient's life story if a clinical team member is time-constrained. The The Life Story Short Form is formatted in bullet points and short-form questions were selected based on stakeholder input to include information deemed most readily applicable to acute care, including evidence-based commonly unmet needs for patients with dementia or at risk of delirium (eg, boredom, discomfort, and loneliness) [36,37], as well as what matters to align with the Age-Friendly Health Systems framework [38]. These short-form unmet needs questions are at the beginning of the co-designed life story interview guide and the life story interviewer outlines the responses in bullet points to allow for immediate sharing. Topics included social support, previous occupation, favorite entertainment (eg, television, reading, and music) and foods, religion or spirituality, what a good day at home might entail, and what matters most to the patient.

The Life Story Narrative is approximately 400 to 500 words and in paragraph format. This is written by a professional writer based on the life story interview recording and transcript and takes approximately 1 to 2 hours to write. It builds upon the summary to provide a rich description of the patient's life experiences and covers life stages, achievements, challenges, and other information the patient or care partner wanted to share that is not covered in the summary. This narrative form is intended to provide a longer summary in case clinical team members want to spend more time getting to know a patient on a less busy clinical day.

EHR Wireframe Selection

After stages 1 to 3, both the Daily Rounds (Figure 3) and the Social History (Figure 4) locations were chosen for future piloting and EHR integration. These 2 options provided a static location that can be viewed in both the inpatient and outpatient context (Social History) and for ease of daily inpatient access (Daily Rounds and Social History pulling into notes), thus giving more opportunities for clinical care team members to read the stories in their usual daily clinical workflow. The Daily Rounds tab would include the Life Story Short-Form section for quick access, while the Social History would include the full life story (both the Life Story Short-Form and Life Story Narrative sections).

Discussion

Principal Findings

This co-design process found that integrating life stories into the acute care setting for patients with dementia or at risk of delirium is a highly acceptable intervention to patients, care partners, and the IDT. Stakeholders were unanimously supportive of the idea of using a life storytelling intervention in acute care. They described potential benefits to integrating life storytelling into acute care including humanizing patients, building patient- and care partner–IDT relationships, sharing information about patients with dementia or at risk of delirium, and addressing potential biases based on age, race, or other factors. Stakeholders described potential challenges including the necessity to focus on acute patient needs, short lengths of stay, the need for IDT member buy-in, and patient capacity and privacy concerns.

The existing MemoryWell life storytelling intervention, previously used in long-term care in the form of 500- to 700-word narratives providing care teams information about patient’s personal histories and preferences, was adapted to meet stakeholder preferences and to best fit the acute care setting needs. These modifications include focusing the life story interview guide to cover stakeholder-selected topics (eg, significant focus on social support), the creation of a brief, bullet point summary to help clinicians quickly learn information most applicable to caring for acute needs and discharge planning, and a multipronged approach to story EHR integration. Stakeholders shared their perspectives on ideal timing for life story interviews, including interviewing the patient as soon as possible while ensuring clinical workflow and medical procedures are not interrupted.

The study resulted in the creation of a co-designed life storytelling interview guide and format for EHR integration and wireframes depicting future EHR integration, and ideas to fit a life storytelling intervention into acute hospital workflows, to be piloted in a future study. A future pilot is needed to explore the actual implementation of the co-designed intervention, including logistics, usability, and impact on the patient, IDT, and care partner outcomes.

Comparison With Prior Work

This study is the first to our knowledge that has co-designed a life storytelling intervention for patients with dementia and at risk of delirium in the hospital setting. Our findings mirror previous patient narrative interventions aimed at sharing patients’ personal histories, values, and beliefs with their care teams in other clinical settings in terms of acceptability, challenges to implementation, and anticipated benefits. Though some life story work has focused on older adults with dementia, none has focused specifically on those with or at risk of delirium. Life story work has most often been implemented in long-term care settings [24,39-41] and has been acceptable among staff, patients, and care partners [20,21,24,39-41]. Evaluations of the My Life My Story program at the Veterans Administration have found that most staff read narratives [21]. One study involving patients with serious illness and without dementia in acute care found a narrative intervention to be acceptable to patients and bedside nurses [20].

The potential challenges to life story implementation uncovered in this study, including barriers to care team engagement, suitability to the acute care environment, and concerns for patient capacity and privacy are similar to previous studies [20]. One feasibility study of life stories for older adults with dementia in the United Kingdom on acute care National Health Service wards found similar time barriers and a need for prioritizing acute needs [42]. Approaches to the involvement of care partners in storytelling varied by study; some studies caution against using care partners to tell patients’ stories [43], while others acknowledge the need for care partner participation dependent on patients’ cognitive status [24]. We found that to co-design a life storytelling intervention for this population in acute care, care partners must be involved for patients with dementia and those at risk of delirium.

The anticipated benefits in our study are similar to anticipated and actual benefits in previous work, including improving individually tailored care; promoting relationships and communication among patients, care partners, and care teams; and particular benefits for people with dementia or risk of delirium, including serving as a communication tool for patients who are unable to communicate for themselves. Life story studies involving older adults with dementia have also shown that stories humanize patients, improve patient- and care partner–care staff relationships, and aid patient care [42-44].

Limitations

This study has several limitations. The primary limitation is that it was difficult to recruit and interview patients with dementia or at risk of delirium while they were in the hospital, due to acute illness, consistent clinical interventions, and limited cognitive capacity. Another limitation was the lack of cultural diversity patients recruited, as we were only able to recruit English-speaking patients and care partners. We did allow for English-speaking care partners to participate even if the patient did not speak English, to include perspectives from families with non-English speakers. Our recruitment was limited to 1 unit at 1 hospital and used only the APeX EHR, which means findings may not be generalizable to other EHRs, which could be a barrier to expanding the intervention. Finally, we experienced challenges in recruitment as the ACE Unit beds were delegated to patients who tested positive for COVID-19 of all ages during the study. As the pandemic numbers waxed and waned, this limited the number of available beds for older eligible patients, thus restricting the pool of eligible patients to recruit for our study.

Conclusions

In this study, we have co-designed with patients, care partners, and interdisciplinary team members, an adapted MemoryWell life story intervention for patients with dementia or at risk of delirium in an acute care hospital setting. This study highlights the anticipated impact of life stories for improving person-centered care in this setting, which often has limited resources and tools to do so. Future studies should be conducted to assess implementation feasibility and if these anticipated impacts on quality clinical and person-centered care can be made.

Acknowledgments

The authors would like to thank all stakeholder informants who took part in this study. The authors would also like to thank Tajalei Willard for her work in recruitment. This study was funded by the National Institute on Aging under award R43AG074775. JDH is supported in part by the National Institute on Aging of the National Institutes of Health (NIH; award K01AG073533) and the National Center for Advancing Translational Sciences of the NIH (award KL2TR001870).

Conflicts of Interest

This study was a partnership between University of California San Francisco and MemoryWell, a patient life storytelling company. Authors SJF and MC were employees of MemoryWell at the time the research was being completed. JN-S is the chief executive officer of MemoryWell. JN-S and MC own stock in MemoryWell.

Abstract

Background: Sleep efficiency is often used as a measure of sleep quality. Getting sufficiently high-quality sleep has been associated with better cognitive function among older adults; however, the relationship between day-to-day sleep quality variability and cognition has not been well-established.

Objective: We aimed to determine the relationship between day-to-day sleep efficiency variability and cognitive function among older adults, using accelerometer data and 3 cognitive tests.

Methods: We included older adults aged >65 years with at least 5 days of accelerometer wear time from the National Health and Nutrition Examination Survey (NHANES) who completed the Digit Symbol Substitution Test (DSST), the Consortium to Establish a Registry for Alzheimer's Disease Word-Learning subtest (CERAD-WL), and the Animal Fluency Test (AFT). Sleep efficiency was derived using a data-driven machine learning algorithm. We examined associations between sleep efficiency variability and scores on each cognitive test adjusted for age, sex, education, household income, marital status, depressive symptoms, diabetes, smoking habits, alcohol consumption, arthritis, heart disease, prior heart attack, prior stroke, activities of daily living, and instrumental activities of daily living. Associations between average sleep efficiency and each cognitive test score were further examined for comparison purposes.

Results: A total of 1074 older adults from the NHANES were included in this study. Older adults with low average sleep efficiency exhibited higher levels of sleep efficiency variability (Pearson *r*=−0.63). After adjusting for confounding factors, greater average sleep efficiency was associated with higher scores on the DSST (per 10% increase, β=2.25, 95% CI 0.61 to 3.90) and AFT (per 10% increase, β=.91, 95% CI 0.27 to 1.56). Greater sleep efficiency variability was univariably associated with worse cognitive function based on the DSST (per 10% increase, β=−3.34, 95% CI −5.33 to −1.34), CERAD-WL (per 10% increase, β=−1.00, 95% CI −1.79 to −0.21), and AFT (per 10% increase, β=−1.02, 95% CI −1.68 to −0.36). In fully adjusted models, greater sleep efficiency variability remained associated with lower DSST (per 10% increase, β=−2.01, 95% CI −3.62 to −0.40) and AFT (per 10% increase, β=−.84, 95% CI −1.47 to −0.21) scores but not CERAD-WL (per 10% increase, β=−.65, 95% CI −1.39 to 0.08) scores.

Conclusions: Targeting consistency in sleep quality may be useful for interventions seeking to preserve cognitive function among older adults.

Introduction

Healthy sleep habits protect memory and cognitive function [1,2]. Sleep quality deteriorates with age, but older adults with cognitive impairments have worse sleep quality than their counterparts without impairments [3-5]. Lower sleep efficiency, a proxy for sleep quality, is associated with worse cognition among older adults [6]. The importance of getting sufficiently high-quality sleep to reduce individual risk of cognitive impairments has been reported [3,7]; however, the relationship between consistent sleep quality and cognition remains understudied. Because it is unreasonable to assume that older adults strictly adhere to a consistent sleep schedule on a nightly basis, the relationship between day-to-day sleep efficiency variability and cognition must be examined.

This cross-sectional accelerometer study aimed to quantify associations between sleep efficiency variability and performance on 3 cognitive tests assessing memory, categorical verbal fluency, and sustained attention while adjusting for demographic factors, chronic diseases, smoking habits, alcohol consumption, cardiovascular risk factors, depressive symptoms, and measures of activities of daily living (ADL) and instrumental activities of daily living (IADL). We additionally fit models using average sleep efficiency metrics to compare any observed relationships between sleep efficiency variability and cognition to those between average sleep efficiency and cognition.

Methods

Data Source and Study Design

Data from the US National Health and Nutrition Examination Survey (NHANES) 2011-2014 waves [8] were used, during which a subset of participants wore an ActiGraph GT3X+ device that objectively measured activity levels over 7 consecutive days immediately after all nonaccelerometer data were collected. Participants aged >60 years were also administered cognitive tests during the 2011-2014 waves. We excluded participants aged <65 years, without complete cognitive test data, or without at least 5 days of accelerometer wear time.

Ethical Considerations

All NHANES participants provided informed consent, and ethics approval was granted by the National Center for Health Statistics Research Ethics Review Board (protocol #2011-17).

Measuring Cognition

The NHANES 2011-2014 waves include 3 cognitive tests: the Digit Symbol Substitution Test (DSST), the Consortium to Establish a Registry for Alzheimer’s Disease Word-Learning subtest (CERAD-WL), and the Animal Fluency Test (AFT; Table 1) [9]. For the AFT, CERAD-WL, and DSST, higher scores correspond to better cognition.

Table . The 3 cognitive tests included in the 2011-2014 waves of the US National Health and Nutrition Examination Survey.

Cognitive test	Description
DSST[a]	Tests processing speed, sustained attention, and working memory. Scores range from 0 to 133 where 1 point is awarded for each symbol correctly written below its corresponding number based on a key mapping the symbols to the numbers.
CERAD-WL[b]	Measures immediate and delayed word recall. Three rounds of immediate recall and 1 round of delayed recall using lists of 10 unrelated words comprise the CERAD-WL. Scores on the CERAD-WL correspond to the number of correctly recalled words across all 3 rounds.
AFT[c]	Measures verbal categorical fluency and requires participants to name as many animals as possible in a 1-minute period.

[a] DSST: Digit Symbol Substitution Test.

[b] CERAD-WL: Consortium to Establish a Registry for Alzheimer’s Disease Word-Learning subtest.

[c] AFT: Animal Fluency Test.

Deriving Sleep Metrics

Sleep efficiency—a proxy for sleep quality—is the ratio of time asleep to the total time between sleep onset and final sleep offset; possible values range 0-1 with higher values corresponding to better-quality sleep. Nightly sleep efficiency values were derived using an unsupervised hidden Markov model that identifies sleep-wake states using a data-driven machine learning approach [10]. The hidden Markov model algorithm has been validated against gold-standard polysomnography with 85.7% accuracy, 99.3% sensitivity, and better performance than commonly used supervised algorithms [10]. Sleep efficiency variability was defined as the SD of sleep efficiency across all nights of valid accelerometer data. For comparison purposes, we further derived each participant’s average sleep efficiency.

Additional Covariates

To account for potential confounders, we gathered each participant’s age, sex, education, marital status, household income, smoking habits, current alcohol consumption, depressive symptoms, measures of functional independence, history of heart attack, history of stroke, and diagnoses of arthritis, heart disease, and diabetes. Depressive symptoms were quantified using Patient Health Questionnaire-9 scores [11]. A functional independence score was derived by summing responses to 20 ADL and IADL questions. Participants were categorized as current, former, or never smokers and drinkers. An explicit explanation of how each covariate was defined can be found in Multimedia Appendix 1. Participants with missing data were excluded to enable a complete-case analysis.

Statistical Analysis

Participant characteristics were reported using the means and SDs for numeric variables and counts and percentages for categorical variables. We first examined the relationship between mean and day-to-day sleep efficiency variability using the Pearson r correlation coefficient and a scatterplot. Thereafter, using cutoffs from previous studies [12], we plotted the distribution of sleep efficiency variability stratified by normal versus low (≥0.85 vs <0.85) sleep efficiency.

We first examined univariable associations between sleep efficiency variability and DSST, CERAD-WL, and AFT scores. Demographic models were adjusted for age, sex, education, marital status, and household income. Finally, the full models in this study were further adjusted for depressive symptoms, ADL and IADL scores, smoking habits, alcohol consumption, diabetes, arthritis, heart disease, history of stroke, and history of heart attack. All univariable, demographic, and full models were refit using average sleep efficiency instead of day-to-day variability for comparison purposes. A sensitivity analysis was then conducted where we excluded extreme outliers (observations ≤1st or ≥99th quantile) for both average sleep efficiency and day-to-day variability. Models with both average and sleep efficiency variability were also examined (Multimedia Appendix 2).

Results

Descriptive Statistics

In total, 1074 NHANES participants were included (mean age 72.3, SD 5.2 years; females: n=528, 49%), among whom 97.8% (n=1051) had ≥7 nights of sleep data (Table 2 and Table S1 and Figure S1 in Multimedia Appendix 1). The average sleep efficiency in the cohort was 0.94 (SD 0.05), while the average DSST, CERAD-WL, and AFT scores were 46.7 (SD 16.0), 25.0 (SD 6.29), and 16.8 (SD 5.25), respectively. The correlation between mean and day-to-day sleep efficiency variability was −0.63 (Figure 1). We found that older adults with low average sleep efficiency had higher levels of sleep efficiency variability than those with normal sleep efficiency levels (Figure 2).

Table . Demographic, sleep, and cognitive characteristics of older adults (N=1074) with valid accelerometer and cognitive test data who were part of the National Health and Nutrition Examination Survey.

Characteristic		Participants
Number of nights of sleep data, mean (SD)		7.8 (0.47)
Age (years), mean (SD)		72.3 (5.2)
Sex, n (%)		
	Male	546 (0.51)
	Female	528 (0.49)
Education, n (%)		
	Less than ninth grade	95 (0.09)
	Some high school	141 (0.13)
	High school graduate or GED[a]	245 (0.23)
	Some college or associate’s degree	307 (0.29)
	College graduate or above	286 (0.27)
Marital status, n (%)		
	Married	613 (0.57)
	Widowed	230 (0.21)
	Divorced	145 (0.14)
	Separated	19 (0.02)
	Never married	42 (0.04)
	Living with partner	25 (0.02)
Sleep efficiency variability, mean (SD)		0.04 (0.05)
Average sleep efficiency, mean (SD)		0.94 (0.05)
DSST[b] score, mean (SD)		46.7 (16.0)
CERAD-WL[c] score, mean (SD)		25.0 (6.29)
AFT[d] score, mean (SD)		16.8 (5.25)

[a] GED: General Educational Development.

[c] CERAD-WL: Consortium to Establish a Registry for Alzheimer’s Disease Word-Learning subtest.

[d] AFT: Animal Fluency Test.

Figure 1. Scatterplot with a fitted regression line of average versus day-to-day variability for sleep efficiency.

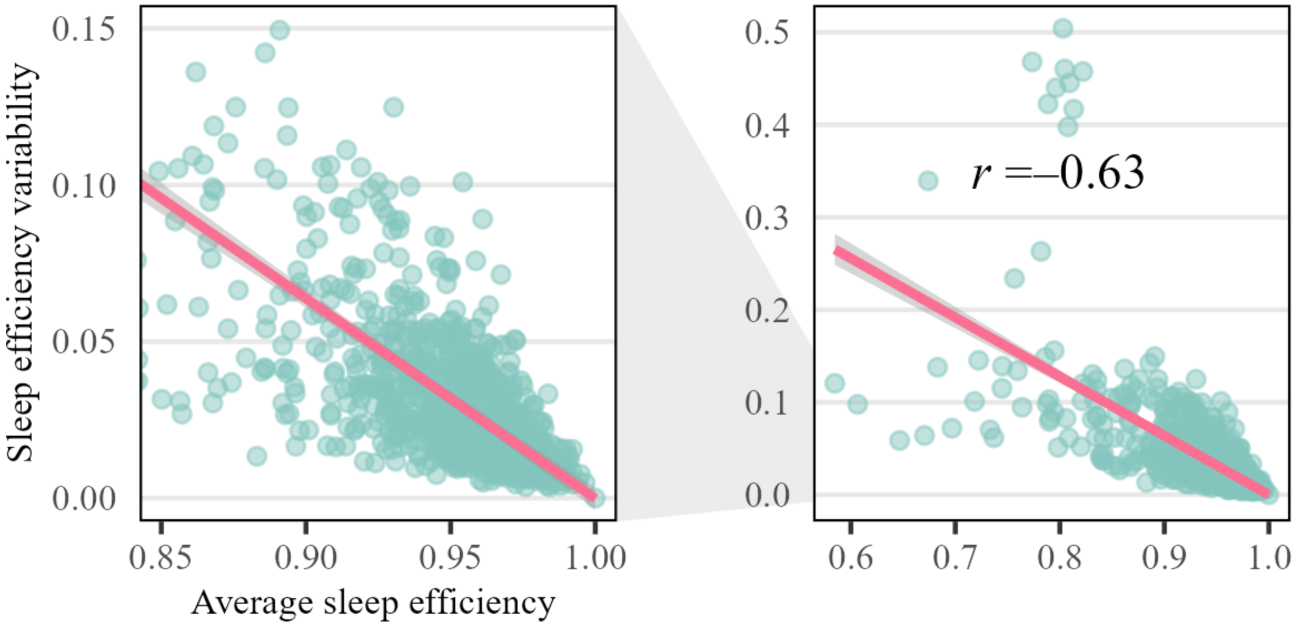

Figure 2. Distribution of day-to-day sleep efficiency variability stratified by average sleep efficiency.

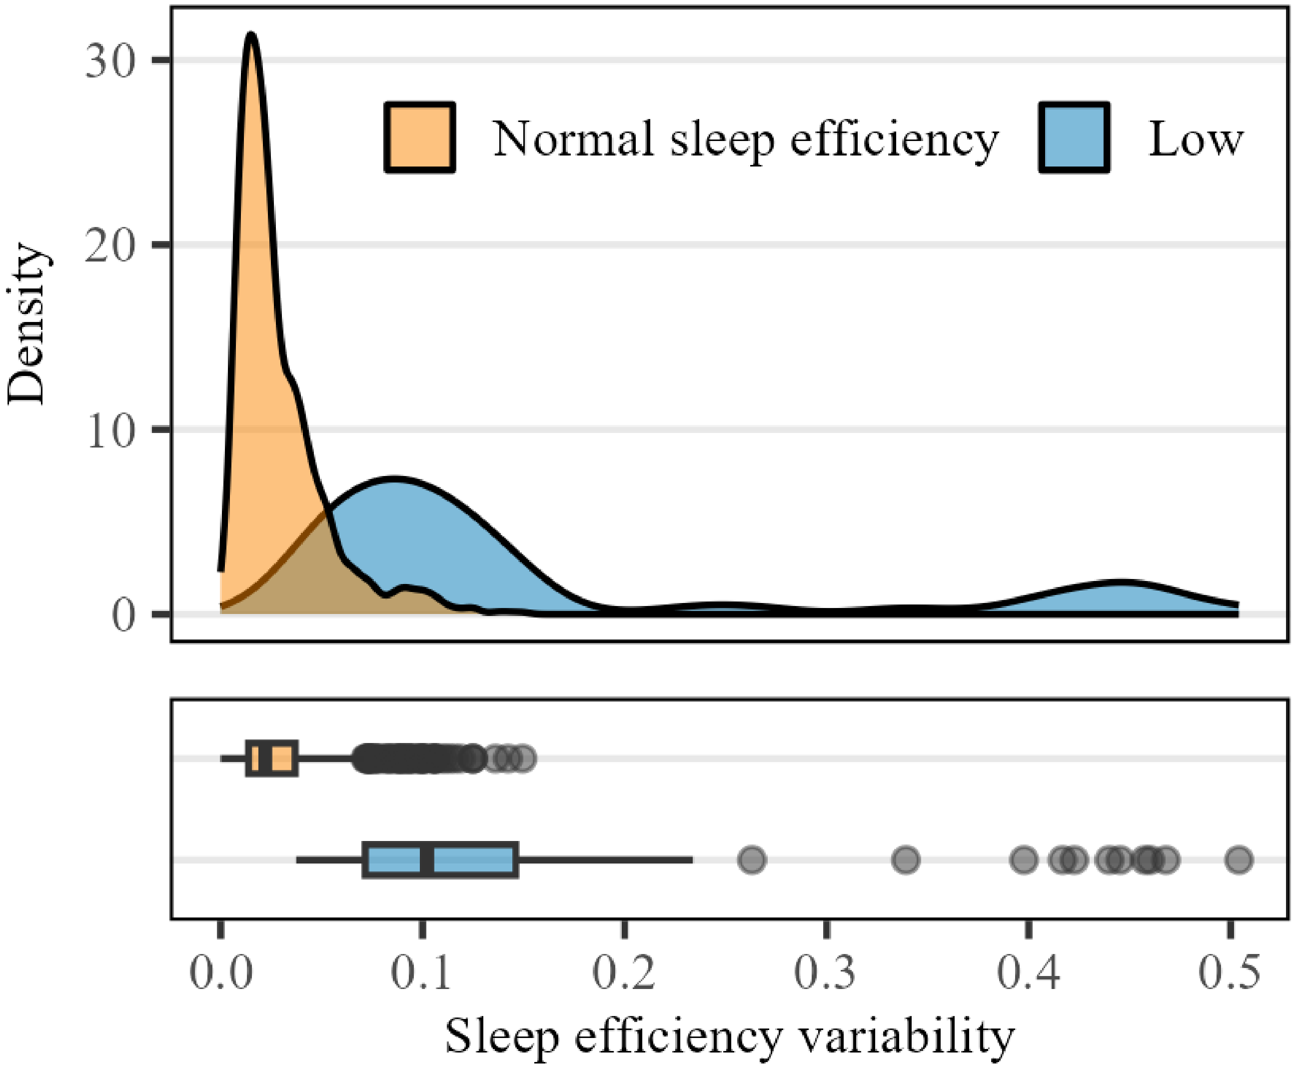

Associations

In the univariable models, greater sleep efficiency variability was associated with lower scores on the DSST (per 10% increase, β=−3.34, 95% CI −5.33 to −1.34), CERAD-WL (per 10% increase, β=−1.00, 95% CI −1.79 to −0.21), and AFT (per 10% increase, β=−1.02, 95% CI −1.68 to −0.36). In the full models, greater sleep efficiency variability was associated with lower scores on the DSST (per 10% increase, β=−2.01, 95% CI −3.62 to −0.40) and AFT (per 10% increase, β=−.84, 95% CI −1.47 to −0.21) but not the CERAD-WL (per 10% increase, β=−.65, 95% CI −1.39 to 0.08; Tables 3-5). Conversely, greater average sleep efficiency was associated with higher scores on the DSST (per 10% increase, β=2.25, 95% CI 0.61-3.90) and AFT (per 10% increase, β=.91, 95% CI 0.27-1.56) but not the CERAD-WL (per 10% increase, β=.46, 95% CI −0.29 to 1.21) in the full models. In the sensitivity analysis, after excluding extreme averages and sleep efficiency variability outliers, all significant results observed in the full models remained significant (Multimedia Appendix 3).

Table . Associations between day-to-day variability and average sleep efficiency with Digit Symbol Substitution Test (DSST) scores.

Model covariates	Association with DSST scores	
	β (95% CI)[a]	*P* value
Sleep efficiency variability	−3.34 (−5.33 to −1.34)	.001
Mean sleep efficiency	4.28 (2.27 to 6.28)	<.001
Demographics + sleep efficiency variability	−2.04 (−3.69 to −0.39)	.02
Demographics + mean sleep efficiency	2.65 (0.97 to 4.32)	.002
Full model + sleep efficiency variability	−2.01 (−3.62 to −0.40)	.02
Full model + average sleep efficiency	2.25 (0.61 to 3.90)	.007

[a] Coefficients are reported per 10% increase.

Table . Associations of day-to-day variability and average sleep efficiency with Consortium to Establish a Registry for Alzheimer’s Disease Word-Learning subtest (CERAD-WL) scores.

Model covariates	Association with CERAD-WL scores	
	β (95% CI)[a]	*P* value
Sleep efficiency variability	−1.00 (−1.79 to –0.21)	.01
Mean sleep efficiency	0.85 (0.06 to 1.65)	.04
Demographics + sleep efficiency variability	−0.70 (−1.43 to 0.03)	.06
Demographics + mean sleep efficiency	0.52 (−0.23 to 1.26)	.18
Full model + sleep efficiency variability	−0.65 (−1.39 to 0.08)	.08
Full model + average sleep efficiency	0.46 (−0.29 to 1.21)	.23

[a] Coefficients are reported per 10% increase.

Table . Associations of day-to-day variability and average sleep efficiency with Animal Fluency Test (AFT) scores.

Model covariates	Association with AFT scores	
	β (95% CI)[a]	*P* value
Sleep efficiency variability	−1.02 (−1.68 to −0.36)	.002
Mean sleep efficiency	1.08 (0.42 to 1.74)	.001
Demographics + sleep efficiency variability	−0.85 (−1.48 to −0.22)	.009
Demographics + mean sleep efficiency	1.02 (0.38 to 1.66)	.002
Full model + sleep efficiency variability	−0.84 (−1.47 to −0.21)	.009
Full model + average sleep efficiency	0.91 (0.27 to 1.56)	.005

[a] Coefficients are reported per 10% increase.

Discussion

Principal Results and Comparisons With Prior Work

This study shows that older adults with higher sleep efficiency variability scored worse on the DSST and AFT after adjusting for demographic factors, chronic diseases, smoking habits, alcohol consumption, depressive symptoms, cardiovascular risk factors, and ADL and IADL scores. Effect sizes for average and sleep efficiency variability were similar in magnitude but in opposite directions, with greater variability being associated with lower DSST and AFT scores, while greater average sleep efficiency was associated with higher scores.

A previous accelerometer study found that greater sleep efficiency variability was associated with lower scores on serial subtraction tests and memory questionnaires [13]. However, the study was limited by a small sample (n<50) and did not consider relevant confounders such as chronic diseases, ADL and IADL, smoking habits, and alcohol consumption. Another study found that greater sleep efficiency variability was associated with a greater β-amyloid burden—a biomarker for Alzheimer disease—but was again limited by a small sample (n=52) [14]. Compared to existing studies, our work, using a larger cohort accounting for more confounders, provides evidence that greater sleep efficiency variability is associated with worse cognitive function among older adults. Furthermore, we found that effect sizes for sleep efficiency variability and average sleep efficiency were similar but in opposite directions, suggesting that getting sufficient and consistent high-quality sleep may be useful targets for interventions seeking to preserve cognitive function among older adults.

Limitations

Given the cross-sectional nature of this study, we could not examine causal relationships. Bidirectional associations exist between certain forms of cognitive impairment and sleep disturbances [15], but they could not be examined herein. Future studies with longitudinal designs are therefore needed to further examine whether high sleep efficiency variability causally influences cognitive function or vice versa. Future studies may also benefit from collecting accelerometer data over longer durations, which more reliably measures sleep parameters [16], and from analyzing data across different countries to assess the generalizability of the findings presented herein. Lastly, polysomnography, the gold standard for measuring sleep parameters, was not used in this study. However, the use of wrist-worn accelerometers helped us assess sleep under natural living conditions, which intrusive polysomnography does not permit.

Conclusions

Greater day-to-day sleep efficiency variability was associated with lower scores on 2 cognitive tests in this study. Our work may motivate future causal inference studies seeking to determine if consistency in sleep quality is a viable target for preserving cognitive function among older adults.

Abstract

Background: Older veterans with anxiety disorders encounter multiple barriers to receiving mental health services, including transportation difficulties, physical limitations, and limited access to providers trained to work with older persons. To address both accessibility and the shortage of available providers, evidence-based treatments that can be delivered via guided self-management modalities are a potential solution.

Objective: This study aims to determine the feasibility and acceptability of a randomized controlled trial of 2 guided self-management interventions. This study compared the treatment effects of these 2 interventions (relaxation and health psychoeducation) on anxiety symptom severity and functioning in older veterans with anxiety disorders. Our exploratory aims examined factors related to home practices and treatment engagement and perceptions of the practices.

Methods: Participants were randomized to one of two video-delivered interventions: (1) Breathing, Relaxation, and Education for Anxiety Treatment in the Home Environment (BREATHE)—breathing and progressive relaxation or (2) Healthy Living for Reduced Anxiety—psychoeducation about lifestyle changes. Telephone coaching calls were conducted weekly. Measures of anxiety, depression, and functioning were obtained at baseline, week 4 (end of treatment), week 8, and week 12. Participants completed a semistructured interview at week 12. Analyses included descriptive statistics to summarize measures of intervention engagement; mixed-effects models to characterize symptom change, and qualitative analyses.

Results: Overall, 56 participants (n=48, 86% men; n=23, 41% from ethnic or racial minority groups; mean age 71.36, SD 6.19 y) were randomized. No difference in retention between study arms was found. The Healthy Living group (29/56, 52%) completed significantly more lessons (mean 3.68, SD 0.86) than the BREATHE group (27/56, 48%; mean 2.85, SD 1.43; t_{53}=2.60; P=.01) but did not differ in completion of coaching calls. In the BREATHE group, greater baseline anxiety scores (r=–0.41; P=.03) and greater severity of medical comorbidity (r=–0.50; P=.009) were associated with fewer completed practices. There was no effect of intervention on change in total anxiety scores or functioning. For specific anxiety subtypes, Healthy Living produced a greater decline in somatic anxiety compared with BREATHE. Qualitative analyses found barriers to practicing, including difficulty setting time aside to practice, forgetting, or having other activities that interfered with BREATHE practices. Some participants described adapting their practice routine to fit their daily lives; some also used relaxation skills in everyday situations.

Conclusions: These findings suggest that a larger randomized controlled trial of guided self-management approaches to treating late-life anxiety is feasible; however, BREATHE was not effective in reducing anxiety compared with Healthy Living. Possible contributing factors may have been the reliance on a single technique. Progressive relaxation was reported to be enjoyable for most participants, but maintaining home practices was challenging. Those with milder anxiety severity and fewer health problems were better able to adhere to practices.

Introduction

Background

Anxiety disorders are pervasive among older adults and especially common in older military veterans. These disorders include generalized anxiety disorder (GAD), social anxiety disorder, panic disorder, agoraphobia, and unspecified anxiety disorders [1]. A meta-analytic review estimated that nearly 1 in 10 (9.1%) older military veterans met the criteria for one of these anxiety disorders [2]. Not only do late-life anxiety symptoms and disorders contribute to detrimental outcomes such as functional and cognitive decline [3-5], but the presence of an anxiety disorder (ie, GAD) is a risk factor for suicide ideation among older non–combat-exposed veterans [6,7]. Thus, access to mental health services for anxiety in older veterans is critical.

Numerous barriers impede older veterans with anxiety from receiving mental health services. These barriers include mental health stigma and beliefs, lack of knowledge about available mental health services, mobility limitations, transportation challenges, and residing in rural areas [8]. Another barrier is the impact of anxiety diagnoses on referral for treatment. Older veterans with anxiety are more likely to receive nonspecific anxiety disorder diagnoses and less likely to receive mental health services compared with younger veterans who receive specific anxiety diagnoses and more subsequent mental health services [9]. Thus, accessible and brief nonpharmacological interventions for late-life anxiety are needed to address the barriers to accessing mental health care faced by older veterans with anxiety disorders. Furthermore, conclusions from a recent systematic review and meta-analysis suggest that these brief interventions may show promise for reducing anxiety symptoms in older adults [10]. One such brief behavioral intervention, progressive relaxation [11], also known as progressive muscle relaxation (PMR), has been shown to be an efficacious behavioral intervention for the treatment of late-life anxiety [12]. PMR is often included as a component within cognitive behavioral therapy (CBT) for anxiety treatments, as well as being a component of digital mental health interventions such as self-management mobile apps. We focused on this skill and developed a 4-week video-delivered intervention that teaches PMR and diaphragmatic breathing and encourages the application of these skills to help patients engage in activities in which anxiety or other types of stress may arise. Activity engagement was selected as a treatment target as discomfort and distress from anxiety symptoms prompt individuals to use coping strategies such as escape from and avoidance of anxiety-evoking situations in the short term [13]. This process (ie, negative reinforcement) makes it more likely for avoidance to be relied upon in the long term and is particularly detrimental to older patients because reduced engagement in activities often leads to isolation and functional decline [7].

This intervention—Breathing, Relaxation, and Education for Anxiety Treatment in the Home Environment (BREATHE)—is organized with weekly video lessons, daily practice videos, and telephone coaching to encourage adherence to the practices. It was initially tested in a proof-of-concept study comparing the 4-week BREATHE intervention to a waitlist control in older adults with anxiety disorders [14]. The BREATHE intervention was found to be superior to the waitlist control in reducing anxiety, depressive, and somatic symptoms; however, the attrition in BREATHE (35%) warranted further investigation. To address these attrition issues, we sought feedback on BREATHE from older veterans and made iterative revisions to the intervention in a second study [15]. The revised BREATHE intervention was then tested in a small feasibility study with 10 older veterans with anxiety disorders [16] in which BREATHE was found to be feasible and acceptable in that 90% (n=9) completed the intervention and 100% felt that BREATHE somewhat or completely met their expectations. While BREATHE is a guided self-management approach to anxiety, it differs from other similar approaches that either rely on manuals and bibliotherapy or are entirely internet delivered (see the study by Cremers et al [17] for a review). BREATHE falls between these 2 approaches, uses familiar technology (web-based videos or DVDs), and focuses on a single skill (PMR) rather than multiple skills (eg, CBT).

Objectives

In this study, we conducted a pilot randomized controlled trial (RCT) comparing 2 guided self-management interventions in older veterans with anxiety disorders. This study was conducted in part to determine the feasibility of conducting an RCT by documenting willingness to be randomized, engagement with the interventions assigned, and dropout. We also examined the preliminary efficacy of BREATHE compared with a psychoeducation intervention (Healthy Living for Reduced Anxiety) on anxiety symptoms and functioning in older veterans. We hypothesized that (1) BREATHE would result in greater reduction in anxiety symptoms compared with psychoeducation at 12 weeks and (2) BREATHE would result in significantly greater improvements in functioning compared with psychoeducation at 12 weeks. Our exploratory aims were to examine whether home practices and treatment engagement were related to patient characteristics or to intervention outcomes and examine participants’ perceptions of the home practices via qualitative interviews.

Methods

A 2-group pilot RCT (ClinicalTrials.gov NCT02400723) was conducted over the course of 12 weeks. The interventions lasted 4 weeks, with data collected at baseline, week 4 (end of treatment), week 8 (4 weeks after treatment), and 12 weeks (8 weeks after treatment).

Ethical Considerations

This study was reviewed and approved by the Stanford University Institutional Review Board (IRB-32454), the institutional review board of record for the US Department of Veterans Affairs (VA) Palo Alto Health Care System. Informed consent was obtained at the baseline visit. Participants were paid US $60 for the initial assessment and the 12 week assessment. Participants were paid US $10 for completing the telephone assessments at weeks 4 and 8. Data were deidentified prior to data entry and analysis.

Recruitment

Participants were recruited from a large VA health care system via posted flyers and brochures. Informational letters were also sent to patients who had at least one encounter during the past year that was related to a diagnosis of anxiety. Recruitment took place from February 2019 to March 2020 (before the COVID-19 pandemic) and from July 2020 to November 2020 (after the COVID-19 pandemic). Participants were eligible if they were aged ≥60 years and proficient in English and exhibited a diagnosis of an anxiety disorder (ie, GAD, panic disorder, agoraphobia, social anxiety disorder, or unspecified anxiety disorder). Participants were excluded if they were currently enrolled in other intervention research studies or were currently involved in individual therapy or group therapy more frequently than once per month. Those with possible cognitive impairment per a brief cognitive assessment or those who reported a diagnosis of bipolar disorder, psychotic disorder, schizophrenia, or other serious psychiatric disorders were excluded during the telephone screening process. If participants were taking psychotropic medications, they needed to be on a stable dose for 1 month before enrollment.

Measures

The following sections describe measures for inclusion and exclusion criteria assessment, outcome assessment, and measurement of covariates.

Assessment of Inclusion and Exclusion Criteria

The Short Blessed Test (SBT), derived from the Blessed Orientation-Memory-Concentration Test, was included as a brief cognitive assessment to ascertain possible cognitive impairment [18]. Participants obtaining scores of ≥6 on the SBT were excluded from the study [18,19]. The Structured Clinical Interview for the DSM-V (SCID-5 [20]), was administered to assess mental health diagnoses and exclude participants with serious psychiatric disorders, as mentioned previously. Those participants exhibiting an anxiety disorder were included if they met all other inclusion criteria.

Demographic Questionnaire

A questionnaire was administered at baseline to assess basic demographic, employment, and health information. Additional questions inquired about participants' previous experience with relaxation, breathing training, meditation, tai chi, and any other similar techniques.

Anxiety Measures

The Geriatric Anxiety Scale (GAS [21]) is a 30-item measure of anxiety that served as a primary outcome measure. The first 25 items measure the frequency of somatic, cognitive, and affective anxiety symptoms and are summed to obtain a total score. The last 5 items assess specific anxiety and fear content and are not included in the total score. Items are scored on a scale from 0 (*not at all*) to 3 (*all of the time*), with total scores ranging from 0 to 75; higher scores indicate greater anxiety. The GAS and its somatic, cognitive, and affective symptom subscales have good internal consistency and convergent validity compared with other anxiety measures [22]. The GAS was administered at baseline, week 4, week 8, and week 12.

The Hamilton Anxiety Rating Scale (HAM-A [23]) assesses the severity of anxiety using clinician ratings of 14 items on a 5-point scale and was included as a secondary outcome measure of anxiety. It has adequate internal consistency, high interrater reliability, and good to adequate concurrent validity [24,25]. The HAM-A was administered at baseline and week 12.

The Patient-Reported Outcomes Measurement Information System 7-item anxiety scale assesses the frequency of experiencing anxiety symptoms within the previous week [26]. Psychometric support for this measure has been found in adult populations [27,28] and in our previous work [16]. The Patient-Reported Outcomes Measurement Information System anxiety scale was administered at baseline and week 12.

The Anxiety Control Questionnaire (ACQ [29]) is a 30-item self-report measure assessing one's perceived ability to control anxiety-evoking situations and emotional reactions to these situations. Gerolimatos et al [30] found good internal consistency in older adults. The ACQ was administered at baseline and week 12.

Functioning

The Activity Card Sort (ACS) [31] was selected as a measure of activity engagement as it assesses the presence and the loss of activities using 80 photographs that depict instrumental, leisure, and social activities. We used an interactive sorting task to calculate lifestyle-adjusted function, which excludes activities that people have never performed in their lifetime [32]. The lifestyle-adjusted function is the number of easy activities divided by the sum of easy activities, hard activities, and no-longer-performed activities. Thus, the lifestyle-adjusted function score accurately reflects loss, gain, or changes in activity participation. This measure was obtained at baseline and week 12. Due to this being an in-person task, the lifestyle-adjusted function scores were only obtained from participants who completed the study before the COVID-19 pandemic.

We also used an individualized scoring of the ACS [33]. In this approach, we asked participants to select 5 activities that they would like to do more frequently if not experiencing anxiety. We ascertained participants' goals for the number of times they would like to do the activity, and we obtained the frequency of performing the activity at baseline, week 4, week 8, and week 12.

The Veterans RAND 12-item Health Survey (VR-12) [34] examines health-related quality of life and generates 2 scores: a physical component summary and a mental component summary (MCS). The MCS was used as a functioning outcome measure. The VR-12 was administered at baseline, week 4, week 8, and week 12.

Additional Measures

The 9-item Patient Health Questionnaire (PHQ-9 [35]) was used to assess participants' depression symptoms. The questionnaire asks about symptoms during the previous 2 weeks, and each item is scored from 0 (*not at all*) to 3 (*nearly every day*), with total scores ranging from 0 to 27. This measure was administered at baseline and week 12.

The Cumulative Illness Rating Scale–Geriatric [36] measures medical illness burden. Retrospective chart review was used to obtain the ratings and drew on recorded history, physical examination, and laboratory tests, consistent with previous work [37,38].

A semistructured interview and brief survey about the BREATHE or Healthy Living intervention was administered to participants at week 12. The survey included a question in which participants ranked the intervention components (video lessons, practices, and coaching calls) from most helpful to least helpful. The semistructured interview encompassed 7 questions about different domains, including changes made in one's life as a result of the intervention, effects on one's well-being, changes in activities and function, when improvement was first noticed, sustainability of the practices, recommended changes to the intervention, and whether the intervention would be recommended to other patients. Herein, we focus on questions related to the home practices in the BREATHE participants.

Procedures

Telephone Screening and Baseline Assessment

Participants completed a brief telephone screen to assess for potential cognitive impairment using the SBT, concurrent psychotherapy, presence of serious mental illness, or recent changes to psychotropic medications (if taking any). Eligible participants based on the telephone screen were invited to a baseline assessment that included obtaining informed consent. Baseline assessments were conducted in person up to February 2020 and via telephone after the onset of the COVID-19 pandemic. During the baseline assessment, a structured psychiatric interview was conducted to ascertain the presence of a current anxiety disorder (ie, GAD, panic disorder, agoraphobia, social anxiety disorder, or unspecified anxiety disorder). Participants who did not meet the criteria for an anxiety disorder or individuals who had a potential psychotic disorder or bipolar disorder were excluded at baseline. The remainder of the assessment consisted of completing the clinical interviews (SCID-5 and HAM-A), ACS, and questionnaires (demographics and health questionnaire, GAS, PHQ-9, ACQ, and VR-12).

Randomization

Eligible participants were randomized to BREATHE or psychoeducation in a blocked randomization scheme with blocks of varying sizes (2 to 8), as recommended by the statistician who created the randomization scheme. Each assignment was concealed in an envelope that a research team member opened in sequential order at the time of randomization.

Interventions

BREATHE Intervention

In the BREATHE intervention, participants watched 1 lesson video each week and then were instructed to practice relaxation 1 to 2 times a day. Participants were able to select whether they viewed the videos from a DVD or from a website. Participants also received weekly calls from their BREATHE coaches during which adherence was ascertained (ie, the lesson video viewed and practices completed). Anxiety ratings for each practice were reviewed, questions were addressed, and encouragement for practice adherence was provided. During weeks 2 to 4, patients were instructed to apply the skills during everyday life. In total, 2 team members (CG and LA) with a master's to PhD level of training in psychology served as coaches for both the BREATHE and Healthy Living interventions. Coaches used a coaching manual (available upon request) for each intervention and questions tailored to each week's content to guide the coaching calls. Both BREATHE and Healthy Living coaches addressed any participant challenges with using the DVD or website. Table 1 provides an overview of the intervention components, including the mean duration of the completed coaching calls.

Table 1. Summary of intervention components.

Week	BREATHE[a] components	Healthy Living components
1	• Video lesson: "What is anxiety? Diaphragmatic breathing & progressive relaxation" (37 min 35 s) • Video-guided daily practice: 16-muscle group relaxation (20 min 50 s) • Coaching call: mean 10 min, SD 4 min 42 s	• Video lesson: "What is anxiety?" (18 min 45 s) • Readings: "Coping with Stress and Aging" and "Stress: Causes and Effects" • Coaching call: mean 7 min, SD 3 min 29 s
2	• Video lesson: review 16-muscle group relaxation • Video-guided daily practice: 16-muscle group relaxation (20 min 50 s) • Skill application: use breathing in daily life • Coaching call: mean 11 min, SD 4 min 50 s	• Video lesson: "Coping with Stress and Aging" (19 min 27 s) • Readings: "Sleep Tips" and "Age Page: A Good Night's Sleep" • Coaching call: mean 10 min, SD 5 min 24 s
3	• Video lesson: brief relaxation (7-muscle group; 19 min 31 s) • Video-guided daily practice: 7-muscle group relaxation (11 min 32 s) • Skill application: use progressive relaxation in daily life • Coaching call: mean 12 min, SD 4 min 42 s	• Video lesson: "Taking care of your body through physical activity" (31 min 20 s) • Readings: "Age Page: Exercise and Physical Activity" and "Getting Fit for Life" • Coaching call: mean 7 min, SD 4 min 49 s
4	• Video lesson: review brief relaxation • Video-guided daily practice: 7-muscle group relaxation (11 min 32 s) • Skill application: use progressive relaxation in daily life • Coaching call: mean 14 min, 7 min 42 sec	• Video lesson: "Taking Care of Your Body Through Healthy Eating" (19 min 30 s) • Readings: "Healthy Eating & Physical Activity Across Your Lifespan" and "What's on your plate?" (optional) • Coaching call: mean 8 min, SD 3 min, 46 s

[a] BREATHE: Breathing, Relaxation, and Education for Anxiety Treatment in the Home Environment.

Psychoeducation (Healthy Living for Reduced Anxiety)

In the psychoeducation intervention (ie, active control), participants viewed 30-minute video lessons once a week for 4 weeks. The videos provided information about what anxiety is, coping with anxiety and sleep tips, benefits of exercise and a gentle stretching routine, and healthy eating. A Healthy Living coach (see the aforementioned description) called participants each week to ascertain adherence (ie, the lesson video viewed) and answer specific questions about the materials. Practice assignments consisted only of brief supplemental readings (Table 1).

Assessments at Weeks 4, 8, and 12

At weeks 4 and 8, a total of 4 questionnaires were completed with participants via phone: the GAS, PHQ-9, VR-12, and activity goal frequency (ACS). At week 12 (8 weeks after completion of the 4-week intervention), participants returned for a posttreatment assessment. The posttreatment assessment included the GAS, PHQ-9, HAM-A, ACS, VR-12, and ACQ. A feedback survey for the BREATHE and Healthy Living conditions was completed followed by a semistructured interview. The survey asked participants to rank the helpfulness of each part of the program: video lessons, practices for BREATHE or readings for Healthy Living, and coaching calls. Then, the survey had 5 statements with which participants rated their agreement on a Likert-type scale ranging from *strongly disagree* (1) to *strongly agree* (5). The items asked about the usability of the DVDs, website log-in, and watching of web-based videos and about the frequency of coaching calls and duration of the program. The semistructured interview was recorded with participants' permission, and the recordings or notes (if not recorded) were then transcribed. During the COVID-19 pandemic, the posttreatment assessment was completed by telephone. Assessors were not blinded to participant condition.

Power

An a priori sample power analysis was calculated with an α of .05 and power of 0.80. On the basis of previous research, the controlled effect size (Hedges *g*) for relaxation therapy's effect on anxiety was 0.90 (95% CI 0.44-1.44) [12]. The total estimated sample size was 30 (15 per group; Cohen *f*=0.41). Because of expected attrition and use of self-directed treatment, we estimated a smaller effect of the primary measure of anxiety and, thus, aimed for a sample of at least 26 participants per group (*f*=0.35).

Statistical Analysis

Descriptive statistics were used to help characterize the sample; *t* tests (2-tailed) and chi-square analyses were used to test whether the 2 groups differed on any characteristics. Correlation analyses were conducted to examine whether baseline anxiety or medical comorbidity were associated with homework completion. Analyses were conducted using SPSS Statistics (version 29.0; IBM Corp) [39].

To examine the hypotheses regarding the primary outcomes of anxiety (GAS) and functioning (VR-12 MCS), mixed-effects models, also known as linear growth models or multilevel models [40], were used. Missing data points due to participant dropout were handled assuming that the data were missing at random and conditional on observed information. Mixed models were used to examine the change in outcomes across 4 time points (baseline [T1], 4 weeks and end of treatment [T2], 8 weeks [T3], and 12 weeks [T4]). Growth models with just time were estimated first followed by the fully specified models that included a between factor of treatment group (BREATHE vs psychoeducation); a within factor of time; and an interaction of treatment by time, which was the estimate of the treatment effect over the course of the study.

A total of 3 mixed-effects models with 2 time points (baseline [T1] and 12 weeks [T4]) were conducted on (1) anxiety as measured using the HAM-A, (2) perceived anxiety control as measured using the ACQ, and (3) lifestyle-adjusted functioning using the ACS. Sensitivity analyses were conducted to evaluate the change in anxiety symptoms (GAS) from baseline to 4 weeks.

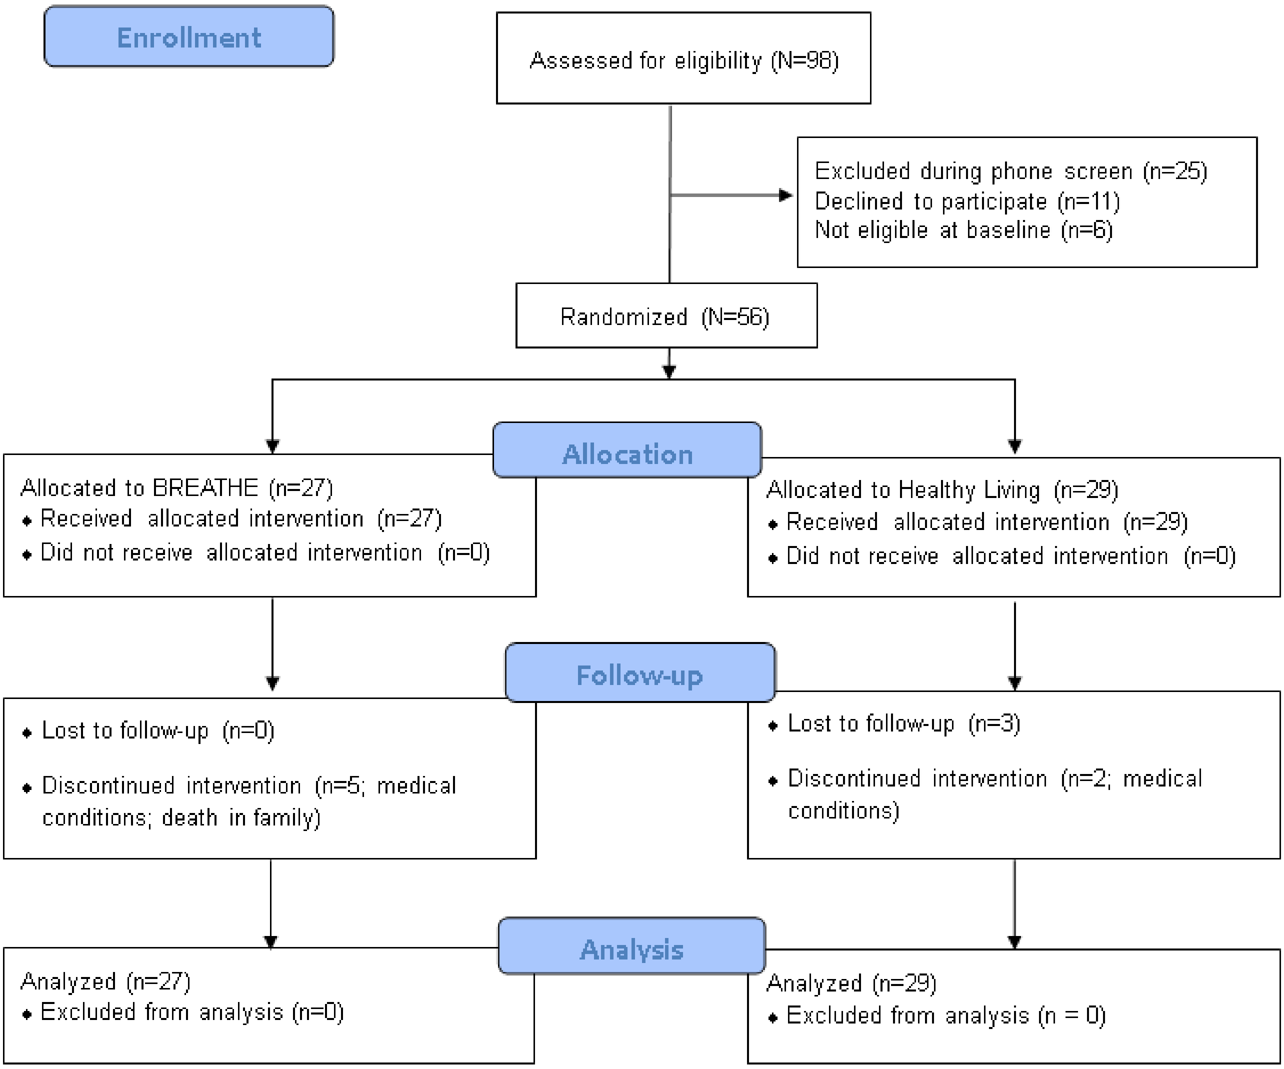
Rapid qualitative analysis [41,42] was used to investigate perceptions of the home practices among the participants assigned to the BREATHE intervention. Interview transcripts were summarized using templates, and then domain summaries were created by 2 authors trained in qualitative techniques (CG and CC). The summaries were reviewed for themes.

Results

Overview

Of the 98 participants assessed for eligibility, 56 (57%) were eligible and were all subsequently randomized. Figure 1 shows the participant flow throughout the study.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram. BREATHE: Breathing, Relaxation, and Education for Anxiety Treatment in the Home Environment.



Randomized participants had a mean age of 71.36 (SD 6.19) years and ranged in age from 60 to 88 years. Table 2 shows the characteristics of participants at baseline. Participants were diagnosed with a current anxiety disorder at baseline using the SCID-5. A total of 16% (9/56) of the participants had more than one concurrent anxiety disorder, 29% (16/56) had co-occurring depression, and 14% (8/56) had subthreshold posttraumatic stress disorder (PTSD; other specified trauma disorder). The most frequently occurring disorders were other specified anxiety disorder (30/56, 54%), GAD (18/56, 32%), social anxiety disorder (11/56, 20%), agoraphobia (2/56, 4%), and panic disorder (2/56, 4%).

[c] Not applicable.

[d] CIRS-G: Cumulative Illness Rating Scale–Geriatric.

Retention and Engagement

Completion of the assessment at 4 weeks and after treatment was 81% (22/27) for BREATHE and 93% (27/29) for Healthy Living (χ^2_2=1.7; *P*=.19). The retention at week 12 was similar across groups, with 81.5% (22/27) of BREATHE participants and 82.8% (24/29) of Healthy Living participants completing the assessment at 12 weeks (T4). The groups did not differ with regard to which modality they used for the delivery of the videos (χ^2=2.4; *P*=.30). Across both groups, 66% (37/56) used DVD delivery, 21% (12/56) used web delivery, 7% (4/56) used both, and 5% (3/56) had missing data on modality due to dropout from the study.

Most of the weekly coaching calls were completed for both interventions, with no differences found in the number of weekly calls completed for each intervention (t_{54}=0.92; *P*=.36). On average, BREATHE participants completed 3.48 (SD 1.05) of 4 (87%) weekly coaching calls. Healthy Living participants completed 3.72 (SD 0.92) of 4 (93%) weekly coaching calls.

With regard to engagement with the intervention as self-reported to coaches, the Healthy Living group completed significantly more lessons (mean 3.55, SD 1.09) than the BREATHE group (mean 2.85, SD 1.43; t_{54}=2.07; *P*=.04). In addition to the weekly lessons, the BREATHE group had daily home practices and 3 assignments to apply the skills in real life. Pearson correlation analyses found that greater baseline anxiety scores (GAS) were associated with fewer completed practices in the BREATHE group (*r*=–0.41; *P*=.03). In addition, greater severity of medical comorbidity (Cumulative Illness Rating Scale–Geriatric) was associated with fewer completed practices in BREATHE (*r*=–0.50; *P*=.009). On average, BREATHE participants completed 23.07 (SD 17.38) practices during the 4-week intervention. A total of 22% (6/27) of the participants completed 1 application of the skills, 19% (5/27) completed 2 applications of the skills, and 30% (8/27) completed ≥3 applications.

Participants shared feedback about the interventions through a postsurvey (Table 3). Participants generally agreed to strongly agreed regarding the ease of use and the usability of the DVD and website to access the videos. Most participants agreed to strongly agreed that the coaching calls were frequent enough and the program length was sufficient.

Table 3. Intervention feedback survey[a].

Survey item	BREATHE[b], mean (SD)	Healthy Living, mean (SD)	Test of significance	
			t test (*df*)	*P* value
The DVDs were easy to use.[c]	4.67 (0.69)	4.35 (0.93)	1.18 (36)	.25
The log-in for the website was easy.[d]	4.17 (0.72)	4.79 (0.43)	–2.72 (24)	.01
It was easy to watch the videos on the website.[e]	4.33 (0.71)	4.69 (0.63)	–0.13 (20)	.23
The calls from my coach were frequent enough.[f]	4.30 (0.66)	4.21 (0.83)	0.40 (42)	.69
The program was the right length of time.[f]	4.25 (0.79)	4.29 (0.75)	–0.18 (42)	.86

[a] Responses ranged from *strongly disagree* (1) to *strongly agree* (5). Due to some participants choosing to use DVDs and others using web delivery, the number of responses to the postsurvey question varied.

Primary and Secondary Analyses

Treatment effects were examined using mixed-effects models conducted on total anxiety scores as measured using the GAS. The models were best fitted with a fixed effect of time and group and random intercept. Table 4 shows the means for the BREATHE and Healthy Living groups across 4 time points (baseline [T1], 4 weeks and end of treatment [T2], 8 weeks [T3], and 12 weeks [T4]). Notably, there was substantial variability for baseline GAS scores, with some participants reporting low symptoms in the previous week despite meeting the criteria for an anxiety disorder. There were no differences in the rates of decline in anxiety between the groups. That is, the effects of time (*P*=.07), group (*P*=.64), and interaction of treatment by group (*P*=.07) were not significant. An inspection of the subscales revealed that there was a significant time by group interaction for somatic anxiety symptoms ($F_{3, 145.6}$=2.81; *P*=.04) but not for affective or cognitive anxiety symptoms. This significant interaction indicated that the Healthy Living group experienced a significant decline in somatic anxiety over time compared with the BREATHE group.

[a] With the exception of the Activity Card Sort and Anxiety Control Questionnaire, higher scores indicate worse symptom severity. On the Activity Card Sort, higher scores indicate a greater percentage of activities that are easy to do. On the Anxiety Control Questionnaire, higher scores indicate greater perceived anxiety control. Due to missing data, the number of participants at baseline varied.

Effects at Week 4 and Association With Engagement Measures

As shown in Table 4, the BREATHE and Healthy Living groups did not differ in effects at week 4 and end of treatment with the exception of GAS somatic scale scores, which were lower for Healthy Living compared with BREATHE at this time point. We also investigated whether changes in scores from baseline to week 4 were associated with home practice completion. Using Pearson correlation analyses, we found the association with practice completion to be nonsignificant (r=0.33; P=.13). Reduction in GAS scores from baseline to week 4 (end of treatment) was not associated with completion of lessons (r_s=–0.09; P=.53) or coaching calls (r_s=–0.009; P=.95) across the BREATHE and Healthy Living combined samples.

Individual Activity Goals

Individual activity goals set by participants were examined with regard to the number of goals identified, types of goals, and change in individualized goal frequencies from baseline to 4 weeks. On average, participants selected at least 4 activities to focus on (mean 4.7, SD 1.2; range 2-7). Of 263 total activities identified, the 3 most frequently selected activity categories were social activities (72/263, 27.4%); high-demand leisure activities (70/263, 26.6%) such as hiking or swimming; and low-demand leisure activities (63/263, 24%) such as photography, reading, or playing a musical instrument. The remaining activities were instrumental activities (35/263, 13.3%) or other activities identified by participants (23/263, 8.7%).

Change scores for each activity goal were calculated from 0 to 4 weeks. Scores were then collapsed into 2 categories: increase in activity frequency (change score of >0) or no change or decrease in activity frequency (change score of ≤0). The BREATHE and Healthy Living groups did not differ in their distribution of increased activities at 4 weeks (χ^2=0.2; P=.64). A total of 79% (23/29) of Healthy Living participants and 74% (20/27) of BREATHE participants reported an increase in frequency of one or more goals at 4 weeks. On average, participants in both groups attained ≥1 goal at 4 weeks (BREATHE: mean 1.6, SD 1.4; Healthy Living: mean 1.6, SD 1.3; consistent with an intention-to-treat approach, all participants were retained in these analyses. Those individuals who were lost to follow-up were coded as not attaining their goal).

Qualitative Feedback Regarding Practice Routine and Challenges

Feedback regarding the experience of the practices in the BREATHE group, including the overall experience of the practices, mechanics and frequency of practices, challenges encountered, and application of skills to real-world situations, was analyzed to better understand participants' experience with the BREATHE intervention (22/27, 81% completed the interviews). While Healthy Living participants relayed the same type of information, in this section, we focus on the BREATHE intervention as the condition of interest.

Experience With Practices

Participants expressed varied experiences with the practice components of the BREATHE intervention, that is, the diaphragmatic breathing and the PMR exercises. Overall, most participants ranked the practices as the most (9/21, 43%) or second (9/21, 43%) most helpful component of the intervention compared with the weekly coaching calls and video lessons. Some described the diaphragmatic breathing exercises as the most effective part of the intervention and the easiest skill to use outside of home. One participant (BR1) noted the following:

> *The breathing definitely was important. That's probably a big part of it. The breathing practices, because I didn't normally do this before, but by doing breathing exercises, it definitely helped me.*

Participants described adjustments made to PMR exercises. These included tensing for less time (BR12); adjusting for physical issues (BR18), which could include imagined tensing as specified in the videos; and grouping some muscles together (eg, lower extremities and facial muscles; BR18). Another participant liked tensing from the waist up (ie, face and upper torso) "because I get a lot of tension there" (BR4). A smaller number of participants felt that the practices and skills were not helpful in that breathing would not solve the problems they were facing. One individual explained the following:

> *I don't think learning how to breathe a certain way is gonna make anything go away that I'm dealing with.* [BR5]

Another participant noted that tensing their muscles was not helpful "because I'm tense already" (BR3).

Mechanics and Frequency of Practices

The mechanics of how and when people practiced varied. Creating a practice habit through timing, frequency (eg, once or twice a day), or location seemed to help with accomplishing the practices without stress or feeling pressured. One participant described the following:

> *...that the only time that I could do this was lying down—was in bed, lying down. And I thought—Oh, gosh, it's not going to be as effective. But after life quieted down somewhat, I was able to attain my goal and start to do it twice a day. Attempt to do it twice a day. But it was still lying down, and I loved it.* [BR8]

For some, setting a schedule to practice was stressful and, instead, practicing during a block of time (eg, mornings and evenings) helped:

> *It's like I like to do stretching exercises every day and I would kind of keep myself physically fit and this was more kind of a mental exercise of imposing discipline on myself to be able to do this twice a day.* [BR6]

With regard to the frequency of practice, participants described practicing once or twice a day for the first month or 2; however, many participants described that their practice frequency decreased after the first 4 weeks, which coincided with the weekly check-in calls ending after the first 4 weeks. For some participants, the relaxation procedures may have been too static (ie, the same video used to guide practice), and after several weeks, this contributed to diminished engagement. In contrast, some described returning to the practices to help with anxiety. One participant explained the following:

> *I didn't do it [progressive relaxation] as much for a while. And then out of necessity I said, "This is what I need to do," and I have done it more in the past months.* [BR16]

Another individual expressed an intention to continue practicing:

> *I will keep doing this 'cause I enjoy setting aside a time for a disciplined approach to trying to relax.* [BR6]

Personalization of the practices seemed to facilitate continued use of the techniques. One participant described adjusting their practice over time:

> *I changed it from watching the videos to just actually sitting, closing my eyes, and going through the process. I felt most comfortable doing it that way.* [BR1]

The guidance helped one participant "keep my mind on track" (BR8).

Challenges

Participants identified several challenges with completing the practices. Setting time aside to practice daily was a challenge due to timing, forgetting (BR2 and BR15), traveling (BR7), having visitors (BR6), or other activities. One participant described the following:

> *So, carving out the time is a little bit of a challenge. It's not overwhelming, because the program is really not that demanding, really, when you think about the time. But you just get busy.* [BR2]

Health and other life challenges deprioritized the study for some participants (BR5). Technology difficulties were noted by 9% (2/22) of the participants, and 5% (1/22) encountered difficulties, but described learning the technology. Documenting anxiety scores was identified as tedious by another individual.

Application of Skills in the Real World

Participants described multiple applications of the relaxation and breathing practice in the real world. The most common applications were using the skills when experiencing anxiety, tension, or stress or whenever a situation dictated it. Some described noticing tense or anxious feelings and then using the practices to alleviate the symptoms:

> *...when I began to feel periods of anxiety, I would either go to immediately and practice, or I'd set time aside [to practice].* [BR10]

Others described specific situations in which they applied the skills, including dentist appointments (BR4), at the hospital

(BR9), or when having an operation (BR11). Some used the breathing or tensing and releasing tools while driving and in traffic or while waiting for VA appointments (eg, BR8 and BR13). Another veteran described deep breathing when a task became more complicated or frustrating:

> *What helps me is that if I'm sitting there making breakfast and I see that it's getting complicated, something is frustrating me that maybe I dropped something that immediately I will just close my eyes and breathe slow. And sometimes I can only breathe three and then, if I feel I need it, I just go into doing more. And it's not a big conversation, I just do it.* [BR16]

Discussion

Principal Findings

The findings of this pilot RCT of BREATHE compared with Healthy Living demonstrate the feasibility of conducting an RCT in that all participants were willing to be randomized and retention was similar between study arms at 12 weeks. Some variation in engagement with and acceptability of the interventions emerged, as discussed in the following sections, but does not decrease the feasibility of conducting an RCT. The hypotheses were not supported with regard to the greater reduction in total anxiety symptoms or improvement in functioning (as measured using the VR-12 MCS score) in BREATHE compared with the psychoeducation control of Healthy Living. On the anxiety symptom subscales, participants in the Healthy Living condition experienced a greater reduction in somatic anxiety symptoms, but no other differences were found for the other 2 subscales of cognitive and affective anxiety symptoms. There are several reasons for these findings. First, as observed in most previous late-life intervention studies [43], the inclusion of an active control may have diminished the potential effect of relaxation. Furthermore, a growing body of research has focused on the importance of well-being–focused interventions, including yoga [44], nutrition [45], and other alternative interventions [46], and the presence of some of these factors may have contributed to the benefits that participants achieved in the Healthy Living intervention. This intervention did include gentle stretching and some basic sleep and coping tips in addition to nutritional information, which all may relate to physical and mental health while aging. It is possible that a single-component intervention was not effective for engaging participants across a 4-week period. Recent studies have demonstrated that CBT for depression and anxiety is effective at not only reducing anxiety but also preventing relapse over a 10-year period [47]. In addition, the heterogeneity of anxiety disorders, as detected using structured interviews, and the range in anxiety severity based on baseline GAS scores may lead to attenuated findings with a single-component intervention rather than a multicomponent intervention to address varied facets of anxiety (ie, cognitive, somatic, and affective symptoms).

Our exploratory aim examined factors related to home practices in the BREATHE condition or related to intervention outcomes which revealed that greater self-reported anxiety symptom severity and greater medical comorbidity at baseline were associated with fewer progressive relaxation practices completed during the 4-week intervention. The qualitative findings helped us further probe the potential effect of practices. Qualitative findings suggested that, for some, practicing breathing, relaxation, or both breathing and relaxation was not viewed as enough to manage their anxiety and stress, thus dovetailing with the quantitative finding of those participants with greater anxiety practicing less. Accordingly, BREATHE or Healthy Living may be better suited for individuals with mild to moderate anxiety, which should be tested directly in a future study. It is possible that older veterans with greater distress would have preferred having access to group or individual psychotherapy and may have had previous exposure to these modalities as a function of the integration of mental health into the Veterans Health Administration [48].

Other challenges to practicing were recounted by participants, including difficulty finding the time to practice, having other things to do (eg, visitors and other activities), or worsening of health problems and experiencing acute health changes. Some participants reported a decline in practices after the coaching calls ended at the 4-week mark. Thus, the challenges with practices were 2-fold and included both adhering to the practices and maintaining a practice routine over time, which parallels the challenges of having sustained engagement with digital mental health interventions [49] and with any behavioral intervention requiring practice. Perhaps improvements and variations in the types of relaxation are needed to maintain interest in practices over time.

These findings led to the question of whether home practice is the issue itself. Integrating an ongoing relaxation practice into daily life while facing multiple medical conditions may have required extra effort and motivation from participants. The qualitative interview findings revealed that participants were able to personalize their practices based on their own needs, tailor their routine, and implement the relaxation procedures in their daily life when they needed it. Another possible future direction would be to provide multiple skills in a modular approach consistent with digital mental health interventions [50] or consider adding a session focused on motivational interviewing to the intervention.

Participants described using the skills in a myriad of settings, including when facing worries or anxiety, when in a stressful situation, or when simply waiting for an appointment, and they achieved one or more goals on average. Future studies should clarify the dose of PMR needed and whether preferences for psychotherapy compared with technology [51] play a role in practice completion and overall adherence. Alternatively, while these interventions were designed to be widely accessible and scalable, it is possible that a more mechanistic consideration of breathing approaches for specific individuals may be needed (ie, precision medicine approaches [52]). In addition, more engaging and adaptive technology–based interventions could be of benefit for late-life anxiety and lead to more sustained engagement with practices. Further refinement of goal setting to promote intervention engagement alongside skills to cope with anxiety is needed. On average, BREATHE and Healthy Living participants attained at least one goal at the end of treatment, but this could be strengthened using more directed, individualized outcome measures for the goals (eg, goal attainment scaling approaches [53]).

Limitations

This study is not without limitations. One of the key limitations may be the heterogeneity of anxiety disorders and symptom presentation in a relatively small pilot study. Rather than including multiple types of anxiety disorders, focusing on specific symptoms (eg, worry that exceeds a particular threshold on a questionnaire) may be a better approach, as used with other studies [44,54]. As this sample included veterans, we likely encountered higher rates of co-occurring PTSD compared with other nonveteran samples. This particular comorbidity of PTSD may have made the anxiety presentation more complex and difficult to treat using guided self-management interventions. Additional limitations include the small sample size as the study was designed to be a pilot, the use of nonblinded assessors, and the absence of a validated measure of acceptability. Another limitation to our design was that only a portion of the outcome measures were assessed at the end of treatment (T2). This study took place earlier in the COVID-19 pandemic, which led to some modifications in data collection methods and limited our ability to collect complete data, in particular from the lifestyle-adjusted ACS.

Comparison With Prior Work

These findings differ from those of earlier studies on progressive relaxation for late-life anxiety in that the effects of progressive relaxation were not as robust as those found in earlier studies [55]. The use of a primarily male, ethnically and racially diverse military veteran sample may have contributed to some differences compared with earlier studies, in which older nonveteran White women made up much of the samples. The benefits derived from the Healthy Living intervention fit with the evidence for complementary and integrated health approaches for late-life anxiety [44] and the Whole Health program in the Veterans Health Administration [56].

Conclusions

These findings suggest that guided self-management approaches to treating late-life anxiety in older veterans are feasible but that further refinement and study are needed to identify what works best for whom using a video-delivered format with remote coaching. Our findings suggest that a psychoeducation-based approach may help older adults with somatic anxiety symptoms. While progressive relaxation was deemed to be feasible and enjoyable to most participants, those with mild to moderate anxiety symptom severity and fewer health problems were more likely to adhere to the recommended home practice. Thus, based on the qualitative feedback, the BREATHE intervention in particular might not be a good match for all older adults with anxiety disorders due to some participants needing a higher-intensity treatment and others experiencing negative reactions to progressive relaxation, primarily “relaxation-induced anxiety” [57]. Further work is needed to delineate the role of intervention design factors and individual participant baseline characteristics on the effect of guided self-management approaches on late-life anxiety.

Abstract

Background: Previous studies have explored how sensor technologies can assist in in the detection, recognition, and prevention of subjective loneliness. These studies have shown a correlation between physiological and behavioral sensor data and the experience of loneliness. However, little research has been conducted on the design requirements from the perspective of older people and stakeholders in technology development. The use of these technologies and infrastructural questions have been insufficiently addressed. Systems generally consist of sensors or software installed in smartphones or homes. However, no studies have attempted to use smart textiles, which are fabrics with integrated electronics.

Objective: This study aims to understand the design requirements for a smart textile loneliness monitoring system from the perspectives of older people and stakeholders.

Methods: We conducted co-design workshops with 5 users and 6 stakeholders to determine the design requirements for smart textile loneliness monitoring systems. We derived a preliminary product concept of the smart wearable and furniture system. Digital and physical models and a use case were evaluated in a focus group study with older people and stakeholders (n=7).

Results: The results provided insights for designing systems that use smart textiles to monitor loneliness in older people and widen their use. The findings informed the general system, wearables and furniture, materials, sensor positioning, washing, sensor synchronization devices, charging, intervention, and installation and maintenance requirements. This study provided the first insight from a human-centered perspective into smart textile loneliness monitoring systems for older people.

Conclusions: We recommend more research on the intervention that links to the monitored loneliness in a way that addresses different needs to ensure its usefulness and value to people. Future systems must also reflect on questions of identification of system users and the available infrastructure and life circumstances of people. We further found requirements that included user cooperation, compatibility with other worn medical devices, and long-term durability.

Introduction

Background

Loneliness is a common experience in later life and describes a subjective feeling, whereas social isolation is an objective state that is not necessarily associated with felt loneliness [1,2]. While people can be alone and lonely, they can also be lonely while cohabiting with their families [3]. Risk factors for loneliness and difficulties dealing with loneliness at an older age include physical health issues; lack of social resources, such as quality and frequency of contacts; lower educational attainment; and loss of a partner [3-6]. Loneliness can have health implications for individuals and economic impacts on the health care system. Loneliness has been shown to affect stress responses by increasing fibrinogen levels and diastolic blood pressure [5], risk of malnutrition [7], frailty [8], sleep deterioration [5], greater sensitivity toward self-rated health [2], depressive symptoms [9], and higher mortality risk [10].

Loneliness monitoring can help older people communicate with health care providers [11,12] and provide reassurance to family members. Another motivation is to assess loneliness objectively and understand its relation to health outcomes [11,13]. Previous systems used sensors at home, in corridors, and on doors and monitored phone and computer activities [11,12]. In this paper, we focus on the use of smart textiles in wearables and furniture for loneliness monitoring. Smart textiles have the potential to support a comfortable, accessible method of detection for physiological and behavioral data [14-16]. No previous systems designed to detect and systematically assess loneliness have used smart textiles for detection. Only 1 study detected the frequency of speech through a textile band; however, it did not evaluate whether this could be associated with the experience of loneliness [17].

Lessons From Loneliness Monitoring Systems for Older People

Loneliness has been associated with depressive symptoms [18], sleep disturbance [19], sleep dysfunction, lower sleep quality, and differences in heart rate [20] and blood pressure [21]. Previous monitoring systems for loneliness also found associations with decreased daily phone use and incoming calls [13], time spent outside the home [11,12], the number of computer sessions [11], and speech characteristics [22]. Some of these symptoms could potentially be detected with smart textile sensors positioned on beds [23], embedded electrocardiogram sensors [24], sensors in insoles [25], or pressure sensors [26] on seat covers.

Design considerations for current loneliness monitoring systems concern the need for privacy, system unobtrusiveness [11,12], and durability (ie, battery efficiency) [27]. Having sensors installed intuitively on walls or devices was considered more comfortable and could be more easily remembered by older people than those on wearables [11]. There have been a few proposals for the application of a loneliness monitoring system. One proposal was to implement the technology in community settings to raise awareness for people who are on the verge of becoming lonely and to address the issue or share the data with physicians or nurses [11]. There is also a need to gain consent from older people to use the proposed technology [11]. Furthermore, a consideration is the question of how to serve lower-income and rural populations in accessing this technology [12]. No studies have presented in-depth findings on the needs and preferences of older people or stakeholders in loneliness monitoring systems using smart textiles. Thus, we drew on user studies and insights into design requirements from the literature on smart textile technologies.

Lessons From Smart Textile Wearable Technologies for Older People

Compared to pervasive computing systems, smart textile systems are predicted to acquire denser data, be less obtrusive, and reduce the number of devices required to detect diverse symptoms simultaneously [28]. Greater privacy is also a reason for positioning sensors in insoles for monitoring falls compared to alternative video cameras [25]. Positioning of sensors in furniture, such as a mattress topper, has previously been considered less invasive than worn sensors [23]. Positioning sensors on wearables, such as socks, allows for continuous monitoring including at home [29]. Even in older patient groups, there was a high adherence to the continuous use of wearable sensors, helping continuous monitoring of potential health risks [30]. Other examples of textile sensors include Taekwondo suits (pants and jackets) [26], floor mats [31], waistbands [24], and head ornaments [32]. Previous applications have contributed to the development of strain, pressure [26], electrocardiogram textile sensors, and explored the possibility of sensors with combined functions [26]. There has been a proposal for “intelligent health agents” based on smart textiles, which can support monitoring and treatment through textile technologies, such as thermotherapy, electrical stimulation, or phototherapy [33].

The commonly mentioned requirements are comfort [34-36] and wearables being made of breathable [34,37], lightweight, and permeable materials [34]. Furthermore, smart textile applications would need to function during daily and sports activities [35], be discrete [36], be safe on the body, and resist bodily fluids [35]. Aesthetic properties, such as color, fit, and diverse choices, to adapt clothing to the cultural context of the wearer and the possibility of mass production of such design choices should be further considered for greater acceptance [35,38]. Moreover, smart textile wearables must adapt to different body measures, genders, postures, and movements [35]. Further requirements include greater accuracy, reliability, privacy, and safety of the transmitted information [38]. The requirements for the material can vary according to the application context, but they did involve resisting large deformations and strikes in sports [26] and resisting abrasions from moving a topper on a mattress [23].

Furthermore, washability is considered an essential requirement for smart textiles [34]. Current applications can range from approximately 5 washing cycles by hand [26] to 40 cycles at 25 °C by a machine [36]. This implies potential additional requirements for washing [39]. One proposed solution to protect the textile sensors was microelectronic systems that could “be detached from the clothing component before washing” [40].

However, this might also contradict being a user-friendly washing process [38]. Thus, it is recommended that smart textiles are machine washable, support known washing processes, and do not require complicated washing instructions [38]. Power sources are also vital as currently available power sources are often too bulky [41]. Hence, one requirement is reduced energy consumption as one way to use less bulky power sources and the option to use energy from motion and body heat [34,35,38]. Enough power should be provided to last throughout monitoring activities [35]. Another important consideration is the recyclability and potential biodegradability of smart textiles produced without using harmful materials [34,41].

We are an interdisciplinary research group consisting of experts in gerontology, psychology, design, sensor technology, and machine learning, aiming to develop a loneliness monitoring and communication system from a human-centered design perspective [42]. This study aims to understand the needs of older individuals and the expectations of stakeholders to inform the system design.

Methods

Overview

We obtained user and stakeholder feedback from workshops and focus groups to develop the design requirements and initial design concept of the smart textile loneliness monitoring system for older adults. The study design and topic guides were developed in collaboration with team members who are developing the textile sensors and explored symptoms of loneliness in previous interviews [40]. For instance, sensor development required an understanding of user expectations in the positioning of sensors, washing, and charging. In addition, our initial prototypes developed and presented during the studies were informed by insights from interviews on potential symptoms of loneliness.

On March 27, 2023, and April 12, 2023, we conducted 2 co-design workshops with people aged ≥65 years who had experienced loneliness (n=5). On June 7, 2023, and June 15, 2023, we conducted a second co-design workshop with stakeholders (n=7). Therefore, we derived a set of design requirements implemented in an initial service system scenario and a smart home wearable system prototype. In October 2023, the design requirements were evaluated in a focus group study that included older people and stakeholders (n=7).

Participants

Participants for the workshop and focus group studies were contacted based on their previous expression of interest in the DELONELINESS project, as specified by Rees et al [4]. Invitations were sent via email newsletters within a housing network specialized for older people. We engaged individuals who had previously responded through a newsletter in a study involving older participants. Participants were also contacted through a study pool on wearable technologies from the Remote Assessment of Disease and Relapse-Major Depressive Disorder program focused on the passive monitoring of depressive disorders through smartphone data and wearables. Older participants were eligible for the workshops if they were aged ≥65 years, spoke fluent English, and experienced loneliness within the last 10 years since reaching the age of 65. Participants were ineligible if they had any cognitive impairment or dementia.

The severity of loneliness measured by the University of California, Los Angeles 3-item Loneliness Scale [43] has been associated with various health effects and restrictions. Higher and medium levels of loneliness were associated with a higher risk for frailty than lower levels of loneliness [8]. Another study showed that higher levels of loneliness were associated with greater mortality risk [9]. Higher levels of loneliness were also associated with people who might face functional restrictions, which have potential difficulties in engaging in activities [44]. Severe loneliness might have different requirements for a monitoring system and linked interventions. When participants were unable to attend on the day due to ill health, follow-up sessions were organized.

For both the workshop and focus group, stakeholders were recruited through the People in Research website by the National Institute for Health and Care Research to offer opportunities for public engagement and through the researchers' professional networks. The eligibility criterion for stakeholders was being aged >18 years. We searched for family members of older people who had experienced loneliness, industry representatives, carers, social workers, social prescribers, housing providers, and charity workers.

Participant characteristics in the studies have been summarized in Table 1 and Textbox 1.

We chose a qualitative approach with the aim of gaining more in-depth insights into participant perspectives and needs, which serves well to inform the initial system design. Previous qualitative research on design requirements for technologies for susceptible people and with stakeholders have been based on sample sizes such as 12 patients and 4 stakeholders [45], 10 experts to develop and 4 to evaluate a system [46], or 15 stakeholders [47]. For a qualitative evaluation in user research, we followed the recommended participant number of 3 to 15 [48].

Table 1. Older participant demographics in the co-design and focus group study.

Characteristic	Study 1: co-design workshop (2 groups; n=5)	Study 2: focus group (2 groups; n=4)
Age (y), mean (SD; range)	74.6 (3.8; 70-83)	73.3 (5.4; 68-78)
Sex, n (%)		
Female	4 (80)	2 (50)
Male	1 (20)	2 (50)
Hughes Scale for Loneliness, mean (SD; range)	6.2 (1.7; 3-8)	5.8 (2.2; 3-9)
Experience in using health monitoring technology, n (%)		
Yes	3 (60)	2 (50)
No	2 (40)	2 (50)
Living circumstances, n (%)		
Living alone	3 (60)	2 (50)
Living with others	2 (40)	2 (50)

Textbox 1. Stakeholder characteristics in the co-design and focus group study.

Stakeholders in study 1: co-design workshop (2 groups; n=7)

- Family member and private carer
- Representative for a housing network for older people
- Company founder for housing for older people
- Representative for a smart textile company
- Social prescriber and social worker
- Charity founder for loneliness
- Public contributor with non-English, international family background

Stakeholders in study 2: focus group (1 group; n=3)

- Family member and private carer
- Family member and care home manager
- Health and well-being coordinator (social housing)

Procedure

Study 1: Co-Design With Older People

The first co-design sessions were held with older people to discuss their design preferences for the function and positioning of a textile monitoring system on the body and in the home environment. The session involved the activities mentioned subsequently, which were relevant to the overall system development. Topics include the positioning of sensors; what to detect; overall system components; and washing, charging, and service requirements.

Initially, participants were asked to brainstorm about behaviors indicative of loneliness and the strategies to detect them. They were also asked what objects they surrounded themselves with and in which situations they experienced loneliness. This served as a basis for further thought on how a system for monitoring loneliness could be positioned.

Participants received preprinted outlines of a human figure and a home environment in a task. They were asked to indicate through red and green markers where they would accept or avoid the positioning of sensors. The previously discussed and exemplary symptoms were added. Subsequently, each person shared their materials and presented them to the group. This first indicated how the system would be positioned and what should be detected. For the positioning, they were not presented with symptoms or preferred sensor positions from a technical perspective to avoid influencing them.

Afterward, a presentation by the researchers summarized specific questions relevant to the sensor development. Pictures and questions prompted the discussion on existing wearables (eg, t-shirts, underwear, and leggings), charging and washing requirements, and whether participants would accept detachable electronic components for wearables and furniture. They were also asked to comment on some proposed positionings for the system based on initially hypothesized symptoms and preferred sensor positionings as recommended by experts in our team.

Study 2: Co-Design With Stakeholders

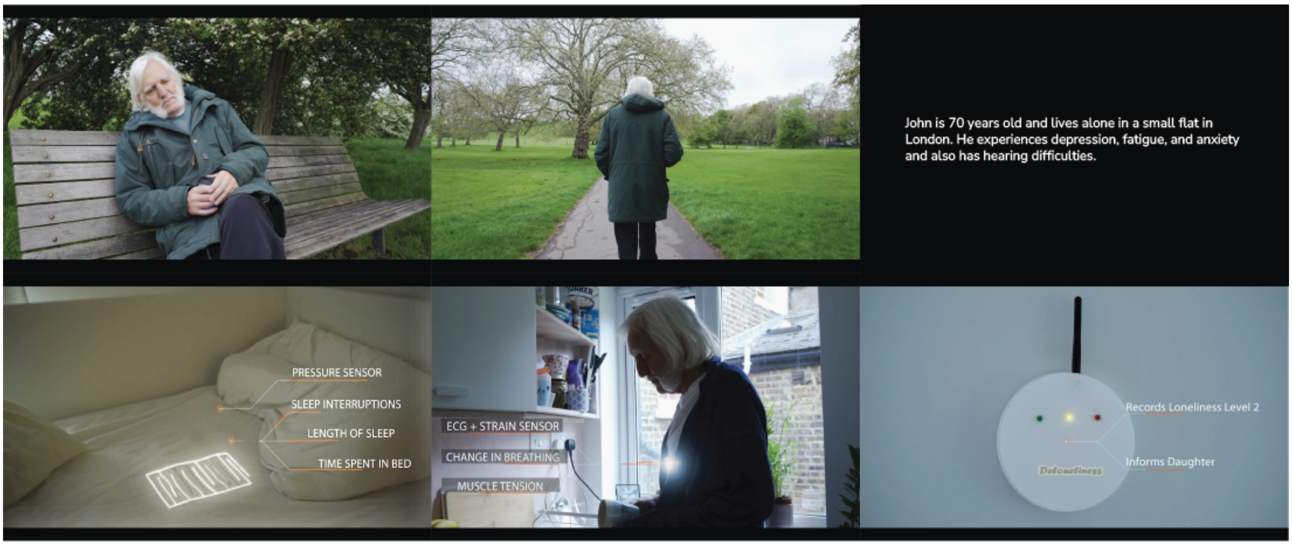
The workshop with stakeholders was built on the previous co-design session with older adults, which helped inform and develop the first concept and use case and elicited further discussion (Figure 1). In addition, the stakeholder's workshop aimed to explore the overall device implementation in the existing health care and personal environment. Therefore, the session involved additional activities mentioned subsequently.

First, participants were shown a video scenario (Figure 1). The video presents the case of John, an older man living with the loneliness monitoring system. It displays the locations where sensors are positioned, what symptoms are sensed, and what response is expected. The video shows that if a medium level of loneliness is detected, a family member will be informed, and they will initiate a call. A dedicated expert or social prescriber will be informed if severe loneliness is recognized. On the basis of the video, the stakeholder participants were provided materials to brainstorm about initial questions or concerns from their perspectives.

Afterward, stakeholders were presented with the human shape and home environment previously provided to older people to indicate how they suppose such a system should be positioned.

Finally, participants were asked to envision the implementation and installation of the system and the process while the researcher summarized comments in a sketch with preprinted elements.

Figure 1. A short film about the main character, John, who experiences loneliness and uses the developed monitoring device. ECG: electrocardiogram.



Study 3: Focus Group Evaluation

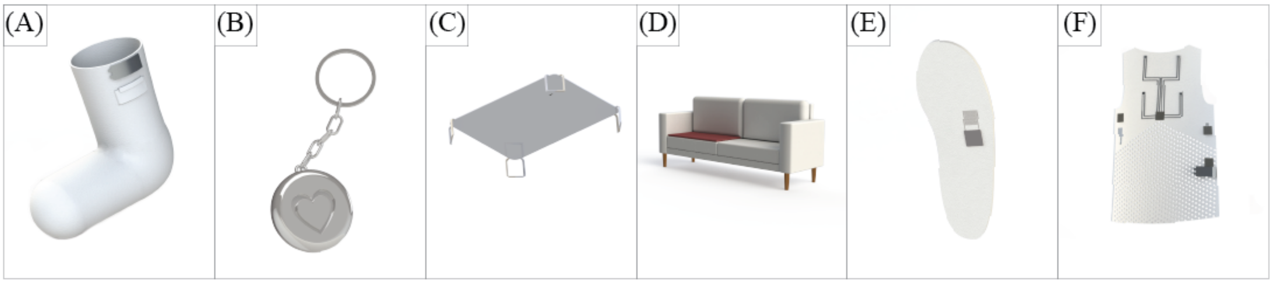
A list of design requirements was developed based on the analysis of previous co-design sessions. These were implemented in digital and physical models (Figure 2) with materials recommended by the team members developing smart textile sensors. The focus group evaluated whether the proposed system design and requirement implementation were perceived as valuable and easy to use, which are predicting variables for older people's use of new technologies [49].

The session was divided into 3 main parts. First, we presented the system's physical components, showing its function and use process over time. Participants were asked to interrupt at any time to express their thoughts [50]. Afterward, open-ended questions followed, such as "What are your initial thoughts on the system?" "What are the benefits and drawbacks of how the system is positioned on the body and in the home?" and "Do you believe the system will be more or less useful to older people that were identified to experience loneliness?" In addition, a set of Likert-type questions (5-point items) was presented to get responses from everyone on the usefulness and expected ease of use (Textbox 2). The questions were inspired by the System Usability Scale [51] and measures for perceived usefulness [52]. Although participants had not yet tested the system's usability, the rating was intended as the first evaluation step before the system was implemented and tested in the field.

In the second part, methods of washing and charging were presented. Washing would need to take place as efficiently as possible, as was determined by the previous co-design sessions. Participants were asked to rate the expected ease of washing, ease of remembrance, and comfort. Then, participants were asked open-ended questions, such as "What do you like or dislike about the way of washing proposed?" and "Would it be easy or difficult for an older person to maintain these forms of charging?"

Finally, participants were presented with 4 personas based on the previous interview data [4]. Participants were asked to comment on interventions that might be helpful to support the personas (Multimedia Appendix 1). Afterward, an initial proposal for a mobile app was shown and discussed (Figure 3).

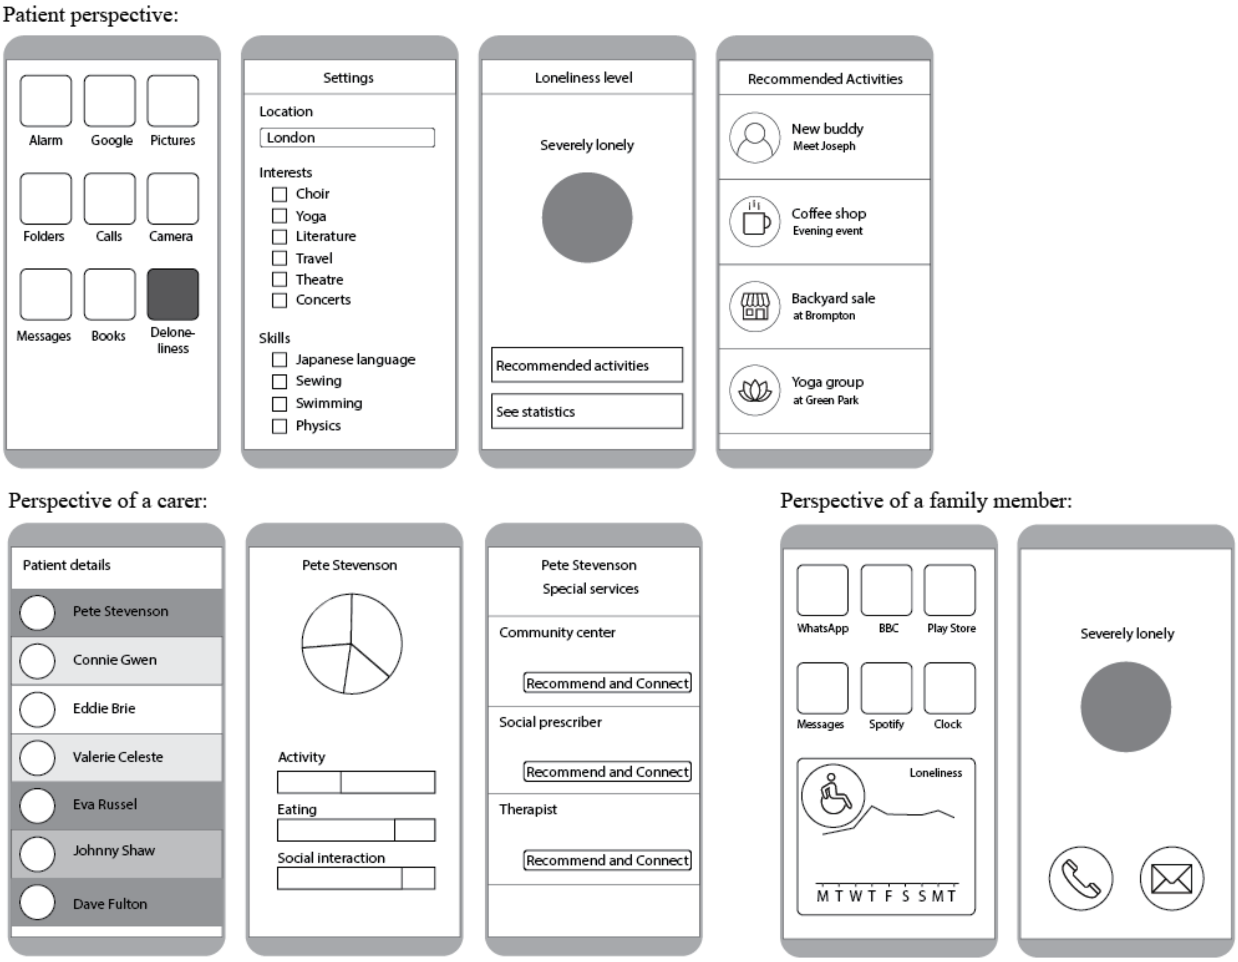
Figure 2. 3D model of system components. From left to right: (A) a sock with a battery, (B) a sensor synchronization device shaped as a key charm, (C) a mattress cover, (D) a seating cover, (E) a shoe insole with an integrated pressure sensor, and (F) a vest that indicates the positioning of sensors and microchips.



Textbox 2. Rating questions asked in the focus group evaluation and 5-point scales.

- The system can be used intuitively by older people: strongly disagree to strongly agree
- The system is useful to reduce loneliness for older people: strongly disagree to strongly agree
- How do you rate the comfort of the sensing (socks or mattress cover or seat cushion or vest or insoles)? not at all comfortable to very comfortable (1-5)
- How easily would older people remember to use the sensing (socks or mattress cover or seat cushion or vest or insoles)? not at all easily to very easily (1-5)
- The system is easy to wash for the older adult: strongly disagree to strongly agree (1-5)

Figure 3. Proposed mobile app linked to the loneliness monitoring system.



Analysis

The workshops and focus groups were transcribed by the first author and, in part, by a professional transcription service with the consent of the participants. Our analytical approach was an inductive qualitative content analysis [53]. Content analysis is a "technique for making replicable and valid inferences from texts...to the contexts of their use" [50]. A qualitative approach differs in coding, the determination of categories, and how researchers interpret data frequencies [54,55]. Categories are often developed inductively close to the dataset at hand and reading data in depth rather than by applying automated analysis approaches based on predetermined codes [54,55]. According to the approach [53], we first applied open coding by reading the material, assigning codes, and developing categories with the help of NVivo (Lumivero) software. Then, the codes were classified and grouped into categories (eg, "accuracy in detection," "economical inclusivity," and "instructions for carers"). The categories developed were further grouped into superordinate categories (eg, "general system requirements," "wearable requirements," "installation and maintenance requirements," "material requirements—wearable," and "material requirements—furniture"). For part of the material, the coding was done independently by a second researcher. Differences in coding were resolved through discussion. This led to additional codes in a few categories. The categories were further presented to 2 coauthors. This led to the summary and further grouping of codes, such as soft and lightweight materials. Moreover, it led to renaming some categories, such as "machine washing" rather than "direct washing." We considered frequencies and how often different participants mentioned a concept. The detailed quotes and frequencies in each category are enlisted in Multimedia Appendix 2. This served to structure the observed requirements. The frequency count is not intended to be statistically significant or generalizable but to better compare different requirements and their potential importance.

Ethical Considerations

The study was approved by the research ethics committee at King's College London (LRS/DP-22/23-34602) on January 16, 2023. Participants were provided with an information sheet and the consent form before the initiation of the study for their information and they were informed about being able to opt out at any time in the study and asked to sign the consent form on the day the study started. In all data processing, data were labelled with a unique non–personally identifiable participant identification number. This made the data pseudoanonymous. A password-protected file contained the name and contact details with an ID that is stored separately. Participants were not provided with any direct incentives to participate. However, travel and lunch costs were reimbursed.

Results

General System Requirements

The general system requirements addressed the overall system function or were mentioned concerning multiple aspects of the system.

Accuracy of Detection

Older people and stakeholders wished for the system's effectiveness. Some older participants were skeptical about how a subjective feeling of loneliness could be associated with physical symptoms or behaviors:

> *A sensor's not gonna pick up my feelings of emptiness.*

They were also incredulous that sensors could accurately detect the intended symptoms:

> *I wonder if that would work with my dog. I talk to my dog all the time.*

A couple of stakeholders suggested that sensors would need to be able to differentiate data from home visitors:

> *But when other people come to visit you or use your house or even if their care workers or something. Then they would they might access the toilet, the kitchen sink. They wouldn't be in your bed though, you tend to have your own side of the bed don't you. So, I think bed probably works well. But what about towels? I don't know if in a towel would work.*

The company representative and expert in smart textiles also noted the importance of data detection during the wearable's movement.

Economic Inclusivity

Stakeholders with a background in charity, social work, or housing provision raised the question of how such a system could become affordable to more people. They recommended a tiered system:

> *Being a tiered service, a basic service, open to all. And if I can afford it and can afford to pay a subscription maybe a better-quality service or a wider range of monitoring.*

People could choose from a basic or more elaborate sensor system and intervention for loneliness based on their financial possibilities and individual needs.

Cultural Inclusivity

Some stakeholders questioned the compatibility of such a system for different cultures. For instance, some cultures might prefer seats on the floor rather than a traditional settee:

> *Some people might not use settees but sit on the floor.*

The monitoring system and linked interventions would also need to be delivered in multiple languages or visual symbols that are universally understood:

> *Different cultures respond to different phrases.*

Flexibility to Change

An expert on housing provision to older adults mentioned the importance of system flexibility concerning future technological developments:

> *Builders and housing developers want something flexible. Because if you look at things like the existing, the old-fashioned emergency call systems, a lot of providers had difficulties retrofitting.*

Previous emergency call systems had proved challenging to replace in care housing. Thus, systems need to avoid becoming integrated into the home infrastructure.

Comfort

Comfort was mentioned by some older participants in workshops, describing it as a crucial element of wearable acceptability:

> *But then surely we are back to the Velcro thing, aren't we, which we discussed, and we don't really like because it is stiff and uncomfortable.*

It was a key argument for where they wished the sensor system to become positioned on the body. Older adults expressed concerns regarding wearables with detachable components, with 1 participant describing Velcro as "stiff" and "uncomfortable." The mattress cover and seating cushion were rated most comfortable (mean 4.5, SD 0.56). The vest was perceived as less comfortable (mean 3, SD 0.71). One participant felt he would be unwilling to wear a vest but would accept a watch:

> *I could see being prepared to wear a watch.*

It also seemed related to the fact that participants felt concerned about the comfort of such a vest:

> *It might go underneath of their own vest or if it can go on top of their vest, there are two sides there. Their own vest is comfortable, and they are used to it so the other one could be on top of it, if it still works.*

Environmental Consciousness

Concerns about the environmental impact of the technology were expressed by 3 of the older participants. Environmental consciousness affected peoples' charging and material preferences. Moreover, a stakeholder with experience in providing smart textile applications emphasized the importance of enabling the exchange of batteries at the end of their life span to avoid the wastefulness of the overall technology. It needs to be outweighed whether people want easier washing or longer durability of the components. Participants disagreed that it would be acceptable to dispose of a vest after 3 months of use (mean 2, SD 1.41). In addition, participants disagreed with disposing of the detachable sensors after 3 months of use (mean 2, SD 1.50), indicating environmental and economic consciousness.

Cooperation With Other People

The social worker reported cases where people liked manipulating activity monitoring and supporting systems:

> *It's actually critical, is accuracy. I think you mentioned earlier that, you know, if people are given a walking stick with G.P.S. monitoring, they can give the walking stick to somebody else and wander off.*

A family member reported that their relative misused a sensing doormat to call staff more frequently, so it had to be unplugged:

> *My mother is actually in a residential home. She started off with a mattress cover and a floor mat, but when she gets annoyed at the staff, she consciously hits it to make sure that the staff are required to come and see her. And they have given up with using them because she does it so often and they have to respond to her.*

Thus, the monitoring system's functioning will need people to cooperate, and developers need to expect that some people are willing to trick or use a system in unintended ways.

Aesthetics

In response to the presented digital and physical system concepts, focus group participants felt that aesthetics and a gentle appearance were missing. The system components were found to be too sterile and cold in appearance:

> *It does remind me of the original cars in America when everything was black, black, or black and this feels like it's surgical. It doesn't have a pretty pattern for example.*

The indication of loneliness in graphics or visual data also needs to convey information more sensitively. A red color or light on a display or device might indicate a lower level of physical and mental well-being or a need to charge the device. However, this needs to be designed in a more sensitive and friendly manner. According to an older participant, red colors should be avoided and instead, more friendly, soothing colors should be used:

> *That one goes red, they wouldn't like that. Now they know that I feel lonely, you know, because there is a stigma attached as well, so sweet colors, you know the meaning of them, but you don't want to scare them.*

Requirements for Wearables and Furniture

Compatibility With Existing Clothing and Furniture

A few stakeholders asked how a wearable would integrate with people's existing wardrobe and how it would match the broad range of clothing styles. They felt that everyone had their preferences and style in clothing. Two older women also expressed how certain wearables, such as socks, would not suit dresses or tighter shoes, and a wearable would need to be compatible with different outfits and match one's wardrobe:

> *If you are wearing skirt or dress you are not going to want to wear socks, aren't you?*

Many participants preferred the system's attachability to existing furniture (eg, cushions). Due to sentimental and financial reasons, older adults expressed that it was unlikely that people would be willing to exchange their existing furnishing:

> *I can't see people being able to afford to have new furniture.*

Seasonal, Intuitive, and Unisex

Participants from both interviews and workshops noted that a wearable must function in different seasons:

> *On a summer's day you wouldn't have it on the sleeve.*

Interview participants frequently mentioned underwear (ie, brassiere and pants) as an item of clothing that is close to the skin and intuitively worn daily:

> *I think the picture with this attached to your bra makes the most sense to me, because it is something*

> *you automatically put on and you wear under your clothing.*

Older adults in workshops expressed the importance of integrating a wearable sensor into clothing that would be habitually worn to avoid additional burdens. While most women in the first co-design session agreed to have sensors positioned on bras, they felt it would not be adequate for men:

> *It would be a problem for men, presumably men, I mean we are all female.*

Thus, unisex options for the wearables would need to be available, such as vests and socks.

Discretion

The device's conspicuous design or positioning could risk drawing unwanted attention. A few workshop participants expressed concern that a conspicuous design or positioning (eg, wrist-worn wearable) could also feel stigmatizing or become the subject of conversation:

> *I think people would ask you what it was. I think you would draw attention to it if it was on your wrist.*

The loneliness sensing system would need to be presented inconspicuously.

No Detachable Components on Wearables

Detachable sensor components were proposed to support the sensor's durability over washing cycles. The detachability of sensors could also enhance the recycling of the sensors on the garment and reduce waste. Multiple participants argued against attachments to apparel and clothing due to comfort, cleanability, and the risk of breaking the sensors. There was a risk that Velcro would feel “bulky,” and detachable components would still need to be cleaned, as they were close to the skin. Furthermore, people could easily forget to remove the detachable components and accidentally break the device:

> *People will forget to remove stuff...Things will break because of that.*

Material Requirements

Lightweight and Soft Materials

Older adults from workshops mentioned the need for lightweight materials to increase the discretion of the device (“You want to make it seamless”) and the need for greater comfort. Participants recommended soft materials or materials that are not rough. It is important to select a preferred and comfortable material, particularly for textiles worn close to the skin continuously.

Natural and Antiallergic Materials

Most participants preferred natural materials for comfort and mentioned the likelihood of allergic reactions to synthetic fabrics:

> *And cotton I suppose because some people are allergic to, if I wear something artificial over a certain percentage, I get rashes all over the place.*

Nonmagnetic Materials

A private carer mentioned the potential interference of sensors with pacemakers worn to regulate one's heart rhythm. Thus, all components embedded in clothing will need to be noninterfering.

Wrinkle-Free Materials

One older participant also wished for a material that does not wrinkle, to avoid ironing it. Otherwise, it would need to be a material that resists ironing:

> *Because some shirts nowadays, you know, you don't really need to iron them.*

Positioning Requirements

Privacy

Privacy was a key determinant in how participants positioned the sensing textiles on the body and in the home. Most participants mentioned they would not position any wearables closer to the lower torso region, excluding shorter pants or underwear in that area. Moreover, some individuals found the positioning of sensors in the bed or bedroom unfitting due to privacy issues. Conversely, 4 participants found positioning in the bed and bedroom reasonable and acceptable. Therefore, privacy needs vary from person to person.

Use in Daily Activities

The preferred positioning of smart textile wearables on the body and furniture also depends on people's daily activities. Some participants felt that a sensor positioning on longer sleeves, socks, or in the bathroom would pose a risk of getting the sensors wet. This would lead to a more frequent need to wash the wearable or home-based device. Interview participants also highlighted the importance of the wearable being discreet and unnoticeable, with specific reference to its use, and not being inconvenient or impacting daily activities. A wearable must be integrated to appear subtle, hidden, imperceptible, and inconspicuous.

Washing Requirements

Washability of All System Parts

Older adults in workshops discussed how any textile would need to be regularly washed as they would be in close contact with the skin. In terms of furniture, covers must be regularly washable, for instance, in cases of incontinence or spills, whereas clothing wearables, specifically underwear, would need to be washed daily. Workshop participants also discussed how any detachable components close to the skin would need to be clean and washable. Therefore, the detachable components would take more effort to clean than when directly printed on the wearable, but they could be treated more sensitively.

Machine Washing

The device or wearable should be machine washable as not everyone might like to do a separate washing, as mentioned by few individuals. More individuals preferred a wearable that allows a washing without having to remove any detachable components beforehand (eg, batteries and sensors). This also means that the sensors must resist stronger kinds of detergent and need printed batteries. Participants were neutral (mean 3, SD 1.07) regarding whether they found the system easy to wash. Some were happier to apply a special washing cycle:

> *I like doing hand washing. I hand wash a couple of times a week.*

Others were more critical and unwilling to introduce a separate gentle washing cycle:

> *I only use one cycle on my washing machine and it's going to destroy this. I use the hand washing cycle about once every five months.*

Life Span of 2 Years

A wearable would have an expected life span; however, it was difficult for participants to determine an exact period. The industry representative suggested 2 years after an estimation of yearly washing cycles. This was deemed an acceptable life span for consumers.

Requirements for the Sensor Synchronization Device

Memory Support and Prevention of Loss

The sensor synchronization device is a technical component that helps collect and transmit sensor data outside the home. This could be integrated into a phone or kept as a separate device that an older person can carry. The device should be easily remembered when going outside:

> *It is much less likely that they forget about it if it is attached to their key or to their trousers.*

The industry expert on smart wearable textile applications found a synchronizing device could be easily forgotten and this should be fixed so that people automatically carry outside with them. Alternatively, they could be reminded by a light or noise. One older participant felt a device of a smaller size could be more easily lost. In the evaluation, the mattress cover was rated highest for being easily remembered (mean 4, SD 0). The insoles and socks were considered less easy to remember for an older person (mean 3, SD 0.71). Participants were neutral (mean 2.8, SD 0.75) when asked whether the system is easy to use, also due to potentially forgetting to use it: people "might forget or not bother using it."

Charging Requirements

Little Cognitive Strain and Notifications

A couple of stakeholders also mentioned that older people might forget how to change batteries. Carers would potentially be supportive of charging and exchanging batteries for the devices. Notifications were a recommended feature by the industry expert. A display, light, or notification sound could help inform older adults and carers about the charging status. On average, participants in the focus groups disagreed on whether it would be acceptable to remove a battery before washing (mean 2, SD 1.06). Written comments included "too fiddly," "not practical at all," and "dexterity." This is particularly relevant for batteries attached to the vest or socks, due to more frequent washing. When questioned about their thoughts regarding an inductive charging station, participants wished for a dedicated area to place all device components to be loaded:

> *If there was a single place that you could throw the whole lot and they be charged in the morning.*

Fewer Plugs

The industry expert who had previous experience working with older people with disabilities mentioned that there can be few plugs in apartments. Therefore, the system should not require too many plugs:

> *We have a project with older people who also have learning disabilities. People don't necessarily have a lot of power, lot of plugs.*

Accessibility

Some charging processes can require the agility of the hands. While many found the idea of smaller batteries preferable, participants were concerned about the size and process of replacing batteries:

> *I would have a comment about removable batteries and everything because I know of at least two people who have problems with hearing aids putting batteries in, and it depends how like fiddly it is. For people who don't have the dexterity.*

Older people could have arthritis and might find certain charging processes difficult. Simple charging methods that require less precision, such as inductive charging, might be an appropriate solution.

Requirements for the Linked Intervention

Providing a Linked Intervention

Participants were neutral on whether they considered the system useful to help address loneliness (mean 2.7, SD 1.25). Many older participants found it difficult to comprehend the value of the monitoring system, as they did not see how it could immediately help them address their loneliness. A notification about their loneliness was not perceived as valuable. Few older participants determined that they were already aware of when they felt alone. One participant also did not have any children or family members to be contacted. Thus, determining how the interventions are valuable to different individuals is important to their perceived value. This finding was also reflected in the focus group evaluation, where it became apparent that people were pressing on what happened due to the detection of loneliness. One participant expressed as follows:

> *I am not sure what help I will be for this research. If I know I am isolated or lonely, why do I need that? I don't need that to tell me.*
>
> *It is useful to use the system as an older person that experiences loneliness. Yes, it depends on what you do about it... The system is useful to reduce loneliness for older people, not in itself. It depends on what is done because you are just monitoring.*

Personalization

Multiple stakeholders mentioned the importance of personalization concerning the linked intervention. A personalized intervention could better appeal to people who might feel discouraged from engaging in activities:

> *All of your interests. Something that really interests you and you will make the effort.*

Avoiding Burden on Family Members

The monitoring system could communicate data to family members. However, a few older participants expressed concern about how such a system could burden their family members:

> *I don't want it to be family because I think I mean I've got this memory of my grandmother guilt tripping people all the time. And I think this would be a very formal way of guilt tripping. And you know, they've got their own lives.*

Infrastructure

Some stakeholders were concerned about not only the functioning of the technology but also the infrastructure requirements:

> *You felt you were having a heart attack and you phoned nine, nine, nine, it still might take six hours. So, I suppose that's not that this doesn't change that, does it. That's an extra thing.*

In addition, from the perspective of a family member, it was also noted that older people might be in a carer position themselves, which restricts their time and resources to take action to address their loneliness. One participant recalled previous experiences with dedicated staff for loneliness and long waiting times for being contacted. Infrastructural requirements are particularly relevant for interventions that respond to detected loneliness.

Motivation

One difficulty addressed by a few stakeholders was how to help with "chronic" or almost paralyzing loneliness. In such cases, older people might struggle to find motivation or see purpose in acting to change their situation:

> *For people who are lonely or who are isolated, it's generalized again but they are not necessarily, they are in that situation because they potentially aren't the type of person...or there aren't the opportunities to go and do something. Actually, stepping through the door of some kind of group activity for some people they just wouldn't do it.*

Installation and Maintenance Requirements

Identification

One of the first questions to be addressed is identifying people most in need of receiving such a system:

> *You need to know whether they're likely to be lonely in the first place.*

The monitoring system could become privately acquired, but it could also become part of housing schemes. Stakeholders discussed that identification should occur through individuals in regular closer contact with the older person, ranging from medical staff to people in the community and delivery service staff, as they can sometimes identify changes over time or be the only existent touchpoint. The social worker drew attention to the potential stigmatization connected to revealing one's feelings of loneliness, and it might be preferable to make such a system the norm and offer it to everyone as part of the housing scheme.

Consent

Consent needs to be acquired before installation. Consent should confirm that people are willing to have such a system installed in their homes, and it should indicate who can access the data collected. Further considerations need to be made in case someone cannot make an informed decision for themselves:

> *The person whose data people are accessing, they need to give people permission, and they might not want to share certain things with the carer, they might not want to share with the family.*

Easy Installation, Instructions for Carers, and Continuous Support Provision

The system needs to be easily installable, as recommended by an expert in textile wearables. It should ideally function readily when it arrives ("plug and play"). Carers will likely be involved in helping to charge the system or washing the textile wearables and furniture covers. Therefore, clear instructions need to be provided at the older person's home. The instructions should be visibly placed as one needs to expect a regular change in carers, who will need to be directed. According to the industry expert, a technology provider would also need to have a customer service facility that can be called to provide help in case people have technical difficulties.

Discussion

Principal Findings

This research aimed to understand user and stakeholder requirements for a smart textile loneliness monitoring system. Overall, a key finding is the participants' concern regarding what applications and interventions become linked to the sensor monitoring system for loneliness. Previous work found that older adults' acceptance of smart textile technology and smart home devices depends strongly on perceived usefulness [56-58]. Whether the monitoring system was perceived as useful often depended on what actions would be taken in response to the monitoring. Previous rationales for developing loneliness monitoring provided in the literature were the importance of loneliness as a health concern [11,59]; the identification of loneliness, as directly communicating it might be associated with stigma [11,12,22]; potential bias in self-reporting and the nonobjective reporting of one's state, also due to cognitive decline, to help prevent loneliness early on [11]; and research purposes to better understand the relationship between loneliness and health outcomes [11,13]. While questioning older participants and stakeholders, we found that participants perceived particular applicability in dementia, particularly as family members who wished to be notified of the status of loneliness of their loved ones. This might require future research to better involve such susceptible populations in the development of loneliness monitoring systems for accuracy. In contrast, it raises issues of consent and the state at which it would be achievable. Other potential applications considered by participants were buddy systems, being part of a group to improve technology development for older people to provide agency, and an artificial intelligence–recommendation system.

A proposition has also been made to potentially detect changes in individuals earlier on, in terms of loneliness, than is currently possible [13]. These suggestions elicit questions about available infrastructure and about an efficient distribution of the system. In case a loneliness monitoring system is intended warn people of loneliness in its early states [13], it could require a wider distribution than what might be affordable. A suggestion was to involve people who are in regular contact with potentially affected people to support a more targeted distribution.

Our findings showed that some older adults felt that the monitoring process did not solve their loneliness directly. Some also thought that they would not need a system to tell them when they are lonely.

Other propositions are informing family members or caregivers [12], overcoming stigma to receive help where necessary, and assessing current risks for greater mental health consequences [12]. Some declined the idea of contacting their family members in response to detected loneliness due to fears of burdening them. Stakeholders also noted that time constraints by health care professionals or social work professionals would not change via the introduction of a monitoring system. In contrast, 2 family members wished they had such a system to inform them about the well-being of susceptible family members (eg, those with mild dementia) across distance.

Similar to previous literature, participants expressed a preference for natural, soft, and lightweight materials useful in daily activities [34,37]. They also expressed a need for comfort [34-36] and discretion [36]. We found that furniture-embedded smart textiles (on a mattress or sofa) were rated more positively regarding comfort and ease of remembrance than smart apparel (eg, a smart vest), which has been predicted in previous literature on loneliness monitoring systems [11,23]. This was not only due to the individual preferences in clothing (whether one was used to wearing a vest or a watch) but also due to the greater potential effort in washing and charging. Therefore, it should be possible to consider individual preferences in the choice of sensor devices for monitoring [58]. In addition to the cultural sensitivity for clothing and wearable styles [35,38], we observed the same considerations in the context of textiles on furniture. In our study, we observed that colors that could elicit negative emotions should also be avoided, particularly for mental health applications. This aligns with findings from previously developed websites, robots, and devices to address the loneliness of older people [60-63]. Many vests and smart textiles developed for older people do have a plain design [64]; however, there have been exceptions that experimented with more friendly motifs of cats and flowers on smart textiles for patients with dementia [65]. Participants required the current system to function along with their existing furniture and clothing as they were unlikely to be replaced. Embedded electronics and their positioning must be compatible with other wearable health care devices, such as pacemakers or stoma bags. Regarding considerations of reliability and accuracy [37,38], participants also noted the possibilities of manipulation by them and the potential impact through people's movement.

Washing and charging procedures are key concerns for the usability of the proposed technology. Current washing cycles [26,36] are not sufficient for user requirements, as participants did not agree with a life span of approximately 3 months. Most people did not accept special washing requirements, such as hand washing, or the use of a special washing cycle [39]. The proposed solution of detachable components [38,40,65], which could protect electronics from being washed as part of the overall textile, appeared more reasonable for furniture but less applicable for wearables that must be washed often. Participants emphasized the importance of washability of all parts (in particular, the materials close to the skin). Smart textile wearables and furniture covers are required to be washed frequently, due to the risk of spilling liquids at an older age or the possibility of incontinence. For maintenance, there will also need to be notifications and instructions for charging and washing and the requirement for fewer plugs, which is supported by previous findings from technologies addressing loneliness for older people. While current charging options are developed for smart textiles to become less obtrusive, they need to consider the potential limited dexterity of older people to handle them while washing or charging.

Strengths and Limitations

There has been little understanding of the needs of stakeholders and older people for the development of smart textile loneliness monitoring systems. Our insights were based on people envisioning the system by presenting a prototype and use case. Therefore, it was not possible to determine the proposed system's actual usability. In the future, we would like to undertake system testing in the field.

Conclusions

This study presented key design requirements for a loneliness monitoring system embedded in smart textiles in wearables and smart home furniture from the perspectives of older people and stakeholders, touching on questions of usefulness and usability. Sensors on smart home furniture seem to face fewer difficulties in terms of individual habits, washing, and charging than applications that are wearable. Overall, the linked intervention in response to monitored loneliness remains a question that needs more in-depth understanding, including what individuals perceive as most valuable in connection with such a sensing system. We found additional aspects in the system design that have not found much consideration in previous work, such as the need for user cooperation, compatibility with other worn medical devices, user expectations regarding life span and washing requirements, questions about identifying the recipients of the system, and initial insights into possible linked interventions and purposes of loneliness monitoring systems.

Acknowledgments

The authors are grateful to all participants who have shared their perspectives in the workshops and focus groups and have sometimes traveled far to contribute. This work was supported by the UK Engineering and Physical Sciences Research Council and the National Institute of Health and Care Research (grants EP/W031434/1 and EP/W031442/1).

Abstract

Background: Implementing technology-based counseling as a complex intervention in dementia care poses challenges such as adaptation to stakeholders’ needs and limited resources. While studies have examined the effectiveness of technology-based counseling, its successful implementation remains largely unexplored.

Objective: We aimed to review the knowledge about the implementation success of technology-based counseling interventions for people with dementia and their informal caregivers.

Methods: We conducted a scoping review and systematically searched CINAHL, the Cochrane Library including the Cochrane Central Register of Controlled Trials, MEDLINE, PsycINFO, and Web of Science Core Collection databases (April 2021) in combination with citation searching and web searching (November 2021). Studies reporting on technology-based counseling interventions for people with dementia or their informal caregivers were included, irrespective of the design. We used the conceptual framework for implementation outcomes to operationalize *implementation success* and applied the outcomes acceptability, adoption, appropriateness, feasibility, fidelity, implementation cost, penetration, and sustainability as categories to inform data extraction. We identified dimensions within the categories and synthesized results narratively and graphically.

Results: We included 52 publications reporting on 27 technology-based counseling interventions. The studies were conducted in 9 countries and published between 1993 and 2021. As the design of the included studies varied, the number of participants and the type of data reported varied as well. The intervention programs were heterogeneous and ranged from single counseling interventions (such as helpline services) to counseling as part of a multicomponent program. Telephone, email, videoconferencing, social media (respectively chats), and web-based platforms were used for delivering counseling. We found data on appropriateness for all interventions and data on acceptability for most interventions, describing aspects such as consumer-perceived usefulness and helpfulness of services, as well as satisfaction. Information on the other categories of adoption, feasibility, fidelity, implementation cost, penetration, and sustainability was fragmented.

Conclusions: The scope and depth of information on conceptual categories of the implementation success of technology-based counseling for people with dementia and informal caregivers varied. The data only partially covered the concept of *implementation success*, which highlights the need for a systematic evaluation accompanying the implementation. The application of theoretical approaches for implementation and adherence to the framework for developing and evaluating complex interventions are required to promote the implementation of complex interventions and to comprehensively assess implementation success.

Introduction

During the course of dementia, people with dementia, their families, and informal caregivers may need professional support to deal with the consequences of the disease [1-4]. Supportive interventions [5] are complex in their development, delivery, and impact, as they involve multiple components, aim at multiple outcomes, and are delivered in different settings. In addition, a broad range of skills are required of those who deliver the interventions [6] in dementia care.

Counseling for people with dementia and their informal caregivers is a supportive intervention that can be defined as conversational therapy in which a trained therapist listens to the person, enhances the individual's ability to cope with the effects of dementia, and provides information and education [7,8]. Counselors provide information about the disease and support service options, offer the opportunity to share and discuss feelings or problems, and can enhance problem-solving and coping skills [9,10]. In the context of dementia, counseling services provided by professionals and tailored to individuals aim at various outcomes, such as reducing depressive symptoms and perceived burden, improving quality of life and self-efficacy, and encouraging the uptake of support services in the community [11]. Counseling interventions are therefore complex interventions comprising several components, such as specific training for providers, tools and instruments to individualize services, or different ways to access the available services [9,11]. Information and communication technologies may improve accessibility to counseling [12,13], and this aspect gained importance during the COVID-19 pandemic when remote counseling offered the possibility of providing support without the risk of infection [10,14].

To successfully translate complex interventions into practice, various challenges need to be overcome. Implementation can be defined as an "actively planned and deliberately initiated effort with the intention to bring a given intervention into policy and practice within a particular setting" [15]. The challenges described in implementing eHealth interventions in dementia care include adapting the interventions to match the skills and abilities of the target population, achieving user friendliness in the context of rapidly evolving technology, and addressing users' concerns about security issues, especially when personal information is disclosed [16]. In implementing organizations, the lack of staff resources or the lack of interaction with staff as well as the reluctance of the provider to use the technology may impede implementation [16]. Furthermore, financial and time constraints can also act as barriers to implementation [16]. In the wider context, aspects such as stakeholders' limited capabilities to support innovation or preferences for classically delivered care were identified as significant barriers [16].

Another challenge in the implementation of complex interventions is to operationalize and measure the success or effectiveness of implementation efforts. In a Cochrane Review on remotely delivered information, training, and support (including counseling) for informal caregivers of people with dementia, the authors found information on various aspects indicating implementation success such as acceptability, user satisfaction, or fidelity of implementation. As the indicators and assessment areas varied substantially across studies, data synthesis could not be conducted [9]. There are theoretical approaches that facilitate a comprehensive evaluation of implementation efforts [15]. One of them is the conceptual framework for implementation outcomes introduced by Proctor et al [17], which provides implementation-specific outcomes for assessing implementation success.

While there are studies investigating the effectiveness of technology-based counseling [8,9,11], the extent to which these interventions are successfully implemented remains unexplored. To address this gap in knowledge, we aimed to review the evidence and pursue the question of what is known about the implementation success of technology-based counseling interventions for people with dementia or their informal caregivers.

Methods

Design

According to the methodological approach of scoping reviews [18], we aimed at mapping evidence of implementation success to provide a comprehensive overview. We followed the methodological guidance [18] of the Joanna Briggs Institute and structured our report according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [19].

Protocol and Registration

This scoping review is embedded in the project "Technology-based counselling in dementia (TeCoDem)," for which a protocol has been developed [7] and registered with the international prospective register of systematic reviews (PROSPERO CRD42021245473; see the section *Deviations From the Protocol*).

Eligibility Criteria

We included studies, irrespective of their design in English and German, that reported on technology-based counseling interventions for people with any type and severity of dementia or their informal caregivers. Interventions had to be tailored to individuals and provided remotely by professionals using various information technologies. Studies on people with mild cognitive impairment as well as studies on standardized interventions, such as cognitive behavioral therapy, on genetic counseling, and on counseling regarding diagnostics or screening for dementia were excluded. We also excluded studies describing interventions that focus mainly on care coordination or case management. Furthermore, publications reporting exclusively on the development of interventions were excluded [7].

Information Sources and Search Strategy

We searched CINAHL, the Cochrane Library including the Cochrane Central Register of Controlled Trials (CENTRAL), MEDLINE via PubMed, PsycINFO via Ovid, and the Web of Science Core Collection databases (last search: April 22, 2021) without any filters and limiters. We systematically developed a search strategy that contained 3 components: *dementia*, *technology*, and *counseling*. Corresponding search terms and synonyms (eg, dementia/Alzheimer, technology/electronic, counselling/counseling/consultation) were identified through an orienting search using MEDLINE via PubMed, and we checked entry terms given in the Medical Subject Headings browser. The strategy was peer-reviewed by applying the Peer Review of Electronic Search Strategies [20]. In addition, we performed forward and backward citation searches of included studies and pertinent reviews via Scopus (last search: October 7, 2021) and a web search via Google and Google Scholar (last search: November 26, 2021) [21,22]. Full database-specific search strategies are provided elsewhere [7].

Selection of Sources of Evidence

Titles, abstracts, and full texts were independently screened by 2 reviewers (out of AB, JH, and DB) using the Rayyan web application (Rayyan) [23]. Any discrepancies in the decisions were resolved by discussions within the review team.

Data Charting Process and Data Items

A targeted and uniform extraction sheet was developed and consented to by the research team. We extracted study and design characteristics (year of publication, country where the study was conducted, objectives, number of participants or contacts) and assessed the technology-based counseling interventions by applying criteria from the Template for Intervention Description and Replication checklist [24] and from the revised Criteria for Reporting the Development and Evaluation of Complex Interventions guideline [25] to obtain a comprehensive overview of the interventions and their components. Data extraction on implementation success was guided by the conceptual framework for implementation outcomes, which comprises the implementation outcomes acceptability, adoption, appropriateness, feasibility, fidelity, implementation cost, penetration, and sustainability [17]. We adapted the definitions of the outcomes by specifying the intervention of interest and adjusting it to the research interest of our scoping review. Adaptations were consented to by the review team. The original and adapted definitions are listed in Table 1.

Table 1. Original and adapted definitions of implementation outcomes.

Outcome	Original definition according to Proctor et al [17]	Adapted definition for our review
Acceptability	"*Acceptability* is the perception among implementation stakeholders that a given treatment, service, practice, or innovation is agreeable, palatable, or satisfactory."	*Acceptability* is the perception among implementation stakeholders of technology-based counseling that the intervention is agreeable, palatable, or satisfactory.
Adoption	"*Adoption* is defined as the intention, initial decision, or action to try or employ an innovation or evidence-based practice."	*Adoption* is defined as the intention, initial decision, or action to try or employ a technology-based counseling intervention.
Appropriateness	"*Appropriateness* is the perceived fit, relevance, or compatibility of the innovation or evidence based practice for a given practice setting, provider, or consumer; and/or perceived fit of the innovation to address a particular issue or problem."	*Appropriateness* is the perceived fit, relevance, or compatibility of the technology-based counseling intervention for the given practice setting, provider, and consumer; and/or perceived fit of the intervention to address a particular issue or problem.
Feasibility	"*Feasibility* is defined as the extent to which a new treatment, or an innovation, can be successfully used or carried out within a given agency or setting (Karsh 2004)."	*Feasibility* is defined as the extent to which the technology-based counselling intervention can be successfully used or carried out within a given agency or setting.
Fidelity	"*Fidelity* is defined as the degree to which an intervention was implemented as it was prescribed in the original protocol or as it was intended by the program developers (Dusenbury et al. 2003; Rabin et al. 2008)."	*Fidelity* is the degree to which a technology-based counseling intervention was implemented as it was prescribed in the original protocol or as it was intended by the program developers.
Implementation cost	"*Cost (incremental or implementation cost)* is defined as the cost impact of an implementation effort."	*Implementation cost* is the cost impact of an implementation effort.
Penetration	"*Penetration* is defined as the integration of a practice within a service setting and its subsystems."	*Penetration* is defined as the integration of a technology-based counseling intervention within a service setting.
Sustainability	"*Sustainability* is defined as the extent to which a newly implemented treatment is maintained or institutionalized within a service setting's ongoing, stable operations."	*Sustainability* is defined as the extent to which an implemented technology-based counseling intervention is maintained or institutionalized within an organization's ongoing, stable operations.

Quotations from the included studies were extracted and assigned to the outcomes by 1 reviewer (out of DB or JW) and cross-checked for accuracy by another reviewer (out of DB or JW). Any discrepancies were resolved by consensus between these 2 reviewers.

Synthesis of Results

Data on the implementation success of technology-based counseling interventions were summarized by applying the framework mentioned in the preceding section [17]. The following 8 conceptually distinct implementation outcomes were used as conceptual categories to operationalize *implementation success*: acceptability, adoption, appropriateness, feasibility, fidelity, implementation cost, penetration, and sustainability.

Our approach to data synthesis involved the following steps:

1. Concept specification: identification of dimensions in the definition of each conceptual category: as these conceptual categories incorporate various aspects [17] and therefore represent multidimensional concepts, a concept specification was performed by determining the dimensions of the categories [26,27]. Dimensions are defined as characteristics according to which empirical facts can be distinguished [28]. The 2 reviewers (DB and JW) independently identified dimensions matching the attributes of the conceptual categories [27] described by Proctor et al [17] with the characteristics of the extracted data. Consensus on the dimensions was reached through discussion between the 2 reviewers.
2. Reduction of data and assignment to dimensions in analysis matrices: the extracted data were reduced without paraphrasing and assigned to the dimensions using tables as analysis matrices.
3. Specification of the level of analysis: we specified the level at which data were provided (level of analysis: consumer, provider or providing institution, organization, setting, and administration), as indicated by Proctor et al [17].
4. Narratively synthesizing of findings and graphical presentation: findings were narratively synthesized and presented in the form of a net diagram.

Each synthesis step was cross-checked (DB and JW) and consent was obtained from the review team.

Study characteristics and characteristics of the included interventions are presented in narrative and tabular forms.

Deviations From the Protocol

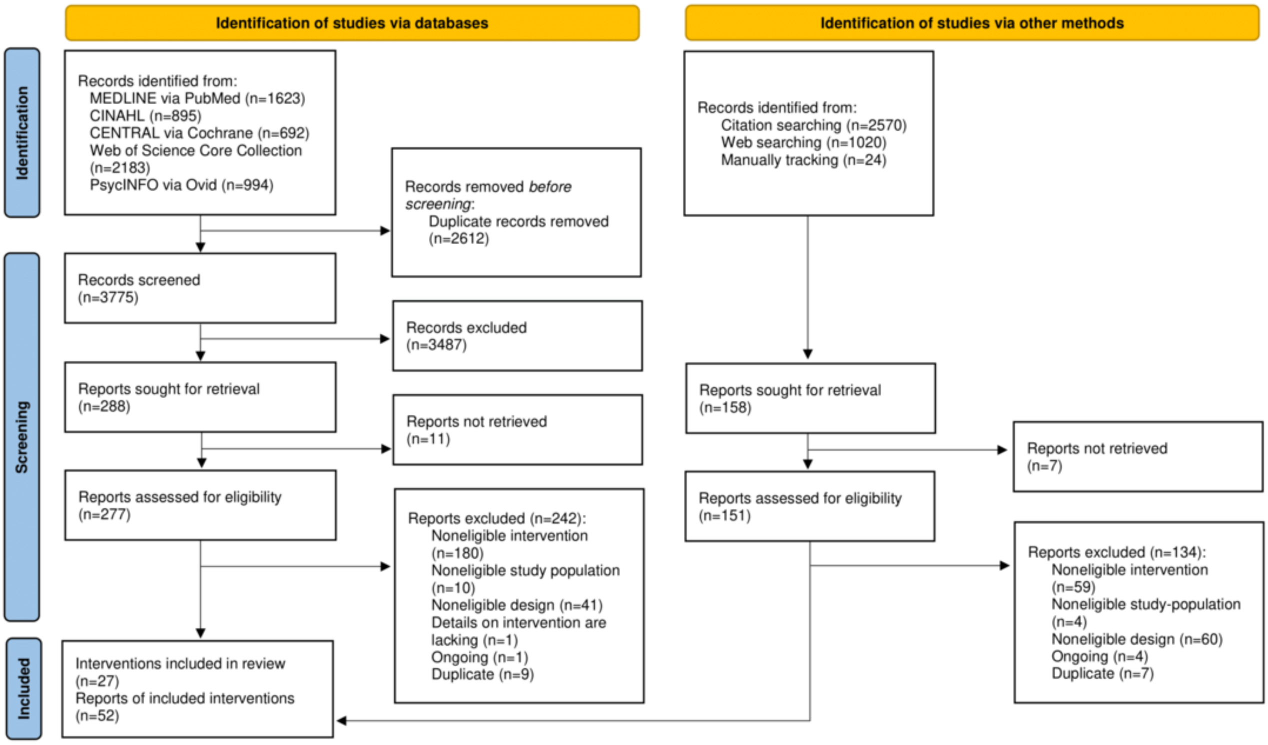
The prespecified method of conducting a Qualitative Comparative Analysis on the conditions of successful implementation of technology-based counseling interventions [7] could not be realized because of the heterogeneity of the data found in the literature. In addition, reports that were not written in English or German were excluded because of a lack of professional translation resources.

Results

Selection of Sources of Evidence

The electronic database yielded 6387 records. After removing duplicates, we screened the titles and the abstracts of 3775 records, reviewed 277 full texts for eligibility, and included 35 records. We identified 3614 records from additional sources and assessed 151 full texts, of which 17 were included. Finally, 52 publications [29-80] reporting on 27 technology-based counseling interventions were included (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of study selection.



Characteristics of Sources of Evidence

Interventions ranged from single counseling interventions, such as helpline services, to multicomponent programs combining nontechnology-based components, such as day care for people with dementia, with technology-based counseling for informal caregivers. All 27 interventions [29-80] focused on informal caregivers, mostly in combination with people with dementia, and 4 also addressed professional caregivers [29-32,34,35,37,40]. Counseling was provided by professionals from different disciplines, such as psychologists, geriatricians, or nurses. If volunteers were involved, they were professionally supervised or had received training. The technologies used for delivery included telephone, email, videoconferencing, social media, and chats, as well as web-based platforms. Additional (personalized) information material was frequently offered and delivered via email or postal mail. We differentiated the following types of interventions (refer to Table S1 in Multimedia Appendix 1): counseling via telephone or email and counseling via videoconferencing; web-based psychosocial intervention: information, communication, and counseling; videoconference- or telephone-based counseling combined with tele-monitoring or psychoeducation; and technology-based counseling as part of a comprehensive program with nontechnology-based components.

The design of the included studies varied (refer to Table S2 in Multimedia Appendix 1). Studies applying a quantitative descriptive design mostly focused on users' demographics, topics discussed and advice provided in counseling sessions, and satisfaction with services. Few of the included studies exclusively focused on implementation, and we found process evaluation reports [79,80] related to 2 interventions. Furthermore, the publication type of the included reports varied greatly, as we aimed to depict the broad spectrum of interventions. In addition to research reports, we identified abstracts, letters to the editor, and practical project reports.

The interventions are displayed in Table S2 in Multimedia Appendix 1 and characteristics of the included studies are described in Table S3 in Multimedia Appendix 1.

Results of Individual Sources of Evidence

Table 2 provides an overview of the data extracted from the included studies.

The label ("✓") indicates the presence of data without any information on content or scope. None of the interventions included reported data in all categories. The information available ranged from 1 to 7 conceptual categories for each intervention (also refer to the analysis matrices in Multimedia Appendix 1).

Table 2. Overview of reported data on conceptual categories.

Synthesis of Results

Acceptability

We defined *acceptability* as the perception among implementation stakeholders of technology-based counseling that the intervention is agreeable, palatable, or satisfactory [17]. Within the data related to the conceptual category (reported for 20 interventions [29-36,38,40,43-69,74-80]; refer to Table 2), we identified the dimensions *measures to promote acceptability* and *impact*, which can be further differentiated into *impact of parts of the service* and *impact of the overall service*. Measures to promote acceptability were reported, specifically from the perspective of the organizations. These were mainly aimed at promoting acceptability among providers, for example, through supervision, debriefings, or training. The impact on parts of the respective intervention or service was described from the perspective of both the provider and the consumer. The provider reported satisfaction with their role, whereas the consumer described individual parts of the service, including the helpfulness of the conversations, the competence of counselors, accessibility, materials, etc. The impact on the overall service was reported from the provider's perspective, namely, satisfaction with the experience of the team members. Other interventions reported on the impact of the overall service from the consumer's perspective, illustrated by relief, satisfaction with the intervention, or comfort with the service.

Adoption

Adoption is defined as the intention, decision, or action to use an intervention [17] (reported for 12 interventions [29-32,36,37,40,42,47-54,65,67-69,74-80]; refer to Table 2). Dimensions of adoption were *organizational motive*, *mode of decision*, and *uptake of interventions motivated internally or externally*. The motives of organizations included their commitment to helping families affected by dementia, connecting individuals to helpful information, providing access to support services, and providing support. Some authors described organizational motives in more general terms by referring to aspects that need to be addressed, for example, increased service demands or restrictions in the living conditions of people with dementia in the community. The mode of decision was characterized in different ways: as a response to developments in the setting, such as mobility restrictions or the increasing use of the internet in the target groups; as consent to participate at the organizational level; or as permission sought and obtained to implement the program. External reasons for the uptake of the specific intervention were evidence of the effectiveness of the intervention found in the literature or evidence indicating that the previously used mode of delivery needed to be adapted. Internally motivated uptake is based on the development, modification, or advancement of one's own interventions.

Appropriateness

Appropriateness is understood as the perceived fit [17] of technology-based counseling for stakeholders, the setting, and the problems addressed. We defined the dimensions *overall compatibility with stakeholder needs*, *tailoring to individuals*, *skills and instruments for enhancing fit*, and *concepts for fit* for this conceptual category and found extensive information for all interventions [29-80]. If assignment of the quotes to experimental and comparator interventions was not possible, we assumed that the information was applicable for both interventions (refer to Table 2).

The dimension *overall compatibility with stakeholder needs* comprises information on accessibility, availability, tailoring to consumer groups, and usefulness of service. In the area of accessibility, the ways to access were described, ranging from the use of a single technology to multiple ways via email, telephone, and videoconferencing, or in combination with home visits. The availability of counseling in terms of service hours, for instance, permanently or during regular working hours on weekdays, was discussed against the background of availability when needed or in times of crisis. From the perspective of organizations, providers, and consumers, technology-based counseling was viewed as a mode of delivery that can solve logistical issues such as making appointments or long-distance travel. People who are homebound can access support without leaving their homes, and caregivers do not have to arrange substitute care. The limitations of remote delivery, such as the loss of context or consumers' different capacities for using technology, were discussed from the perspective of the provider and the consumer. In addition, the advantages and disadvantages of anonymous services and services in which providers know the caregiver or the person with dementia are debated. Tailoring to consumer groups included services focusing on early-onset dementia or rare diseases, considering cultural and ethnic backgrounds, and providing multilingual services. To ensure the usefulness of the services, the appropriate amount and delivery of information were discussed. Tailoring to individuals included statements from the perspective of the provider that services were individualized, personalized, adapted, or flexible and aimed at responding to or addressing individual clients' needs by offering the most appropriate intervention or the best approach to resolve problems. Providers' skills for enhancing fit were described as specialist communication or counseling skills based on the training, knowledge, or experience of the person providing the service. Instruments used in organizations for enhancing fit comprise assessment instruments, information material, or written summaries of counseling sessions, such as letters, scripts, or proposals for individual use. Concepts for fit were reported from the providers' perspective and described in terms of person-centered and holistic approaches by applying techniques such as validation or empathetic understanding and psychological strategies to enhance coping and problem-solving processes.

Feasibility

We defined *feasibility* as the extent to which technology-based counseling can be successfully used [17] and identified the dimensions *practicability*, *factors impeding feasibility*, and *factors promoting feasibility* (reported for 13 interventions [29-32,36,39,40,43,47-64,68-79]; refer to Table 2). The practicability of the interventions was stated from the perspective of the provider, the organization, or the setting. The quotes refer to the general practicability of the intervention, stating its successful application or conceptual clarity. Practicability was also discussed with reference to the use of technology. Factors impeding feasibility comprised general aspects such as lack of financial and staff resources, technology-related aspects such as legal standards and technical challenges, and the lack of visual and nonverbal cues when counseling was delivered via telephone. Special training of providers to overcome technical problems or to compensate for technology-related issues was reported as a factor promoting feasibility.

Fidelity

Fidelity is the degree to which an intervention was implemented as prescribed or intended [17] (reported for 9 interventions [29-32,37,38,40,47-54,62-64,68,69]; refer to Table 2). We determined *formalization of intervention* and *quality assurance in delivering the intervention* as dimensions of fidelity. *Formalization of intervention* was addressed by mentioning standardized manuals, guidelines, frameworks, protocols, or assessments. Proceedings for *quality assurance in delivering the intervention* comprised senior staff supervision to ensure adherence to the protocol and monitor fidelity, the analysis of audiotaped counseling sessions, and the use of adherence and competence scales.

Implementation Cost

On the basis of Proctor et al [17], we defined the conceptual category *implementation cost* as the cost impact of an implementation effort reported from the perspective of a provider or the providing institution (reported for 3 interventions [36,62-64,74-79]; refer to Table 2). We identified the dimensions *cost impact of delivery because of complexity of intervention*, *cost impact of implementation because of complexity of implementation strategy*, and *cost impact because of varying complexity of settings*. Data on the first dimension comprised the costs of delivering the complex intervention and its financing through previously paid travel costs. The costs of the implementation strategy were illustrated by the impact of existing and lacking financial resources for staffing on the implementation process. Within the third dimension, failed expansion or implementation because of a lack of resources was exemplified.

Penetration

Within the conceptual category of *penetration*, defined as a step of integrating the technology-based counseling intervention into the service setting ([17] reported for 11 interventions [29-37,40,62-65,67,74-80]; refer to Table 2), we identified 3 dimensions: *collaboration with stakeholders*, *access to the service*, and *spread*. Data from interventions describe cooperation with stakeholders to implement the intervention, initiated either by the implementing organization itself or jointly through cooperation with other stakeholders in the setting. Access to the service occurred through referrals from other stakeholders in the setting, for example, physicians, or through information from other sources, such as telephone books or newspapers. From the perspective of the implementing organization, the degree of utilization of the intervention by different professional groups (eg, physicians, social workers, and nurses) was described. The level of spread was reported from the perspective of the implementing organization as well as the setting and is often reflected as the regional spread of interventions, for example, at the national or international level.

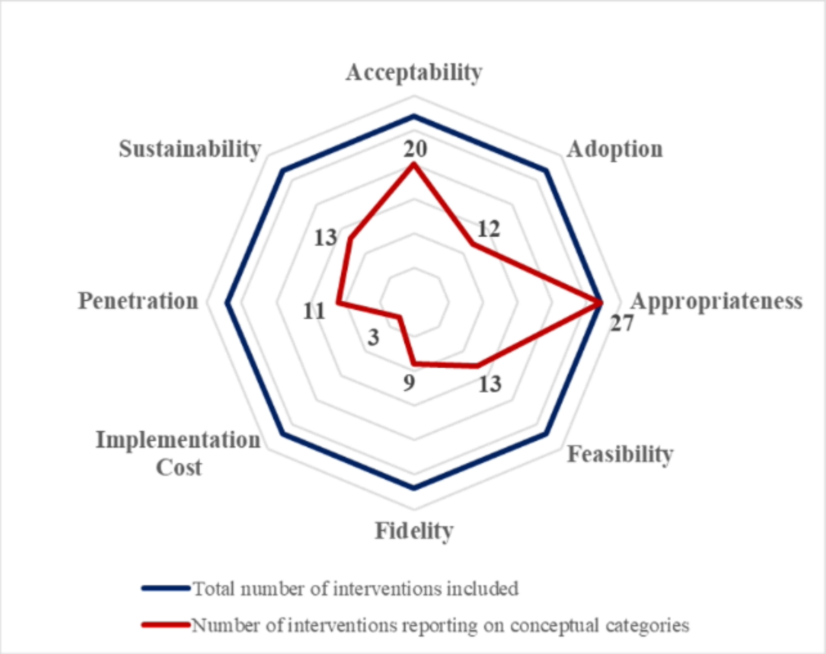
Sustainability

Following Proctor et al [17] and consequently Steckler et al [81], we understand *sustainability* (reported for 13 interventions [29-38,40,42,47-53,62-67]; refer to Table 2) as the final phase of the diffusion process in which innovations become entrenched in organizations. We were able to identify specifications of the data in 3 dimensions: *routinization*, *passage*, and *incorporation*. These dimensions were mainly reported from the perspective of the implementing organization; once, the perspective of the administration was also taken. The data on the dimension *routinization* provided information on the permanence and the degree to which the intervention was established, especially related to the number of versions of the intervention developed, the stakeholders involved, or the period from the start of the program. The duration varied greatly, ranging from a recent introduction to a multiyear build-up with many contacts. Statements were found in the interventions indicating maintained procedures, with the (planned) transition to expand the intervention often explained from the perspective of the organization with the aim of maintaining the intervention. An administrative perspective was also taken, referring to the discontinuation of support after the end of the research project and, thus, the termination of the program. For example, this dimension was clarified by the integration of another target group or expansion to another region. Incorporation, for example, the final integration into (existing) organizational structures with the aim of maintaining the intervention, was mentioned, describing the dissemination of the service within existing structures.

Graphical Presentation of Synthesized Data

Figure 2 shows the graphical synthesis of the data. Data on the conceptual categories of *implementation success* were sought for 27 interventions (blue line). The number of interventions for which data were extracted is indicated by the red line. While the categories *appropriateness* and *acceptability* are largely covered, substantial parts of the other areas remain unconsidered (refer to Figure 2).

Figure 2. Net diagram on reported data of conceptual categories.



Discussion

Principal Findings

We aimed to review the knowledge about the implementation success of technology-based counseling interventions for people with dementia or their caregivers. In our scoping review, we included 52 publications that reported 27 interventions. Interventions were heterogeneous and ranged from single counseling interventions, such as helplines, to counseling as part of multicomponent programs. To operationalize *implementation success*, we used the 8 outcomes of the conceptual framework for implementation outcomes [17] as conceptual categories. Only a few studies evaluated the implementation. Reporting on implementation outcomes was found to be fragmentary, and the comprehensiveness of the information varied widely. Overall, the focus of reporting was on the outcomes of *appropriateness* and *acceptability*, which may be because great efforts were made to adapt the interventions to a vulnerable target population.

As our data show, reporting on *acceptability* is inconsistent in terms of the perspective taken: data reports on measures to promote acceptability, but only from the perspective of the provider. At the same time, reporting on impact from this perspective was underrepresented. As already discussed in the literature, there are difficulties in unifying the wealth of perspectives in the context of implementation research [16].

The information reported on the dimension of *adoption* illustrates the importance of the fit between organizational motives and the type of intervention chosen for successful implementation. Little data are available on the mode of decision but differences in organizational culture can be identified that may influence the success of implementation efforts. We found data indicating that decisions from administrative stakeholders had an impact on sustainability by limiting the duration of the implementation of an intervention. Increasing the administrators' enthusiasm for implementing the intervention by promoting familiarity with the specific intervention and using the effect of name-brand recognition may facilitate long-term commitment [82]. In some cases, the uptake of a specific intervention was based on evidence of its effectiveness, and there is a need for further effectiveness trials to expand the evidence base for decision-making regarding the implementation of technology-based counseling interventions.

The data provided on *appropriateness* comprised the largest amount of information extracted for categories and document the efforts undertaken to fit the target population. In addition to general measures to enhance the perceived fit of individualized support services, providers' skills and instruments, as well as concepts applied by individual providers, were described. Tailoring and personalizing counseling services to individuals' needs has been associated with the usefulness of information and support [55-65]. The benefits and limitations of using technology for delivering counseling are discussed against the background of statements by consumers who would have preferred a different mode of communication with counselors [36]. On the basis of participants' attrition, González-Fraile et al [9] reported that remote support or training interventions appear to be less acceptable to informal caregivers of people with dementia than control interventions, which may limit their applicability in community settings. Further research is needed to determine whether services that are accessible both face to face and technology-based can provide appropriate accessibility and improve the perceived fit of the target populations.

Information on *feasibility* comprised the successful implementation of interventions. Although factors impeding feasibility, such as legal issues and technical challenges, were reported, we found no information on failed or unsuccessful implementation. Barriers to the implementation of eHealth interventions described in the literature are, among others, the lack of digital literacy in the target population and staff's uncertainties and insecurities about their coaching competences [83]. According to Proctor et al [17], the concept of *feasibility* is typically "invoked retrospectively as a potential explanation of an initiative's success or failure." Thus, a more comprehensive reporting of factors promoting or impeding feasibility may inform the implementation of interventions in future projects and may contribute to increasing the implementation success of technology-based counseling interventions.

Ways of formalizing the interventions to ensure fidelity in the delivery of interventions were mentioned, but manuals or guidelines were not made accessible along with publications. In addition, measurements to ensure fidelity were described for some interventions, but the results of assessments, as well as details on aspects where deviations occurred, were not reported. After critically reviewing the literature on the use of fidelity implementation frameworks in early intervention, Lemire et al [84] also stated gaps in defining and assessing implementation fidelity. Drawing on preexisting conceptualizations, the authors proposed a definition of fidelity that comprises the 4 components: adherence, exposure, quality, and participant responsiveness [84].

The cost impact of implementation efforts was rarely reported for the included interventions. Factors that influence the costs are the complexity of the specific intervention, the strategy used for implementation, and the delivery setting [17]. Despite the costs incurred in setting up the technical infrastructure, the costs for remote delivery were lower than when counseling was provided face to face [36,68,69]. Owing to the lower costs, eHealth interventions are considered suitable for widespread implementation [16]. The provision of information on implementation costs is essential to compare the cost impact of different interventions and to inform decisions regarding the uptake of a specific intervention [17].

The data reported on *penetration* often indicates access to the service in multiple ways, which seems to match the preferences and capabilities of consumers. As reported by Jelly et al [85], caregivers use dementia support services primarily when services are able to meet consumers' individual needs. However, it is important to keep in mind that, from an organizational point of view, these extended access options need to be served simultaneously. In particular, cooperation with other stakeholders seems to be central to integrating counseling services into a service setting, but this was only highlighted by some authors in the included publications.

The sustainable anchoring of diffusion processes is described as a difficult phase in the implementation process of support services for caregivers of people with dementia. The reasons for this include a lack of understanding of the barriers to sustainable implementation in practice and a lack of long-term funding [86]. The problem is substantiated in that, as long as researchers focus on measuring the effectiveness of the interventions, the potential goal is not fully realized. However, there are models that can support this sustainable implementation [87].

There are several theoretical approaches, such as generalized theories, models, or frameworks, that address different aspects of implementation [88]. Frameworks "describe more loosely structured constellations of theoretical constructs... or prescriptive approaches for accomplishing implementation goals" [88]. By providing clarity in terms and definitions [88], frameworks contribute to shared language in implementation research. There are different types of frameworks focusing on processes or determinants or evaluations [88]. Evaluation frameworks, such as the conceptual framework for implementation outcomes introduced by Proctor et al [17] and the Reach, Efficacy, Adoption, Implementation, Maintenance (RE-AIM) planning and evaluation framework [89,90], offer guidance on identifying results that can be used to evaluate implementation efforts [88]. While the RE-AIM framework describes outcomes across 5 domains (reach, effectiveness, adoption, implementation, and maintenance) [90], Proctor et al [17] present the concept of 8 implementation outcomes, which are differentiated from service system and treatment outcomes. Implementation outcomes are defined as "the effects of deliberate and purposive actions to implement new treatments, practices, and services" and are reported from different levels of analysis (eg, the provider or the consumer perspective) [17]. Serving as conceptual categories of the implementation success [17], these outcomes provided the appropriate approach to operationalize the object of interest—the implementation success of technology-based counseling interventions in dementia—in our review.

To increase the clarity of terminology used in implementation research, Proctor et al [17] proposed the definitions of 8 conceptually distinct implementation outcomes as a "working taxonomy," including different aspects of implementation success and thus creating a comprehensible framework.

The use of outcomes as conceptual categories was sometimes challenging in our case. The mapping of the extracted data, in particular, was sometimes difficult because of the conceptual similarity of some outcomes, for example, penetration and sustainability, and the inconsistent use of terminology found in the literature. When determining the levels of analysis, we sometimes included additional perspectives, as described by Proctor et al [17].

Altogether, the lack of process evaluation studies, the fragmented reporting, and the unclear use of terms and concepts made it impossible to determine the extent of implementation success of technology-based counseling interventions in dementia care. Because of the impaired comparability of data, we were not able to assess how the different types of interventions affect the conceptual categories of acceptability, adoption, appropriateness, feasibility, fidelity, implementation cost, penetration, and sustainability. For instance, we found data on *appropriateness* for all interventions, but the consumer-perceived usefulness of services was referred to for only 5 interventions. These 5 interventions comprised helplines that provided counseling via telephone [29-32,55] and web-based psychosocial interventions that provided information, communication, and counseling [56-65]. The reported information does not allow any conclusions to be drawn on how the types or components of interventions have an impact on implementation success. Gaining further insight into this issue is important for developing future interventions that can be implemented successfully.

Adherence to the framework for developing and evaluating complex interventions [6] may help overcome these problems, as proper process evaluation and exploration of conditions for implementation are recommended. The update to the Medical Research Council guidance states that "[e]arly consideration of implementation increased the potential of developing an intervention that can be widely adopted and maintained in real-world settings" [6] and thus can increase the success of implementation efforts. In addition, the conceptual clarity of the terms and concepts used in implementation research is needed to enhance transparency. This can be achieved by applying theoretical approaches that are "encapsulated as generalized theories, models, or frameworks" [88]. The consistent use of terms not only creates clarity but also forms the basis for better reporting on the success of implementation efforts, as Lengnick-Hall et al [91] proposed as the first of 6 practical recommendations for improved implementation outcomes reporting.

Strengths and Limitations

We followed a theory-driven approach to review the available evidence on implementation success. As we examined a broad topic with evidence emerging from studies in various designs, a scoping review proved appropriate. We performed a comprehensive and methodologically rigorous systematic literature search and included a variety of technology-based counseling interventions for people with dementia and their informal caregivers. Differentiating counseling from interventions focusing on education and information or from psychotherapeutic approaches brought challenges that we overcame through intensive discussions in the review team. Although we were able to include a considerable number of publications, it was not possible to make reliable statements about the implementation success of technology-based counseling interventions in dementia because of the inconsistent database as well as the heterogeneity in terminology and concepts.

Conclusions

We applied 8 conceptually distinct categories to operationalize the implementation success of technology-based counseling interventions for people with dementia and their informal caregivers. We found considerable data for the categories *appropriateness* and *acceptability*, and limited data on *sustainability*, *feasibility*, *adoption*, *penetration*, *fidelity*, and *implementation cost*. There is an imbalance in the scope and depth of the reported data on the conceptual categories, and the data extracted from the included publications only partially covered the concept of *implementation success*.

This highlights the need for a systematic evaluation accompanying the implementation of technology-based counseling interventions in the context of dementia. Adherence to guidelines for the development and evaluation of interventions and to guidelines or recommendations for reporting conceptualizations, measurements, and results on implementation outcomes is needed to expand knowledge on the effectiveness of implementation efforts and may foster the implementation of complex interventions in diverse contexts.

Acknowledgments

This study was funded by the German Federal Ministry of Education and Research (grant number 01KG2110). The funder had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; or decision to submit the manuscript for publication. We acknowledge the financial support of the Open Access Publication Fund of the Martin Luther University Halle-Wittenberg.

The authors thank Fabian Wilde, MSc, Leipzig (Germany), for supporting them in the selection process of the studies.

Authors' Contributions

DB, JW, JH, GM, and AB conceived the idea of the manuscript and made substantial contributions to this scoping review. JH and AB conducted the literature search. DB, JW, JH, and AB conducted study selection and data extraction. DB, JW, JH, and AB conceptualized and operationalized the object of interest. DB and JW conducted the data analysis and synthesis. DB and JW were involved in the drafting of the manuscript. DB, JW, JH, GM, and AB revised the manuscript for important intellectual content. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Technology-related research on people with dementia and their carers often aims to enable people to remain living at home for longer and prevent unnecessary hospital admissions. To develop person-centered, effective, and ethical research, patient and public involvement (PPI) is necessary, although it may be perceived as more difficult with this cohort. With recent and rapid expansions in health and care–related technology, this review explored how and with what impact collaborations between researchers and stakeholders such as people with dementia and their carers have taken place.

Objective: This review aims to describe approaches to PPI used to date in technology-related dementia research, along with the barriers and facilitators and impact of PPI in this area.

Methods: A scoping review of literature related to dementia, technology, and PPI was conducted using MEDLINE, PsycINFO, Embase, and CINAHL. Papers were screened for inclusion by 2 authors. Data were then extracted using a predesigned data extraction table by the same 2 authors. A third author supported the resolution of any conflicts at each stage. Barriers to and facilitators of undertaking PPI were then examined and themed.

Results: The search yielded 1694 papers, with 31 (1.83%) being analyzed after screening. Most (21/31, 68%) did not make clear distinctions between activities undertaken as PPI and those undertaken by research participants, and as such, their involvement did not fit easily into the National Institute for Health and Care Research definition of PPI. Most of this mixed involvement focused on reviewing or evaluating technology prototypes. A range of approaches were described, most typically using focus groups or co-design workshops. In total, 29% (9/31) described involvement at multiple stages throughout the research cycle, sometimes with evidence of sharing decision-making power. Some (23/31, 74%) commented on barriers to or facilitators of effective PPI. The challenges identified often regarded issues of working with people with significant cognitive impairments and pressures on time and resources. Where reported, the impact of PPI was largely reported as positive, including the experiences for patient and public partners, the impact on research quality, and the learning experience it provided for researchers. Only 4 (13%) papers used formal methods for evaluating impact.

Conclusions: Researchers often involve people with dementia and other stakeholders in technology research. At present, involvement is often limited in scope despite aspirations for high levels of involvement and partnership working. Involving people with dementia, their carers, and other stakeholders can have a positive impact on research, patient and public partners, and researchers. Wider reporting of methods and facilitative strategies along with more formalized methods for recording and reporting on meaningful impact would be helpful so that all those involved—researchers, patients, and other stakeholders—can learn how we can best conduct research together.

KEYWORDS

dementia; technology; patient and public involvement and engagement; co-design; coproduction

Introduction

Background

Worldwide incidence of dementia is increasing. In the United Kingdom alone, there are approximately 1 million people living with dementia, with this figure expected to double by 2050 [1]. The total cost of care for people with dementia in the United Kingdom in 2019 was £34.7 billion (US $44.1 billion), with an expected increase to approximately £94 billion (US $119.5 billion) by 2040 [2]. Technology is increasingly cited as a means of supporting people with dementia and their formal and informal carers and reducing some of this economic burden. "Digitally enabled care" is a core component of the National Health Service Long Term Plan [3]—it is felt that technology has the potential to facilitate aging in place and reduce unplanned hospital admissions, with consequent economic benefits as well as improved health outcomes and quality of life [4,5]. Smart home systems, assistive technology devices, and other technologies are being developed with aims including supporting safety in people's homes; enabling early detection of deterioration or ill health; supporting activities of daily living; and facilitating access to treatment, leisure activities, or social participation [5-8].

Despite rapid advancements in technology, the implementation of health and care–related technology for people with dementia has been slow, and there is increasing recognition of the many challenges in this area [9-11]. These challenges include ethical issues regarding privacy, autonomy, safety, and trust and the risk of creating or exacerbating health-related bias and inequality [12-16]. Researchers and technology developers must also understand the complex and changing needs of individual circumstances—there is a need for research to center on the person and their support network rather than on the technology itself if it is to be successful [17]. Therefore, understanding users' perspectives is fundamental if we are to develop technologies that are acceptable, effective, and ethical [5,10,18,19]. One way to achieve this is through patient and public involvement (PPI).

PPI describes a partnership between patients, the public, and researchers in the research process itself. It is often described as research conducted "with" or "by" service users rather than research "about" or "for" them [20]. In addition to being seen as an ethical imperative, PPI aims to improve the efficiency and value of health research, recognizing that those with lived experience of health conditions or services will bring knowledge and experience that may increase the relevance of studies, improve recruitment and retention of participants, and improve dissemination of research findings [20-22]. PPI is now seen as an essential part of health and social care research—the Health Research Authority strongly advises PPI because of its likelihood of improving research quality and addressing the Research Ethics Committee's key considerations [23]. Stakeholder engagement is a key part of the guidance from the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use [24], and the National Institute for Health and Care Research (NIHR) makes it a condition of research funding [21]. The NIHR describes different approaches to involvement with increasing levels of power and influence for members of the public, from consultation (least power) to coproduction and user controlled (most power) [20].

PPI in dementia-related research has been gathering pace in recent years. Historically focusing more on the involvement of carers or other stakeholders, this has changed with more studies involving people with dementia themselves [25,26]. It is now well established that this supports and promotes a person-centered model of health care [27-31]. PPI should be conducted in a manner that promotes equality, diversity, and inclusion [20]. The NIHR emphasizes the need for researchers to enable the involvement of underrepresented groups and adapt their PPI approaches and activities to ensure accessibility for all groups affected by the project [32]. When planning and carrying out PPI in dementia research, this means the consideration of all groups affected by aging and dementia from diverse ethnic, racial, linguistic, geographic, and socioeconomic backgrounds.

The principle of stakeholder involvement is not unique to PPI. To understand the principles of terms such as "co-design" and "coproduction" within PPI, it is important to appreciate the context in which these terms have developed beyond just the health care sector. Within technology innovation, there has been a steady and increasing emphasis over the past 50 years on ensuring that a "human-centered" approach is taken to developing a new product or service [33]. Human-centered design emphasizes the need for fostering deep empathy with the people one is designing with, bringing end users into the design process as early as possible. Co-design can be a method of human-centered design. Co-design also stems from the 1970s, from a Scandinavian movement of participatory design, in which scientists, technologists, and design researchers acknowledged that "the people destined to use the system [must] play a critical role in designing it" [34]. Wider adoption of these human-centered design approaches has been seen in the last 15 years with methodologies such as the Design Council's "Double Diamond" [35] helping visualize this iterative approach to innovation and widen adoption across nondesigners.

Considering the context of technology within health and social care, it is not surprising that practitioners from health and social care, design, and technology research have found themselves discussing what best practice should look like and what approaches or methods might facilitate meaningful innovation [36]. Regardless of the background, researchers across these disciplines agree on the need to move from a patient-centered or user-centered approach to a "co-production" approach in which users not only are observed or consulted but also work jointly as partners, with mutual respect and understanding of each other's different knowledge and experiences and the contributions they can make [21,37,38]. The NIHR outlines 5 key principles of coproduction as part of a research project (Textbox 1).

Textbox 1. National Institute for Health and Care Research "Guidance on co-producing a research project"—key principles.

1. Sharing of power—the research is jointly owned and people work together to achieve a joint understanding
2. Including all perspectives and skills—making sure the research team includes all those who can make a contribution
3. Respecting and valuing the knowledge of all those working together on the research—everyone is of equal importance
4. Reciprocity—everyone benefits from working together
5. Building and maintaining relationships—an emphasis on relationships is key to sharing power" [32]

Despite the recognition of the value of PPI and the recommendation of coproduction approaches [10,19], patient or other stakeholder involvement in technology-related dementia research is known to be variable in breadth and depth and sometimes absent altogether [11]. Older reviews show that the involvement of people with dementia has usually been as passive participants to be observed or at most as a group to consult but without any sharing of decision-making power [19,39,40]. A review of the literature published between 2011 and 2017 by Suijkerbuijk et al [41] demonstrated that, although there has been an increase in the involvement of people with dementia in technology research, reporting on the methods, barriers, facilitators, and impact remains minimal, making progress in this field challenging. This mirrors issues with PPI reporting (especially of impact) in the wider field of dementia research [25,42,43]. Given the increased attention that PPI has received in recent years as well as the rapid advances in technology-related health research, we anticipated that there would be many more papers published in the period from 2017 to 2022 worthy of review. In addition, the review by Suijkerbuijk et al [41] included papers with a broad range of methodologies to cover the concept of "involvement," including the involvement of people with dementia as participants in qualitative research. To our knowledge, no review to date has explored the specific concept of PPI in technology-related dementia research.

Objectives

Therefore, the objectives of this scoping review were as follows:

1. To describe the approaches to PPI used to date in technology-related dementia research, exploring who is involved, when, and how,
2. To describe the reported barriers to and facilitators of effective PPI in this area, and
3. To examine and report on the impact of PPI in this area.

Methods

Review Type

To gather the available literature in this area, a scoping review was conducted. Scoping reviews are often used in preference to systematic reviews in cases in which the body of literature is likely to be large and heterogeneous and to answer broad questions (such as "what is known about this concept?") [44]. They are a useful way to map out the evidence, as opposed to systematic reviews, which often bring together literature on a particular subject with a more defined question, for example, about the efficacy of interventions [45]. The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines [44] were followed to ensure appropriate reporting.

Search Strategy and Eligibility Criteria

A search strategy was developed and used a search string consisting of words related to dementia; technology designed to support health, care, or well-being; and PPI. Knowing that the terminology used varies considerably, definitions were kept broad, in particular of "patient and public involvement," adapting and building on existing search strings from previous reviews [11,19,25,41,42]. Our definition of technology was similarly broad. Assistive technology may be described as "products or systems that support and assist individuals with disabilities, restrict mobility or other impairments to perform functions that might otherwise be difficult or impossible" [46]. We included any type of assistive technology as well as, more broadly, any technology that could be deemed to be a part of technology-enabled care (such as telehealth systems, telecare, telemedicine, and self-care apps) [47]. Inclusion criteria were developed (Textbox 2). PPI activities do not usually require ethics approval [20], yet we did not exclude those who sought ethics approval so as to ensure that we captured a range of approaches.

Textbox 2. Inclusion and exclusion criteria.

Inclusion criteria

- Research about dementia (any type) or mild cognitive impairment
- Research focused on technology designed to support the health, care, or well-being of people with dementia or their carers
- Research describing ways in which patients or other stakeholders were actively involved in the research process itself (not only as research participants)
- Full text available in English
- Any publication date up to the end of 2022

Exclusion criteria

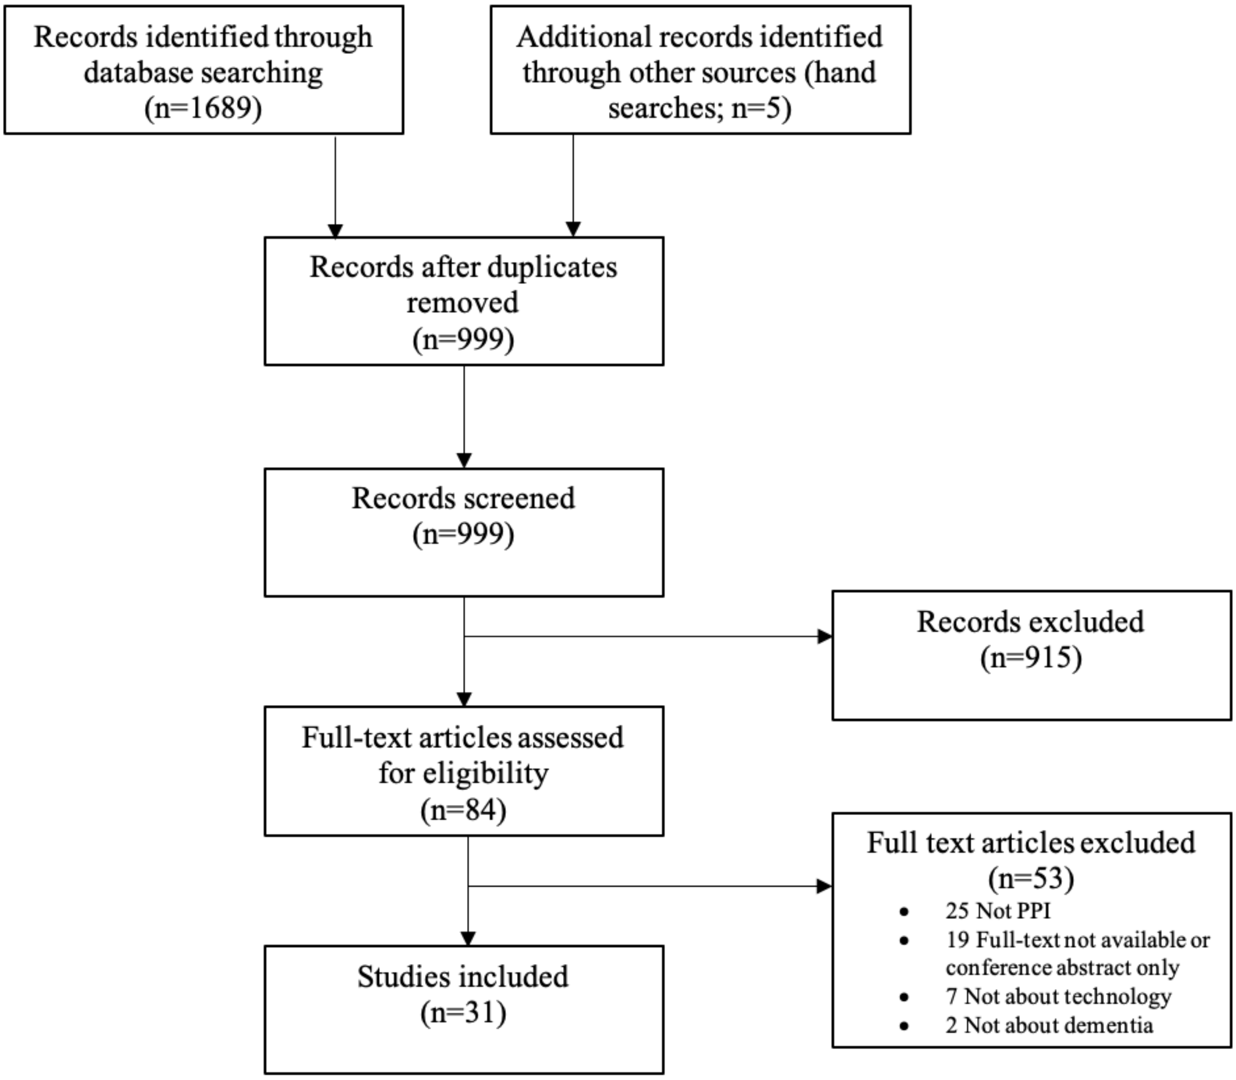
- Dementia only mentioned incidentally (eg, primary focus was Parkinson disease)
- Technology in which target beneficiaries are not people with dementia, family or carers (eg, web-based education programs for health care workers)
- Studies in which the patients or stakeholders are positioned as research participants only (eg, participants in a qualitative study) and are not actively involved in conducting the research
- Reviews
- Opinion pieces
- Conference abstracts

Data Sources and Charting Process

The search was conducted in 4 databases: MEDLINE, PsycINFO, Embase (using Ovid), and CINAHL (using EBSCO). All papers published until the end of 2022 were included. Abstracts had to be available in English, and opinion pieces and reviews were excluded (refer to Multimedia Appendix 1 for the full MEDLINE search string). The search was last conducted in January 2023. References were exported to EndNote (Clarivate Analytics) and then to Covidence (Veritas Health Information) [48] for screening. After the removal of duplicates, 2 reviewers (PK and HL) screened the titles and abstracts against the eligibility criteria. The full texts were then further screened for eligibility. The 2 reviewers then independently charted the data from the included studies using a predesigned extraction table. For the first 10 papers, detailed discussions were held to clarify interpretations of PPI. Subsequent discussions were held to reach a consensus where required. A third author (CMA) was available if a consensus was not reached. As the purpose of this review was to provide an overview of existing evidence regardless of quality, no formal appraisal of methodological quality was conducted, in line with guidance [45]. Facilitators of and barriers to effective PPI were grouped and analyzed by the first author to draw out themes, which were then refined in discussion with the other authors. The impact of PPI, where described, was summarized and categorized into impact on the study, impact on the patient and public partners, and impact on the research team.

Initial database searching identified 1689 records, with an additional 5 found through hand searches following references from papers identified in the initial search. After removal of 695 (41%) duplicates, the remaining 999 abstracts were screened. Most of these (915/999, 91.6%) did not meet the eligibility criteria (were not about dementia, involvement in research, or technology). Determining whether papers described active involvement in the research process or merely involvement as participants was frequently unclear from the abstracts alone, and the authors erred on the side of inclusion here, in line with guidance. When analyzing full texts (84/999, 8.4%), not meeting the “involvement in research” criteria was the most common reason for exclusion (25/53, 47% of the papers excluded at this stage). A total of 31 papers were included in the scoping review. Figure 1 shows the flow of information for this process.

Figure 1. Record identification and screening process. PPI: patient and public involvement.



Results

Study Characteristics

Of the 31 papers included in the review (Table 1), most (n=18, 58%) were published between 2020 and 2022. Only 13% (4/31) were published before 2010. Most papers were authored by groups from multiple disciplines, for example, authors from design engineering backgrounds and health sciences and health care professionals. A total of 13% (4/31) of the studies included patient or public partners as coauthors [17,49-51]. In total, 21 of the studies originated in Europe, including 10 (48%) from the United Kingdom. Others were from Canada (7/31, 23%) and Australia (3/31, 10%), and 1 of the studies (1/31, 3%) included discussions of collaborations with groups in Ireland, Hong Kong, Brazil, and India [52].

Table 1 also outlines the stakeholders involved, the stage or stages of the research they were involved in, and the methods used for this involvement. When determining which stage of research stakeholders were involved in, the authors mapped involvement onto NIHR stages of research in which PPI might typically take place (eg, “design of the research”). Where Table 1 states “did not fit model,” this was because participants were positioned as both coresearchers and research participants. This is explored further in the following sections (Table 2).

A range of technologies were described with varied purposes (Textbox 3), apart from in Liddle et al [17], which did not focus on any one type.

Table 1. Study characteristics describing the technology, stakeholder involvement, stage of the research process in which the involvement took place, role of the stakeholder, and methods used to involve patients and the public.

Study, year	Origin	Technology type and purpose	Stakeholders involved	NIHR[a] stage of research in which PPI[b] took place	Role of stakeholders involved	PPI methods
Davies et al [53], 2019	United Kingdom	Website to provide information and peer and professional support for caregivers of people with dementia toward end of life	Research development group including 6 HCPs[c], 2 members of a dementia charity organization, and 1 carer	Design of the research, undertaking and management of the research, and analysis of data	Refining the aims of the wider project and steering the project throughout	Steering group, group meetings, and 1:1 meetings
Kort and van Hoof [54], 2014	The Netherlands	Website with information about home modifications for people with dementia and their family caregivers	3 dyads (people with dementia+carer) and, separately, a group of 20 (carers or residential home staff)	Did not fit model	Contributing to the iterative design process	Observations, consultation rounds, and questionnaire
Schikhof et al [55], 2010	The Netherlands	Monitoring system in residential home for people with dementia to detect anomalies (eg, panicking and falls)	8 nursing home staff members and 13 family representatives (as proxies for people with dementia)	Did not fit model	Contributing to the iterative design process	Interviews, workshops for prototype testing, informal group meetings, and focus groups
Muñoz et al [56], 2022	Canada	Virtual reality game to support engagement in exercise for people with dementia	7 people with dementia or MCI[d], 5 older adults without dementia, industry partners, and HCPs	Design of the research and undertaking and management of the research; elements did not fit model	Contributing to the iterative design process; HCPs and industry representatives also had a role in designing and managing the study	Prototype testing and interviews (people with dementia or MCI and older adults), research group meetings (HCPs), and focus group (older adults without dementia, members of the research team, and industry representatives)
Eisapour et al [57], 2020, also with reference to Eisapour et al [58], 2018, and Eisapour [59], 2018	Canada	Virtual reality game to support engagement in exercise for people with dementia	HCPs and 3 people with dementia	One PPI representative involved in the main research team, presumed to be throughout; other elements did not fit model	Contributing to the iterative design process and involved in the main research team	Focus groups, observations, informal discussions in care home, and prototype testing; one member of the original focus group subsequently joined the research team
Hanson et al [60], 2007	Sweden	Home computer-based education and support program providing information, support tools, and exercises for people with dementia and their carers	7 people with dementia	Did not fit model	Contributing to the iterative design process	Group meetings to develop support program content and computer skills tuition for group members
Orpwood et al [61], 2004	Finland and others part of the ENABLE project	Various assistive technology devices: picture gramophone, calendar, tap monitor, lost object locator, gas cooker monitor, and night-light	Family carers (as proxies for people with dementia), paid carers, and older adults without dementia	Did not fit model	Contributing to the iterative design process	Informal group meetings and focus groups

Study, year	Origin	Technology type and purpose	Stakeholders involved	NIHR[a] stage of research in which PPI[b] took place	Role of stakeholders involved	PPI methods
Kort et al [62], 2019	The Netherlands	Various projects described: a smart pill box and real-time location systems (also a website as documented separately [51])	People with dementia and carers (past or current)	Did not fit model	Contributing to the iterative design process	Varied between projects: observations, consultations, storytelling, focus groups, and "thinking aloud" sessions
Hendriks et al [63], 2017, also with reference to Hendriks et al [64], 2014	Belgium	System for monitoring the mealtimes of people with dementia in a care home using sensors and data input by carers into the app	Industry representatives, academics and HCPs, professional carers, people with dementia, and informal carers	Did not fit model	Contributing to the iterative design process	Meetings, feedback sessions with HCPs or professional carers, integration of research team into daily life at care home, and group "mapping" sessions with people with dementia and carers
Orpwood et al [65], 2007	United Kingdom	Various technology projects: music player, video streaming of outside world scenes into the homes of people with dementia, conversation prompter for people with dementia, and "sequence support" tool for prompting ADLs[e]	Varied across projects: people with dementia; carers; and other "user representatives," including academics from the social sciences, engineering, and dementia organizations	Did not fit model	Contributing to the iterative design process	Varied across projects: user survey, co-design workshops, observations, 1:1 user testing, and interviews
Savitch et al [66], 2012	United Kingdom	Website providing information about assistive technology for people with dementia	People with dementia and, separately, a steering group that also included 1 person with dementia	Steering group: detail not given; elements did not fit model	Contributing to the iterative design process (people with dementia); steering group also provided input throughout	Interviews, focus groups, co-design workshops, and involvement in steering group meetings
Perkins et al [52], 2022	United Kingdom, Ireland, Hong Kong, India, and Brazil	Web-based delivery of CST[f]	4 people with dementia, 4 family carers, 4 service managers, and 8 CST group facilitators from the United Kingdom and Hong Kong; additional stakeholders in India	Design of the research and undertaking and management of the research	Designing and developing a protocol (people with dementia, carers, service managers, and CST facilitators) and field-testing of the protocol and subsequently giving feedback following testing (CST facilitators)	Focus groups (web-based); CST facilitators then tested the protocol with people with dementia in 5 countries; interviews with CST facilitators following field-testing
Hwang et al [67], 2015	Canada	Animated videos for prompting people with dementia with ADLs	6 family carers	Did not fit model	Contributing to the iterative design process	Co-design workshops first to develop the concept and then refine the designs; 2 home visits for paper prototype evaluation
Oksnebjerg et al [68], 2019	Denmark	An app to support self-management for people with dementia, including a calendar and diary	4 people with dementia, 4 family carers, and 4 paid carers	Did not fit model	Contributing to the iterative design process	Co-design workshops

Study, year	Origin	Technology type and purpose	Stakeholders involved	NIHR[a] stage of research in which PPI[b] took place	Role of stakeholders involved	PPI methods
Hung et al [50], 2021	Canada	PARO, a commercially available robot seal that uses AI[g] to support the social and emotional needs of the people with dementia interacting with it	5 "patient and family partners"	Undertaking and managing the research, analysis of data, and dissemination of research findings	Supporting data collection, thematic analysis of data, and authoring of the paper	Supporting data collection with some patients or particular settings, analysis (4 × 1-h thematic analysis group sessions), and coauthoring the paper
Rathnayake et al [37], 2021	Australia	A mobile health app that provides information about dementia, care strategies, and tips for managing ADLs	Carers, HCPs, and IT experts	Did not fit model	Contributing to the iterative design process	Web-based survey, interviews, and co-design workshops
Kowe et al [69], 2021, also with reference to Kowe et al [70], 2022	Germany	Sensor-based activity management system	6 family carers	Analysis of data	Supporting thematic analysis of interview data	30-min group analysis session or workshop
Daly Lynn et al [51], 2021, also with reference to Daly Lynn et al [71], 2019, and Daly Lynn et al [72], 2022	United Kingdom	Smart home system for people with dementia in supported living	Peer researchers: 7 older adults without dementia; steering group: including 2 people with dementia, 1 family carer, and 2 dementia organization employees	Undertaking and management of the research, analysis of data, and dissemination; steering group: detail not given	Peer researchers: conducting interviews with research participants and supporting data analysis; steering group: ensuring that the voice of older people was central to the project and coauthoring the paper	2-d training for peer researchers, conducting interviews jointly with a member of the research team, group thematic analysis session, and evaluation forms
Banbury et al [73], 2021	Australia	Virtual support program to provide information and peer support for carers of people with dementia	6 family carers	Did not fit model	Contributing to the iterative design process	Co-design workshops and group meetings (all virtual) following the Double Diamond approach
Fox et al [74], 2022	United Kingdom	A mobile health app that delivers memory tests throughout the day to monitor cognition changes	7 people with dementia, 7 family carers, and a PPI officer	Did not fit model	PPI officer as "proxy patient representative" in the research team; people with dementia and carers contributed to the iterative design process	Co-design workshops; PPI officer part of the main research group
Rai et al [75], 2020	United Kingdom	Virtual delivery of CST	People with dementia and family carers	Did not fit model	Contributing to the iterative design process	Consultation meetings and co-design workshops
Owens et al [76], 2020	Consortium spanning organizations in Europe and the United States	Remote monitoring and measurement technologies for people with dementia	People with dementia and family carers	Design of the research	Patient advisory board—supporting research planning and design and feedback on relevance and priorities	Provision of feedback on researchers' literature review, group discussions, workshops, and other meetings of the patient advisory board

Study, year	Origin	Technology type and purpose	Stakeholders involved	NIHR[a] stage of research in which PPI[b] took place	Role of stakeholders involved	PPI methods
Stavropoulos et al [77], 2021	Greece, with involvement from multiple countries across Europe	A range of commercially available wearable devices	11 people with dementia and 10 carers from 11 countries across Europe	Design of the research	Reviewing devices and providing information to guide the design of future research, aiming to make it more relevant and accessible and improve participant experience	One-off 2.5-h session including presentations, roundtable discussions, hands-on experimentation, and voting
Liddle et al [17], 2022	Australia	No specific technology discussed—study explored factors related to engagement with technology for people with dementia and carers	15 people with dementia and carers (living experience expert reference group); 4 of them (2 people with dementia and 2 carers) were also members of the core research team and were listed as coauthors	Design of the research, undertaking and management of the research, analysis of data, and dissemination of research findings	Setting research priorities, supporting the design of interviews and developing the topic guide, thematic analysis of data, reflexivity sessions with the research team, and writing up of the study	Group sessions, discussions and meetings with reference group, group analysis sessions, and discussions of reflexivity
Hassan et al [78], 2017	United Kingdom	A range of commercially available wearable devices	>30 in total: people with dementia or MCI, carers, people with early-onset dementia (aged <65 y), and older adults without dementia	Design of the research	Contributing to research design (producing guidelines to optimize design and improve acceptability) and informing procurement decisions	Exploratory workshops in groups according to diagnosis (people with dementia+carers, people with early-onset dementia, and older adults without dementia), individual 1:1 meetings (people with MCI), and opportunities for stakeholders to try the devices at home
Jacklin et al [79], 2020	Canada	A wearable (wristband) for capturing movement-related behaviors (eg, falls, wandering, and agitation)	Indigenous community representatives, carers, community elders, and health and social care workers	Did not fit model	Informing the design of the research to ensure that culturally appropriate and inclusive methods are used	Community-based participatory research approach, focus groups (with carers), and preparation meetings with the Community Advisory Council to plan the research and ensure that appropriate methods are used
Ghafurian et al [80], 2022	Canada	App to support professional carers in communicating with people with dementia in nursing homes	17 professional carers and 1 nurse	Did not fit model	Contributing to the iterative design process	Survey, focus groups, and co-design workshops
Berge et al [81], 2022	Norway	Tablet-based music app primarily used as a relational tool to support positive interactions between people with dementia and carers	People with dementia or other psychiatric conditions, carers, and HCPs	Did not fit model	Contributing to the iterative design process	Observations, interviews, and 2 focus groups; user testing of a prototype with 4 older adults with dementia or other psychiatric conditions

Study, year	Origin	Technology type and purpose	Stakeholders involved	NIHR[a] stage of research in which PPI[b] took place	Role of stakeholders involved	PPI methods
Shadarevian et al [49], 2020	Canada	Tablet for sharing family videos in hospital with people with dementia to support care provision, reduce social isolation, and reduce aggression	People with dementia, family carers, HCPs, and students	Undertaking and management of the research, analysis of data, and dissemination of research findings	Positioned as part of the research team throughout, guiding the research process; thematic analysis of interview data; creating a toolkit to support wider dissemination and adoption of the intervention; and coauthoring the paper	Monthly research project meetings, making videos, interviews, group thematic analysis session, manuscript reviewing and editing
Tiersen et al [82], 2021	United Kingdom	Smart home system for people with dementia in their own homes	People with dementia, carers, and HCPs	Did not fit model	Contributing to the iterative design process	Various across 9 substudies: semistructured interviews, focus groups, co-design workshops, surveys, home visits, online group meetings, and observations
van der Roest et al [83], 2008	The Netherlands	Website with customized information for people with dementia and their carers about health care and welfare services	People with dementia, carers, and HCPs	Did not fit model	Contributing to the iterative design process	Workshop exploring user needs (people with dementia, carers, and HCPs), further co-design workshops (HCPs), prototype testing, and questionnaire (family carers)

[a] NIHR: National Institute for Health and Care Research.

[b] PPI: patient and public involvement.

[c] HCP: health care professional.

[d] MCI: mild cognitive impairment.

[e] ADL: activity of daily living.

[f] CST: cognitive stimulation therapy.

[g] AI: artificial intelligence.

Table 2. Patient and public involvement (PPI) in the different stages of research as recommended by the National Institute for Health and Care Research [21] (n=31).

Stage of research	Studies with PPI at this stage, n (%)	Example
Design of the research and development of the grant application	7 (23)	PPI representatives (here a “Patient Advisory Board”) supported research planning and design, giving feedback on relevance and priorities [76].
Undertaking and management of the research	7 (23)	PPI representatives, here termed “peer researchers,” collected data for the study interviewing people with dementia [51].
Analysis of data	6 (19)	PPI representatives were part of interview data analysis and discussions of reflexivity [17].
Dissemination of research findings	4 (13)	PPI representatives coauthored the paper [49].
Did not fit model	21 (68)	PPI representatives were positioned both as co-designers along with the research team and as research participants testing the prototype [81].

Textbox 3. Types of technologies and their purposes.

Sensor monitoring systems (including smart home monitoring systems) [51,55,63,69,76,82]

- Safety alerts
- Monitoring (of health, activity, behavior, and cognition)

Wearables [77-79]

- Safety alerts
- Monitoring (of health, activity, behavior, and cognition)

Apps [37,60,68,74,80,81]

- Monitoring (of health, activity, behavior, and cognition)
- Self-management
- Exercises
- Information provision or education
- Supporting social interaction
- Social and emotional well-being

Miscellaneous assistive technology devices (not wearables and not app based, eg, gas cooker monitor or smart pill box) [50,61,62,65,67]

- Safety alerts
- Self-management
- Leisure access
- Supporting social interaction
- Social and emotional well-being

Websites [53,54,66,83]

- Information provision and education
- Accessing peer support
- Accessing professional support

Videoconferencing platforms [73,75]

- Therapy delivery
- Information provision and education
- Accessing peer support

Virtual reality games [56,57]

- Exercises

Who Was Involved?

Studies involving only 1 stakeholder group in their PPI activities were in the minority (5/31, 16%), and many (17/31, 55%) involved ≥3 different stakeholder groups, with the range of these shown in Multimedia Appendix 2. Family carers were the most frequently involved group (27/31, 87% of the studies), followed by people living with dementia (23/31, 74%). Most papers gave little detail about recruitment methods or the background of their PPI representatives. Where papers mentioned attempts to recruit diverse viewpoints, this generally referred to involving different stakeholder perspectives (eg, patients as well as carers and health care professionals), and where inclusivity was dwelled on, this usually referred to the involvement of people living with dementia. Some papers mentioned the linguistic mix or geographical spread of those involved, in particular [52,76,77]. Discussions of racial or ethnic diversity within PPI groups were almost entirely absent. There was one exception [79] in which the inclusion of First Nations representatives was central to the study.

When Were They Involved?

The NIHR recommends PPI throughout the research cycle, highlighting in particular 4 key areas where PPI can take place [21]. The studies in this review were mapped to these stages, as shown in Table 2. In total, 29% (9/31) of the studies had involvement from patient and public partners at multiple stages throughout the research cycle [17,49-53,56,57,66], although sometimes a lack of detail on methods meant that this multistage involvement was presumed (eg, description of a steering group providing oversight "at key milestones" [66] without further description).

As shown in Table 2, a total of 68% (21/31) of the sources did not fit into this NIHR description. These were papers describing a co-design or participatory design process in which the stakeholders involved were both the "co-researchers" or "co-designers" and yet were also positioned as research participants. Typically, these studies involved stakeholders in the iterative design process of a technology prototype. Participants collaborated with the research team on the design process while also being positioned as study participants, for example, being observed testing prototypes or providing feedback as part of interviews. Their involvement could not clearly be classified as designing the research (the study protocol having been designed before their input) or quite as "undertaking/managing the research" as they were the targets of data collection, not involved in the process of collecting them themselves. However, as the authors positioned these stakeholders as collaborators or co-designers along with the research team, these studies were not excluded in the same way that others were when they were more clearly set up as qualitative studies (eg, a focus group to collect end users' views on technology where ethics approval had been sought for this research process).

How Were They Involved?

Approaches to PPI varied (Table 1). Every paper mentioned at least one form of group activity for their involvement work. Varying terms were used for this—co-design workshops and focus groups were the most frequently mentioned, along with group meetings, group discussions, prototype testing sessions, consultation rounds, group consultations, informal meetings, group feedback sessions, and workshops. Most papers (26/31, 84%) described more than 1 type of activity. In addition to group activities, many conducted interviews [37,49,51,52,55,56,65,66,81,82], observations [54,57,62,65,81,82], or surveys or questionnaires [37,54,65,80,82,83]. A total of 19% (6/31) of the studies set up steering groups that were regularly involved in the research process, described variously as a research development group [53], living experience expert reference group [17], steering group [51,66,71], and patient advisory board [76,77], although details were minimal or absent about what this entailed. A total of 19% (6/31) of the papers [17,49-51,57,74] described some form of integration of patient and public partners (or, in 1 case, a PPI officer as proxy for the PPI group itself [74]) into the main research team, although, again, details were often very minimal about what this entailed. In total, 13% (4/31) of the papers were coauthored by patient and public partners [17,49-51].

Barriers to and Facilitators of Effective PPI

A total of 74% (23/31) of the papers included at least some reporting of either facilitators or barriers faced when conducting PPI. In many cases, this reporting was minimal, for example, listing one challenge the team faced. Only 26% (8/31) of the papers had what we considered to be a more thorough discussion of barriers or facilitators [51,56,60,63,64,69,70,73,74,78] (the papers by Hendriks et al [63,64] refer to the same study, as do those by Kowe et al [69,70]). Barriers and facilitators were grouped into themes (Textboxes 4 and 5). Facilitators often focused on ways to achieve richer, more meaningful involvement, for example, working with multiple stakeholder groups and creating a trusting, supportive group dynamic. The barriers identified principally regarded issues with working with dementia as a condition as well as practical issues such as time and budget.

Textbox 4. Facilitating effective patient and public involvement (PPI).

A person-centered approach: choices and adaptability in involvement

1. Prioritizing the well-being and positive experience of those involved [60,77]
2. Offering choices and being led by those involved (how to take part, methods, environment, and level of involvement) [17,69,82]
3. Use of extra time and flexibility for people with dementia, including modification of activities to make them more accessible, acknowledging that there will be no *one-size-fits-all* [60,77]

Building the group: rapport, trust, and equality

1. Spending time developing group relationships, finding commonalities, and building connections within the team [51,73,77]
2. Building time for chatting and eating together. Informality helps build rapport and flatten hierarchies [60,63,65]
3. Use of a nonresearcher as facilitator [69]
4. Being face-to-face rather than web-based [77]
5. Use of small groups [60]

Multiple viewpoints

1. Including views from multiple stakeholder groups as a way of improving the quality of involvement work and the richness of the data gathered [78,82]
2. Planning a range of methods to recruit and work with different groups (carers, people with dementia, health care professionals, and others) seen as important [82]
3. Considering ways of involving seldom heard groups—from practical adaptations (researchers traveling and not asking patient and public partners to do so) [80] to cultural considerations [79]
4. Group members from different backgrounds learning from each other [65]
5. Support to access different groups was beneficial (eg, working with community organizations or having managerial support to enable staff to take time away from their main role [56])

The right environment

1. Considering accessibility and proximity to local amenities and transport [60,78]
2. Considering who owns the environment—researchers going to those involved (eg, integrating into nursing home environment) may help create a greater sense of equality, flatten hierarchies, and support researchers' understanding of the group they are working with [56,63,80]
3. Being face-to-face enabled hands-on workshops, improved group dynamics, and reduced technology barriers [77,78]
4. Web-based environments enable geographically diverse groups to come together and may keep discussions more focused [73]

Support and training

1. Having facilitators or members of the research team who are skilled and experienced working with people with dementia [60,78]
2. Providing training for patient and public partners (eg, data collection, thematic analysis, and computer skills) [51,60]
3. Supporting patient and public partners with adequate time to reflect and debrief with members of the academic research team [51]
4. Using paper prototypes to overcome technology barriers [66]
5. Providing adequate support for people with dementia (family carers [60] or modified activities [60,77,78])

Pragmatism and compromise

1. Proxy involvement (of family, PPI officers, and nursing home staff) used in place of people with dementia (or people with moderate to severe dementia) in cases in which their involvement was not seen as feasible [55,61,74]
2. One-to-one sessions found to be easier to organize than group sessions [53]
3. Virtual meetings may be easier to organize than face-to-face meetings [73]

Textbox 5. Barriers to effective patient and public involvement (PPI).

The nature of dementia

1. Cognitive impairments seen as too great a barrier to attempt PPI with people with dementia [55,61]
2. Input from people with dementia described as very minimal [62]
3. Attempts at adaptations unsuccessful [63,64]
4. Variations in presentation making it difficult to plan a particular approach or manage a group [63,64]
5. Carers and people with dementia both overestimating the abilities of the latter [63,64]
6. Unreliable historians— for example the challenge of interpreting someone’s account of their ability to participate in activities of daily living while they also recount recent interactions with long-dead relatives [63,64]
7. The emotional load faced by researchers working with this group, including challenges such as being asked for support or advice out of their scope [63,64]

Inequality of relationships within the group

1. Some authors highlighted issues with patient and public partners feeling undervalued or not equal within the team; this applied to those without dementia [51,63], though dementia was also seen as an additional barrier to a sense of equality [63,64]
2. Lack of payment for PPI also contributed to this, as well as the limited scope or lack of defined roles and responsibilities for patient and public partners [63,69]

Time pressures

1. Researchers’ time pressures—co-design or other involvement activities as time-consuming processes that can be difficult to manage alongside the time pressures of a research study [75,81,83]
2. Family carers’ time pressures—busy schedules and stressful lives [37,69]
3. Staff time pressures—nursing home staff and health care professionals’ strict shift patterns and limited flexibility for time away from work [80], in some cases exacerbated by the COVID-19 pandemic [52]
4. Limited time resulting in reduced or inadequate training for patient and public partners [51,69]
5. Rapport building in the group suffering as a result of lack of time [51,56]

Recruitment and diversity

1. Small numbers of people involved resulting in reduced diversity of opinions and a poorer representation of stakeholders [56,57,75]
2. Challenges with generating interest in the study or reaching particular groups [74,78] and COVID-19 causing staffing pressures [52] and a lack of face-to-face options for people with dementia [82]

Processes and communication

1. Communicating complex content (the ethics of smart homes, technology use, and design processes) was particularly challenging for people with dementia [62,68]
2. Use of jargon terminology by researchers was a barrier for all patient and public partners (not only those with dementia) [63,69]
3. Methods of communication—use of phone for people with dementia was limiting [82], and sending too many emails was unpopular [56]
4. Processes for PPI members experienced as boring or repetitive (eg, completing multiple assessments), especially when combined with a lack of communication about the purpose or the results of their input [56]
5. Lack of involvement and communication early in the study resulting in stakeholders having less of a connection or understanding of the project or feeling that their contributions were less valued [51,63]

Impact of PPI

Although most papers (28/31, 90%) implied or briefly commented that stakeholder involvement had some impact on their study (usually on the iterative design process), this was sometimes without any description of what the impact was. Where any details were given, as was the case in 52% (16/31) of the papers [51,54-57,60,61,63,69,73-79], the results are summarized in Textbox 6.

Textbox 6. Impact of patient and public involvement (PPI) activities.

Impact on the research

- PPI activities helped set groups' research agendas, with clearly defined stakeholder priorities for research [76,77]. PPI data were identified as something that can be shared with and used by the wider research community when planning research [77].
- Involvement in research design resulted in a set of recommendations that the authors hope will improve the acceptability for research participants [78] and in specific cultural adaptations and approaches [79].
- Involvement in data collection was reported as adding richness to the data on account of the rapport and connections that peer researchers built with the people with dementia they were interviewing [51].
- Many papers (21/31, 68%) commented that the methods used (eg, co-design and participatory design) had an end result that was in some way grounded in the views or priorities of users but often with minimal detail. In total, 13% (4/31) of the papers [55,57,74,75] gave detail about the extent to which user groups drove the development or design of technology, reflecting on the value of their input.
- Coresearcher involvement in a thematic analysis workshop made for a more robust analysis, with differing perspectives between the research team and coresearchers showing the need for more PPI at the analysis stage in the future [69]. The limited impact that PPI activities had at the analysis stage was also reflected on, citing inadequate time and training for coresearchers resulting in brief and surface-level group analysis sessions [51,69].

Impact on patient and public partners

- Feedback on positive experiences of patient and public partners was provided in general terms [74,78]. Positive relationships between team members were developed, with feelings of mutual respect as well as the value of finding connections being reported [51,56,73].
- Some reported empowerment and satisfaction with the project and their role in it [54,60,61].
- Patient and public partners developed new skills [51].
- Negative experiences were reported on, including finding tasks boring or repetitive or processes complex [56]. Some papers also reported that patient and public partners felt underinvolved [51] or not treated as equal partners [63].

Impact on the academic research team

- Researchers gained a deeper understanding of the needs and priorities of the group they were seeking to conduct research with and for [79].
- Researchers developed a sense of connection with and respect for other disciplines or stakeholders they had not previously worked with [60,65].
- One paper reflected on the emotional burden associated with close working with people with dementia and the need for support for researchers as well as the people with dementia themselves [64].
- The initial challenges of stepping back when sharing responsibility with peer researchers was reported on, which became easier with experience [51].

In general, no formal methods were used for evaluating the impact of PPI activities. Where papers reported on impact, it was usually limited to the authors' reflections, including when reporting on the impact on patient and public partners. In the case of 13% (4/31) of the papers [51,56,63,73], the authors reported seeking direct feedback from those who had been involved, for example, in the form of interviews; evaluation forms; or, in 3% (1/31) of the studies, a much more extensive retrospective analysis using formalized methods [63].

Discussion

Principal Findings

In this scoping review, we set out to explore the concept of PPI in technology-related dementia research. The papers reviewed in this study revealed that dementia researchers are embracing PPI, with varied and sometimes ambitious methods, values centered on inclusivity and coproduction, and involvement of a range of stakeholder groups. We found that approaches often blurred boundaries between those involved as "researchers" and those involved as "participants" so that most studies' (21/31, 68%) PPI activities did not fit into a strict definition of PPI, for example, as set out by the NIHR [32]. Although the involvement activities being undertaken demonstrate this to be a rapidly expanding and developing field, the brevity in the reporting of such activities (often without comments on the impact of PPI) perhaps highlights the need for clearer reporting guidelines. Where mentioned, the impact of PPI was generally reported as being positive on research quality, patient and public experience, and the learning experiences provided to researchers. We comment further on our objectives in the following sections.

Objective 1: To Describe the Approaches to PPI Used to Date in Technology-Related Dementia Research (Exploring Who Is Involved, When, and How)

We found that there was a narrative across many of the included papers about the value of involvement and coproduction methods, with many authors describing their aspiration for high levels of involvement with a sense of partnership and equality with stakeholders. A few consciously excluded people with dementia from this aspiration, citing cognitive impairments as making it either practically or ethically too challenging to involve this group. These views were chiefly expressed in older papers (before 2010). More recent papers were broadly inclusive, with some describing their efforts to involve people with dementia along with other stakeholder groups such as carers, health care professionals, and older adults without dementia. Sometimes, these groups were involved in similar ways, and sometimes, there were 2 very separate approaches, for example, a set of workshops with people with dementia and carers and more extensive involvement of health care professionals or others without dementia in the research process (eg, playing a role in designing the protocol or as members of a steering group). The fact that a significant majority (26/31, 84%) involved more than one stakeholder group, with many involving ≥3 groups (17/31, 55%), reflects the value placed on hearing from multiple viewpoints.

Despite this widespread acknowledgment of the value of collaborative or coproduction methods, it was not always clear from the papers to what extent their methods reflected these values. Some used methods that perhaps lend themselves better to a consultative approach (such as one-off focus groups or surveys) rather than a collaboration or coproduction approach [20]. Consultative methods have some value in enabling researchers to find out more about people's views and experiences. They are also relatively easy to organize (often one-off events as opposed to longer-term involvement), meaning that they are a practical way of hearing from a wide range of stakeholders [20]. However, these methods mean that involvement will always be more limited in scope—there is no 2-way discussion, and there is the risk of disengagement from stakeholders who feel that their views are not being listened to [20], as indeed was reported by Hendriks et al [63]. Where stated methods or approaches may have enabled more of a partnership approach to take place (eg, the use of a series of co-design workshops or involvement of a steering group), the brevity of the write-up often prevented us from understanding whether or how this happened.

The most common methods of involvement were through some form of group activity such as focus groups, workshops, prototype testing sessions, or roundtable discussions. Every paper mentioned some form of group activity such as these, with or without other methods. Involvement often occurred at just one stage of research—most commonly, this was contributing to the design of a prototype but with no involvement either before or after this (eg, in protocol design, recruitment, analysis, or dissemination), although there were exceptions to this, with studies involving patients or the public throughout multiple stages of the research.

Most studies (26/31, 84%) used multiple methods of involvement. There will be practical reasons for using different methods, some suiting particular groups or settings more than others, especially when we consider involving people with dementia and the flexibility of approach that this requires. Tiersen et al [82] described many different methods in their paper, reflecting that this "resulted in triangulation of investigators, methods and data sources to develop a more comprehensive understanding of the phenomena being studied." The use of multiple methods also allowed for more flexibility of involvement, with some able to take on a more active or sustained role than others as able or desired. This was cited as an aspiration or suggestion for future PPI by groups who did not have such flexible approaches, such as Kowe et al [69]. The paper by Liddle et al [17] described the flexibility of roles and high levels of involvement. Their "Living Experience Expert Reference Group" involved 15 people with dementia and carers, of whom 4 (2 people with dementia and 2 carers) were also integrated into the main investigator team. Roles included helping set research priorities, developing the interview topic guide, analysis of data, reflexivity sessions, and the write-up of the study. Shadarevian et al [49] and Hung et al [50] also described the integration of stakeholders into the main research group, mentioning roles in undertaking and managing the research along with analysis and dissemination, although there was little detail about the methods used for this involvement. PPI in data collection was rare. It was described in most depth by Daly Lynn et al [51], who worked with "peer researchers" (older adults without dementia) to interview research participants with dementia about their experiences with smart home living, with an insightful write-up detailing both the positive experiences and the challenges they faced.

Finally, although the notion of diverse viewpoints being included in PPI was often celebrated, this almost always referred to the inclusion of a variety of stakeholder groups (eg, patients, carers, and health care professionals). In general, there was very little explicit discussion of the demographics of PPI representatives. To reduce health-related inequalities and bias, researchers should consider not only how to involve people with dementia but also the demographics of this heterogeneous population, explicitly seeking ways to involve underrepresented groups.

Objective 2: To Describe the Reported Barriers to and Facilitators of Effective PPI in This Area

The general lack of evaluation or reflections on barriers to and facilitators of involvement means that the themes described in this paper result from a minority of studies, with most derived from just 26% (8/31) of the studies [51,56,60,63,69,73,74,78]. Themes drawn out broadly matched those frequently documented in the literature [11,25,41,42], in particular barriers such as time and budget, recruitment issues, and the specific challenges of adapting activities to be suitable for people with dementia.

Facilitators tended to focus on the manner in which activities were carried out (eg, how informality helped flatten hierarchies) rather than on specific methods or approaches, such as focus groups or interviews. The themes here mirror the key principles of coproduction outlined by the NIHR [21,32]. The NIHR emphasizes that coproduction does not require a specific method but a more nuanced focus on interpersonal skills, relationship building, and power sharing (Textbox 1) [32]. However, although many papers stated the need for approaches using these principles or claimed to have worked with such values in mind, details about what was done were often limited. We would welcome further and more detailed reporting on these activities so as to build the knowledge base among research teams and enable more high-quality PPI to be conducted in the future with this population. As also emphasized by Hendriks et al [64], there is a need for more than anecdotal evidence in the literature about how to involve people with dementia—the lack of guidelines or a strong evidence base makes progression challenging.

The barriers identified reflect the challenging nature of PPI in technology-related dementia research. Time and resources were frequently cited as limiting factors. Some studies avoided the challenge of making PPI activities accessible to people with dementia by not involving them at all. Hendriks et al [64] detailed the challenges of involving people with dementia in a particularly frank manner. They reported on the difficulty of sufficiently modifying activities to make them accessible, difficulties with variability in dementia presentations, and overestimation of abilities by people with dementia and their family carers. They went as far as to say that "the differences between the designer and the person to design for are too big to speak about equality in participation" [64]. A few papers highlighted the complex topics under discussion (eg, smart home technology, ethics, and design processes) and the difficulty of translating these issues into something someone with dementia could understand and contribute to [62,63,68]. Kort et al [62] went as far as to say that the complexity of content meant that input from people with dementia was very basic, commenting that "the actual participation in the project was deemed more important than the actual contribution." Although pessimistic sounding in tone at times, these honest admissions of the challenges faced and the inability of researchers to overcome them to a meaningful degree help the research community understand the current landscape of PPI in technology-related dementia research. They reinforce the need for significant investment to be made for the involvement of people with dementia to be successful. This is not merely in the creation of accessible resources or the provision of the right environment. Rather, it may be that significant cultural shifts need to take place for researchers to be able to plan and conduct effective coproduction based on the key principles of power sharing, inclusivity, respect, reciprocity, and relationship building [32]. It seems likely that researchers would benefit from significant training and support in understanding power dynamics and coproduction as well as support to learn more about how to work with people with cognitive impairments.

Objective 3: To Examine and Report on the Impact of PPI in This Area

Papers with more than a brief comment on the impact of involvement were scarce in this review, mirroring the findings by Suijkerbuijk et al [41] as well as the findings of those studies considering PPI in dementia research more broadly [25,26,42,84]. A few papers, notably those by Daly Lynn et al [51], Muñoz et al [56], Banbury et al [73], and Hendriks et al [63,64], provided valuable discussions and evaluations of impact.

Where papers reported on the impact of their involvement work, the results were largely positive. The studies demonstrated that PPI can have a positive impact on research quality at multiple stages of the research cycle as well as on those taking part. To achieve this, the authors reflected on the need to involve multiple stakeholder groups and use multiple methods of involvement to provide a person-centered and flexible approach in which people feel well supported and valued for their contribution. To do this evidently requires significant investment of time and resources. Even those papers detailing what we considered to be relatively high levels of involvement spoke about the need for more time and resources, for example, to improve levels of training or offer more formalized PPI roles [51,69].

It was helpful to see negative experiences with PPI also reported [56,63,64]. These are often missing from the literature [85] but provide helpful learning points. Another area that received little attention is the emotional impact of PPI on researchers. This was commented on briefly by Hendriks et al [64] but otherwise did not feature in the studies we reviewed, although it has been noted as a feature of PPI in dementia research more broadly [43,84]. The emotional impact on researchers might be seen as both positive and negative—as a research community, it would be helpful to recognize and value the learning and increased empathy that can come from close working with patient and public partners. It is also important to recognize the potential distress or emotional burden felt by researchers, which might be associated with this relationship, in particular for those unused to working with people in cognitive decline [43]. It is important that future studies consider these impacts and that researchers as well as patient and public partners have access to adequate training and support.

Across most studies (27/31, 87%), formal or standardized methods were not used to capture impact. Reporting was generally limited to the authors' personal reflections. In only 13% (4/31) of the papers did the authors report seeking direct feedback from those who had been involved, for example, in the form of interviews or evaluation forms [51,56,63,73]. Hendriks et al [63] included a detailed evaluation of impact. This team retrospectively analyzed their participatory design process, mapping out the decision-making process at each stage of the project and considering the extent to which coresearchers had been involved and, therefore, whether participation had been truly meaningful. They also interviewed some of those who had been involved and analyzed themes that emerged. There is a risk that reporting on the impact of PPI can lead to an overvaluing of that which is easily measured but of little meaning (such as the number of people involved) instead of these more complex issues such as research culture or power relations [85]. Therefore, this example by Hendriks et al [63] reflecting on and evaluating the power dynamics at play and the processes that took place is particularly commendable.

In the future, it would be helpful for all involved—researchers, patients, and the public—if there were more recording and reporting of the impact of involvement to help all parties understand if, when, how, and why partnership working is beneficial [20,43]. Capturing this in a meaningful way is the challenge ahead of us [85,86]. A focus on the dialogue and the learning is felt to be helpful—Russell et al [85] recommend exploring "the complexity and richness of this relationship, using methods that emphasise illumination rather than measurement, and asking when, why, and with whom the dialogue happens or fails to happen."

Defining PPI: Challenges We Faced in This Review

One of the challenges we faced was the varying terminology and approaches used to involve groups in research. We applied a broad definition of "involvement" and, therefore, included papers using co-design or participatory design processes, as described, for example, by Hendriks et al [63]. Within a participatory design approach, there is a deliberate blurring of the roles of "designer" and "end user." When written up in a research context, this can lead to a blurring of the roles of researcher, designer, end user, and research participant. From a PPI perspective, it is not usually considered appropriate for people involved in research to also be research participants as this can compromise both the researcher and person involved [20]. However, the NIHR gives the example of participatory or action research as a possible exception to this rule, and it was often these types of studies that we reviewed. Nevertheless, it was often difficult to determine which studies met our inclusion criteria, in part because of this mixing of roles and because of lack of detail in the methodology sections. Where studies explicitly used qualitative research methods (stating a qualitative approach and collecting data for analysis with appropriate ethics approval), they were excluded from this review. However, details were often missing, or sometimes subsections of a study appeared to be qualitative, whereas other sections were framed more like PPI activities. Terminology could not be relied on as it was applied inconsistently among studies. Similarly, information about ethics applications was not always available, and we did not use this as part of the inclusion and exclusion criteria. Had we used a stricter definition of PPI, we would have excluded a significant portion of the literature (21/31, 68% of the studies in this review). We felt that doing this would result in a misrepresentation of the type of involvement work being carried out and in missing key learning points from these studies.

Strengths

We used a comprehensive search strategy considering all types of technology, all types of dementia, and many terms for "patient and public involvement" to reflect the different types of involvement in the field, building on search strategies from other reviews [11,19,25,41,42] that at times had been narrower in scope (eg, looking at "patient and public involvement" but not "co-design"). The 2 reviewers overcame the difficulty of defining PPI through regular communication and close working throughout the screening stages, consulting with a third member of the team where required. The review is further strengthened by multidisciplinary team input, with representatives from health care and health sciences as well as from design and technology backgrounds, which we hope ensures that our reflections and conclusions are of interest and applicable to a wide range of disciplines.

Limitations

We did not conduct a gray literature search. Doing so might have resulted in a broader range of accounts of involvement being included. In addition, we did not involve patients or the public in this review, which may have contributed additional perspective and depth. However, we have planned and started recruitment for a much broader PPI strategy for our research center. The results of this review will be shared with our steering group so as to jointly consider how the findings should inform our PPI work as a center.

Conclusions

At present, most involvement in technology-related dementia research is limited in breadth (often to just 1 stage in the research cycle) and depth (often consultative rather than with any sharing of power). We see across the literature shared aspirations of high levels of meaningful involvement in research, and it is encouraging to see some evidence of this being put into practice, with some reporting on methods used for involvement and the impact this has. Where papers gave details, it appears that a flexible approach with multiple methods used at different stages of the research cycle may be the most successful, tailoring methods to the various groups or individuals involved and facilitating greater depth or breadth of involvement according to people's wishes and abilities. When this is done well, PPI can have a positive impact on both the research and those involved. This evidently will take significant time and resources, particularly if the approaches used are to move beyond consultations to collaboration or coproduction. Wider reporting of methods and facilitative strategies along with more formalized methods for recording and reporting on meaningful impact would be helpful so that all those involved—researchers, patients, and other stakeholders—can understand and learn how best to jointly conduct research.

Acknowledgments

PK is supported by the National Institute for Health and Care Research Imperial Biomedical Research Centre and Imperial Health Charity. HL is funded by the UK Dementia Research Institute and Imperial College London President's PhD Scholarship.

Authors' Contributions

PK wrote the manuscript. PK and HL developed the protocol with supervision from CMA and SD. PK and HL screened the results and extracted the data with third-author support where necessary from CMA. All authors reviewed and contributed to the final manuscript.

Abstract

Background: Research suggests that digital ageism, that is, age-related bias, is present in the development and deployment of machine learning (ML) models. Despite the recognition of the importance of this problem, there is a lack of research that specifically examines the strategies used to mitigate age-related bias in ML models and the effectiveness of these strategies.

Objective: To address this gap, we conducted a scoping review of mitigation strategies to reduce age-related bias in ML.

Methods: We followed a scoping review methodology framework developed by Arksey and O'Malley. The search was developed in conjunction with an information specialist and conducted in 6 electronic databases (IEEE Xplore, Scopus, Web of Science, CINAHL, EMBASE, and the ACM digital library), as well as 2 additional gray literature databases (OpenGrey and Grey Literature Report).

Results: We identified 8 publications that attempted to mitigate age-related bias in ML approaches. Age-related bias was introduced primarily due to a lack of representation of older adults in the data. Efforts to mitigate bias were categorized into one of three approaches: (1) creating a more balanced data set, (2) augmenting and supplementing their data, and (3) modifying the algorithm directly to achieve a more balanced result.

Conclusions: Identifying and mitigating related biases in ML models is critical to fostering fairness, equity, inclusion, and social benefits. Our analysis underscores the ongoing need for rigorous research and the development of effective mitigation approaches to address digital ageism, ensuring that ML systems are used in a way that upholds the interests of all individuals.

Introduction

The rapid progress of machine learning (ML) has revolutionized health care decision-making, medical diagnosis, and other domains [1]. However, as the influence of ML systems expands, so do concerns regarding potential fairness issues that may arise from ML systems encoding human biases [2]. As an example, population health management systems have been found to underestimate the health risks facing Black patients, who are typically underrepresented in health care data due to systemic challenges accessing health care [3]. Concurrent with the rise of ML, there has also been a growing demand for efforts to improve the fairness of ML systems by better representing systemically disadvantaged groups in their data [4,5], such as gender and ethnic minority individuals [6-8]. To better understand the scope of this problem, frameworks to classify the various forms of bias present in ML have been developed. Our previous work used the framework developed by Mehrabi et al [5], which classified numerous types of bias according to the characteristics of each bias as well as where it would be introduced into an ML system in the cycle of providing training data (data to algorithm), the ML model interacting with the public (algorithm to user), and the public's data being used for future testing (user to data). In our earlier investigation, we delineated 9 distinct categories of ML bias that could provide avenues for age-related bias to affect ML systems [9], using the conceptual framework by Mehrabi et al [5]. In this investigation, the prevalent forms of bias from their framework were: (1) representation bias, which emerges when the data set used for training the ML model inadequately reflects the diversity of the user population compromising the performance for specific demographic groups; (2) evaluation bias, which can occur when the model is tested with unrepresentative data and inappropriate evaluation benchmarks are used; (3) aggregation bias, in which distinct demographics within a larger sample are categorized in a way that makes their unique characteristics indistinguishable; (4) algorithmic bias, where the algorithm itself is the origin of the bias leading to distorted outcomes; and (5) measurement bias, which arises from how certain features are selected, measured, and used. When data are measured or gathered using improper tools or techniques, the resulting evaluation of the data by an ML model does not reflect the relevant variables within the data [5,9]

Digital ageism is a form of ageism perpetuated through the development, use, and deployment of technology and ML models [10,11]. Recently, the World Health Organization released a brief report about age-related bias in ML models and raised critical questions about the equitable treatment of older people across various sectors [12]. The rising concerns about digital ageism highlight the pressing need for further research and policy interventions to address the potential biases and discriminatory practices that may affect older adults in the digital era [13-15]. Recent studies have demonstrated instances of digital ageism, emphasizing the urgency of designing and deploying technologically inclusive solutions to ensure equitable treatment and opportunities for individuals of all ages [16]. The exclusion of older adults from the development of digital technologies has been previously researched [15,17,18] and can manifest in many ways. Older adults may not be adequately represented in training and testing data for ML models, resulting in models with reduced accuracy for older adult data and being vulnerable to multiple intersecting disadvantages [19]. For example, older adults who live in long-term care homes may have limited access to the internet and may be excluded from technological advances [20]. Data may also aggregate older adults into arbitrary age blocks, replicating problematic assumptions that link functional decline with age and failing to represent the diversity of the older adult population [10]. The marketing strategies for these ML systems often highlight their use in health care, reinforcing the idea of aging as a period of physical and mental decline [21]. As ML models and technologies become inextricably part of accessing opportunities and services, older adults' risk of being left behind by a growing digital divide increases [22]. This is particularly alarming considering that the older population represents the fastest-growing demographic worldwide [23].

The topic of digital ageism is gaining prominence in scholarly discussions, leading researchers to investigate these phenomena from various perspectives [9,19,24,25]. Previous investigations have focused on developing conceptual frameworks to comprehend and define the nature and implications of digital ageism [13]. Previous reviews of facial image data sets have also found that older adults, particularly older adults aged 85 years or older, are underrepresented in a majority of data sets [18]. While this research has been foundational in identifying and characterizing these biases, there is now a critical need to focus on the mitigation strategies that can address age-related bias in ML models. The purpose of this scoping review is to advance this crucial discussion by shedding light on the mitigation strategies currently being used to address age-related bias in ML models. By bridging the gap between theory and practice, this research aims to pave the way for meaningful and impactful interventions that can rectify biases and promote inclusivity in the digital age. Our research focuses on two main questions: (1) Which mitigation strategies have been used to address age-related bias in artificial intelligence, and how successful were these strategies? and (2) Specifically, what types of biases were targeted and mitigated during these efforts?

Methods

Overview

This review is part of a larger scoping review about digital ageism that follows a 6-stage methodology framework developed by Arksey and O'Malley [26] and further refined by Levac et al [27]. A scoping review was appropriate to explore the study's aims of summarizing the available evidence, identifying gaps, and establishing future directions regarding mitigation strategies. As the breadth and depth of the literature are unclear, a wide and interdisciplinary approach was used [10]. The description of the review was published elsewhere [28] and registered in the Open Science Framework database [29]. This review also followed the PRISMA-ScR (Preferred Reporting for Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) format [30].

Information Sources and Search

An information specialist helped develop the search strategy in Scopus, which was then translated into 5 other databases (Web of Science, CINAHL, EMBASE, IEEE Xplore, and the ACM digital library). The search strategy included the terms "machine learning," "artificial intelligence," "algorithms," "neural networks," "deep learning," "algorithmic bias," "biased," "discrimination," "ageism," "age," and "older people."

Eligibility Criteria

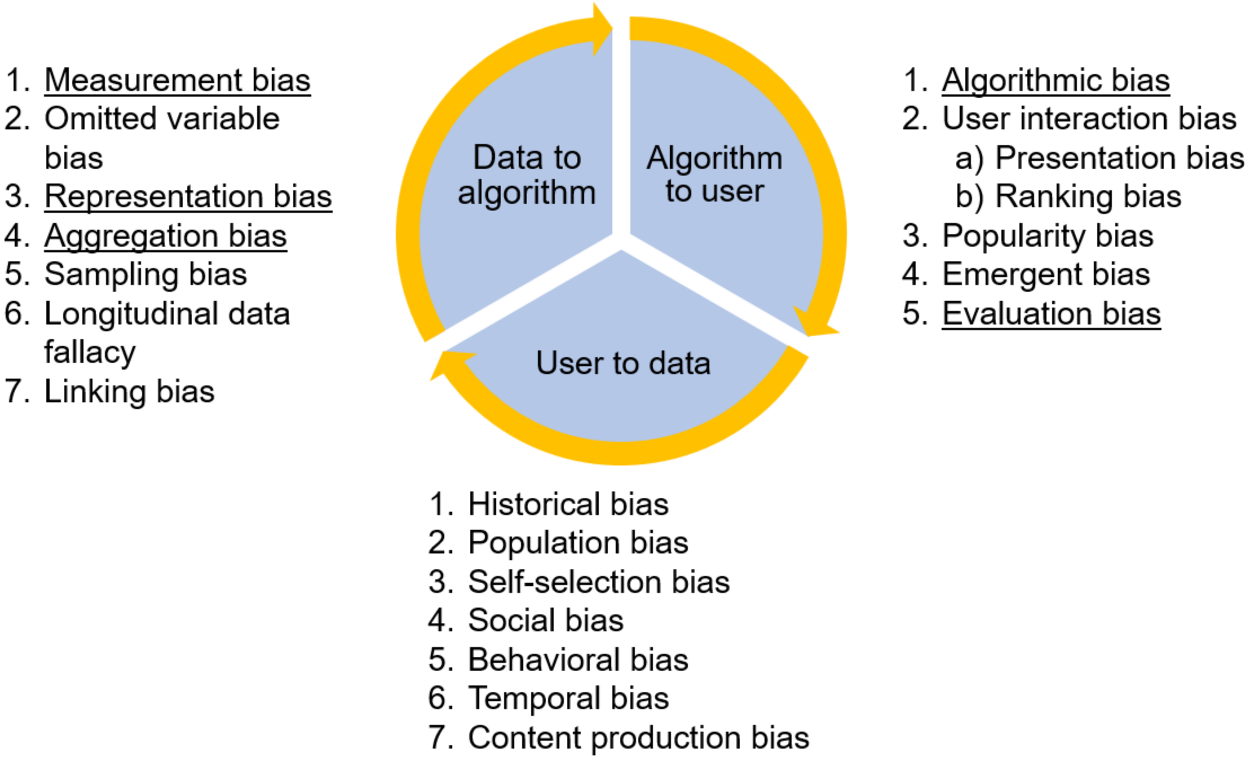
Articles were included if they were published in English and focused on "artificial intelligence" in the context of algorithms that make predictions and classifications about data; "bias"; and age-related terms such as "aging," "older," and "demographic." As the term "artificial intelligence" is over 50 years old [31], the search strategy was also not restricted by publication date, and databases were searched from inception. Papers were excluded if they included nonhuman topics. Theses, conference abstracts, dissertations, nonpeer-reviewed conference proceedings, books and book chapters, perspectives, editorials, and editorial letters were also excluded.

Selection of Sources of Evidence and Charting the Data

The academic literature search was completed in January 2022. All citations were uploaded to Covidence (Veritas Health Innovation), a systematic review software, and duplicates were removed. The titles and abstracts of all articles were screened by 2 independent reviewers according to the eligibility criteria. Once the abstract screening was complete, the full text of each article was reviewed by 2 independent reviewers to judge the article's relevance to the research questions. Data extraction included the manuscript information (title, authors, year, and location), study design, type of ML model and purpose, database used, type of data, presence of age-related bias, mitigation strategy used, and effectiveness of the strategy if reported. The framework by Mehrabi et al [5] (Figure 1 [5]), which identified different sources of biases that can affect ML according to the data-to-algorithm (data), algorithm-to-user (modeling), and user-to-data (deployment) interaction loops, was used in this review to identify the different types of bias in the included studies [5]. A total of 5 of the 19 different types of biases in the framework by Mehrabi et al [5] (Figure 1) were included in the extraction table, including representation and evaluation bias, aggregation bias, measurement bias, and algorithmic bias.

Studies were selected if they acknowledged the presence of any bias against older adults in either their data or results, and the researchers then took any action to correct that bias, regardless of its effectiveness. For example, publications were selected based on whether authors attempted to enhance the performance of their model on older demographics, regardless of the success of their efforts. Biweekly meetings were held to discuss the progress of the charting process. Disagreements were resolved through discussion or by having the first author (CC) act as a third reviewer. The extracted information was converted into table format, which allowed the authors to develop a narrative description according to the type of mitigation strategy (Table S1 in Multimedia Appendix 1 [32-42]). The team conducted additional analysis of the databases in the included studies to identify data disparities among older adults and provide further directions for future studies in the field of digital ageism. The results of the literature search are reported in tables. One of the challenges involved in assessing the inclusion of older adults involves defining the age at which someone is considered "old." While the commonly accepted age for legal recognition as a "senior citizen," based on general eligibility for a public pension, is 65 years [43], the data sets and articles we reviewed grouped older adults into a much wider range of age categories (Table S2 in Multimedia Appendix 1), starting with adults aged 50 or older. When we refer to "older adults" throughout this paper, we are referring to either (1) the participants in the data set aged 60 years or older, or else (2) the oldest age category found in the data set or publication being discussed.

Figure 1. The framework by Mehrabi et al for bias in machine learning. The specific biases discussed in this review are underlined.



Ethical Considerations

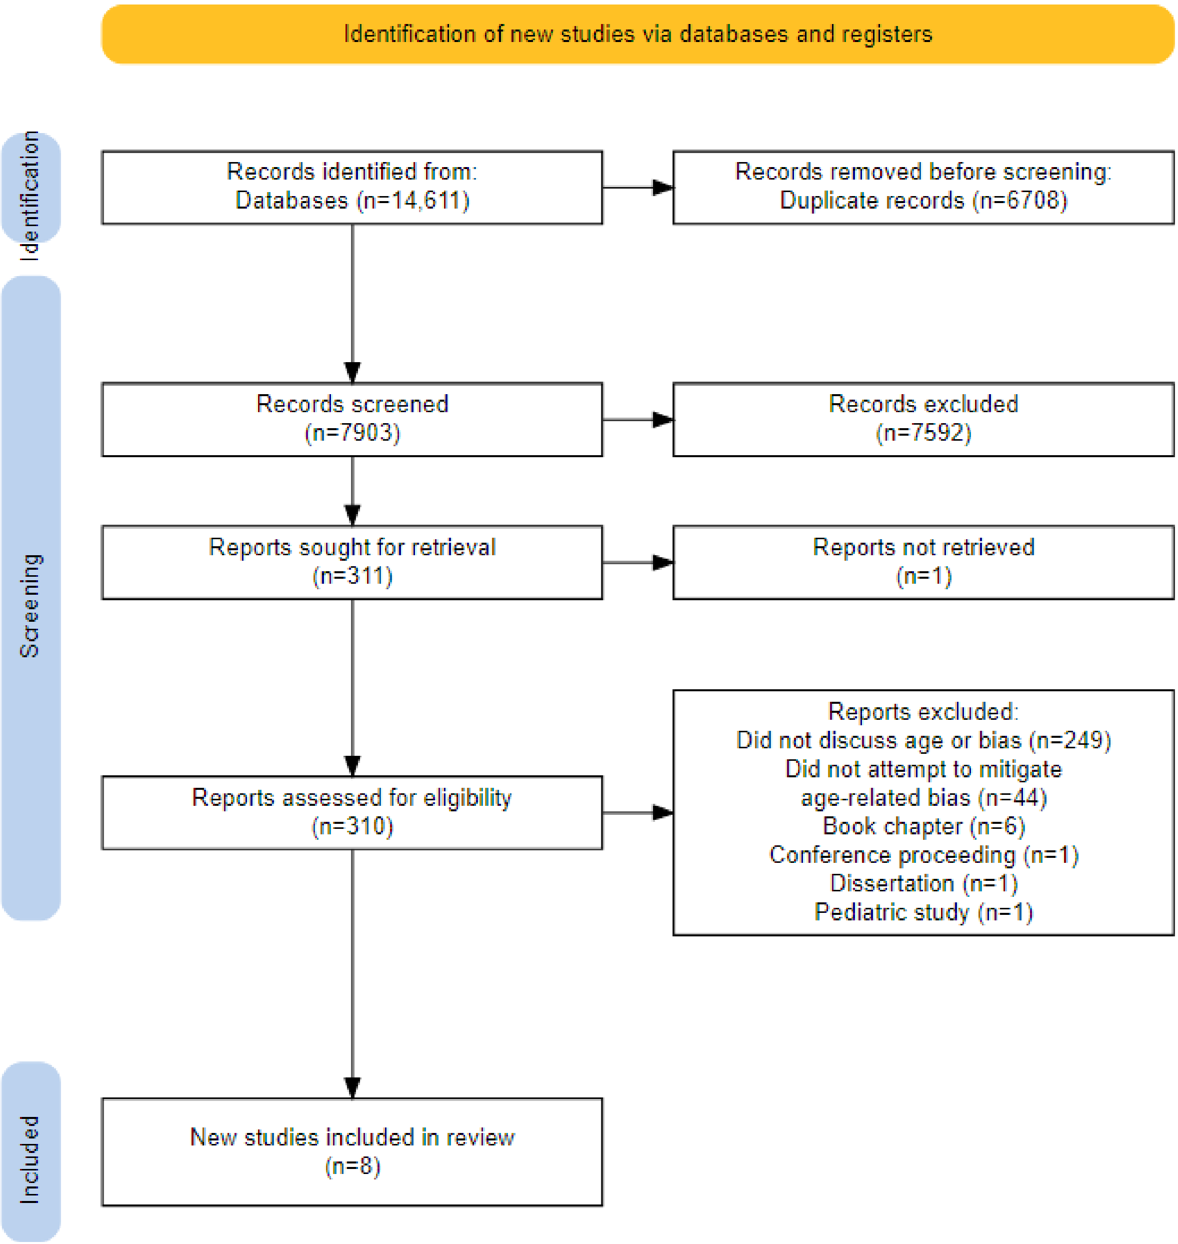
Ethics approval was obtained from the (University of Toronto) Research Ethics Board (REB #40095) for a larger study on the same topic. This study does not contain any studies with human participants performed by any of the authors.

Results

Overview

From our search, 14,611 academic publications were identified. After removing duplicates, we screened the abstracts of the remaining 7903 publications. During the abstract screening process, we excluded 7592 publications. Subsequently, we conducted a full-text screening of 310 articles, ultimately including 8 academic publications in this review (Figure 2).

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the literature review.



Types of Ageist Bias in the Selected Publications, per the Framework by Mehrabi et al

After reviewing the full text of each of the 8 publications, 5 types of bias found in the framework by Mehrabi et al [5] (Figure 1) were identified. Representation bias occurs when the data set underrepresents or misrepresents specific demographics within the overall population, resulting in a nonrepresentative data set [5]. Evaluation bias is similar to representation bias: it occurs when inappropriate evaluation benchmark data are selected to assess ML models [5]. In this review, this amounted to using the same underrepresentative data sets for training as well as testing the model, which was found to be the case in 7 publications [32-38]. Aggregation bias occurs when conclusions are drawn based on observations about a larger group, overriding unique characteristics about a smaller demographic within that group [5]. As a result, the data set fails to account for the unique characteristics of more specific demographics within the overall data set. Aggregation bias was found in 2 publications in this review [34,35]. Algorithmic bias occurs when the bias is generated at the level of the algorithm's calculation itself rather than being a by-product of biased data or measurement tools being provided to that algorithm. Algorithmic bias was found in 2 papers in this review [36,39]. Measurement bias occurs when the data being processed by the algorithm fail to represent the variable of interest accurately. It can often arise from the methods used to collect or measure the data or respective variables. Measurement bias was demonstrated in 1 publication in this review [35]. A complete list of each type of bias found in each publication, along with a rationale, can be found in Table S1 in Multimedia Appendix 1.

Data Sets Used in the Included Studies

Table S2 in Multimedia Appendix 1 presents the demographic breakdown of the data based on age to determine the extent of underrepresentation of older adults in common data sets. Overall, there was a large data disparity between the data of older adults compared with younger individuals in all the databases in this review. In the FG-Net data set, the oldest age group was "aged 61 years old or older." In this age group, the FG-Net data set only had 7 images (0.7%) [40]. In the MORPH Academic data set, there were only 3933 (7.1%) images of individuals in the "aged between 50 and 77 years" category [44], and in the MORPH Longitudinal data set, only 5615 (1.4%) of the data set's 402,055 images were from the "aged between 60 and 69 years" (5021 images) and "aged 70 years or older" (594 images) categories [45]. The CACD data set contains 163,446 images, divided into age groups of 10 years (0-10 years, 10-20 years, 20-30 years, 30-40 years, 40-50 years, 50-60 years, and 60 years or older). However, only 2912 (1.78%) of these images depict participants older than 60 years (the fifth figure in Georgopoulos et al [34]). Grouping all older adults into one 60+ demographic category also raises the risk for aggregation bias [5].

The APPA-Real data set contains 7591 images (from public internet repositories), aged between 10 and 95 years. When we combine the APPA-Real data set's 4 oldest age groups: between 60 and 70 years (254 images), between 70 and 80 years (111 images), between 80 and 90 years (68 images), and between 90 and 95 years (13 images), the combined total of 446 images accounts for just 6% of the entire data set [41]. Lastly, the 100 Celebrities data set created by Jung et al [35] has a smaller-sized balanced data set to offset the imbalances in the IMDB-Wiki and Twitter (subsequently rebranded as X) Profile data sets also used in the same study. Participants were divided into 3 age groups: between 14 and 34 years (33 images), between 35 and 55 years (34 images), and 55 years or older (33 images), with the "55 years or older" age group having equal representation with the other demographics, although grouping all older adults into 1 category of aged 55 years or older increases the likelihood of aggregation bias [5].

For the other data sets present in this review (11,000 Hands, ABIDE, CoRR, DLBS, NKI Rockland, Pilots Parliament Benchmark, and a data set comprised of Twitter Profile data), the exact data for the age demographics in each data set was not readily available (Table S2 in Multimedia Appendix 1).

Bias Mitigation Strategies

We found 8 studies that attempted to mitigate bias against older adults. The studies were all related to "computer vision" systems, systems that rely on an ML model's processing and interpretation of images, although with varying aims: 1 study focused on hand images [32], another study focused on radiological scan interpretation [36], and 6 others focused on facial images [33-35,37-39]. A complete list of the papers, the data sets that were used, and the strategies used to mitigate bias and their outcomes can be found in Table S1 in Multimedia Appendix 1. We identified 3 broad categories of bias mitigation strategies: data set balancing, data set augmentation, and algorithm alterations. This section will provide a comprehensive overview of each bias mitigation strategy and its effectiveness [34,36].

Data Set Balancing

Data set balancing involves the practice of ensuring balance within the data sets used for training and testing ML models [5]. This strategy aims to address representation bias due to the imbalance in the representation of older adults and subsequent evaluation bias against different age groups in the data set, which can lead to biased predictions and unfair outcomes [5]. By ensuring a more balanced distribution of samples across age groups, the model can learn from a more diverse and representative set of examples, reducing the potential for age-related bias. A total of 4 papers used data set balancing techniques to achieve an equitable distribution of data across different classes or categories within the data sets, such as altering their data set or creating a new data set (as was the case for Jung et al [35]) that would balance their previously unrepresentative data.

For their study to demonstrate the effect of bias on older adults with dementia on facial expression analysis models, Taati et al [39] developed a data set of test participants comprised entirely of older adults for their study. This data set was comprised of images of 86 older adults (aged 65 years or older), of whom 42 were affected by dementia and 44 were cognitively healthy, creating a balanced data set with the target population [39]. Frontal and profile photos of each participant's face were taken at baseline, and a physiotherapist guided each participant through a series of exercises to identify painful positions. Images were then annotated manually according to the facial action coding system (FACS) and the "Pain Assessment Checklist for Seniors with Limited Ability to Communicate-II" (PACSLAC-II) pain scales. This method helped avoid potential representation biases that could arise from an imbalanced representation of different cognitive states. Taati et al [39] also used a fine-tuning method, in which they pretrained their models with images of cognitively healthy older adults and then fine-tuned their models with images of cognitively impaired older adults. They found that when this strategy was tested on active appearance models (AAMs), the number of images in the fine-tuning data set with a normalized root-mean square error (NRMSE) of <5% improved from 87% to 91% accuracy. However, when fine-tuned with the same strategy, facial alignment networks (FANs) performance remained around 90% (for an NRMSE threshold of 5%). When the NRMSE threshold was lowered to 4%, the performance disparity became even more significant: AAMs and FANs both started between 65% to 70%, but the number of fine-tuning images with an NRMSE of <4% continually increased into the 75% to 80% range when the AAM was fine-tuned, while FANs did not see any increase (second and third figures in Taati et al [39]). The gaps in performance between AAMs and FANs indicate that the bias present in these results is at least partially algorithmic in nature, as both models were tested using the same strategy but only the AAMs showed any improvement [5].

In another paper, Zou et al [38] tested a model intended for cost-sensitive facial age estimation using the FG-Net and MORPH data sets, along with an image database of 14,238 images taken from Wikipedia Commons. They modified the FG-Net data set by adding images from their Wikipedia data set to balance it for age, particularly for the groups aged between 40 and 49 years and between 50 and 59 years. Doing this corrected the representation bias in the FG-Net database, 87% of which consists of participants aged 30 years or younger [38]. This mitigation strategy effectively resulted in a significant reduction in mean absolute error (MAE) for those age groups, along with a smaller reduction in MAE for the other age groups in their test. The balanced data set using the cost-sensitive function showed the lowest MAE in age predictions (MAE 8.25, SD 0.03) versus the cost-insensitive data set (MAE 9.31, SD 0.4) and an unmodified data set (MAE 8.6). This approach effectively reduced the MAE for the groups aged between 40 and 49 years and between 50 and 59 years, so it was similar to the younger groups aged between 20 and 29 years and between 30 and 39 years. However, the representation of the groups aged between 60 and 69 years and 70 and 79 years appear to have been largely unchanged (fifth figure in Zou et al [38]), with every other age category receiving a substantial number of additional images except for the 2 oldest, and as a result, the MAE for these groups seems to be substantially higher, even using the cost-sensitive model (eg, for the group aged between 60 and 69 years, the MAE was 17, and for the group aged between 70 and 79 years, the MAE was 30), while the younger age groups did not have an MAE above 10 [38].

Jung et al [35] worked with several databases on facial recognition, including the IMDB-Wiki data set, a data set composed of Twitter profile images, and the 100 Celebrities data set. Jung et al [35] created the 100 Celebrities data set after noticing that the other data sets were imbalanced for age and ethnicity. Celebrity images were selected due to the wide availability of high-quality images of celebrities from a wide range of angles and the simplicity of establishing the participant’s true age when the photo was taken (celebrity birthdates are easily determined). Creating this data set would help mitigate the representation and evaluation bias found in the IMDB-Wiki data set, although using those data sets without balancing them would still expose the outcomes to those biases [5]. Age detection by the Face++, IBM Bluemix Visual Recognition, AWS Rekognition, and Microsoft Azure Face API detection systems found that on the balanced 100 Celebrities data set, age was underestimated by 15.2 years. The highest accuracy of all the models trained on the 100 Celebrities data set was the IBM model, at 53% (although the Microsoft model achieved 66% accuracy when trained on the Twitter-Age data set). However, it is worth noting that the 100 Celebrities data set is comprised of celebrities who fall under entertainment-industry beauty standards, which may explain the large variance. While the creation of a balanced data set is a step toward mitigating biases, the fact that the age detection models still exhibited significant inaccuracies in this study raises questions about the overall effectiveness of the strategy with this specific data set. By grouping all older adults into a single category (aged 55 years or older), the 100 Celebrities data set may also increase the likelihood of aggregation bias, as mentioned in the previous section.

Finally, Liang et al [36] attempted to balance their combined data set that originally contained magnetic resonance imaging (MRI) scans of the brain from 2026 participants. These were comprised of samples from the ABIDE, CoRR, DBLS, and NKI Rockland data sets that had a higher number of participants aged 40 years or younger. To help balance representation bias within this sample, the authors resampled the full data set in 5-year age intervals to address overrepresentation and underrepresentation of age groups. They duplicated samples from overrepresented age groups to match the number of samples in underrepresented age groups (ie, participants aged 75 years or younger), resulting in a more balanced distribution of age groups within the new data set (n=782), reducing the bias toward certain age ranges, and ensuring a more representative representation of the population [26]. However, the researchers noted that a significant bias persisted even after training their model on their more balanced data set. Testing their model on the imbalanced data set returned r=.91 and an MAE of 6.77 years, while the balanced data sample returned r=.91 and an MAE of 8.02 years. The correlation between the brain-age gap and chronological age remained the same (–0.52) for both the imbalanced full data set and the balanced data sample. This indicates that, despite accounting for representation bias by balancing the data set, the strategy alone did not achieve the desired reduction in bias. Moreover, the MAE increased from 6.7 years to 8 years; although the correlation remained the same, the higher MAE suggests a decrease in the accuracy of the model’s predictions when using the balanced data set. These findings suggest that additional strategies or factors may need to be considered to further mitigate bias and improve the accuracy of the model. It is possible that the resampling strategy, while addressing representation bias to some extent, may not have fully addressed other sources of bias present in the data set. Therefore, this strategy had limited effectiveness in addressing bias while aiming to improve accuracy.

Data Augmentation

Data augmentation strategies can mitigate bias related to ageism in ML models by enhancing the diversity and representativeness of the data set. This enables the model to learn from a wide range of age groups, reducing potential bias toward specific age categories. In 3 papers that applied data augmentation techniques, the actual images in their data set were modified without adding images from an external source. For example, Georgopoulos et al [34] applied digital age progression methods to the images in the data sets selected for their study, generating realistic images of what their participants may look like as they age but modified images of the participant. Smith and Ricanek [37] used random cropping and Gaussian tinting, and Abderrahmane et al [32] used an unspecified technique.

Using the MORPH, Cross-Age Celebrities data set (CACD), and FG-Net data sets, Georgopoulos et al [34] tested the ability of a generative adversarial network (GAN) to synthesize aging patterns realistically. They divided the participants’ images from each data set into 4 groups: those aged 30 years or younger, between 31 and 40 years, between 41 and 50 years, and 51 years or older. For each data set, their model would then take an image from these data sets and either age or de-age new images for each of the other 3 categories to which the participant did not belong, creating new images for each of the other 3 age groups and balancing the data set in the process. The approach was effective in creating a data set 4 times the size of the original data set, and their results were able to significantly improve both the data set diversity (measured using the Shannon D and Simpson H metrics) and overall balance (measured using the Shannon E and Simpson E metrics) of the data sets they studied, demonstrating superior performance over contemporary models (Conditional Adversarial Auto Encoders [CAAEs] and Identity-Preserved Conditional Generative Adversarial Networks [IPCGANs]). While CAAEs generated the most accurate images for the group aged between 31 and 40 years after being trained on the MORPH data set (MAE 1.18), and IPCGANs generated the most accurate images for the demographic aged between 31 and 40 years after being trained on the CACD data set (MAE 0.04), the novel method presented in the paper was most accurate for the groups aged between 41 and 50 years and 51 years or older, for both the MORPH and CACD (MAE of 1.21 and 1.69, and MAE of 1.33 and 1.04, respectively). The images generated by the novel method also produced the best scores on the Simpson and Shannon data diversity indices after augmenting the MORPH, CACD, and FG-Net databases. This approach effectively reduced the representation and evaluation bias against older adults in these data sets. In doing so, the researchers acknowledged the possibility of their model enabling researchers to overcome demographic bias in facial image data sets, the most popular of which heavily underrepresent older adults [34]. The method used could also have the impact of increasing aggregation bias, as all older adults were grouped into a single group (aged 51 years or older) [5].

Smith and Ricanek [37] studied age and gender prediction models using data sets taken from IMDB, Wikipedia, and the MORPH data sets, which underrepresent older adults and present representation and evaluation bias [37]. They sought to expand the robustness of their data sets by applying random data-augmentation policies, which are transformation techniques used to modify existing data. For instance, they used random cropping and Gaussian tinting techniques to increase the diversity of the images in the data set. After training and testing, they also composed a separate challenge data set, which applied the data-augmentation policies to images from categories that their model had difficulty identifying accurately, including female individuals, older adults, and individuals with darker skin. The MORPH data set lacks images of older adults, so adding additional images was effective in addressing representation and evaluation bias in the data set [5]. The data augmentation policies would be randomly applied to these images as they were loaded during training [37]. This method to augment the training data was effective, as the overall MAE fell from 4.62 to 4.21, with a final MAE of 4.13 for male individuals and 4.90 for female individuals. The overall gender prediction accuracy increased slightly, from 98.44% to 98.92%.

Abderrahmane et al [32] developed an algorithm for age prediction based on hand images. They acknowledged that their data set initially had a highly imbalanced age distribution, which could introduce bias in their model. To address this, they used data augmentation techniques to create a more balanced data set from the 11,000 Hands Database, which contained 11,000 images of hands from 190 participants, showing the dorsal and palmar aspects. The authors recognized that the data set was underrepresentative of older adults and appeared to use data augmentation to balance the data set. There were no specific details regarding the augmentation processes used, but the figures suggest that additional images were added to the data set to address the underrepresentation of certain age groups. The underrepresentation of older adults in the 11,000 Hands data set is noteworthy in light of the significant use of hand images to represent older adults (more details on this issue have been provided in the *Discussion* section).

Algorithmic Alteration

Papers were listed under algorithmic alteration if the researchers adjusted the calculations of their algorithm itself and applied statistical methods to their algorithms to reduce the bias in their outcomes [5]. We found that 2 papers had adjusted their algorithms to improve performance [33,36]. Liang et al [36] applied linear regression to correct for the bias produced by their model after balancing the data set, which proved unsuccessful. Noticing a bias in age prediction based on MRI scans, which resulted in less accurate predictions for older participants, they unsuccessfully attempted to balance their combined data set, as was previously discussed. After examining multiple possible additional sources of the bias, including noise within the data, heterogeneity of the data sets, and the use of specific ML models, they were able to correct the bias statistically with a linear regression, fitting a linear regression model for predicted age to the chronological age and sex that improved MAE. By ruling out the other sources of bias (such as representation and evaluation bias, which they corrected for by balancing their data set), they were able to determine that the algorithm itself was the source of the issue (algorithmic bias, per the framework by Mehrabi et al [5]). The study by Liang et al [36] is unique in that they attempted to correct for more than one type of bias: first working on representation bias, and then solving for algorithmic bias (biases introduced by the algorithm itself) after balancing their data set was unsuccessful, which was an overall effective approach.

In the second paper, Clapes et al [33] sought to correct the bias between estimated age and true age by dividing participants into smaller groups based on mutually exclusive image categories and recalculating the estimated age for each real age. This produced a fitted curve for the difference between estimated and real ages, which was then used to correct the bias between the estimated and real ages. Linear interpolation was used to correct bias for ages that had fewer examples. This effectively addressed the measurement bias in the study. Clapes et al [33] also added labels for expression, ethnicity, makeup, gender, and the age of the photograph itself to the APPA real database. The resultant model's overall performance improved, reducing the MAE from 13.57 to 12.07. The reduced representation of older adults is mirrored by trends in the consistency between age predictions in Clapes et al [33], where the difference between real age and estimated age widens as age increases (panels A-F in the eighth figure in Clapes et al [33]), which they theorized was due to the decreasing representation of older age groups (ie, representation bias).

Discussion

Overview

Our review included 8 publications that used mitigation strategies to address age-related bias. To our knowledge, this is the first review to examine this topic. Our analysis revealed that age-related bias predominantly stemmed from the underrepresentation of older adults in the data sets used to build the models (representation bias). Notwithstanding the 100 Celebrities data set, the data sets in this study (for which data were available) contained only 0.05% to 7% of data representing older adults. Our first research question explored the variety of strategies used to address this bias and their effectiveness. Researchers used three approaches: (1) creating a smaller yet more balanced data sample from their existing data set (n=4) [35,36,38,39], (2) augmenting and supplementing the available data (n=3) [32,34,37], and (3) modifying the algorithm directly to account for bias specifically (n=2) [33,36]. There was heterogeneity in the outcome measures, so a meta-analysis was not possible. Our findings emphasize the multifaceted nature of bias in ML models and the strategies available to address it, as well as the critical imperative of identifying and mitigating age-related bias in ML models to ensure fairness and equity for older adults in society [32-39].

The effectiveness of mitigation strategies aimed at reducing age-related bias in ML models varied based on several factors, including the types of data used, the ML approaches used, and the specific purpose of the ML model. While the included papers covered a range of uses, including facial and age recognition and MRI brain-scan interpretation, it is crucial for researchers to recognize that the solutions that may apply to one type of model may not apply to others due to qualitative differences in the data each model depends on. While many researchers reported successful outcomes with their methods, some encountered challenges and limitations. Jung et al [35] conducted experiments with a more balanced data set but found that the accuracy of their model reached a peak of only 53%. This suggests that achieving complete mitigation of age-related bias may be difficult, even with an improved data set balance. Taati et al [39] explored a mitigation strategy that showed mixed results and discovered that adding images of older adults affected by dementia to the training data for models trained on cognitively healthy older adults improved landmark detection significantly, but this approach improved the performance of AAMs significantly more than FANs. This highlights how specific types of algorithms can affect outcomes and how that must be considered when selecting which models to use when attempting to reduce bias. In a follow-up study, Asgarian et al [40] also identified performance differences in models intended to identify facial landmarks between healthy older adults and older adults with dementia [46]. In another example, Liang et al [36] encountered challenges in their attempts to balance data set representation and ultimately settled on a linear regression alteration for their algorithm. Making algorithmic alterations appears to have been most effective at mitigating measurement bias, but this is an extremely small sample (n=2) [33,36]. Overall, these findings highlight the complexity and context-dependence of mitigating age-related bias in ML models. While some strategies showed promising results, achieving complete elimination of bias remains challenging, and alternative approaches may need to be explored. Researchers must consider how both the data and the models they are using may affect outcomes.

Our second research question explored the types of bias being mitigated. Our previous work has demonstrated that age-related bias is present across the ML life cycle [9]. Bias affects ML models at multiple levels, including the data that trains the models (data to algorithm), the models themselves (algorithm to user), and the people who rely on the models (user to data) [5]. Our results found that researchers who attempted to correct for bias primarily focused on representation bias (n=7), with algorithmic bias (n=2) and measurement bias (n=1) being far less common targets of mitigation efforts. Representation and evaluation bias and measurement bias were most commonly mitigated by data set balancing [35,36,38,39], but this method did not consistently achieve the desired reduction in bias [35,36], while algorithmic bias [33,36] was resolved by algorithmic alterations, to the satisfaction of their respective authors.

Moreover, we noted that 2 papers may have aggregation bias [34,35], which occurs when a demographic is grouped in a way that does not account for its heterogeneity [5]. Many data sets in this review grouped all older adults into arbitrarily large categories (eg, those who were aged 55 years or older and 60 years or older). For example, Georgopoulos et al [34] aggregated the oldest participants into a single category of those aged 50 years or older [34]. While this worked to address one type of bias (representation bias), it reinforced another type of bias (aggregation bias), which impacts older adults significantly and essentially erases older adults as a distinct group, given that the legal cutoff to be considered a senior citizen is usually 65 years old [5]. While the 100 Celebrities data set by Jung et al [35] offered older adults equal representation compared with other age groups, it also grouped all older adults into a single category (ie, aged 55 years or older). This point of discussion holds significance but is often not fully acknowledged when tackling bias in ML. It highlights that bias can manifest in various interconnected ways, and while addressing the most prominent and evident forms of bias remains crucial, it may not completely eradicate bias from a model. Much of the discussion of bias in ML focuses on representation bias of specific demographics (it was the most common type of bias in this review), but there are other forms of bias that may be more easily neglected (such as aggregation bias, which was not addressed in the included studies). Sometimes, efforts to mitigate bias did not reach the data set's oldest demographics. Panel 5A from the fifth figure in Zou et al [38] shows that the authors only balanced the FG-Net data set, and while they balanced the representation for all other age groups, they did not significantly improve the representation of the groups aged between 60 and 69 years and 70 and 79 years, which remained underrepresented. There are also ageist contradictions that emerge when representation is examined, with the strongest example in these papers being how even the images of the hands of older people were underrepresented in the 11,000 Hands data set, despite the prominence of wrinkled, disembodied hands as a dominant social representation of older people in media and societal images [47]. Such imagery may have a dehumanizing effect by portraying older adults as a pair of hands rather than a face or a whole person, which could result in their apparent exclusion from a data set of images with similar subject matter being compiled for practical purposes [48].

An important implication is for developers to consider the practical significance or real-world impact of the mitigation strategy. For example, Clapes et al [33] reduced their MAE from 13.6 to 12.1, while Smith and Ricanek [37] reduced their overall MAE from 4.6 to 4.2, with a final MAE of 4.1 for male individuals and 4.9 for female individuals. While these are quantifiable improvements, it is also important to consider the extent of an improvement and whether it has practical meaning or relevance in decision-making processes.

To address age-related bias in ML, researchers and designers can take steps from research design, methodology, and technical perspectives to ensure that technology is accessible and inclusive. From a research design perspective, an alternative mitigation strategy for developers collecting their data sets is to provide a representative sample of participants. Jung et al [35] created an age prediction training data set using celebrity images from IMDB. The researchers intended to create balanced data sets for their target populations, which aimed to prevent representation and evaluation bias, reducing the potential for age-related biases in the analysis and evaluation of the data. Although the effectiveness of this specific approach is not explicitly stated, the use of balanced data sets likely played a role in mitigating potential biases stemming from an imbalanced representation of age groups. Consequently, their study results may be more reliable and less susceptible to age-related biases, contributing to a more unbiased understanding of age recognition algorithms (although they may still be affected by other varieties of bias, as was previously discussed). By emphasizing the importance of representative sampling and the creation of balanced data sets, researchers can minimize the risk of introducing age-related biases into artificial intelligence systems and foster more accurate and equitable results.

Lastly, promoting the consideration of age as a variable of interest could help draw the attention of researchers and developers to digital ageism and disparities within their data sets. Recognizing age as a crucial factor requires a multidisciplinary approach that involves educational institutions, industry leaders, and policy makers. Within educational curricula, emphasizing the significance of critical demographic parameters can sensitize future engineers and computer scientists to the diverse needs of populations, including older adults. Technical approaches that use robust statistical approaches can begin to minimize age-related bias in ML. Techniques such as stratification and oversampling can ensure adequate representation of older adults in training data sets, attenuating the risk of underperformance or misclassification for this demographic group. These techniques are particularly relevant where the intersections of social locations of age and known underrepresentations of disability, race, and sexual orientation in ML models are concerned for 3 reasons. First, many of these types of bias (racism, sexism, and ageism) have their roots in similar problems, such as underrepresentation [4,9]. For example, a 2022 study of 21 age-recognition systems found that artificial intelligence systems consistently identified age with less accuracy across all age, gender, and ethnic categories, which the authors speculated was due to older adults being underrepresented in training data [49]. Second, the methods used to balance age-related bias in these papers may also have applications for other types of bias. For example, Sixta et al [50] reported a combination of strategies to reduce bias, including balancing their data for underrepresented demographics using external data and then further augmenting the data with different lighting and image quality adjustments. Third, the discussion around these types of bias in ML is much broader than the focus on digital ageism, making them an effective tool for drawing attention to these issues and advancing work in this area [9]. In a comparison of commercial facial emotional recognition (FER) systems, Kim et al [51] found that performance did improve for all demographics from 2019 to 2020, but that FER systems still performed best on younger adults and most poorly on older adults. The “black box” nature of these commercial systems, in which the method’s underlying algorithm is inaccessible, makes it impossible for external reviewers to assess the source of these improvements from an algorithmic standpoint [51]. However, digital ageism is not limited to ML and is a broader issue that stems from societal biases in the design, development, and deployment of ML models [9,16]. The multivalent nature of age-related bias in ML requires solutions from multiple sectors of society, including the public, private developers, government, and academic research [24]. Future research should focus on developing a global consensus of priorities that can mobilize the multitude of players from these sectors to advance knowledge about age-related bias and best practices to address this bias.

Limitations

One limitation of this study is the exclusion of publications in languages other than English, potentially excluding the viewpoints and solutions to these challenges found within other cultures. Also, our review would not have captured all examples of implicit age-related bias, only in papers that mentioned the keyword “bias.” However, the studies included in this review can serve as exemplars of implicit and explicit bias. The implicit nature of ageism in the context of the technology sector with limited ethical oversight and regulations underscores the importance of further research and policy development. Our review also only examined papers that attempted to mitigate age-related bias, not other types of bias (such as gender- or ethnicity-related biases). One major concern is that these biases and omissions may continue to produce exclusion and push older people whose experiences are not read as “youthful” further outside the peripheries of shared social and cultural everyday spaces, including (but not limited to) those mediated through technological systems. This is perhaps especially the case where age intersects with locations already known to experience bias, such as gender, race, and ethnicity.

Conclusion

This study explored and synthesized mitigation strategies for age-related bias in ML. The results underscore the value of 3 primary strategies for bias mitigation: data set balancing, data augmentation, and statistical techniques. However, the efficacy of these tactics demonstrated variability contingent upon factors such as data type, ML methodologies, and the intended purpose of the ML model. Although some researchers reported successful outcomes by diversifying their data sets, achieving complete elimination of bias remains challenging, and alternative approaches should be explored. The practical significance of the intervention should also be considered, as improvements in bias reduction may not always have substantial real-world impact, and further bias reduction and mitigation may still be required. A greater understanding of how digital ageism and age-related bias are propagated in ML and reproduced is needed across multiple sectors, including researchers and policy makers. Future research and policy agendas should include developing collaborative, comprehensive transdisciplinary strategies to foster fairness and inclusivity in the digital landscape.

Data Availability

Data sharing is not applicable to this article as no data sets were generated or analyzed during this study.

Conflicts of Interest

None declared.

Multimedia Appendix 1

Extracted information. The following data sets appeared in publications included in this review, but subject demographic data was not readily available; thus, they were not included in the tables: 11k Hands, ABIDE, CoRR, DLBS, NKI Rockland, Pilots Parliament Benchmark, and a data set comprised of Twitter Profile data.

Abstract

Background: Long-term care (LTC) homes face the challenges of increasing care needs of residents and a shortage of health care providers. Literature suggests that artificial intelligence (AI)–enabled robots may solve such challenges and support person-centered care. There is a dearth of literature exploring the perspectives of health care providers, which are crucial to implementing AI-enabled robots.

Objective: This scoping review aims to explore this scant body of literature to answer two questions: (1) what barriers do health care providers perceive in adopting AI-enabled robots in LTC homes? (2) What strategies can be taken to overcome these barriers to the adoption of AI-enabled robots in LTC homes?

Methods: We are a team consisting of 3 researchers, 2 health care providers, 2 research trainees, and 1 older adult partner with diverse disciplines in nursing, social work, engineering, and medicine. Referring to the Joanna Briggs Institute methodology, our team searched databases (CINAHL, MEDLINE, PsycINFO, Web of Science, ProQuest, and Google Scholar) for peer-reviewed and gray literature, screened the literature, and extracted the data. We analyzed the data as a team. We compared our findings with the Person-Centered Practice Framework and Consolidated Framework for Implementation Research to further our understanding of the findings.

Results: This review includes 33 articles that met the inclusion criteria. We identified three barriers to AI-enabled robot adoption: (1) perceived technical complexity and limitation; (2) negative impact, doubted usefulness, and ethical concerns; and (3) resource limitations. Strategies to mitigate these barriers were also explored: (1) accommodate the various needs of residents and health care providers, (2) increase the understanding of the benefits of using robots, (3) review and overcome the safety issues, and (4) boost interest in the use of robots and provide training.

Conclusions: Previous literature suggested using AI-enabled robots to resolve the challenges of increasing care needs and staff shortages in LTC. Yet, our findings show that health care providers might not use robots because of different considerations. The implication is that the voices of health care providers need to be included in using robots.

Introduction

Background

Long-term care (LTC) provides various services designed to meet the chronic health and personal care needs of those who can no longer perform daily activities independently [1]. LTC health care providers face challenges to meet the increased demand from older adults and their family caregivers due to a dramatically increasing aging population and growing chronic disease burden [2]. Health care providers in LTC homes often engage in repetitive tasks, many involving physical labor, which could lead to a high risk of job stress, physical or emotional exhaustion, burnout, and high turnover, all of which contribute to a lower quality of care [3-5]. Thus, innovative solutions are required to meet LTC home residents' health care needs and reduce the workload for health care providers.

Artificial intelligence (AI)–enabled robots have been perceived as a solution to the crisis in LTC homes, where significant labor shortages will accompany rapidly increasing care demand [6-8]. AI-enabled robots have been used to support person-centered care for older adults and attend to the emotional, social, and physical needs of older adults. For example, PARO, a socially assistive robot, can interact with and provide emotional support for patients with dementia [9]. Physically assistive robots can perform tasks such as dressing and sit-to-stand support [10]. Evidence has suggested that using AI-enabled robots in LTC homes could optimize resources, enhance resident outcomes, create patient-centered care, satisfy residents' needs, and improve health care providers' workflow [2]. While AI-enabled robots may potentially alleviate the burden on health care workers and enhance efficiency in LTC homes, they also pose risks. Issues associated with AI-enabled robot use were explored in the literature. In LTC homes, the adoption and use of robotics are associated with ethical issues and technological risks such as safety, privacy and data security, liability, and effects on the incumbent workforce [11]. Accordingly, research has been focusing on examining attitudes and perceptions of AI-enabled robots [12].

Recent AI-enabled robot studies evaluate the acceptance of this technology in older users, including in the settings of care facilities, as well as private homes and living lab contexts [13-18]. Findings of the literature show that older adults are generally open to robot assistants, while robots provide social interactions, cognitive stimulation, home-based tasks, personal care, and information management [19,20]. However, very few studies have been focused on measuring the health care providers' perception of AI use, although their acceptance of AI-enabled robots is crucial to future research and development and the implementation of AI-enabled robots in LTC homes [21]. Some studies have shown that approximately 40% of technologies, such as home health care robots and information systems, have been abandoned in the last 2 decades [22,23]. Several barriers to health care providers' adoption of AI-enabled robots were explored, including clinicians' inadequate knowledge [24] and lack of understanding of the sociotechnical aspects of the technology [24]. These barriers lead to a fear of job loss among health care staff, who are concerned about being replaced by robots for repetitive or manual tasks, even when robots are intended to assist rather than replace workers [21,24]. Therefore, understanding the perspectives of health care providers on AI-enabled robot use is crucial, as they can offer the most pertinent insights into the risks and impacts, as well as to understand users' needs and expectations [25].

This scoping review aims to synthesize and analyze the existing literature on the potential barriers and the strategies to overcome these barriers by adopting AI-enabled robots in LTC homes from the perspectives of health care providers. Two research questions guided the review: (1) what barriers do health care providers perceive in adopting AI-enabled robots in LTC homes? (2) What strategies can be taken to overcome these barriers to the adoption of AI-enabled robots in LTC homes?

To our knowledge, no scoping review has been conducted on this topic. Existing scoping reviews focus on using AI in older adult care or health care, such as promoting shared health care decision-making [26], monitoring diabetes-related parameters [27], and facilitating digital health care interventions [28]. However, these settings are not LTC homes. There are also scoping reviews on LTC homes, such as making decisions about moving into LTC homes [29] and physical rehabilitation in LTC homes [30]. Yet, they are not related to the use of technology. There are scoping reviews about technologies in LTC homes, such as using eHealth to support assessment and decision-making with residents living with dementia in LTC homes [31] and defining the concepts of smart nursing homes and technology-assisted LTC homes [32]. Nevertheless, these reviews are not specifically about AI. Lukkien et al [33] conducted a scoping review about responsible AI, that is, using AI ethically in LTC homes. Yet, the review is from the perspectives of researchers, not health care providers.

The paper addresses the critical gap concerning LTC health care providers' perspectives in adopting AI robots. Staff perspectives are essential as they directly impact the acceptance, use, and effectiveness of AI technologies in care settings. Our findings highlight the importance of an inclusive approach to engaging LTC staff in robot development and implementation. The practical insights and strategies can empower staff to support the integration of AI technologies into LTC.

To begin with, we will define some terms used in this paper. We have published a protocol for this scoping review and will refer to the definitions of *robot*, *AI*, and *AI-enabled robot* as outlined in the protocol [34]: "*Robots* are mechanical devices that can be of various physical forms and are designed to perform a wide range of tasks.... *AI* is known as 'the science of making [a] machine or computer to act intelligently'.... The *AI-enabled robot*, or intelligence robot, can be defined as 'a physically situated intelligent agent in the "real world," regardless of shape, that can sense and act on its operational environment.' AI allows robots to (a) present the world symbolically in a way that can be easily understood by computers, (b) understand natural language and explore clear communication required for comfortable social interaction between humans and robots, (c) learn by self-iterative trials and apply that learning to a range of functions, (d) plan and solve problems, (e) generate an answer without complete information,

(f) use search algorithms to generate solutions in navigation or search for optimal knowledge representation and (g) improve robotic actions with vision systems in the robots" [35]. *Health care providers* refer to paid staff caring for LTC home residents (eg, nurses, care aides, and allied health professionals). *LTC* refers to "care settings that provide 24-hour personal care support for people with complex needs who are unable to remain at home" [34].

Theoretical Frameworks

In this scoping review, the Person-Centered Practice Framework (PCPF) [36] and Consolidated Framework for Implementation Research (CFIR) [37] are the supplementary theoretical frameworks that guided our synthesis and analysis of results to explore the barriers and the strategies to overcome these barriers to the adoption of AI-enabled robots in LTC homes.

PCPF Philosophy

McCormack and McCance [38] coined *PCPF*. Person-centered care is a care philosophy with people living with dementia [39]. Despite cognitive impairment, person-centered care recognizes that a person living with dementia still has personhood; should be seen as a person; and has diverse needs, such as psychosocial needs, which need to be met by care to achieve the person's holistic well-being. PCPF provides a framework for understanding the factors influencing the practice of person-centered care with people living with dementia [38,40]. Our review focuses on adopting AI-enabled robots to care for people with dementia. PCPF is, therefore, a good fit for our review. PCPF initially focuses on nursing practice with people living with dementia [38]. However, gradually, it has been adopted by other disciplines, such as social work [41] and rehabilitation [39]. PCPF is an evolving framework since its first publication in 2001; its author continues to enhance it over the years by absorbing lessons from new research and practice [36,38,40]. We have adopted the latest version of PCPF as published by the authors in 2023 [36].

PCPF comprises 5 domains: prerequisite, practice environment, person-centered process, outcome, and macrocontext. Figure 1 presents the framework from the authors' recent publication in 2023 [36].

Figure 1. Developing healthful cultures through the development of person-centered practice. Reproduced from McCance and McCormack [36] with permission from Elsevier.

PCPF considers that person-centered care practice is shaped not only by factors at the level of the patient and the health care provider but also by factors at the level of organization and society. These domains are interrelated with each other, as elaborated by the authors [36]: "to reach the centre of the framework, one must first take account of the *macrocontext*, followed by consideration of the attributes of staff, as a *prerequisite* to managing the practice *environment*, and in order to engage effectively through the *person-centred processes*. This ordering ultimately leads to the achievement of the *outcome*." Under each of the 5 domains, there are constructs. There is no hierarchy among the constructs; constructs in the same domain can be related or even overlap [36].

The *prerequisite* domain examines the "attributes" of health care providers required to provide person-centered care, and the constructs under this domain are "being professionally competent, having developed interpersonal skills, being committed to the job, being able to demonstrate clarity of beliefs and values, and knowing self" [36]. The practice *environment* domain looks into "the context," that is, the care setting and organization, where person-centered care is provided, and under this domain, the constructs include "appropriate skill mix; systems that facilitate shared decision making; the sharing of power; effective staff relationships; organisational systems that are supportive; potential for innovation and risk taking; and the physical environment" [36]. The *person-centered process* domain explores health care providers' "ways of engaging that are necessary to create connections between persons (living with dementia)," and the constructs under this domain include "working with the person's beliefs and values; engaging authentically; being sympathetically present; sharing decision making; and working holistically" [36]. The *outcome domain* looks into the "result of effective person-centred practice," and the authors suggest that effective person-centered practice should "enable human flourishing for those who give care and for those who receive care" [36]. Under this domain, the constructs are that "decision-making is shared, relationships are collaborative, leadership is transformational, and innovative practices are supported" [36]. The *macrocontext* domain refers to regional, national, and international "factors that are strategic and political in nature that influence the development of person-centred cultures" [36]. The constructs under this domain include "policy frameworks, strategic frameworks, workforce developments, and strategic leadership" [36].

CFIR Framework

Damschroder et al [42] developed the CFIR by consolidating constructs from 19 implementation frameworks or theories in 2009. The authors updated it by incorporating new literature and feedback in 2022 [43,44]. Our review will refer to the latest version of CFIR, which is freely accessible on the CFIR website [45]. CFIR is a framework for understanding the contextual factors that influence implementation in a clinical setting or organization [44]. Our review concerns the implementation of AI-enabled robots in LTC. Thus, CFIR and our review are a good match. In addition, previous literature suggested that CFIR can be used with other frameworks [44]. In our review, we are using it with PCPF.

According to the authors, one way to use CFIR is to better understand the findings on implementation [44]. We will use CFIR to understand the findings from the literature on health care providers' perspectives on the barriers to implementing AI-enabled robots and the strategies for overcoming them. The authors suggested 2 approaches to using CFIR to understand the findings on implementation: deductive and inductive. Our study will use a mixed approach, which will be further elaborated.

CFIR comprises 5 domains: innovation, inner setting, outer setting, individuals, and implementation process; there are constructs under each domain, and CFIR has 48 constructs in total [37]. The *innovation domain* explores "the 'thing' being implemented," such as research, programs, policies, and innovations [37]. The constructs under this domain include "innovation source, innovation evidence-base, innovation relative advantage, innovation adaptability, innovation trialability, innovation complexity, innovation design, and innovation cost" [37]. The *outer setting domain* examines "the setting in which the inner setting exists," such as the health and community organizations [37]. Under this domain, the constructs are "critical incidents, local attitudes, local conditions, partnerships and connections, policies and laws, financing, and external pressure" [37]. The *inner setting domain* looks into "the setting in which the innovation is implemented," such as an LTC home or a hospital [37]. The constructs under this domain are "structural characteristics, relational connections, communications, culture, tension for change, compatibility, relative priority, incentive systems, mission alignment, available resources, and access to knowledge and information" [37]. The *individuals domain* explores "the roles and characteristics of individuals" involved in implementation [37]. Under this domain, the constructs include "high-level leaders, midlevel leaders, opinion leaders, implementation facilitators, implementation leads, implementation team members, other implementation support, innovation deliverers, and innovation recipients" [37]. The *implementation process domain* examines "the activities and strategies used to implement the innovation" [37]. The constructs under this domain are "teaming, assessing needs, assessing context, planning, tailoring strategies, engaging, doing, reflecting and evaluating, and adapting" [37].

Methods

Overview

Scoping reviews are pivotal for identifying and summarizing evidence in emergent fields and highlighting significant themes, contexts, and research gaps [46]. Given the nascent stage of AI-enabled robots in LTC homes, a scoping review was apt for our study. Our interdisciplinary review team was comprised 3 researchers, 2 health care providers, 2 research trainees, and 1 older adult partner. We each brought different expertise: researchers and research trainees brought research knowledge and skills, health care providers brought frontline experiences, and the older adult partner brought in lived expertise. Our group represented diverse backgrounds: nursing, social work, engineering, and medicine. Diverse expertise and backgrounds enriched our team discussions, especially during data analysis. We followed the guidelines on scoping reviews outlined by the Joanna Briggs Institute [47]. We published the objectives, inclusion criteria, and methods of this scoping review in a protocol [34]. We conducted the scoping review over 6 months. As data were synthesized solely from existing literature, ethics approval was not required for this scoping review.

Search Strategy

We followed the three-step search approach recommended by Joanna Briggs Institute: (1) conducting a preliminary search using 2 databases (MEDLINE and CINAHL) to identify keywords and index terms; (2) using keywords and index terms from the previous step to search selected databases (CINAHL, MEDLINE, PsycINFO, Web of Science, ProQuest, and Google Scholar); and (3) hand-searching the reference lists of selected items.

The participants, context, and concept of our scoping review were as follows: participants were health care providers working with older adults in LTC, the context was LTC, and the concept was AI-enabled robots. The search string was based on these participants, context, and concept, that is, “healthcare provider” AND “older adult” AND “LTC” AND “AI.” Our search was limited to the items published in the last 10 years (2013-2023), and we only included publications in English.

Item Selection

We used a web-based software platform, Covidence (Veritas Health Innovation), to assist us in conducting the scoping review. Initially, we identified 279 items and uploaded them to Covidence. Subsequently, we performed 2 screening levels according to the inclusion and exclusion criteria (Textbox 1).

We adopted an inclusive approach to how we considered a robot an AI-enabled robot. We considered a robot an AI-enabled robot if it has AI features according to our AI-enabled robot definition as mentioned in the Introduction section. Textbox 2 explains how each robot included in this scoping review is related to our AI-enabled definition.

Textbox 1. Eligibility criteria.

Inclusion criteria

- Includes health care providers working with older adults in long-term care (LTC) homes
- Includes artificial intelligence (AI)–enabled robots
- Includes LTC home setting
- Published in English language
- All study designs (eg, qualitative, quantitative, and mixed methods)
- All sources (eg, peer-reviewed journal articles, books and book chapters, conference proceedings, reports, theses, and dissertations)
- Include data that address the 2 objectives of our paper

Exclusion criteria

- Does not include health care providers working with older adults
- Does not include AI-enabled robots
- Acute care or community settings other than LTC home (eg, home care, older adult care centers, and adult day health care programs)
- Published in language other than English
- Do not include data that address the 2 objectives of our paper

Textbox 2. How robots are related to artificial intelligence (AI) by definition.

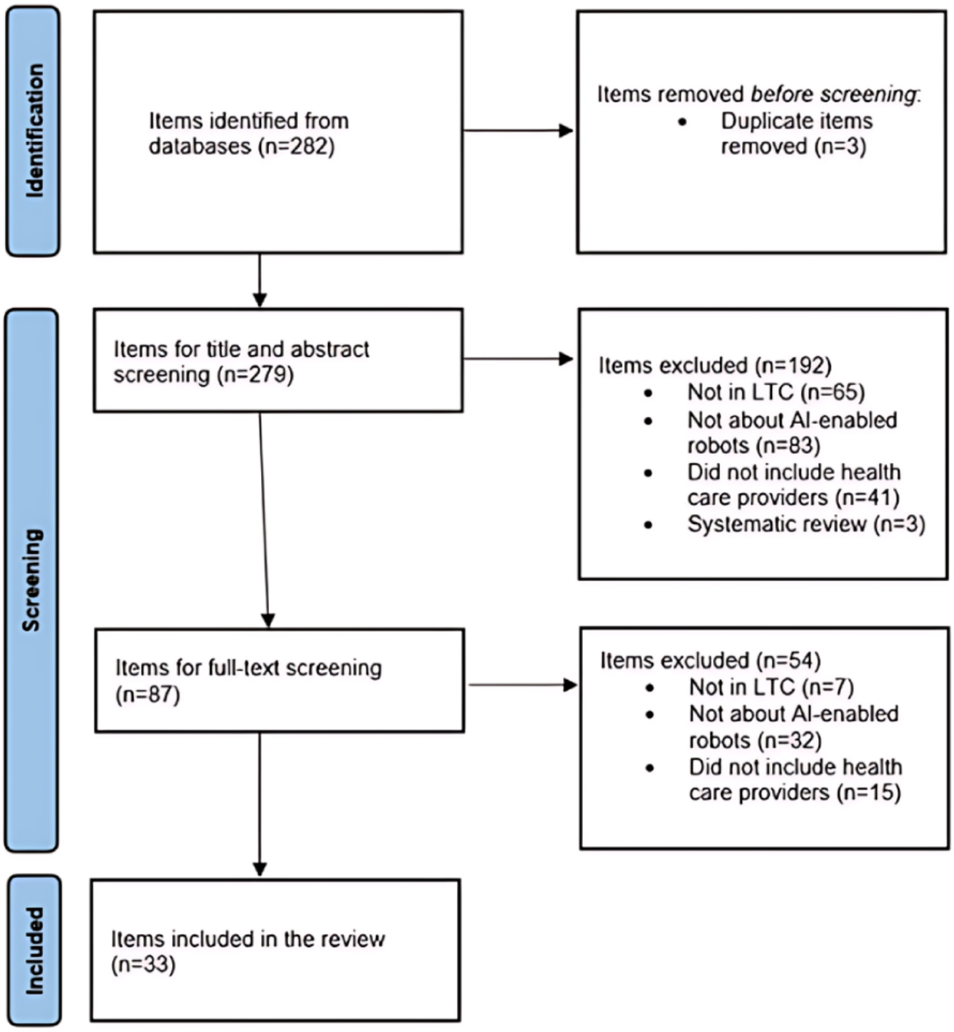
Robot name and how it is related to AI by definition

- Stevie [48,49]
    - Stevie is a social robot designed to be used in care settings for older adults. The robot incorporates AI to enhance its functionality and communication abilities. Like other AI-enabled robots, Stevie II can autonomously map and navigate 3D environments in real time. Unlike other robots, Stevie uses AI to support its enhanced communication functionality. Through the use of humanlike speech, gestures, and facial expressions, the robot is able to engage in clear communication required for social interaction. Furthermore, the robot leverages AI to perform various tasks such as setting reminders, entertaining older adults, and problem-solving.
- PARO [50]
    - PARO is a seal-shaped interactive robot that incorporates sensory receptors to interface with its environment. The robot is used in various health care environments to reduce stress anxiety, improve socialization, and so on by replicating the effects of animal therapy. PARO can be held, spoken to, and stroked as if it were an actual animal. AI enables PARO to remember users' actions and learn to adapt its behavior accordingly. Actions that result in positive user feedback will be repeated, while actions resulting in negative user feedback will not.
- NAO [51]
    - NAO is a bipedal interactive humanoid robot designed for various applications, including education and research. The robot supports open-source functionality, allowing users to curate the robot to their specific needs. NAO uses AI at the lowest level to perceive the surrounding environment, understand and respond to human emotion, solve tasks, navigate using advanced vision systems, and so on.
- Pepper [52]
    - Pepper is a humanoid robot designed for social interaction and customer service. Leveraging its ability to recognize faces and human emotions, Pepper is available in businesses and schools as a helpful assistant. The robot uses AI to map and navigate its environment and solve tasks, among many other things. Above all, Pepper uses AI to recognize and respond to human emotions, making it capable of humanlike communication. It also learns from interactions, allowing it to adapt and improve its responses over time.
- SCITOS [53]
    - The SCITOS is an autonomous robot designed to be used in various applications such as research and many customer service positions. The robot is designed to interact with people through its voice, head movements, and touch display, as well as guide people in various settings. It uses AI to map and navigate its environment, avoiding obstacles and identifying its position in a 3-D space. AI is also used for effective communication, equipping SCITOS with the ability to interact with and understand humans. This AI-enabled emotional recognition allows the robot to guide visitors, provide explanations, and play fun games such as hide and seek.
- Tangy [54]
    - Tangy is a social robot designed to assist with social and interactive tasks. The main use case for Tangy is as a bingo assistant in long-term care settings. Using AI, Tangy can autonomously support older adults in playing bingo. The robot is able to call bingo numbers, help individuals, ensure the accuracy of winning bingo cards, and congratulate winners. These functionalities are supported by AI, which enables Tangy to perceive and influence its surrounding environment. AI also allows the robot to recognize certain bingo cards as winners, an ability made possible with improved computer vision systems. Tangy also uses AI to integrate information from different sensors, and this allows it to identify and communicate when certain bingo numbers are called out.
- MARIO [55,56]
    - The MARIO robot is a social robot that builds on existing Kompai architecture with the purpose of providing companionship and support. The robot is intended for use with individuals who have dementia in long-term care settings. The robot applies AI at various levels to supplement its predetermined functionalities. Simultaneous mapping and navigation are possible through the AI-driven integration of sensor data, although this requires more constant environments. It is also able to understand and respond to human communication, and this allows it to effectively engage with residents. The robot supports various applications, including fall or hazard detection, which are facilitated by AI.
- Roomba [57]
    - The Roomba is a robotic vacuum cleaner designed to automate the floor cleaning process. There are several iterations of the device that support different types of cleaning and more efficient automation. At the lowest level, the Roomba uses AI to perceive and influence its surrounding environment. Advanced sensor and mapping technology is leveraged to create a computer-readable rendition of a 3D space, enabling systematic and efficient cleaning patterns.
- TUG [58]
    - The TUG autonomous mobile robot is made specifically to deliver linens, medications, and meals in hospital settings. The robot functions to maintain order in the hospital and reduce the physical workload that the staff are required to manage. The TUG robot uses AI to enhance its computer vision capabilities, allowing it to map and navigate 3D environments and make use of existing navigation infrastructures (eg, elevator). The AI-enabled robot also can identify hazards in real time, which is integral in health care settings that may contain patients, caregivers, and other individuals.

- PaPeRo [59]
    - PaPeRo is a social robot that was developed to appeal to various populations, with the intention of providing companionship. The robot uses AI to engage in human conversation, recognizing >200 words and speaking in a natural voice. The robot can also perceive the volume of sounds in the environment and adjust its behavior accordingly. Furthermore, the robot makes use of image-recognition technology to identify faces. While not actively engaging with individuals, the robot makes use of AI to map and traverse through its environment while dancing and singing on its own. PaPeRo is also able to identify hazards in its environment.
- Temi [60]
    - Temi is a social robot designed for home and business applications. The robot acts as an autonomous personal assistant following users, saving locations, setting tasks, and providing Face Time functionalities. Temi uses AI to map and navigate its environment, facilitating autonomous motion. The robot can also identify environmental hazards and adapt its movement to suit different types of surfaces to suit different types of surfaces (wood, carpet, etc). It can also understand and respond to voice commands, demonstrating an ability to engage in humanlike communication while also learning and adapting to users' behaviors over time.
- Grace [61]
    - Grace is an advanced humanoid robot designed for health care applications. The robot emulates health care professionals with a humanlike appearance and its ability to interact with patients, record key vitals (temperature and responsiveness), engage in therapeutic conversation, and help other health care professionals. AI is deeply embedded into almost all components of Grace, allowing for autonomous movement, diagnosing of some conditions, and most of all, humanlike communication. The robot uses AI in conjunction with electrical components to replicate facial expressions, and this facilitate its ability to communicate and provide companionship. The robot is mainly used to provide social stimulation to older adults and others isolated in health care settings.
- PR2 [62]
    - PR2 is a service robot that supports a wide array of use cases and can be adapted to fit different environments. PR2 robots have the dexterity to fold towels, grab drinks, pick up various items, and even make purchases in stores. The robot relies heavily on AI to perform these tasks. A variety of sensors are integrated through AI tools to create 3D representations of environments, allowing for real-time mapping and navigation. The robot also supports complex problem-solving skills that allow it to adapt to complete many different tasks. AI also enables the robot to interact with humans through voice and gesture recognition.
- Sota [63]
    - Sota is a social robot optimized for social interaction and communication. Sota is designed to give PowerPoint presentations, making use of its versatile communication skills. The robot has a unique communication style, making use of its tone of voice, arm gestures, expressions, body language, and other sounds to convey certain emotions. Sota uses AI to integrate its different skills in a coherent way suitable for presentations. For example, the 3D environment is mapped in real time, and this allows Sota to move around while speaking and point to key features in the presentation. Sota's voice and gestures are all decided on using AI algorithms that can learn and adapt to audience reactions over time.
- Smart Walker [64]
    - The Smart Walker is an AI-assistive device that is intended to aid individuals with mobility challenges. The robot can precisely detect users' movements and adjust its own behavior accordingly by moving forward, stopping, or adjusting its speed. AI allows the robot to map and navigate its environment while also detecting hazards in real time. The hazard detection functionality uses AI to detect objects in the path of the user and stop the walker, preventing collisions. Furthermore, the robot also supports gait detection and health monitoring, a feature enabled by the integration of various sensor data through AI.
- Artificial Intelligence Lightweight Android (AILA) [65]
    - AILA is an autonomous robot designed as a research platform for autonomous mobile dual-arm manipulation. The robot can understand and navigate its environment in real time, a feature facilitated by integrating AI technologies with various sensor modalities. Moreover, AI enables AILA to recognize specific objects in its environment through feature matching and 3D pose estimation. On the basis of this information, AILA can autonomously adjust its arms and determine the best orientation to grasp different objects. Furthermore, AILA can use different strategies to lift and relocate objects depending on their characteristics (fragile, soft, and hard).

In the first screening level, 2 research trainees of our team independently screened the titles and abstracts of the 279 identified items. We removed 192 (68.8%) items that were not conducted in LTC homes, were not about AI-enabled robots, did not include health care providers, or were systematic reviews, and 87 (31.2%) items remained. In the second screening level, the 2 research trainees independently reviewed the full text of the 87 selected items. Subsequently, we removed 54 items (reasons for removing were the same as those in the first screening level), and 33 items remained. We used the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [66] to record the selection process (Figure 2). When the 2 research trainees did not agree with each other, the researcher (LH) made the final decision.

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) chart. AI: artificial intelligence; LTC: long-term care.



Data Extraction and Analysis

We extracted data from the chosen items by domain and documented the data extracted in the data extraction table (Multimedia Appendix 1 [11,49,67-97]). The domain included "author, year, and place" of the literature; "literature type and study design/method"; "setting, population, and sample size (if mentioned)" of the study; "type of AI-enabled robot and use of the robot" mentioned in the literature; "barriers to the use of the AI-enabled robot (from healthcare providers' perspectives)"; and "strategies to overcome the barriers." The data extraction tool was an enhanced version compared with the one we published in the protocol: most of the categories of the tool in the enhanced version were similar to the protocol version. The main difference was that we removed the category on "results and implications" and added a category on "the type of AI-enabled robot and use of the robot." We initially had a category on "results and implications," just in case we needed additional information to help us address the review questions. However, after we started data extraction, we realized that the category on "results and implications" did not provide additional information to help us address the review questions and might even divert our attention away from addressing the review questions. Therefore, after discussion, we removed this category. By contrast, during data extraction, we found that the differences in the types and uses of AI-enabled robots might relate to the review questions on the barriers and the strategies to overcome them. Therefore, after discussion, we added this category.

Each team member was randomly assigned items for data extraction. Since our older adult partner expressed interest in helping with data extraction despite being less familiar with academic work, he was assigned fewer items (3 items) than other members. We met to discuss the challenges we encountered during the data extraction process and resolve them together under the guidance of the researcher (LH), who is experienced in the scoping review. For items that include both health care provider participants and non–health care provider participants (eg, residents and families), we only extracted the data on the barriers and the strategies to overcome these barriers from the perspectives of health care providers. For items that include AI-enabled and non–AI-enabled robots, we only extracted the data on AI-enabled robots.

After data extraction, a research trainee of our team did a preliminary thematic analysis of the extracted data using NVivo (version 12; Lumivero), a qualitative data analysis software [98]. The trainee coded the data, grouped similar codes into categories, grouped similar categories into themes, and then presented the findings to the team. The team members gave inputs to refine the findings, which were finalized through team analysis. When differing opinions on the themes arose, we reached a consensus through discussion. Team members then compared the findings with PCPF and CFIR to see how the frameworks further our understanding of the findings. We followed a mixed inductive and deductive approach in data analysis. The research trainees coded the data, and the team developed the themes inductively. However, we also compared the findings with PCPF and CFIR to further our understanding of the findings deductively.

Results

Overview

In our review, we included 33 studies conducted across 16 different countries. Most studies were from Canada and Australia, with 12% (5/33) of the studies from each country [11,72,78,80,84,85,90,94,96]. Moreover, 9% (3/33) of the studies were conducted in Austria, and the United States [49,68,75,89,91,95]. There were 4 (12%) studies that took place in Japan [74,86,93,97]. The remaining countries contributed to either 3% (1/33) of the studies (China, the Netherlands, New Zealand, Turkey, and the United Kingdom) or 6% (2/33) of the studies (Finland, Germany, Switzerland, and Taiwan), while 1 (3%) [67,69-71,73,81,82,87-89,92] study involved >1 country (Italy, Ireland, and the United Kingdom) [81]. Most of the studies (20/33, 61%) were journal articles [11,49,67-72,74-77,79,80,82,83,86,87,92,97]. Furthermore, 24% (8/33) of the studies were conference proceedings, and 9% (3/33) of the studies were book chapters [73,78,81,84,85,88,89,91,93,95,96]. There was 1 (3%) web-based news article and 1 (3%) dissertation [90,94]. The most frequently researched robot among the studies was the social robot PARO, mentioned in 33% (11/33) of the studies [11,69,73,77,80,81,84-86,89,96]. The humanoid robots NAO and Pepper were mentioned by 15% (5/33) of the studies and 12% (4/33) of the studies, respectively [67,70-72,79,84,86,97]. While 2 (6%) studies were found mentioning the following robots: SCITOS, Sota, and Tangy, 1 (3%) study mentioned the remaining robots [49,68,73-76,78,83,87,88,90,91,93,94].

Barriers to the Use of AI-Enabled Robots

Overview

One of our primary research questions is to explore the barriers that health care providers perceive in adopting AI-enabled robots in LTC homes. After reviewing and analyzing the existing literature, 3 barriers related to this regard were identified (Textbox 3).

Textbox 3. A summary of the barriers to the use of artificial intelligence (AI)–enabled robots.

Barriers and summary

- Perceived technical complexity and limitation
  - Perceived using AI-enabled robots complex or troublesome
  - Reported not having the knowledge and skills to use the robots
- Negative impact, doubted usefulness, and ethical concerns
  - Worried about the AI-enabled robots’ negative impacts on residents
  - Worried about the AI-enabled robots’ negative impacts on staff
  - Doubted residents’ interests in the AI-enabled robots
  - Doubted the usefulness of the AI-enabled robots to residents
  - Doubted that the robots would fit the LTC home context
  - Worried about the potential ethical issues of using AI-enabled robots
  - Raised ethical concerns on privacy
- Resource limitations
  - Lack of human and time resources
  - Not enough robots
  - A lack of infrastructure
  - Worried about maintenance costs

Perceived Technical Complexity and Limitation

Health care providers perceived the technical complexity and limitations of robots as a barrier to adopting robots. For example, in the study by Huisman and Kort [67], using the humanoid robot NAO to entertain residents and stimulate them to do physical exercises, health care providers expressed frustration with the complex robot’s operation steps and the robot’s short battery life. In the study by Hebesberger et al [68], the autonomous robot SCITOS was used to perform safety checks around the LTC home (eg, checking if doors were closed and fire extinguishers were in place) and greet visitors at the LTC home’s lobby. Nevertheless, health care providers reported that the robot’s slow response and rigid system discouraged their use of it. In the study by Pfadenhauer and Dukat [69] on the social robot PARO, health care providers mentioned that as the robot could not move independently, they had to carry it around the LTC home for residents' use, which was inconvenient.

In addition, a lack of knowledge and skills contributes to the reluctance to adopt these technologies. For example, in the study by Papadopoulos et al [70], using the humanoid robot Pepper to interact with residents socially, health care providers reported not being fully equipped to operate and maintain the robot. In the study by Melka et al [71], using the humanoid robot NAO for rehabilitation and recreational assistance, health care providers hesitated to use the robot as they feared making mistakes because of a lack of knowledge and skills using it. Even if there is training, the willingness to participate is low due to existing heavy workloads. For instance, referring to the study by Li et al [72], using humanoid robots Pepper and NAO to entertain residents, health care providers expressed concerns about the time needed to join training as they already had heavy workloads.

Negative Impact, Doubted Usefulness, and Ethical Concerns

Health care providers have expressed concerns, including potential negative impacts, doubts about their usefulness, and ethical implications.

Potential Negative Impacts

Some health care providers are concerned that AI-enabled robots might negatively impact residents. For example, one of the robots used in the ethnographic study by Chang and Šabanović [73] was the robotic vacuum Roomba, and health care providers expressed concerns about residents' risk of falling. In the study by McGinn et al [49], using the social robot Stevie to communicate with residents, health care providers were worried about hygiene hazards, such as the robot not being adequately sterilized after use and the potential spread of germs among residents. The study by Obayashi et al [74] used the social robot Sota; The health care providers were concerned that the robot's flashing eyes might scare residents.

Some health care providers were concerned that the AI-enabled robots might negatively impact them. For example, in the study by Hung et al [11], on the use of robots, including social robot PARO, in LTC, health care providers expressed their concerns that using these robots increased their workloads, such as teaching and assisting residents to use the robots, cleaning and charging the robots, and handling technical glitches. The study by Mitzner et al [75] used service robot PR2 to assist in caregiving tasks such as medication dispensing and transferring residents. Health care providers were concerned that the robot would replace human functions. In the study by Melkas et al [71], using the humanoid robot NAO to assist in rehabilitation and recreation, health care providers were reluctant to use it as they had established workflows, and including the robot would interrupt how they had been doing things. Erebak and Turgut [76] studied health care providers' attitudes toward robots, such as the autonomous robot Artificial Intelligence Lightweight Android (AILA). They found that the health care providers did not trust robots to be fully autonomous in decision-making. Instead, they preferred robots that allowed them to make certain decisions as humans (although the authors did not specify what these decisions would be).

Doubted Usefulness

Some health care providers have raised doubts about the usefulness of AI-enabled robots for residents in LTC homes. Some providers doubted whether residents would be interested in robots. For example, in the study by Robinson et al [77], on social robotic pet PARO as a companion with residents, health care providers raised doubts that residents would be interested in it because residents preferred real pets, and PARO looked like a toy. In the study by Louie et al [78], using the social robot Tangy, health care providers said residents preferred humans, and Tangy's appearance and voice were too mechanical. In the study by Huisman and Kort [67], using the humanoid robot NAO, health care providers said that residents would be bored by the lack of choices of programs that the robots could offer for recreation and physical exercise.

Other health care providers doubted the practicality of AI-enabled robots for residents. For instance, in the study by Louie et al [78], the primary function of the social robot Tangy was to speak to residents and interact with them. However, Tangy could not speak the languages of some residents. Some health care providers pointed out that these residents could not understand and interact with Tangy. The study by Bäck et al [79] used humanoid robot NAO to demonstrate physical exercise to residents. However, health care providers hesitated to use the robot because its size was too small for residents with eyesight impairment to see it, its voice was too soft for residents with hearing impairment to hear its instructions, and residents with cognitive impairment could not follow its demonstration.

Furthermore, providers doubted that the robots would fit the LTC home context. For instance, one robot used in the study by Chang and Šabanović [73] was the autonomous mobile robot, TUG, which was designed to help health care providers deliver care and medical supplies and clean the LTC home. However, health care providers did not find it helpful because its size was too large to navigate the LTC home's narrow hallways.

Potential Ethical Issues

Health care providers have expressed ethical concerns about using AI-enabled robots in LTC settings. For example, in the study by Moyle et al [80], social robot PARO was used to interact with residents. Health care providers raised concerns that the use might infantilize residents due to the robot's toy-like appearance. In the study by Lehmann et al [81], PARO was used as a robotic pet for companionship with residents. Health care providers expressed concerns that the robot could deceive residents with cognitive impairment as a real pet.

Privacy concerns have also been raised, particularly concerning surveillance. For instance, Christoforou et al [82] looked into different types of nursing and social and physical assistive robots. Some health care providers expressed the feeling that the robots were monitoring their work. In the study by Papadopoulos et al [70], using the humanoid robot Pepper to communicate with residents, health care providers worried about residents' privacy, especially since Pepper had cameras on its forehead.

Resource Limitations

The last barrier expressed by health care providers is that LTC homes lack the resources to use AI-enabled robots. The types of resources that LTC homes lack include time, robots, infrastructure, and maintenance costs. First, as suggested, health care providers expressed concerns about the lack of time to learn, maintain, and assist residents using the robots [11]. Second, some health care providers said that their LTC homes did not have sufficient robots. In the study by Hung et al [11], a nurse recalled how 2 residents fought with each other for 1 social robot PARO. Third, some health care providers mentioned that their LTC homes lacked infrastructure for robot use. Melkas et al [71] used a humanoid robot NAO for diverse purposes (eg, rehabilitation and recreation), and NAO needed Wi-Fi. However, some health care providers mentioned that their LTC home had a poor internet connection. They also added that their LTC home did not have sufficient physical space to store the robot. Finally, keeping a robot is expensive, and some health care providers were worried about the maintenance costs. In the study by Casey et al [83], using the social robot MARIO to stimulate residents' cognition and memories, such as giving them updates on news, health care providers were concerned about the costs of keeping the robot and suggested that it would be a better idea to spend money hiring more health care providers than keeping the robot.

Strategies to Overcome the Barriers to the Use of AI-Enabled Robots

Overview

To overcome the barriers, another primary question of our review is to identify the strategies suggested in the literature, including (1) accommodate the various needs of residents and health care providers, (2) increase the understanding of the benefits of using robots, (3) review and overcome the safety issues, and (4) boost interests in the use of robots and provide training. The strategies can be summarized in an acronym, "AI-ROBOT" (Textbox 4).

Textbox 4. Summary of the strategies to overcome barriers.

AI-ROBOT and illustrative examples from literature

- Accommodate various needs of residents and health care providers
    - Incorporate songs in languages other than English to meet the language needs of residents [84]
- Increase the understanding of the benefits of using robots
    - Health care staff found that the robot could enhance residents' emotional well-being and bring them joy [67]
- Review and overcome the safety issues with staff
    - Incorporate safety designs suggested by staff into robots [88]
- Boost interests in the use of robots
    - Dress up the robots to make them more attractive [90]
- Provide training and involve staff in the planning and implementation
    - Set up a help desk for health care staff to contact by phone or email when they encounter any challenge using the robot [67]

Accommodate the Various Needs of Residents and Health Care Providers

One strategy is to collect feedback from health care providers to design AI-enabled robots that better accommodate the various needs of residents and health care providers. For example, one of the robots used in the study by Yuan et al [84] was the humanoid robot NAO for communication with residents. Health care providers raised a concern that some residents could not understand English. In response to this feedback, Yuan et al [84] suggested incorporating songs in languages other than English into the robot to meet these residents' language needs better. The study by Bäck et al [79] used NAO for demonstration of physical exercise. In response to the feedback from health care providers that residents with sight impairment could hardly see the robot and the residents with hearing impairment could not hear the instructions by the robot clearly, Bäck et al [79] recommended painting the arms of the robot in sharp color and giving it a loud and clear voice to accommodate the visual and hearing needs. In the study by Cavenett et al [85] who used the social robot PARO for social interaction with residents, corresponding to health care providers' concerns that using the robot would add to their workload and interrupt their established workflow, Cavenett et al [85] proposed acknowledging the concerns and discussing with health care providers to understand their work needs and explore how the use of robot could address these needs and fit with their existing workflow.

Increase the Understanding of the Benefits of Using Robots

Another strategy is to increase health care providers' understanding of the benefits of using robots. The authors of the literature reviewed mentioned that when health care providers better understand the benefits of using robots, they will accept and use them more. For example, in the study by Huisman and Kort [67], some health care providers supported using the humanoid robot NAO because they found that it could enhance the emotional well-being of residents and bring them joy. In the study by Kolstad et al [86], some health care providers welcomed the social robot PARO because they found that it could stimulate residents' functions, such as interactions with people. In the study by Follmann et al [87], the social robot Temi was used to contact residents' relatives. Health care providers welcomed the robot because they found different benefits to it: it was easy for residents to use and health care providers did not need to transport the robots between residents, did not need to stand by to provide supervision when residents were using the robot, and did not need to disinfect the robot.

In addition, the reviewed literature suggests letting health care providers learn that the relationship between health care providers and robots is not competitive but complementary, emphasizing that humans perform certain tasks better than robots. A collaborative approach leverages the strengths of robots and humans, ensuring a higher quality of care. For example, Cavenett et al [85] used social robots to communicate with residents. Corresponding to health care providers' worry that robots would replace their communication role, the authors suggested that robots only complemented health care providers' communication role because robots were not as capable as humans to catch the nonverbal cues of residents.

Review and Overcome the Safety Issues With Staff

The third strategy is to review the safety issues with staff and address their concerns. The study by Shin et al [88] used the robot SmartWalker to guide residents to walk. The health care providers asked if the robot was safe, considering that the residents were prone to falling. Shin et al [88] recommended incorporating safety designs into the robot. For example, when there were obstacles and stairs in front of residents, the robot would give audio warnings to the residents. In the study by Hung et al [11], in response to health care providers' concerns about residents' safety that residents might fight over the robots, Hung et al [11] proposed having risk assessment and management guidelines in place to avoid conflicts and violence over robots and guide health care providers on what to do in case these happen.

Boost Interests in the Use of Robots

It is crucial to boost interests in using the AI-enabled robots from both the health care providers and the residents. The authors of the reviewed literature suggested increasing health care providers' interest in using robots. For instance, in the study by Chang and Šabanović [89], the researchers used the social robot PARO with residents in public areas of LTC so that health care providers could see the process of using the robot and witness how the robot provided therapeutic effects to residents. The researchers found that this raised the health care providers' interest in using the robot because they told the researchers that seeing how the researchers used the robot with the residents stimulated them to think about how they could use it in their work.

Since health care providers expressed concerns that residents might not be interested in using the robot, the authors of the reviewed literature also suggested increasing residents' interest in using robots to address their concerns. Robinson et al [77], who used the social robot PARO, proposed changing the robot's color from white to a more appealing color. Louie [90] recommended dressing up the social robot Tangy so that it looked more attractive. In the study by Hebesberger et al [91], using the robot SCITOS to accompany residents doing walking exercises, the researchers suggested giving the robot a name so that residents felt the robot was more personalized and thus more interested in it. In addition, in response to health care providers' comments that SCITOS's voice was too mechanical, they proposed giving the robot a more attractive, more natural voice.

Provide Training and Involve Staff in the Planning and Implementation

The last strategy is to provide training. The authors of the reviewed literature recommended training and support to health care providers. Huisman and Kort [67], who used the humanoid robot NAO, proposed that the training should give health care providers clear instructions on how to use the robot for physical and recreational activities with residents. They added that time needed to be reserved for training. Otherwise, health care providers could not find time to do the training within their busy work schedules. They also recommended setting up a help desk, which health care providers could contact by phone or email when they encountered any challenges using the robot. When health care providers were more familiar with using the robot, they recommended peer learning (ie, encouraging the health care providers to support each other in using the robot). Yuan et al [84], who used the social robot PARO and humanoid robot NAO for interaction and communication with residents, raised the need for an instruction manual in place so that health care providers could refer to it after training.

Comparing Findings With Theoretical Frameworks

Overview

As suggested, we compared our findings with PCPF and CFIR to further our understanding of the findings. The authors of PCPF [40] and CFIR [99] suggested that discussing all constructs in 1 paper is not feasible, so they recommended that the users of their framework select a few most relevant constructs to the research. We selected constructs most relevant to our review through team discussions.

Comparing Findings With PCPF

In our review, one barrier to adopting AI-enabled robots is that health care providers feel that they lack the knowledge and skills to use the robots [70]. One strategy is providing training to health care providers so that they can improve their knowledge and skills [67]. The knowledge and skills needed to use robots to provide care may be part of "professional competence," a construct under the "prerequisite" domain of PCPF. This construct refers to "the knowledge, skills and attitudes of the person to negotiate care options and effectively provide holistic care" [36].

Another barrier mentioned in our review is that health care providers are concerned that robots might replace human functions [75]. One strategy is to let health care providers know that they are better at providing these human functions, such as communication, than robots, as they are humans [75]. The constructs “engaging authentically” and “being sympathetically present” under the “person-centered process” domains of PCPF help us further understand why health care providers are better than robots. “Engaging authentically” refers to “the connectedness between people, determined by knowledge of the person, clarity of beliefs and values, knowledge of self and professional expertise” [22]. Robots cannot engage with residents “authentically” because robots are not authentic humans, despite being equipped with AI. “Being sympathetically present” means “an engagement that recognizes the uniqueness and value of the patient by appropriately responding to cues that maximize coping resources through the recognition of important agendas in the person’s life” [36]. The study by Cavenett et al [85] in our review mentioned that humans are better than robots at responding to nonverbal “cues” of residents, which are a crucial element to show residents “being sympathetically present.”

The “shared decision-making” construct under the “person-centered process” domain of PCPF refers to “engaging persons in decision-making by considering values, experiences, concerns and future aspirations” [36]. This construct made us wonder why health care providers did not mention too much about how the lack of residents’ involvement in decision-making was a barrier to the adoption of robots or suggest involving residents’ voices in the adoption process, especially since many barriers that the health care providers mentioned were related to the residents, such as potential negative impacts of robots to residents [49,73,74], perceived lack of usefulness of robots to residents [67,77,78], and ethical concerns related to residents [70,80,81]. One explanation might be that health care providers thought that they knew the residents well and could represent the voices of residents, so involving residents in decision-making was not a concern from their perspective. Future studies might examine this further. Another construct is “health and social care/policy” under the “macrocontext” domain of PCPF, which refers to “the decisions, plans, and actions that are undertaken to achieve specific health and social care goals within a society” [36]. Health care providers in our review did not mention too much about the influence of health and social policy on their adoption of AI-enabled robots, although there were international and national policies about the use of AI, such as the guidelines by the World Health Organization [100] and Health Canada [101].

Comparing Findings With CFIR

One barrier to adopting the AI-enabled robots mentioned in our review is health care providers’ perceived technical complexity [68]. CFIR has a construct of “innovation complexity” under the “innovation” domain, which resonated with our findings. This construct states that “the innovation is complicated, which may be reflected by its scope and/or the nature and number of connections and steps” [37].

Another barrier is a lack of resources, such as time for health care providers to learn, maintain, and assist residents in using robots [11]; infrastructure such as Wi-Fi and storage place [71]; and maintenance costs [83]. CFIR has the construct “available resources” under the “inner setting” domain [37]. “Available resources” means “resources (that) are available to implement and deliver the innovation” [37]. This construct helps us think that the lack of resources is an organizational-level barrier, as the “inner setting” in our review context means the LTC home (ie, the organization). In other words, the organization needs to be involved in resolving these barriers.

The construct “need” is under the “individuals” domain of CFIR [37]. The “need” construct refers to the following: “the individual(s) has deficits related to survival, well-being, or personal fulfillment, which will be addressed by implementation and/or delivery of the innovation” [37]. Our findings include barriers such as health care providers’ doubted usefulness [79] and ethical concerns [81] about using robots for residents. The “need” construct helps us realize that these barriers are related to health care providers’ concerns about the “needs” of residents. For example, in the study by Bäck et al [79], health care providers doubted the usefulness of the humanoid robot NAO in facilitating exercises because its size was too small for residents with visual impairment to see it, and its voice was too soft for residents with hearing impairment to hear it. It does not meet the visual and hearing “needs” of residents. In the study by Papadopoulos et al [70] on the humanoid robot Pepper, health care providers were worried about residents’ privacy as the robot had a camera on its forehead: they were concerned about the privacy “need” of residents.

In our review, some health care providers hesitated to use robots because they were concerned that doing so would interrupt their existing workflow [71]. One strategy identified was to discuss with health care providers how to integrate the robot into their workflow [85]. The construct “compatibility” under the “inner setting” domain of CFIR helps us to understand that these are “compatibility” concerns [37]. “Compatibility” refers to the following: “the innovation fits with workflows, systems, and processes” [37].

Discussion

Principal Findings

This scoping review addressed two review questions: (1) health care providers’ perceived barriers to using AI-enabled robots in LTC and (2) the strategies to overcome the barriers to the adoption of robots. We identified the barriers to adopting AI-enabled robots in LTC homes, including (1) perceived technical complexity and limitation; (2) negative impact, doubtfulness, and ethical concerns; and (3) resource limitations. We also identified the strategies to overcome these barriers to adopting AI-enabled robots: (1) accommodate various needs of residents and health care providers, (2) increase the understanding of the benefits of using robots, (3) review and overcome the safety issues, and (4) boost interest in the use of robots and provide training.

As suggested in the Introduction section, LTC homes face the challenges of increased resident care needs and a shortage of health care providers [3-5]. Researchers and technology developers expect that AI-enabled robots could address these challenges by sharing the workload of health care providers [6-8]. However, according to the results of our review, health care providers had a different opinion. For example, some suggested that using robots would increase instead of reducing their workload, such as assisting residents in using the robots and cleaning them [11]. Some suggested that using robots would interrupt their existing workflow [71]. An explanation for the gap between researchers or technology developers' expectations and health care providers' opinions might be health care providers' lack of involvement in developing and researching AI-enabled robots. Therefore, health care providers' opinions did not align with researchers' and technology developers' expectations that robots could address the challenges in LTC homes.

In this scoping review, health care providers identified a few ethical concerns about using AI-enabled robots. Frennert and Östlund [102] summarized the main ethical concerns of using robots with older adults from previous literature. Although the literature summarized by Frennert and Östlund [102] did not specifically address AI-enabled robots or LTC contexts, it could still be a good reference for understanding the findings on ethical concerns in our review. Some ethical concerns mentioned in the paper by Frennert and Östlund [102] were found in our review, including concerns about the privacy of residents [70] and health care providers [82]; deception to residents [81]; infantilization of residents (as many robots, especially social robots, look like a toy) [80]; equitable distribution of the use of robots in a group setting [11]; and residents' attachment to the robots and negative emotions triggered when they break down [70]. However, when Frennert and Östlund [102] mentioned the ethical concern of humans' loss of control of the robot, they did not specify the particular aspects of control involved. In our scoping review, for example, in the study by Erebak and Turgut [76], health care providers mentioned specifically the control of decision-making. One possible reason health care providers in our scoping review highlighted the control of decision-making is that among different aspects of control of AI-enabled robots, decision-making is a key feature of AI that is widely discussed in society [103].

In our review, health care providers had different opinions on whether the AI-enabled robots should look real. Some providers suggested that residents preferred real people or pets and doubted that residents would be interested in robots if they were not real enough [77,78]. Corresponding to this feedback, some literature proposed making the robot more real by adding features (eg, a more natural human voice) [91]. However, some health care providers had an ethical concern that residents with cognitive impairment would be deceived that the robots were real [81]. The concern about deception was also previously discussed in the literature on non–AI-enabled robots. For example, in the study by Koh et al [104], health care providers raised their concern that residents misperceived a Joy for All companion cat as a real cat. We considered that the opinion divide would be even more intense as AI-enabled robots develop. Compared with non–AI-enabled robots, AI-enabled robots could be even more "real" due to AI technology. Future research might further explore this topic.

Recommendations

As suggested, a possible explanation for the gap between researchers or technology developers' expectations and health care providers' opinions on using AI-enabled robots is health care providers' lack of involvement in developing and researching AI-enabled robots. Previous literature on using technologies in older adults care highlighted the importance of involving health care providers [105]: working on the frontline, health care providers use technologies according to the context. Their experiences with technologies may differ from what researchers and technology developers expect. Thus, researchers and technology developers need to work with health care providers to understand, for example, their training requirements, how technologies can support their work, and how these technologies can be integrated into their established work routines and workflows. Involving health care providers and understanding their perspectives should increase their acceptability and sense of ownership and reduce their concerns about using technologies.

We propose that administrators be involved in addition to health care providers. Some barriers to using AI-enabled robots found in this scoping review could not be resolved without administrators' involvement. For example, health care providers said that they did not have time for training [72], and the administrators are responsible for reserving time for them for training. Some health care providers are worried about the safety risks of using robots [49,73]. Administrators need to implement protocols for assessing and managing the risks.

We propose that residents be involved in addition to health care providers and administrators. When we compared our findings with PCPF, it was interesting that the health care providers in our review did not mention much about residents' involvement, although they provided person-centered care. Residents are the users of the robots, and they can give feedback on using them.

All stakeholders, researchers, technology developers, health care providers, administrators, and residents need to get involved in developing and implementing AI-enabled robots. Each stakeholder has strengths to contribute: health care providers know the potential day-to-day challenges of using robots as they work on the front line, while administrators know the policies and regulations of LTC, so they can advise on how to ensure that the use of robots aligns with these policies and regulations. Technology developers have technical knowledge about robots, and residents provide feedback as users of the robots. This scoping review explored the barriers and the strategies to overcome the barriers to the use of robots from the perspectives of health care providers. Future scoping reviewers may consider conducting scoping reviews on other stakeholders' perspectives.

Limitations of the Review

This scoping review included only English-language studies because of the limited language capacity of our team. However, in many parts of the world, there is rapid development in the use of AI-enabled robots in LTC homes. Relevant studies published in languages other than English may have been omitted. Future scoping reviews should consider how to search for and include items in languages other than English, such as including team members with language capacity other than English or using translation tools. Furthermore, a quality assessment of the included studies was not conducted. However, the scoping review methodology mainly focuses on identifying the breadth of existing research rather than evaluating the quality of evidence [106]. Finally, the review only examined the point of view of health care providers, not residents. Future researchers may consider conducting a scoping review on the same topic but from residents' perspectives.

Conclusions

This scoping review examined the barriers to using AI-enabled robots in LTC homes from health care providers' perspectives and identified the strategies to overcome these barriers to the adoption of such robots. We anchored our analysis in established theories, specifically the PCPF and the CFIR, to guide our further understanding of the findings. By addressing the barriers and identifying the strategies to overcome them, we hope to foster the effective deployment of AI-enabled robots in LTC homes.

Abstract

Background: Care robots have been proposed in response to nursing shortages in assisted living facilities (ALFs) and the growing population of older adults. While the use of care robots may improve the general health and well-being of older adults, their introduction changes the work of nursing staff fundamentally, and it has implications for the entire health care system. In developing such technology, it is important to include end users, but so far, the nursing staff’s perspectives have largely been ignored.

Objective: This study aims to examine the literature on nursing staff’s attitudes, needs, and preferences related to the use of care robots in ALFs, in order to discover gaps in the literature and guide future research.

Methods: This review follows the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 protocol. On May 12, 2023, we searched PubMed, CINAHL Plus with Full Text, PsycINFO, the IEEE Xplore Digital Library, and the ACM Digital Library using predetermined search terms. Included publications, written in English, focused on the predevelopment phase, in which information was gathered on nursing staff’s attitudes, needs, and preferences regarding care robots for ALFs. Publications were excluded if they did not provide peer-reviewed empirical data. The studies’ findings were summarized, coded, and analyzed into major themes using thematic analysis and narrative synthesis. Their quality was assessed using McGill University’s Mixed Methods Appraisal Tool and the Joanna Briggs Institute’s critical appraisal tools.

Results: The final sample included 15 studies. Most of the studies (n=11, 73%) were rated as good quality; however, there was a general lack of reporting on important methodological decisions and sample characteristics. Nursing staff desired care robots that could assist with physically demanding tasks and reduce their workload but had mixed feelings on whether robots could or should assist with social tasks. In addition, nursing staff are concerned about the ethics of care robots, as well as about their safety, accessibility, and operability. The nursing staff’s culture, qualification, and role in the facility may influence their perspectives of care robots. The studies lacked theory-driven designs and large sample sizes. Eight (53%) studies mentioned using a participatory design approach, but a lack of established criteria for what constitutes participatory design leads to varying degrees of methodological quality.

Conclusions: There was consensus among nursing staff that care robots should serve as nursing assistants to reduce workload. Whether robots could or should assist with social tasks remains a question. Further research is needed to mitigate nursing staff’s concerns and understand the socioecological factors that influence their perspectives of care robots and their adoption in ALFs. In addition, theory-driven and large sample size study designs are necessary, as well as work to develop clear criteria for related participatory design research.

Introduction

Across the world, the population of older adults is growing at an unprecedented rate. It is estimated that the US population of older adults—those aged 65 years and older—will grow from 49 million in 2016 to 95 million in 2060 [1]. This trend in aging will be associated with increased care demands: 70% of older adults will eventually require some form of long-term care, including residential care facilities [2]. Older adults who reside in these facilities rely on nursing staff as their primary caregivers. Depending on the level of care the facility provides, the nursing staff can include advanced practice registered nurses, registered nurses, licensed vocational or practical nurses, certified nursing aids or assistants, patient care technicians or assistants, and unlicensed paid caregivers.

At the same time as care demands rise, assisted living facilities (ALFs), or residential settings that provide long-term care to older adults, face a severe nurse staffing shortage. It is estimated that the number of professional care workers will need to increase by 60% globally (or 13.5 million new care workers) by 2040 just to maintain the current ratio of caregivers to older adults [3]. The COVID-19 pandemic exacerbated this staffing crisis, and the US Bureau of Labor Statistics estimates that an additional 245,600 employees are needed just to return ALFs to prepandemic levels [4]. Nurse burnout has contributed to this shortage and also resulted from it; burnout is associated with increased turnover, high workload, and inadequate staffing [5,6]. In fact, some argue that the staffing crisis is not due to a shortage of available nurses, but to a shortage of nurses willing to work under unsafe conditions [7]. The nurse burnout thus has far-reaching implications for the health of nurses, patients, and health care systems. Burnout is significantly related to poor nurse health; poor quality of care and adverse events for patients; and increased nurse turnover, costing hospital systems US $16,736 per nurse per year employed [6,8,9]. ALFs show higher rates of nurse burnout and turnover than do all other health care settings [4,5].

Care robots, which include both social and assistive robots, show promise for addressing the mismatch between the aging population and the shortage of professional caregivers in ALFs. Interest in care robotics is growing, with a 585% increase in publications on health care robots from 2011 to 2021 [10]. Social robots, which include companion robots, perform work tasks based on "interactional performances" between humans (eg, caregivers and patients) or with pets [11]. Assistive robots (also referred to as mobility or service robots) perform physical work tasks such as lifting patients, helping with activities of daily living, or assisting at mealtimes [11]. Some evidence suggests that care robots may improve the general well-being of older adults [12-14]. In a scoping review of 69 studies, the most commonly reported therapeutic benefits consisted of improved mood and emotional states and increased social interaction [13].

Despite the positive effects for older adults and the frequently stated objective of addressing the nursing shortage, very few studies have managed to reduce workload [15]. Furthermore, the perspectives of nursing staff on the use of care robots have been largely ignored. In the previously mentioned review of 69 studies, only 15 included nursing staff as participants [13]. In those 15 studies, the robots relieved nurses of certain tasks (eg, responding to call lights [16]), but they often required the assistance of staff for operation (27/69, 39%) and thereby increased workload [13,17,18]. A scoping review on the effects of care robots on professional caregivers supports these findings: the introduction of care robots had both positive and negative effects, reducing physical and mental demands in some scenarios and increasing workload in others [11]. These examples highlight the fact that although care robots have the potential to improve the health of older adults, such benefits are in part due to skilled use by nursing staff [19]. Further, the implications of introducing care robots into ALFs extend beyond the recipient of care (ie, older adults) to the entire health care system. Care robots will fundamentally change the nature of nursing work. These findings are important, given today's climate of widespread nursing shortages and burnout.

Although this research topic is gaining popularity, the usability and acceptability of care robots remain a barrier to widespread adoption. High workloads and negative attitudes have been identified as barriers to staff's adoption of care robots [20,21]. In their scoping reviews on robots in nursing, Maalouf et al [22] and Ohneberg et al [23] identified usability and acceptance issues, the need for further research on the psychological barriers to acceptance, and the need to improve collaboration between nurses and robots [22,23]. Successful deployment of care robots into health care systems and facilities requires a comprehensive understanding of multiple stakeholders' perspectives of their use, and their design must be informed by an awareness of the context in which they will be used [24,25].

Participatory design is a research approach that actively involves stakeholders in the design process of emergent technologies to ensure that their needs and preferences are addressed by the developed technology [26-28]. Previous literature reviews have been conducted to examine the participatory design and other similar research approaches for the design and development of care robots for ALFs, but they have mainly included the receivers of care (ie, older adults), leaving the perspectives of nursing staff underexplored [29-31]. In addition, these reviews have aimed to evaluate and compare different research methodologies, not to synthesize participants' perspectives [29-31]. A 2018 scoping review explored the views of nurses and other health care providers on the use of assistive humanoid and animal-like robots and identified mixed opinions, but more positive than negative, and concerns related to patient safety and privacy [32]. While this review did focus on the perspectives of health care providers, including nurses, the authors excluded robots without a social or interactive element and did not focus on older adults or the ALF setting. Furthermore, this scoping review did not include a quality assessment of the selected articles, which limits its ability to offer suggestions for practice. Our review builds on these findings by including all types of care robots, focusing on the assisted living setting, and including a quality assessment of the reviewed publications. We have chosen to focus on the ALF setting because the world's growing population of older adults and subsequent rising need for residential long-term care, coupled with widespread staffing shortages, has led to a growing interest in care robots for ALFs [13]. Additionally, it is important robots are customized to the specific end user and health care setting, as the needs of staff and care receivers differ greatly between different care settings [33].

Nurses' perspectives have not been fully implicated in the design, development, and implementation of care robots. Without consideration of nursing staff and the care environment of ALFs, care robots may further exacerbate the nurse staffing crisis and are unlikely to be adopted into care. To address these research gaps, we have conducted a systematic literature review in order to answer the following research questions: (1) What is known about the attitudes, needs, and preferences of nursing staff in ALFs in relation to the use of care robots? (2) What research methods, designs, and populations have been used in this research? (3) What are the gaps in the literature that warrant future research? The results of this systematic literature review were originally published as part of the 2024 ACM/IEEE (Association for Computing Machinery/ Institute of Electrical and Electronics Engineers) International Conference on Human-Robot Interaction [34]. This study expands on those findings and provides additional methodological details, as well as a quality assessment of the included publications.

Methods

Study Design

This literature review follows the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 protocol for systematic literature reviews [35]. The PRISMA 2020 checklist is provided in Multimedia Appendix 1. A protocol was not registered for this systematic literature review.

Round 1: Keyword Search

The topic of care robots in ALFs is an interdisciplinary concern; therefore, we searched databases in engineering, computer science, and health sciences: PubMed, CINAHL Plus with Full Text, PsycINFO, the IEEE Xplore Digital Library, and the ACM Digital Library. On May 12, 2023, these databases were searched using the following search terms: ("robot*") AND ("senior living facilit*" OR "residential facilit*" OR "independent living" OR "assisted living" OR "senior living center*" OR "nursing home*" OR "skilled nursing facilit*" OR "intermediate care facilit*") AND ("aged" OR "older" OR "elderly") AND ("nurse*" OR "nursing" OR "staff" OR "professional caregiver*" OR "professional carer*") AND ("perspective*" OR "preference*" OR "need*" OR "user-centered design" OR "user-driven design" OR "participatory design" OR "co-design" OR "usability" OR "universal design" OR "user experience*"). These search terms build on a previous literature review and were informed by the authors' previous experience and other relevant literature in the field [13]. To retrieve the full scope of literature on our topic, we imposed no limit for years of publication. PubMed, CINAHL Plus with Full Text, and PsycINFO were searched by titles and abstracts, the IEEE Xplore Digital Library was searched by metadata (titles, abstracts, and indexing terms), and the ACM Digital Library was searched using the 2012 ACM Computing Classification System with the filter "Robotics." This strategy was adopted from a previous review [13]. A detailed search strategy for each database is provided in Multimedia Appendix 2.

Round 2: Screening of Titles and Abstracts

Next, the first author screened the retrieved publications by title and abstract using predetermined inclusion and exclusion criteria. To be included, the publications had to meet the following criteria: (1) full text written in English, and (2) focus on the predevelopment phase, on gathering information on nursing staff's attitudes, needs, and preferences regarding care robots for ALFs. Following a previous literature review [13], we adopted the National Library of Medicine's MeSH (Medical Subject Headings) definition of robotics: "the application of electronic, computerized control systems to mechanical devices designed to perform human functions" [36]. Smart assistive devices (eg, walkers, canes, and transfer devices) and ambient assisted living technologies without a robotic platform were thus excluded from the review. Studies of the implementation of a care robot or of perspectives of an already developed care robot were also excluded. We defined "assisted living facility" as any residential setting that provides long-term care to older adults, consistent with prior literature reviews [12]. Publications that did not focus on such facilities (eg, aging in place) were excluded. Publications were also excluded if they were not peer-reviewed empirical studies (eg, literature reviews, opinion pieces, system architectures, and dissertations). We included all other research designs: quantitative, qualitative, and mixed methods.

Round 3: Screening of Full Text

The remaining papers were screened by full text using the same inclusion and exclusion criteria.

Round 4: Coding and Analysis of Full Text

The final 15 publications for review were coded by publication year, study aim, research method, sample characteristics, country and setting where data collection occurred, and key findings. Qualitative study findings were synthesized using applied thematic analysis to understand the main themes regarding nursing staff's perspectives of care robots for ALFs [37]. Quantitative data were examined using narrative synthesis to gain a richer understanding of the perspectives of nursing staff, as well as methodological trends and limitations of the existing literature.

In addition, we assessed the levels of evidence reported in the 15 publications. To assess studies with a mixed methods design, McGill University's Mixed Methods Appraisal Tool was used [38]. For all other study designs, the critical appraisal tools developed by the Joanna Briggs Institute were used to evaluate study quality [39]. To compute scores, questions answered as “Yes” received 1 point and questions answered as “No” or “Unclear” received no points. The total score was then divided by the number of questions and multiplied by 100. Depending on the score, studies were rated as very poor (0%-30%), poor (31%-50%), fair (51%-70%), good (71%-90%), and excellent (>90%). Two reviewers (KT, a doctoral student in Nursing, and JL, a doctoral student in Robotics) independently completed the checklist for each study; their interrater reliability reached 87%; disagreements were resolved through discussion.

Results

Search and Screening Results

During round 1, keyword search, the 5 databases yielded 231 publications (n=53, 23% from PubMed; n=44, 19% from PsycINFO; n=42, 18% from CINAHL; n=35, 15% from IEEE; and n=57, 25% from ACM). When these publications were combined, 11 duplicates were identified and removed using Rayyan, an electronic screening tool [40]; a total of 220 nonduplicate publications remained for screening.

During round 2, screening of titles and abstracts, a total of 185 publications were excluded (Figure 1), resulting in 35 publications for full-text review.

In round 3, screening of full text, 22 additional publications were excluded; a total of 13 remained. Additionally, 2 publications were added via citation searches of the included studies, for a total of 15 publications. Figure 1 presents the full search and screening process.

Quality Assessment Results

Multimedia Appendix 3 [41-55] shows the results of the quality assessment. From the results, 2 (13%) publications were rated excellent, 11 (73%) were rated good, and 2 (13%) were rated fair. The qualitative publications overall lacked philosophical and theoretical frameworks. With regard to the quantitative publications, points were deducted for a lack of valid and reliable instruments, as well as a lack of consideration of confounding variables. Although the majority of studies were rated good, there was a general lack of reporting on important methodological decisions and sample characteristics.

Descriptive Results Based on the Coding of Full Text

A summary of the 15 studies is presented in Multimedia Appendix 4 [41-55]. The 15 studies in our final sample were published from 2007 to 2023; the majority (8/15, 53%) were published in the last 5 years. They were conducted in 11 countries—in North America (7/15, 47%), Europe (5/15, 33%), Asia (2/15, 13%), and Oceania (2/15, 13%). One study was conducted in both Europe and Asia, so it is accounted for twice [45]. Qualitative designs were most common (8/15, 53%); the remaining studies used mixed methods (3/15, 20%), a cross-sectional approach (3/15, 20%), or quasi-experimental designs (1/15, 6%). Qualitative data collection included interviews (6/15, 40%), focus groups (8/15, 53%), and observation (3/15, 20%). The cross-sectional studies relied on questionnaires. The Robot Anxiety Scale was used in 2 of the 15 (13%) studies; this scale has high reliability (Cronbach α=0.92) [42,43]. Others included A Questionnaire for the Use of a Social Robot in Care for Older Persons [54], which has high reliability (Cronbach α=0.95; intraclass correlation coefficient 0.88) [56], and the Positive and Negative Affect Schedule [42], which has also demonstrated high reliability (Cronbach α=0.84-0.90) and validity [57]. The quasi-experimental study developed new scales from existing literature and calculated high reliability for each scale (Cronbach α=0.70-0.92) [49]. The remaining questionnaires were study-specific and were developed from the literature, from focus groups, or by an undisclosed method, without any reliability or validity testing.

Most of the studies (11/15, 73%) lacked theoretical guidance. Four of the studies included a theoretical framework: the social-ecological model [48], the technology acceptance model [47], the model for the ethical evaluation of sociotechnical arrangements [46], and Forlizzi product ecology [44]. The 4 studies adopted a more holistic approach, exploring the social, environmental, and organizational aspects of ALFs (eg, nursing workflows) in relation to care robots [44,48,52,53]. In addition, 8 studies mentioned using a participatory design or related approach [44,46,48-50,52,53,55]. An overview of how these studies defined and facilitated user participation is presented in Table 1, as well as at which stage of the innovation process the users were involved. Seven studies (47%) used a predetermined definition of "care robot," meaning that aspects of the robot had been decided before the study took place. Three of these studies focused respectively on robots for a specific task or purpose: robot-assisted feeding systems [48], a robotic shower system [46], and robots to address personal mobility challenges [55]. Five studies involved demonstrations with robotic prototypes [44,49,53-55].

All 15 studies relied on convenience samples. Only 2 focused exclusively on nursing staff [49,52]; the remaining included older adults (10/15, 67%), relatives (4/15, 27%), other staff members (4/15, 27%), or experts in the field (4/15, 27%). Nursing staff included registered nurses (10/15, 67%); certified care workers (eg, certified nursing assistants/aides, licensed vocational nurses, or licensed practical nurses; 3/15, 20%); unspecified caregivers or nursing staff members (10/15, 67%); nurse practitioners (2/15, 13%); and nursing supervisors (2/15, 13%). Participants in 1 study were nursing and medical students [54], and another study included roboticists [55]. Sample sizes ranged from 3 to 286 nursing staff members; a majority (8/15, 53%) had fewer than 10 participants. Four studies provided no additional demographic information besides the participants' roles in the ALF [41,47,50,55]. Of the studies that did provide additional demographic information, all but one [49] had mainly female participants; the average age of participants ranged from 22.2 to 50 years, and average years of experience ranged from 2.5 to 12 years. Level of education, reported in only 3 studies, ranged from 26% to 43% college educated [43,45,54]. Most studies were conducted in a single setting, but 6 included participants from multiple facilities [42-45,51,55]. Eight of the studies focused on not-for-profit or government-funded facilities [41-43,47,50-53]. Participants were recruited in 1 study through a medical university [54]. Three studies, in addition to investigating ALFs, also examined community-based care for older adults [45,46,55]. Key characteristics of the 15 studies are provided in Table 2.

Table 1. Overview of participatory design or related approaches.

Author (year)	Definition/facilitation of user participation	Stage of innovation
Chang and Šabanović (2014) [44]	User-centered design approach: emphasis is on the perspectives of users instead of technology development. Uses task analysis, interviews, field observations, and focus groups.	Predesign
Klein and Schlömer (2018) [46]	User-centered requirements analysis: users are involved in all relevant stages of development. Uses interviews and focus groups to analyze requirements for the shower system, discuss renderings and mock-ups, and identify sociotechnical arrangements and ethical problems.	Predesign; postrenderings and mock-ups
Bhattacharjee et al (2019) [48]	Community-led relational approach shifts away from focusing on a single user to supporting multiple users at multiple layers of the social network. Uses contextual inquiry and surveys.	Postinitial design
Erebak and Turgut (2019) [49]	Human-centered technology approach: human and robot are evaluated as a team to understand the work prior to implementing technology. Participants evaluated existing robots.	Preproduction
Johnson et al (2020) [50]	Need finding design approach prioritizes the needs of older adults first and caregivers and clinicians second. Uses focus groups and surveys.	Predesign
Fiorini et al (2021) [55]	Cocreation or co-design: older adults and caregivers are the principal investigators. Uses interviews.	During design or development
Stegner and Mutlu (2022) [52]	Co-design: to help understand caregivers' work and guide the design of care robots. Uses observations and interviews.	Predesign
Stegner et al (2023) [53]	Situated participatory design enables the design and testing of use scenarios through interaction with the robot prototype. Uses focus groups.	During design or development

[a] Studies were accounted for multiple times if met the criteria.

Nursing Staff Desired Robot Characteristics

Across the 15 studies, nursing staff described their ideal robot as one that could assist with their high workload. The most desired capability of a care robot was to assist with physically demanding tasks (9/15, 60%) [41,43-45,47,48,50,52,55]. These tasks included activities of daily living (eg, bathing, toileting, and feeding) and transferring or lifting patients. The nursing staff also desired a robot that could assist with monitoring patients and alerting staff when patients were in danger (8/15, 53%) [43,45-47,50,52,54,55], physical therapy or mobility exercises (5/15, 33%) [43,45,47,50,54], and medication administration and reminders (3/15, 20%) [45,50,54]. Less commonly desired capabilities included cognitive interventions [47,54], assessments [43], entertainment [44], and assistance with visual or hearing deficits [47].

Although assisting with physical tasks was the most desired function of care robots, participants in 2 studies discussed care that is lost when such work is delegated to robots [46,48]. In one of those studies, the nursing staff discussed how bathing patients involves more than just hygiene—staff used this time to connect with patients and establish relationships, to motivate patients to participate in the bathing process, and to monitor health changes (eg, skin breakdown) [46]. In the other study, staff expressed concerns about the robot replacing important bonding time that occurs during meals [48].

Opinions on whether a care robot could provide social support were mixed. In a few studies, nursing staff believed that care robots were capable of providing such care [51] or a limited version of it [44]. In 1 study, staff had a “wait and see” attitude about robots’ abilities [55]. Although their thoughts about robots’ ability to provide social care were inconclusive, nursing staff agreed that delegating such care to a robot would have serious implications [44-46,51,52,54,55]. In 3 (20%) studies, staff were adamant that robots should not provide social care [46,52,55]. In 3 other studies (20%), staff were less decisive about whether robots should provide social support and feared that their introduction could lead to inhumane or subpar care; however, these participants saw robots as a potential mediator of human social interaction [44,51,54]. For example, participants in 1 study discussed the benefit of using care robots to connect residents with loved ones during the COVID-19 pandemic [51]. In 1 study, beliefs about whether care robots could or should provide social support differed on the basis of the staff's cultural background [45].

Finally, the nursing staff desired robots personalized to older adults' abilities, routines, preferences, and needs [46-48,52-54]. To achieve personalized robots, 1 study suggested "end user programming" where nursing staff (ie, the domain experts) could easily customize robots for older adults [52]. This study also suggested that robots should have the ability to learn and adapt from previous experiences [52]. Another study suggested that nursing staff's intimate relationships with residents could be used to gain knowledge and personalize robots for specific older adults [47].

Concerns

Nursing staff members voiced several concerns about adopting care robots in ALFs. Ethically, there was disagreement about who should control the robots—the older adults or the nursing staff. In 2 (13%) studies, staff argued that they should supervise and have ultimate control over robots, instead of the older adults [52,54]. Their primary argument for needing control of the robots was to ensure older adults' safety. In other studies, however, nursing staff were concerned about maintaining the older adults' autonomy and dignity [46,51,53]. An emergency shutoff button was suggested as a method to increase autonomy and safety [43,44,46-48,51]. In 2 (13%) studies, staff were concerned about surveillance and emphasized the importance of protecting the privacy of older adults and staff [51,54]. Finally, nursing staff worried that robots could replace human caregivers and take away their jobs [42,45,46].

Accessibility was also a common concern across studies. Caregivers in one of the studies thus advocated for "distributive justice," meaning that everyone should have access to care robots [46]. Care robots can be extremely expensive, but finances (whether those of the older adult or of the facility) should not prevent someone from accessing these devices [46,51]. A staff member in 1 study commented that the high cost of care robots can lead to extreme precautions in order to keep the robots in good working order [51]. As a result, the robots were often locked up when they were needed most (ie, when family or staff were unavailable) [51]. In addition to being financially accessible, robots must be easy to hear and see for those with deficits [43].

Finally, nursing staff were concerned about operability. Nursing staff were concerned that care robots might increase workload, and so they desired robots that would be easy to use [44,51,55], easy to clean and maintain [43,51], flexible [44], and reliable [43]. Three of the studies emphasized that robots should save nursing staff time, which could then be invested into providing relational care [43,46,51]. Also related to operability, 3 (20%) studies pointed to a lack of education and training on care technologies in nursing curricula [43,44,54].

Potential Factors Influencing Robot Perspectives

In 5 (33%) studies, the authors examined potential factors in participants' perspectives of care robots—culture, qualification, and the participant's role in the facility. In 1 study, Finnish staff reported significantly greater fear that robots would cause inhuman care and increase loneliness; whereas, Japanese staff were more likely to believe that robots could reduce anxiety and loneliness [45]. In another study, clinicians (therapists and registered nurses) desired robots to help with medications, safety, and mobility tasks, whereas caregivers (certified nursing assistants and other formal caregivers) desired robots to assist with activities of daily living [50]. Medical students in 1 study were concerned about privacy, whereas nursing students were concerned about robots' social functions [54]. In 2 studies with residents and nursing staff, the residents felt more positively toward the robots than did the nursing staff [42,43]. Both the residents and nursing staff desired assistance from care robots: residents desired assistance with managing their health (eg, medication reminders), and nursing staff desired job assistance (eg, escorting residents to meals) [42].

Discussion

Overview of Findings

In this systematic literature review, we have examined 15 studies of nursing staff's attitudes, needs, and preferences regarding the use of care robots in ALFs. We have synthesized our findings into three major themes: (1) desired robot characteristics, (2) concerns, and (3) methodological approaches.

Nursing Staff Desired Robot Characteristics

There was a consensus among nursing staff that care robots should serve as nursing assistants to help reduce high workload; they should not replace nursing work. Assistance with physical tasks was the most desired function. Whether robots could or should assist with social tasks remains a question. However, a previous literature review has identified an overrepresentation of social robots as opposed to assistive robots: 60 of the 69 (87%) included studies in that review investigated social robots [13]. This discrepancy illustrates the necessity of involving stakeholders at the early stages of care robots' development. Whether robots can provide social assistance is a technical question and will require collaboration with roboticists. Whether robots should provide social assistance is an ethical question that requires the involvement of older adults and their caregivers. Existing participatory research in this field has focused on older adults as the key stakeholders [29-31]; however, it is important that future research involve a wide range of perspectives (including nursing staff) to gain a holistic understanding of care robots for ALFs.

In addition, our findings call for future research on what constitutes nursing work in ALFs. The reviewed studies demonstrate that nursing work is extremely diverse, and much of nursing's most essential care work goes unseen or is taken for granted, due to gender and power dynamics [58-60]. In a literature review of 121 articles on this topic, the authors describe nursing work as multifaceted and a composite of physical, emotional, cognitive, and organizational labor [60].

Many important yet invisible aspects of care cannot be accounted for by the technical affordances of a robot. In the included study that investigated a robotic showering system, nursing staff suggest that while a robot may be useful for the functional aspects of washing a patient, it may not replace the interpersonal nor observational labor involved in their work [46]. The same is true of the electronic health care record, which has been widely adopted throughout the health care system but reduces nurses' face-to-face interactions [61]. These examples highlight the unexamined and incomplete notions of what nursing work is today—aspects that developers of such technologies may fail to address [62]. Topol [63] describes a future where medicine harnesses the power of artificial intelligence and robotics to support tasks better suited for automation, freeing nurses and other health care providers to focus on providing real care to patients [63]. To develop ethical, effective, and useful robots, thoughtful discussion and study is necessary on the nature of work that nurses do in ALFs (visible and invisible) and what constitutes good care with robotic systems.

Concerns

Nursing staff had concerns about the ethics, safety, accessibility, and operability of care robots in ALFs. Opinions about who should have control over the robots were mixed. On the one hand, giving older adults control over a care robot may enhance autonomy, but, on the other, nursing staff are responsible for ensuring residents' safety. Further research on how to preserve older adults' autonomy while balancing it with safety is needed. Care robots should be accessible to those who need them, and this should be factored into care robot design, development, and implementation. Accessibility includes financial, physical, and cognitive accessibility. Robots' operability was especially important to nursing staff, who did not want robots to increase their already high workloads. Future research should consider nurse workflows and how to thoughtfully implement robots in a way that does not increase workload. In addition, in the context of the COVID-19 pandemic and widespread staffing shortages, where nurses already feel undervalued, it is important that robots be introduced as assistants to nurses, rather than replace nursing work.

Methodological Approaches

Several methodological limitations were identified across the 15 studies.

First, 7 (47%) studies used predetermined definitions of care robots, which limited the implications of their participants' comments. Participatory design is intended to address the power imbalance between researchers and participants. By involving participants at the very beginning of technology design, stakeholders are empowered to take part in the conceptualization of technologies [27]. When participants act solely as informants, however, study findings are biased by the researchers' assumptions about end users and the types of robots they would prefer, and participants are limited to thinking only within predetermined definitions, which may lead to incomplete or misleading findings [64]. To fully understand the perspectives of nursing staff at the early stages of robot design, future research should use participatory design to empower nurses to describe their ideal robot without any preconceived ideas. Although a majority of the included studies (8/15, 53%) claimed to take a participatory design or related approach, there is a lack of established criteria for what constitutes participatory design, which leads to varying degrees of participants' involvement. To increase rigor and strengthen the quality of research in this field, there is a need for future work to develop protocols for participatory design.

Second, the sample sizes were small; 53% (8/15) of the studies had fewer than 10 participants. In addition, the studies provided very limited demographic information on the nursing staff or facilities. This lack of empirical reporting is a common limitation in health informatics research and has been noted in previous literature reviews on care robots [13] and artificial intelligence for caregivers of persons with Alzheimer disease [65]. Only 5 studies included demographic factors in the interpretation of their results, and findings differed across culture, qualification, and role in the facility. To understand the factors that influence attitudes toward and needs or preferences for the use of care robots, it is important to collect and consider demographic information on nursing staff as well as other end-user groups. This can promote the development of care robots that are personalized and useful, as well as increase the likelihood that care robots will be adopted into practice. Six of the studies included multiple facilities but with little exploration of how differences among facilities might influence users' perspectives of care robots. Studying a single facility may allow detailed exploration, but the inclusion of multiple facilities allows comparisons, with greater potential for generalization. This is especially important in the United States, where licensure and regulations differ greatly between different types of facilities and from state to state.

Finally, several different questionnaires were used to assess nursing staff's attitudes, needs, and preferences, making it difficult to compare findings across studies, and although some of these instruments have been validated, many have not. Further research is needed to develop and validate relevant instruments for understanding nursing staff's perspectives of care robots.

Limitations

The systematic literature review has several limitations. First, only 5 electronic databases were searched, so it is possible that important and relevant studies were missed. To mitigate this possibility, we chose an interdisciplinary selection of databases representing engineering, computer sciences, and health sciences. We also searched the citations of our final sample to reduce the chances of missing pertinent studies and added 2 publications. Second, we included only publications with full text written in English, so it is possible that we missed studies written in other languages. Third, our search terms were not exhaustive, and the language used to describe the participatory design and related research approaches is diverse; therefore, it is possible that we missed important relevant articles. To mitigate this possibility, we reviewed the search terms of previous similar literature reviews. In addition, the language used to describe nursing staff varies, and it is possible that we missed studies that used different terms. Notably, after the conclusion of this review, the authors became aware of a study by Chen et al [66], which investigated the attitudes of Taiwanese health professionals in ALFs toward the use of social robots. The authors validated the Chinese version of attitudes toward the use of social robot questionnaire and found that most participants had positive attitudes toward social robots, these attitudes were positively and significantly correlated with their awareness of robots, and staff working in nursing homes (as opposed to lower-acuity, residential aged care) were significantly more positive toward social robots [66]. These findings support our statement that in order to customize robots to the specific care setting and end user, which in turn will promote the robots' usefulness and adoption, future research is needed on the different individual- and facility-level factors that influence nursing staff's attitudes toward care robots.

Conclusions

In this systematic review of 15 studies on nursing staff's attitudes, needs, and preferences related to the use of care robots in ALFs, we have found that nursing staff desire care robots that will assist with physically demanding tasks and reduce workload. But the nurses wanted to be able to preserve their interpersonal caring work too. Consideration of ethics, safety, accessibility, and operability informed nurses' concerns across the studies. Further research is needed to mitigate these concerns and understand the demographic, social, environmental, and organizational factors that influence individuals' perspectives of care robots and their adoption in ALFs.

Acknowledgments

The authors would like to acknowledge that the results of this systematic literature review were originally published as a late-breaking report in the 2024 ACM/IEEE International Conference on Human-Robot Interaction and presented as a poster. The authors would also like to thank Dr John Bellquist from the Cain Center for Nursing Research in the School of Nursing at the University of Texas at Austin for his professional editing assistance.

Abstract

Background: AgeTech (technology for older people) offers digital solutions for older adults supporting aging in place, including digital health, assistive technology, Internet of Things, medical devices, robotics, wearables, and sensors. This study underscores the critical role of standards and guidelines in ensuring the safety and effectiveness of these technologies for the health of older adults. As the aging demographic expands, the focus on robust standards becomes vital, reflecting a collective commitment to improving the overall quality of life for older individuals through thoughtful and secure technology integration.

Objective: This scoping review aims to investigate the current state of standards and guidelines applied in AgeTech design and development as reported in academic literature. We explore the existing knowledge of these standards and guidelines and identify key gaps in the design and development of AgeTech guidelines and standards in scholarly publications.

Methods: The literature review adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines. Searches were carried out across multiple databases, including Scopus, IEEE, PubMed, Web of Science, EBSCO, CINAHL, Cochrane, and Google Scholar, using a search string incorporating concepts such as “older people,” “technology,” and “standards or guidelines.” Alternative terms, Boolean operators, and truncation were used for comprehensive coverage in each database. The synthesis of results and data analysis involved both quantitative and qualitative methods.

Results: Initially, 736 documents were identified across various databases. After applying specific inclusion and exclusion criteria and a screening process, 58 documents were selected for full-text review. The findings highlight that the most frequently addressed aspect of AgeTech standards or guidelines is related to “design and development,” constituting 36% (21/58) of the literature; “usability and user experience” was the second most prevalent aspect, accounting for 19% (11/58) of the documents. In contrast, “privacy and security” (1/58, 2%) and “data quality” (1/58, 2%) were the least addressed aspects. Similarly, “ethics,” “integration and interoperability,” “accessibility,” and “acceptance or adoption” each accounted for 3% (2/58) of the documents. In addition, a thematic analysis identified qualitative themes that warrant further exploration of variables.

Conclusions: This study investigated the available knowledge regarding standards and guidelines in AgeTech design and development to evaluate their current status in academic literature. The substantial focus on assistive technologies and ambient assisted living technologies confirmed their vital role in AgeTech. The findings provide valuable insights for interested parties and point to prioritized areas for further development and research in the AgeTech domain.

aging in place; technology; gerontechnology; AgeTech; assistive technology; older adult; aging; ambient assisted living; active assisted living

Introduction

Background

As the global population ages, the number of people aged ≥60 years is expected to double, reaching 2.1 billion by 2050, while the number of those aged ≥80 years is expected to triple, reaching 426 million [1-3]. This trend is mirrored in Canada, where older adults are projected to make up approximately 25% of the population by 2050 [4,5]. Notably, >95% of older Canadians would prefer to age in their own homes and communities [6,7]. However, many older adults contend with multiple chronic health conditions that can necessitate long-term care to manage their activities of daily living. A recent Canadian study suggests that between 11% and 22% of older adults transitioning into long-term care could have remained in their homes or community-based care settings with the appropriate supports in place [8].

Addressing the needs of this rapidly aging population requires innovative solutions to overcome the unique social, fiscal, and medical challenges of providing health and social care. Assistive technologies, including a range of devices, equipment, software, or adaptations to the physical environment, offer the potential to improve functional ability, social participation, and well-being, making them a valuable part of the solution. Within this broad category, AgeTech—technology for older people, a specialized subset of assistive technologies—is designed to meet the unique needs and preferences of older adults and their care partners, focusing on preserving and enhancing independence and inclusion for individuals aged ≥65 years [9-11]. For the purposes of this study, a broad definition of AgeTech is used [9]: "AgeTech refers to digital technologies or digitally enabled products designed explicitly for or with the potential to provide benefit to older adults and care partners. This will include a range of innovations supporting aging in place, healthy aging, staying connected, and more. It is expected that technologies in the program will include digital health, assistive technologies, Internet of Things, medical devices/diagnostics, robotics, wearables, and other sensor-based technologies."

Despite the potential of AgeTech to help older adults age longer in the homes and communities of their choice, many technologies have not achieved the expected success rates [12]. Challenges include the development of fit-for-purpose technologies that address the real needs of older adults and that are subsequently adopted by them and their care partners [12,13]. Recent studies have revealed evidence of the potential impact of technology in supporting older adults to age in place [9,14]. Still, AgeTech innovators can struggle with the adoption of AgeTech products or services by older people, their caregivers, and the systems that help care for them. One factor contributing to this translational challenge is the lack of standards-based solutions for AgeTech design and evaluation, which can result in products that are either unfit for purpose or fail to address real needs [13,15]. Standards and guidelines are crucial in AgeTech development for ensuing support for safety, efficacy, reliability, interoperability, and regulatory compliance [16,17]. They address the specific needs of older adults, mitigate risks, and foster user trust. In addition, standards promote seamless integration, improving care coordination and decision-making. Consistency and quality across AgeTech solutions are maintained, fostering innovation and reliability. Compliance with standards streamlines regulatory processes and enhances market acceptance, benefiting older adults and caregivers. Overall, standards are essential in advancing AgeTech, enhancing aging-related care, and improving the well-being of older populations [9,15-19].

Objectives

This scoping review aims to explore the current state of standards and guidelines used in the design and development of AgeTech in the academic peer-reviewed literature and highlights the importance of these frameworks in advancing the field [9,15-19]. The decision to initially focus on academic peer-reviewed literature allows for a rigorous, systematic exploration of the foundational research in AgeTech design and development standards and guidelines. This approach ensures that the review is grounded in scientifically validated findings, providing a robust framework from which to explore the broader, practical implications and innovations captured within the gray literature in a subsequent review. This phased methodology strategically broadens the scope of analysis to include a comprehensive spectrum of insights, from theoretical underpinnings to practical applications in the field. Two research questions helped to guide the search strategy and data extraction process in the academic literature:

1. Research question 1: What is the existing knowledge about standards or guidelines in the design and development of AgeTech?
2. Research question 2: What are the key gaps in the design and development of standards or guidelines for AgeTech?

Methods

Study Design

A scoping review was chosen as the systematic method to comprehensively map the available evidence and provide an overview of the scientific literature concerning existing guidelines and standards for the development of AgeTech [20-22]. The scoping review followed a five-step process: (1)

identifying an initial research question; (2) identifying relevant studies; (3) selecting the studies; (4) charting the data; and (5) collating, summarizing, and reporting the findings [20]. To establish an effective search strategy and search strings, our research team engaged in 3 consultations with a librarian subject matter expert. Following these consultations and using an iterative approach to test database and search terms, a search strategy was finalized. Article selection adhered to the guidelines outlined in the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews).

Information Sources and Study Selection

The research team performed the scoping review search in October 2023. A subsequent search was conducted before submission for publication on January 20, 2024. We searched 8 databases, including Scopus, IEEE, PubMed, Web of Science, EBSCO, CINAHL, Cochrane, and Google Scholar, to identify academic, peer-reviewed journal articles and conference papers. Reflective of the interdisciplinary nature of our research, we searched a broad range of databases and knowledge repositories in the health sciences and engineering disciplines. This strategy was designed to ensure a comprehensive review of relevant literature. The retrieval period for the search was not limited. The search strategy, including keywords and search strings, is summarized in Textbox 1.

Articles were imported into Covidence (Veritas Health Innovation Ltd) screening and data extraction software for conducting systematic reviews. All titles and abstracts were screened by at least 2 members of the research team (SA, TR, or JM) using the inclusion and exclusion criteria detailed in Textbox 2. Any discrepancies were reviewed by a member who was not an original reviewer.

Articles identified in the title and abstract screening as relevant were included in a full-text review using the same inclusion and exclusion criteria and review process. To identify any studies that may have been missed during the initial search, we conducted both forward and backward searching.

Textbox 1. Academic peer-reviewed journal search strategy.

Search strategy

- Databases: Scopus, IEEE, PubMed, Web of Science, EBSCO, CINAHL, Cochrane, and Google Scholar
- Limits: language (only resources in English) and species (studies on human)
- Date: all literature till January 20, 2024
- Search string: #1 AND #2 AND #3
  - #1 “standards” OR “guideline*”
  - #2 “Agetech” OR “ambient assisted living” OR “active assisted living” OR “wearables” OR “mobile digital technology” OR “remote patient monitoring” OR “telemedicine” OR “telehealth” OR “gerontology” OR “digital technology” OR “mhealth” OR “mobile health” OR “assistive technology” OR “internet of things” OR “virtual reality” OR “voice recognition” OR “artificial intelligence” OR “smart technology” OR “smart assistive technology” OR “digital” OR “technology”
  - #3 “Aging” OR “ageing” OR “elderly” OR “seniors” OR “aging in place” OR “older adult” OR “care partner” OR “senior citizens” OR “aging population” OR “gerentol*” OR “geriatric” OR “care givers”

Textbox 2. Inclusion and exclusion criteria.

Inclusion criteria

- English language
- Only peer-reviewed scholarly articles and conference papers (In this study, we limited the inclusion criteria to peer-reviewed journal articles and full conference papers to ensure a high level of quality and academic rigor. We excluded book chapters, dissertations, and conference abstracts as they often lack the comprehensive detail, consistency, and peer-review standards needed for robust analysis, thereby maintaining the relevance and feasibility of our scoping review.)
- Subject matter
    - AgeTech-related technology standards or guidelines (using the definition outlined in the third paragraph of the Background section)
- No restrictions on publication date

Exclusion criteria

- Non-English
- Article types
    - Book chapters
    - Dissertations
    - Conference abstracts
    - Reports
- Subject matter
    - Standards or guidelines that do not emphasize age-related technology
    - Standards or guidelines intended for devices specifically aimed at children aged <18 years
    - Standards or guidelines intended for medical devices delivering clinical health care services within a clinical setting that require professional or medical expertise for use, monitoring, and interpretation (includes all class II, III, and IV medical devices and some class I medical devices if they are intended for medical use)
    - Documents addressing frameworks and models

Data Extraction

Data were extracted into an Excel worksheet with a variety of categories that systematically captured information relevant to the studies' objectives and research questions. Details extracted from documents included author and year, journal or conference name and scope, country, type of study, the document's type, aim of study, AgeTech type, developer of the standard or guideline, the old or new feature of the standard or guideline (the meaning of this variable is the response to the question: was the standard or guideline developed for the first time in this study, or was it developed previously?), methodology of standard or guideline development, target stakeholders of the standard or guideline (the meaning of this variable is the response to the question: who is going to use these standards and guidelines in AgeTech development?), characteristics of older adults as end users of AgeTech, main aspects of the standards or guidelines, results of the evaluation of the developed standard or guideline, important conclusions of the study, main limitations of the study, and gap of the study and recommendations for future studies.

Data Analysis and Presentation of Results

Both quantitative and qualitative methods were used for data analysis. We used descriptive methods to analyze quantitative variables and then conducted a thematic analysis on data from 3 qualitative variables.

For quantitative analysis, extracted data were imported into SPSS (version 26; IBM Corp), and basic descriptive statistics were calculated, representing information on the publication year, country, journal or conference name, scope of the journal or conference, type of study, the document's type, the old or new feature of the standard or guideline, AgeTech type, developer of the standard or guideline, target stakeholders of the standard or guideline, characteristics of older adults as end users of AgeTech, and main aspects of the standard or guideline.

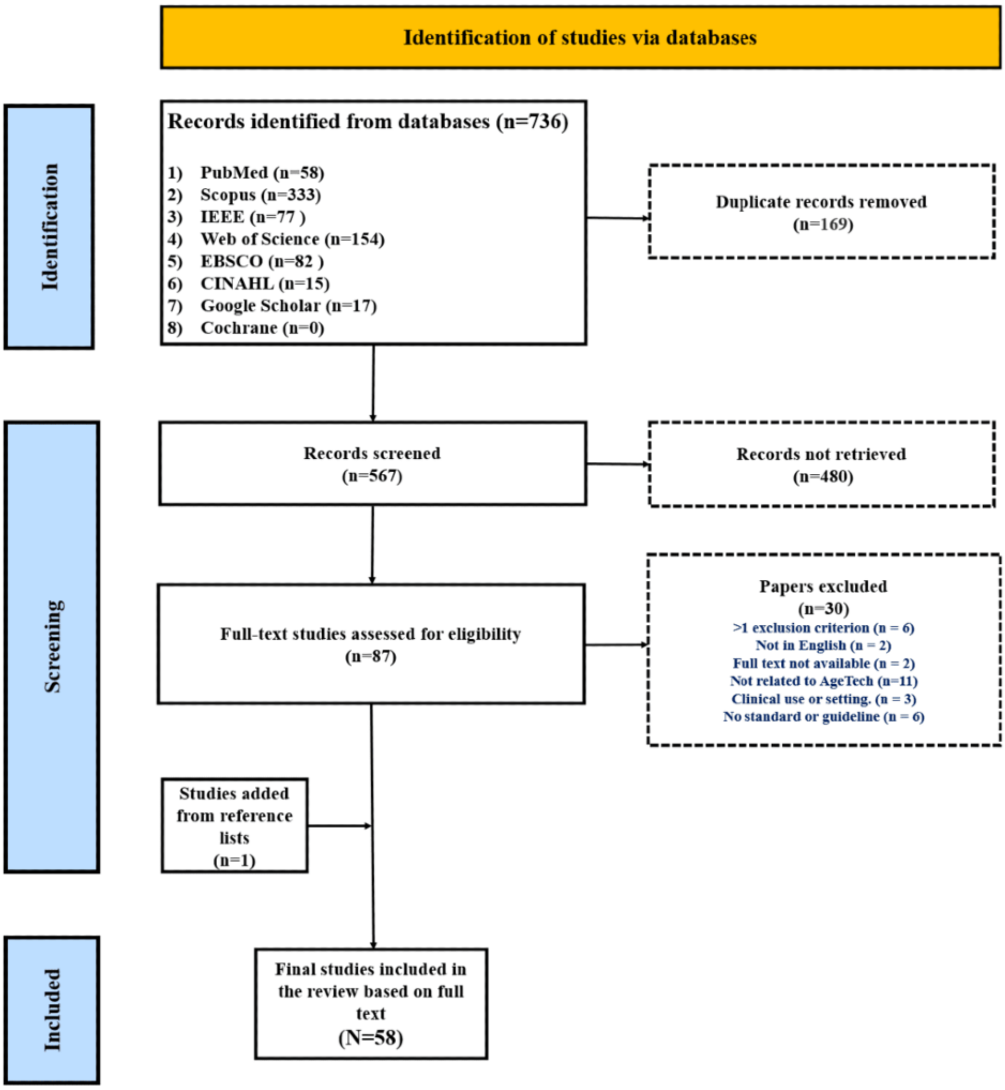
For qualitative analysis, we used thematic analysis to examine 3 qualitative variables: the aim of the study, the main limitations of study, and gap of the study and recommendations for future studies. Thematic analysis is a widely recognized method in both scoping and systematic reviews and has been applied in numerous studies to provide a deeper understanding of qualitative data [23-26]. Data from each variable were individually imported into NVivo (version 14; QSR International). Two coders conducted a thematic analysis following the guidelines established by Thomas and Harden [27]. Thematic analysis was conducted in 3 stages: free coding of primary study findings, organization of these "free codes" into related areas to form "descriptive" themes, and the development of "analytical'" themes.

Results

Overview

We selected 58 research papers [19,28-84] from an initial pool of 736 studies identified through the database search. We organized the information extracted from the 58 included documents into Multimedia Appendices 1-3. Figure 1 outlines the full process based on PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines.

Figure 1. Inclusion flowchart for peer-reviewed articles, based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines.



Multimedia Appendix 1 [19,28-84] presents a summary of the studies, detailing 6 variables: publication year, country, journal or conference name, scope of the journal or conference, type of study, and document's type. Multimedia Appendix 2 [19,28-84] compiles variables that most of them analyzed through quantitative analysis in the subsequent stage, featuring 8 columns: the old or new feature of the standard or guideline, AgeTech type, developer of the standard or guideline, methodology of standard or guideline development, target stakeholders of the standard or guideline, characteristics of older adults as end users of AgeTech, main aspects of the standard or guideline, and results of the evaluation of the developed standard or guideline. Finally, Multimedia Appendix 3 [19,28-84] summarizes variables that 3 of them analyzed using qualitative analysis in the next stage, including aim of the study, important conclusions, main limitations of the study, and gaps in the study, along with recommendations for future research.

In the following sections, we will present the analysis results for Multimedia Appendices 1-3.

Characteristics of the Study and Literature Distribution

Conference papers made up the majority of publications at 59% (34/58), while journal papers accounted for 41% (24/58). The field of computer science accounted for 69% (40/58). Other areas included health sciences (5/58, 9%), management and business sciences (2/58, 3%), multidisciplinary studies (9/58, 15%), and various other fields (2/58, 3%). Most of the publications were original research (46/58, 79%), while review articles constituted 21% (12/58) of the total. The research methods varied, with qualitative methods being the most common (37/58, 64%). Review articles also incorporated a review methodology (12/58, 21%), while quantitative methods (6/58, 10%) and mixed methods (3/58, 5%) were less commonly used (Multimedia Appendix 1). Table 1 provides a summary of the retrieved publications' characteristics.

Most of the papers (28/58, 48%) were published from 2019, as illustrated in Figure 2.

The United States was the leading source of publications (8/58, 14%), while Germany and Portugal each contributed to 9% (5/58) of the publications (Table 2).

United States	8 (14)

Findings From the Descriptive Quantitative Analysis

The analysis of the data included in Multimedia Appendix 2, regarding the status of standards or guidelines as “new” or “old,” indicated that a majority, 55% (32/58) instances, were classified as “new.” In contrast, 24% (14/58) of the instances were labeled as “N/A” (not applicable), indicating that the development status was either not applicable or not specified. The “old” category, signifying previously established standards or guidelines, accounted for 21% (12/58) of the instances.

In categorizing AgeTech types, we adopted a classification framework developed by AGE-WELL [10,85]. This framework includes 9 categories: “supportive homes and communities,” “health care and health service delivery,” “autonomy and independence,” “cognitive health and dementia,” “mobility and transportation,” “healthy lifestyles and wellness,” “staying connected,” “financial wellness and employment,” and “other.” Two authors with expertise in health informatics independently coded the AgeTech types using predefined AGE-WELL categories, achieving a high intercoder reliability with a Cohen κ score of 0.9, indicating strong agreement. Results indicate that the most prevalent AgeTech types with corresponding standards or guidelines are associated with the “staying connected” category (which includes mobile apps, social games, social and telepresence robots, friendly caller programs, and virtual reality technology), with a frequency of 31% (18/58). The “supportive homes and communities” category (encompassing smart homes, socially assistive robots, and age-friendly communities) was the second most frequent (16/58, 28%). Table 3 illustrates these findings.

Table 3. Distribution of studies based on AgeTech type (N=58).

	Studies, n (%)
Supportive homes and communities	16 (28)
Health care and health service delivery	7 (12)
autonomy and independence	5 (9)
Cognitive health and dementia	2 (3)
Mobility and transportation	1 (2)
Healthy lifestyles and wellness	4 (7)
Staying connected	18 (31)
Financial wellness and employment	1 (2)
Other	4 (7)

A substantially finding from the analysis pertains to the primary focus of the standards or guidelines mentioned in the selected publications. For clarity, we organized these into 11 categories. The results show that "design and development" is the most addressed aspect in AgeTech standards or guidelines, accounting for 36% (21/58) of the instances. "Usability and user experience" is the second most frequent area (11/58, 19%). In contrast, aspects receiving the least attention in AgeTech standards or guidelines in the academic literature were "ethics," "integration and interoperability," "accessibility," and "acceptance or adoption," each accounting for 3% (2/58) of the instances, and "privacy and security" and "data quality," each accounting for 2% (1/58) of the instances. These findings are presented in Table 4. It should be noted that in this classification "design and development" encompasses all technical aspects that are important in technology design. We could classify "usability and user experience" under the "design and development" category. However, we decided not to do so because of the significance of "usability and user experience" in technology design as well as the explicit focus of studies on this aspect. Therefore, we preferred to separate them from the broader "design and development" aspect. Furthermore, it should be noted that "not applicable" refers to documents where we could not identify specific aspects related to the standards or guidelines they addressed. In contrast, "others" refers to aspects that did not fit into these categories.

The most frequently targeted stakeholders for whom standards or guidelines were developed were "designers and developers," constituting 33% (19/58). Multiple stakeholders were the second most frequently mentioned, representing 28% (16/58) of the occurrences. Table 5 illustrates this discovery.

"General older adult population" was the largest group of end users for AgeTech, accounting for 71% (41/58). This classification was applied to end users of AgeTech in cases where the study did not define or describe the specific characteristics of older adults but only mentioned older adults or older population. Table 6 presents these results.

Findings From the Thematic Analysis of Qualitative Data

The thematic analysis, which focused on 3 qualitative variables: “the aim of the study,” “the main limitations,” and “recommendations for future research” (summarized in Table 7). This can also be seen in Multimedia Appendix 3.

In the thematic analysis for the “aim of the study,” certain themes, namely, “usability studies and design guidelines,” “assistive technologies for aging,” and “human-centered design and cultural considerations,” were the most frequently referenced in the identified literature. Conversely, critical aspects such as privacy and security, ethical considerations, accessibility considerations, integration and interoperability, user adoption, and data quality had the fewest references in the literature. This finding suggests a noteworthy emphasis within the academic literature on specific themes related to the “aims of the study” in the field of AgeTech. The recurrent references to these 3 main themes indicate a predominant focus on practical and user-centric aspects of technology development, particularly those tailored to aging populations. In contrast, the fewer references to the mentioned aspects indicate potential gaps in the current research landscape. This could imply that the existing literature may not adequately address these crucial dimensions, and there might be a need for more research and attention in these areas to ensure a comprehensive and ethically sound approach to AgeTech development. The findings underscore the importance of a balanced and holistic perspective when conducting research in AgeTech, urging scholars and practitioners to broaden their focus beyond usability and design guidelines to also address ethical, privacy, and accessibility considerations essential for the responsible and inclusive development of technologies for aging populations. In addition, these results indicate that assistive technologies and ambient assisted living (AAL) technologies constitute a significant portion of references in the AgeTech domain. It also suggests that one of the most crucial subsections within the AgeTech domain is associated with solutions related to AAL. These results align with the findings derived from our quantitative analysis. In addition, regarding the thematic analysis for the “aim of the study,” we can summarize all themes into 3 general domains: “inclusive design and accessibility,” “technology-enabled health and well-being,” and “ethics, security, and digital governance.” Textbox 3 illustrates this summary of themes for the aim of the study.

Table 7. Summary of results from the thematic analysis of qualitative data for 3 qualitative variables.

Goal and key emergent themes	Publications defining this theme, n	A short explanation of the theme	Single quotes from literature
Aim of study			
Usability studies and design guidelines	34	Numerous studies aimed to enhance the usability of mobile devices for older adults through the development of comprehensive design guidelines. For instance, 1 study emphasized the creation of a robust set of design guidelines based on 4 design strategies to ensure the usability of mobile devices for older users.	"The purpose of this research study was to develop a robust, integrative set of design guidelines based on the four design strategies to ensure usability of mobile devices by older adults." [35]
Assistive technologies for aging	14	A significant theme emerged around the exploration of assistive technologies for aging individuals. Studies within this theme proposed procedures and guidelines to support further research projects, contributing to internal quality control for testing assistive technologies in real-life settings, such as living laboratories at home.	"The procedure is suggested as a guideline to support further research projects and to contribute to an internal quality control of testing involving people 65+ testing assistive technologies in Living Labs at home." [59]
Human-centered design and cultural considerations	12	This theme delved into the incorporation of culturally competent assistive behaviors in robots. Studies discussed how guidelines could be encoded in robots to effectively adjust their actions, gestures, and communication to align with diverse cultural contexts.	"This paper discussed how guidelines describing culturally competent assistive behaviors can be encoded in a robot to effectively tune its actions, gestures and words." [39]
AAL[a]	5	In this theme, researchers aimed to understand the standards and policy guidelines used by companies in creating AAL technologies. The goal was to identify gaps between available technologies, standards, and policies and what should be available for use in AAL applications.	"The aim of this study was to understand the standards and policy guidelines that companies use in the creation of AAL technologies and to highlight the gap between available technologies, standards, and policies and what should be available for use." [19]
Cognitive stimulation and health software	7	This theme focused on gaining insight into the mistakes made by individuals with mild dementia during wayfinding on independent walks. The objective was to understand cognitive stimulation and the impact of health software in addressing these challenges.	"The goal of our study is to gain insight into frequently made mistakes that people with mild dementia make in wayfinding, while taking an independent walk." [28]
Digital impact on older adults	6	This theme explored the global survey on aging-inclusive digital economy and related standards. The studies aimed to clarify the influence and challenges of the digital economy on the older population, emphasizing the expectations and demands of building an aging-inclusive digital economy.	"This paper introduces the global survey on ageing-inclusive digital economy and related standards conducted in early 2021, which aimed to clarify the influence and challenges of the digital economy on the elderly, and the expectations and demands of building an ageing-inclusive digital economy." [26]
Ethical guidelines and considerations	5	This theme addresses ethics, wherein studies reviewed literature on ethics and home monitoring technology. They proposed ethical models for technology development, discussed issues for reviewers to consider, and recommended ethical guidelines to direct the research and implementation process.	"This paper aims to 1) review the relevant literature specific to ethics and home monitoring technology, 2) present an ethical model for technology development, 3) raise pertinent issues for reviewers to consider in assessing applications, 4) discuss strategies to address IRB concerns, and 5) recommend ethical guidelines to direct the research and implementation process." [54]
Security considerations	2	This theme focused on analyzing the security requirements and challenges of eHealth IoT[b] applications. Studies proposed complete architectures to address security concerns in eHealth IoT applications.	"Analyze the security requirements and challenges of e-Health Internet of Things (IoT) applications and propose a complete architecture to address them." [63]
Telehealth and remote monitoring	3	This theme aimed at developing telehealth principles and guidelines specifically tailored for older adults.	"Development of telehealth principles and guidelines for older adults." [34]
Accessibility considerations	1	This theme contains 1 study that emphasized the unique accessibility issues for persons with disabilities and older adults in online communities.	"The primary goals of this article are to raise awareness of the unique issues of accessibility for persons with disabilities and older adults in online communities and to identify key considerations for future development and research." [32]
Main limitations of study			

Goal and key emergent themes	Publications defining this theme, n	A short explanation of the theme	Single quotes from literature
Scope limitations	9	In this theme, studies acknowledged limitations concerning the scope of proposed guidelines. Notably, some topics crucial to care delivery, such as HIPAA[c] adherence, data privacy, and reimbursement, were not directly addressed. A representative quote emphasized the need for a more comprehensive approach.	"A limitation is that the proposed guidelines are not all-encompassing and certain topics important to care delivery were not directly addressed. These topics include Health Insurance and Portability Accountability Act adherence, data privacy, and reimbursement." [34]
Sample size and recruitment	7	This theme highlighted the limitation associated with sample size and recruitment. Studies frequently acknowledged small sample sizes, as illustrated by 1 study that mentioned a small interviewee sample of 28 participants as a potential constraint.	"The interviewee sample was small at 28 participants." [77]
Validation and bias	7	This theme emerged in studies using design guidelines primarily intended for web applications. In some cases, these guidelines may not be directly applicable to mobile platforms, and there may be bias in the interpretation of the transition from Culture Interface Design Matrix to design decisions. The quote reflects this concern.	"Aaron Marcus's design guidelines are mainly for web, so the design guidelines may not be applicable on mobile in some cases. In addition, the transition from Culture Interface Design Matrix to design decision is interpreted by the research team. Thus, potential bias may exist." [41]
Data collection and analysis limitations	4	This theme highlights studies pointing out limitations in the current approach to interface analysis, which often involve manual processes. This was recognized as time consuming due to multiple scopes and technical debt. Recommendations were made for the automation of the process to enhance efficiency, reduce costs, and maximize test coverage.	"The current approach to interface analysis involves manual analysis, which is time-consuming due to multiple scopes and technical debt. To streamline the process, automation is recommended, offering benefits like cost reduction and test coverage maximization." [29]
Technology and interface limitations	4	This theme highlights the challenges of integrating nonstandardized and standardized wearable activity trackers. Although the approach provided a broad integration, there were difficulties in incorporating proprietary interfaced devices, as they were either unreadable or inaccessible.	"Although the approach provided a very broad integration of nonstandardized as well as standardized wearable activity trackers, it was challenging to integrate existing proprietary interfaced devices as they could not be read or be accessed." [80]
Methodological and research design	3	In this theme, the practical circumstances associated with evaluation studies were acknowledged as potential sources of deviation from standards, leading to heterogeneity in evaluation methodologies. This theme emphasized the impact of real-world circumstances on the adherence to predefined standards in evaluation studies.	"The practical circumstances of an evaluation study can cause deviations in the standards, thus producing heterogeneity in the evaluation methodologies. [65]
External factors impacting the study	2	In this theme, the analysis identified external factors impacting studies in the AAL field. Despite extensive research efforts, the proliferation of AAL technologies into real-world use has not matched expectations. This limitation was attributed to various research and industry organizations active in the field.	"This review has identified a high number of research and industry organizations who are currently active within the AAL field. However, the extensive research effort has not yet led to a significant proliferation of technologies into real world usage." [25]
Main study recommendations for future research			
Refinement and iteration of guidelines	10	This theme predominantly focused on refining and iterating guidelines for various domains, such as psychotherapy, special needs education therapy, jobs screening, and occupational therapy. The aim is to enhance intervention practices, achieve more accurate measurements through game-based approaches, and explore different types of evaluations involving psychotherapy experiments using intelligent methods.	"The proposed criteria and guidelines can be adapted to other psychotherapy domain, such as special needs education therapy, jobs screening, and occupational therapy. Furthermore, this could possibly improve the existing intervention practices by having more accurate measurement through a game-based approach. Future works might consider different type of evaluation involving psychotherapy experiments using intelligent manners." [42]
Future plans for evaluation and trials	9	This theme contained studies highlighting the need for future evaluations and trials of the proposed guidelines. These included user testing, proofs of concept, experiments with developers and older adults, and other assessment methods to ensure the effectiveness of the guidelines in real-world scenarios.	"As future work, new studies will be considered to evaluate the set of guidelines (AGE 1.2.), such as: user testing, proof of concepts, experiments with developers and seniors, among others." [27]

Goal and key emergent themes	Publications defining this theme, n	A short explanation of the theme	Single quotes from literature
Design for aging and user-centered technologies	9	This theme emphasized the evaluation of persuasive strategies and their impact on the motivation of older adults to exercise. Long-term goals include further guideline development to assist researchers and practitioners in designing user-centered assistive persuasive technologies for and with older people.	“As future work, we plan to evaluate the effectiveness of our persuasive strategies and their influence on the elderly’s motivation to exercise. In long-term perspective, we aim to develop our guidelines further in order to help other researchers and practitioners to design user-centered assistive persuasive technologies for and together with elderly.” [45]
Dissemination, implementation, and engagement	8	This theme highlighted the next steps in research that involve investigating older adults’ opinions of robotic assistance, assessing the length of engagement, and exploring robot assistance for older adults with impairments. In addition, this theme suggests a focus on real-world engagement and practical applications of assistive technologies.	“The next step in this line of research would be to investigate older adults’ opinions of seeing the robot in person, length of engagement, or robot assistance for older adults with impairments.” [36]
Development of assistive technologies	6	This theme emphasized future plans to develop an editing tool for therapists, allowing them to customize exercises based on user preferences. Additionally, the goal is to expand mobile games to include more complex exercises related to daily living activities, enhancing the transfer of learning to real-world contexts.	“Future plans involve creating an edition tool for therapists that allows for customization of exercises to fit user preferences. The game will be developed for mobile devices and expanded with more complex exercises related to daily living activities, such as shopping, money management, and social relationships, to enhance learning transfer to real contexts.” [30]
Ethical awareness and AI[d] decision-making	4	This theme contained studies recommending further exploration of the effectiveness of ethical guidelines and a comparison of methods for promoting ethical awareness in the context of AI decision-making.	“One subject for the further studies could be to study the effectiveness of the ethical guidelines or to compare different methods of promoting ethical awareness.” [31]
Refinement of design and data	4	This theme highlighted the need for extending the proposed data format beyond body-worn sensors to include signals from other sources, such as video cameras and ambient sensors. Further efforts were deemed necessary to enhance the applicability of the presented consensus.	“The presented consensus focused only on data recorded with body-worn sensors. The proposed data format should be applicable to other type of signals, for example, from video cameras and ambient sensors, but further efforts are needed to extend the concept.” [33]
Aging inclusivity	3	This theme included recommendations focusing on standards and conformity assessment activities for an aging society and the silver economy. The goal of this theme is to promote research on standardization in the silver economy, encourage stakeholder involvement, and establish a long-term dialogue mechanism.	“The paper recommends a focus on standards and conformity assessment activities for the ageing society and silver economy, discussing problems and solutions, and sharing best practices among countries, territories, and organizations. It also suggests conducting research on standardization of the silver economy, encouraging more involvement, and creating a long-term dialogue mechanism.” [26]
Universal accessibility of online communities	2	This theme urged researchers to contribute to creating universally accessible online communities by developing accessibility guidelines, conducting studies on barriers faced by different groups, and exploring features that provide equal access.	“Researchers can contribute to creating universally accessible online communities by developing accessibility guidelines, conducting studies on barriers faced by these groups, and exploring features that would provide equal access.” [32]
Developing best practices	1	These themes include a single publication that covered various topics, such as developing best practices, ethnography and co-design sessions, privacy and security in AAL technology, safety and instructions in navigational aids, and validation and user experience studies.	“The paper recommends a focus on standards and conformity assessment activities for the ageing society and silver economy, discussing problems and solutions, and sharing best practices among countries, territories, and organizations.” [26]
Ethnography and co-design sessions	1	These themes include a single publication that covered various topics, such as developing best practices, ethnography and co-design sessions, privacy and security in AAL technology, safety and instructions in navigational aids, and validation and user experience studies.	“An ethnography could give us a much better understanding of how well seniors would be able to use the system in real conditions. Future work should also include the perspective of the rest of the stakeholders, as they can provide a more comprehensive view on this strategic application domain.” [40]

Goal and key emergent themes	Publications defining this theme, n	A short explanation of the theme	Single quotes from literature
Focus on standards and conformity assessment activities	1	These themes include a single publication that covered various topics, such as developing best practices, ethnography and co-design sessions, privacy and security in AAL technology, safety and instructions in navigational aids, and validation and user experience studies.	"The paper recommends a focus on standards and conformity assessment activities for the ageing society and silver economy, discussing problems and solutions, and sharing best practices among countries, territories, and organizations." [26]
Privacy and security in AAL technology	1	These themes include a single publication that covered various topics, such as developing best practices, ethnography and co-design sessions, privacy and security in AAL technology, safety and instructions in navigational aids, and validation and user experience studies.	"In terms of Privacy by Design guidelines, future work could include data minimization and anonymization." [63]
Safety and instructions in navigational aids	1	These themes include a single publication that covered various topics, such as developing best practices, ethnography and co-design sessions, privacy and security in AAL technology, safety and instructions in navigational aids, and validation and user experience studies.	"In further studies one could concentrate on adding safety and warning instructions to the default left and right instructions of the current navigational aids for pedestrians." [28]
Validation and user experience studies	1	These themes include a single publication that covered various topics, such as developing best practices, ethnography and co-design sessions, privacy and security in AAL technology, safety and instructions in navigational aids, and validation and user experience studies.	"We found that more validation and user experience studies are required to produce better AAL systems with additional user feedback and participatory development approaches." [25]

[a] AAL: ambient assisted living.

[b] IoT: Internet of Things.

[c] HIPAA: Health Insurance and Portability Accountability Act.

[d] AI: artificial intelligence.

Textbox 3. Summary of themes for the aim of the study.

Inclusive design and accessibility

- Usability studies and design guidelines
- Assistive technologies for Aging
- Human-centered design and cultural
- Accessibility considerations

Technology-enabled health and well-being

- Ambient assisted living
- Cognitive stimulation and health software
- Telehealth and remote monitoring

Ethics, security, and digital governance

- Ethical guidelines and considerations
- Security considerations
- Digital impact on the older adults

In the thematic analysis for the "main limitations of study," the results revealed that certain themes, including "scope limitations," "sample size and recruitment," and "validation and bias," were more frequently referenced in the included documents. On the basis of this finding, 1 hypothesis could be that the limitations mentioned in the literature are likely linked to the complex nature of developing standards or guidelines. Furthermore, it would be advisable for researchers to strive to mitigate these limitations in their future studies. In addition, regarding the thematic analysis for the "main limitations of study," we can summarize all themes into 3 general domains: "scope and applicability limitations," "methodological limitations," and "external and contextual factors." Textbox 4 illustrates this summary of themes for the main limitations of the study.

In the thematic analysis of “recommendations for future research” within the main study, we found that specific themes, such as “refinement and iteration of guidelines;” “evaluation and trials of standards or guidelines;” “design for aging and user-centered technologies;” and “dissemination, implementation, and engagement” were more frequently referenced in the examined literature. These suggestions indicate a forward-thinking and comprehensive approach, addressing not only the theoretical aspects of guideline development but also emphasizing the practical facets of implementation and user engagement. In addition, regarding the thematic analysis for the “recommendations for future research,” we can summarize all themes into 6 general domains: “guideline development and refinement;” “evaluation, trials, and testing;” “user-centered and inclusive design;” “assistive and ethical technology development;” “dissemination, implementation, and real-world engagement;” and “specialized research methods.” Textbox 5 illustrates this summary of themes for the recommendations for future research.

Textbox 4. Summary of themes for the main limitations of study.

Scope and applicability limitations

- Scope limitations
- Technology and interface limitations

Methodological limitations

- Sample size and recruitment
- Validation and bias
- Data collection and analysis limitations
- Methodological and research design

External and contextual factors

- External factors impacting the study

Textbox 5. Summary of themes for the recommendations for future research.

Guideline development and refinement

- Refinement and iteration of guidelines
- Refinement of design and data
- Developing best practices

Evaluation, trials, and testing

- Future plans for evaluation and trials
- Validation and user experience studies

User-centered and inclusive design

- Design for aging and user-centered technologies
- Aging inclusivity
- Universal accessibility of online communities

Assistive and ethical technology development

- Development of assistive technologies
- Ethical awareness and artificial intelligence decision-making
- Privacy and security in ambient assisted living technology

Dissemination, implementation, and real-world engagement

- Dissemination, implementation, engagement
- Focus on standards and conformity assessment activities

Specialized research methods

- Ethnography and co-design sessions
- Safety and instructions in navigational aids

Discussion

Overview

In response to the global trend of an aging population and the call for increasing reliance on technology to address the challenges associated with aging, this academic literature review aims to provide a comprehensive overview of the current state of design and development guidelines and standards for AgeTech to key stakeholders in this field, such as policy makers, developers, researchers, and third parties. Our discussion is structured to reflect the findings across 3 main areas: the characteristics of the study and literature distribution, the evidence of quantitative analysis, and insights from qualitative analysis.

Characteristics of the Study and Literature Distribution

Our analysis showed that most research studies on AgeTech standards and guidelines come from the field of computer science, particularly those focused on technical development aspects such as usability and user interface design.

In examining the characteristics of retrieved publications, the results indicated that the majority were original research. Furthermore, given that the research and development processes related to standards or guidelines tend to be qualitative in nature, this study highlighted the extensive use of qualitative methods in most publications. This finding is consistent with both previous research and our predictions.

Examining the distribution of publications over the years, there has been an increased focus on research in standards or guidelines in the AgeTech and AAL domains, particularly in the years from 2019. This trend is influenced by the growing development of AgeTech and AAL. In addition, in examining the distribution of publications by country, it is observed that scientists from the United States and several European countries, including Germany, Portugal, the Netherlands, Belgium, Finland, and Canada, contributed more publications in this domain. This finding may be associated with the varying levels of technological development and aging challenges present in these countries. It is also possible that these countries view standards and guidelines as a means to better frame AgeTech development, thereby facilitating adoption. It may also be due to the availability of AgeTech standards that are more specific to those regions.

Evidence of Quantitative and Qualitative Analysis

Regarding the findings on the type of AgeTech referenced, the results revealed that the most frequently referenced standards and guidelines were associated with the “staying connected” category, encompassing mobile apps, social games, social and telepresence robots, friendly caller programs, and virtual reality technology, accounting for 31% (18/58) of the instances. Following closely, the "supportive homes and communities" domain, covering smart homes, socially assistive robots, and age-friendly communities, accounted for 28% (16/58) of the instances. The results also indicated a lack of standards and guidelines in existing knowledge within the academic literature in certain AgeTech domains or types such as "mobility and transportation" (including smart wheelchairs, autonomous vehicles, and transportation service mobile apps), "financial wellness and employment" (encompassing financial mobile apps, cybersecurity enhancement programs, technology-based vocational programs, and workplace accommodations), "cognitive health and dementia" (covering diagnostic and predictive tools, wandering detection, and locator and GPS tracking devices), and "health care and health service delivery" (involving nanotechnologies, wearable health technologies, telemedicine, and medication management systems). The lack of standards and guidelines in the academic literature in these specific AgeTech categories may be attributed to 2 factors. The first could be the limited development in these areas of AgeTech, and the second could be the lack of attention to creating standards or guidelines in these specific AgeTech domains. In line with the first reason, a scoping review by Bergschöld et al [11] published in 2024, which included 344 documents exploring the characteristics and range of reviews about technologies for aging in place, found that assistive technologies were the most frequently discussed AgeTech type. This finding probably corresponds with the results of our own study, where AgeTech related to assistive technologies emerged as the second most prevalent category.

A significant finding revolves around the primary aspects of AgeTech standards and guidelines: "design and development" along with "usability and user experience" emerges as the predominant focus, underscoring the industry's emphasis (or literature's focus) on these domains. In simpler terms, most efforts are directed toward developing or addressing standards and guidelines in these specific areas of AgeTech. Conversely, areas such as "privacy and security," "data quality," "ethics," "integration and interoperability," "accessibility," and "acceptance or adoption" receive limited attention, indicating potential gaps in the current landscape of AgeTech standards and guidelines. In light of these findings, there is a need for increased attention to developing or addressing standards and guidelines in these domains. While it is important to clarify that the findings relate to the use of standards and guidelines in academic literature, this does not necessarily signify an absence of standards or guidelines but rather a lack of their documented use in these publications. Furthermore, it is plausible that they are being used in the industry during the development of AgeTech, but their implementation might not be documented in the published literature. In their study, Memon et al [28] conducted a literature survey to explore state-of-the-art AAL frameworks, systems, and platforms, aiming to identify essential aspects and investigate critical issues from various perspectives including design, technology, quality-of-service, and user experience. The main aspects identified in AAL systems include medical device interoperability and integration; AAL system architectures, security, privacy, and data protection; design and development methodologies for AAL systems and services; frameworks and open solutions; quality attributes such as usability, accuracy, dependability, availability, reliability, technology standards, and specifications; and user experience as well as miscellaneous research in AAL systems and reviews or surveys in AAL. These findings offer valuable insights for this study in identifying the main aspects within the ALL and AgeTech domains. It is important to emphasize that a significant area of focus for researchers is the development of guidelines for designing user interfaces and improving user experience specifically for older adults. Numerous studies and systematic reviews have focused on this domain [38,41,54,71,75,81].

Concerning the frequency of stakeholders for whom standards or guidelines were developed, it appears that due to the primary focus on "design and development" along with "usability and user experience," it is logical that the most frequently targeted stakeholders were "designers and developers," accounting for 33% (19/58) of the instances. Furthermore, multiple stakeholders were mentioned in 28% (16/58) of the documents.

Regarding the demographic classification of adults targeted by AgeTech standards or guidelines, the results indicate that the category "general older adult population" is the most prevalent, comprising 71% (41/58) of the studies. Other older adult categories, such as "older adults living with chronic conditions," "older adults living in residential care," and "older adults living with cognitive impairment," have lower frequencies. Although these results align with the early stages of AgeTech standards or guidelines development, it is advisable for scientists, standards development organizations, or associations to focus more on specific groups or populations of older adults in the future, such as those with chronic diseases, aging in place and residential care, cognitive health, and dementia. Each specific group has distinct needs, requirements, and conditions, necessitating the development of tailored standards or guidelines. It is noteworthy that the results of Bergschöld et al [11] are consistent with our study. They reported that in most review studies on AgeTech, the general population of older adults was the most frequently mentioned type of population. This finding aligns with the results of our study.

Limitations

First and foremost, it is essential to emphasize the importance of conducting both a gray literature review and an academic literature review to comprehensively assess the current state of standards and guidelines in the AgeTech field and identify any critical gaps. To clarify, in this project, "gray literature" specifically refers to the collection of relevant practical standards and guidelines for AgeTech design and development, typically published by standardization organizations or other reputable institutions. The gray literature review is currently underway, and the findings will be presented in a subsequent publication by our research team. In addition, despite the robust methodological aspects of the scoping review design, certain limitations should be acknowledged. While we collaborated with an information specialist and conducted pilot tests with various terms to optimize the comprehensiveness of our search strategy, and searched multiple databases using relevant keywords, it is possible that not all pertinent search terms have been included. In addition, during the search process, we only considered English-language articles. Despite our efforts, which included manual searches and consultations with experts, there may still be missing documents. Hence, it is essential to acknowledge the potential risk of overlooking relevant articles.

Conclusions

This review aimed to comprehensively outline the current state of standards and guidelines used in AgeTech design and development as reported in academic literature. Its primary focus was to explore existing knowledge and identify key gaps in AgeTech guidelines and standards. Using a scoping review and thematic analysis, we evaluated 58 academic sources using both quantitative and qualitative methods. Our primary finding emphasizes the predominant focus on "design and development" and "usability and user experience" within AgeTech standards and guidelines, reflecting the industry's concentrated efforts in these domains. Conversely, areas such as "privacy and security," "data quality," "ethics," "integration and interoperability," "accessibility," and "acceptance or adoption" receive limited attention, revealing potential gaps in the use and implementation of standards and guidelines across the academic landscape. Furthermore, the study highlights significant references to the "staying connected" and "supportive homes and communities" categories within AgeTech types, whereas categories such as "mobility and transportation," "financial wellness and employment," "cognitive health and dementia," and "health care and health service delivery" lack sufficient standards and guidelines in academic literature. Moreover, the study highlights the notable presence of assistive technologies and AAL technologies in AgeTech, underscoring the prevalence of these solutions within the field. These insights are valuable for stakeholders, including AgeTech innovators, policy makers, health and social care providers, researchers, and experts by experience, as they guide efforts toward priority areas within AgeTech.

Acknowledgments

The authors declare that financial support was received for the research, authorship, or publication of this paper. Funding was provided by the National Research Council of Canada Aging in Place Challenge program, the Canadian Standards Association, and AGE-WELL. The authors sincerely appreciate the financial support provided by Mitacs through their grant (IT35141). In addition, we extend our gratitude to the participants of the workshop titled From Innovation to Adoption: Standards-Based Solutions to Support Technology for Aging in Place at the AGE-WELL Annual Conference in Toronto in October 2023.

Authors' Contributions

SA, JM, HM, FM, PD, JT, and PPM conceived the idea of the manuscript and made substantial contributions to this scoping review. SA conducted the literature search. SA, JM, TR, GBN, and TH-P conducted study selection and data extraction. SA, JM, TR, GBN, and TH-P conceptualized and operationalized the object of interest. SA and TR conducted the data analysis and synthesis. SA was involved in the drafting of the manuscript. SA, JM, HM, FM, PD, JT, GBN, TH-P, and PPM revised the manuscript for important intellectual content. PPM, JM, HM, FM, PD, and JT supervised the project and allocated resources accordingly. All authors read and approved the final manuscript.

Abstract

In this article, we will provide a rationale for a web-assisted acceptance and commitment therapy (ACT) approach to loneliness among older adults, drawing upon theories from the literature on adult development and aging, emotion regulation, and loneliness. The intervention program was developed using the principles of ACT, which is a cognitive behavioral approach and unified model of human behavior change and psychological growth. The ACT intervention focuses on developing nonjudgmental present-focused awareness of internal experiences (thoughts, emotions, and memories) through strategies such as acceptance and mindfulness rather than directly modifying or removing them per se. The ACT intervention appears well-suited to assist older adults in coping with the challenges of aging, as the focus is on an individual's willingness to sit with internal experiences out of one's control (ie, acceptance), stepping back from negative or critical thoughts and developing greater kindness toward oneself (ie, defusion), discerning what is most important to one's true self (ie, values), and building larger patterns of effective action based on such values (ie, committed action). The ACT intervention was developed as a resource for older adults who are socially isolated or having difficulty with social connectedness. Eight modules comprise the web-assisted ACT intervention program, which includes reading materials, video clips, and activities. Each module is followed by a summary, a homework assignment, a short quiz to assess learning, and a moderated discussion with a coach. The intervention program begins with reconnecting participants with their values. The goal of the ACT intervention program is to foster flexibility in a participant's behavior so they can behave consistently with their chosen values, rather than becoming locked into a pattern of behavior that is driven by avoiding distress or discomfort. The ACT intervention approach is both novel and innovative, as it is based on ACT and leverages a behavioral health web platform that is flexible and inclusive in its design. The ACT intervention aims to help older adults become more socially connected, less lonely, and more satisfied with their relationships with other people. The emphasis that ACT places on values and living life in accordance with one's values renders it an approach ideally suited to older adults. Finally, recommendations for future research regarding this approach to addressing loneliness among older adults is addressed.

Introduction

Loneliness, the subjective experience of feeling socially isolated, occurs at all stages of the life span [1]. Loneliness has been observed to impact older adults' experience of depressive symptoms and lead to functional limitations [2,3]. In addition, loneliness has been found to impact older adults' cognition, with loneliness positively associated with dementia [4-6]. Individuals who score high on loneliness visit physicians more frequently [7]. Loneliness has also been associated with cardiovascular risk and risk of mortality [3,8-10]. The crucial point from these studies is that across the life span, loneliness or lack of social relationships puts individuals at greater likelihood of mortality [11].

Older adults are an underserved population; the majority of older adults in need of mental health treatment do not receive care [12]. During the COVID-19 outbreak in early 2020, older adults were disproportionately affected with high rates of mortality and difficulty accessing telemedicine services [13]. COVID-19 has increased calls for the adoption of technology-based approaches to ensure older adults are able to access mental health services [14]. If older adults do receive treatment, it is typically pharmacological, despite the fact that many prefer counseling [15]. Reasons why older adults do not receive treatment include lack of knowledge about mental health services, lack of perceived need for services, and stigma [16,17]. In addition, provider factors such as biases and misconceptions about aging also contribute to mental health services being underused by older adults [12,18].

To date, most research examining the effectiveness of psychosocial treatments with older adults has examined cognitive behavioral approaches. Studies have shown that these types of treatments are effective in treating depression in older adults in the community and primary care [19]. However, studies have produced mixed findings on their effectiveness with some subpopulations, such as depressed, medically ill, homebound older adults [20,21]. Cognitive behavioral therapy (CBT) approaches may also be suboptimal in the treatment of anxiety in later life [22,23]. Thus, there is a need to further develop and test psychosocial treatments to provide better care to older adults.

The purpose of this paper is to present an acceptance and commitment therapy (ACT)–based intervention program comprising a cognitive-behavioral web-assisted intervention to enhance social connectedness in older adults. We will review the literature on evidence-based programs for older adults and provide the theoretical basis for our ACT-based intervention program [24]. We will review the rationale for such an approach and provide a brief description of the ACT intervention program, as well as describe current evaluation efforts and future directions for the work.

Ethical Considerations

The study was approved by the New England Institutional Review Board (IRB tracking number: 120180244).

Loneliness Interventions

The deleterious impact of loneliness on physical and mental health points to the need for evidence-based intervention programs for older adults. Few evidence-based interventions have been developed for older adults, and creative approaches are needed. There have been various intervention approaches for addressing loneliness. Interventions approached at the individual level have included CBT, interpersonal therapies, and psychoanalytic therapies; interventions at the group level have focused on social skills training and groups centered around addressing shyness and depressive symptoms [25]. For older adults, interventions that may lessen the experience of loneliness have focused on social resources (eg, family and friends) and individual pursuits (eg, spending time on meaningful activities) [26].

Meta-analyses on the effectiveness of loneliness interventions have pointed to the effectiveness of psychological interventions [27,28]. A recent meta-analysis was conducted to specifically examine the effectiveness of psychological interventions in reducing loneliness [27]. The effectiveness of the various types of interventions did not significantly differ; however, reminiscence therapy had the largest effect size, followed by social identity interventions; CBT had the lowest effect size [27]. Similar results were observed in another meta-analysis where reminiscence therapy and social skills training had the largest effect size, followed by CBT [28]. However, there was only 1 study that used reminiscence therapy. In addition, the meta-analysis found higher effect sizes for intervention studies that (1) used the UCLA Loneliness Scale to assess loneliness, (2) used technology (telephone or computer) to deliver the intervention, and (3) addressed maladaptive social cognition [28]. This meta-analysis indicated that the use of technology (ie, telephone or computer) in delivering the intervention can be an effective way to address loneliness [28].

A major challenge in developing evidence-based programs for older adults has been access. Telehealth, the use of video conferencing to provide social support for older adults, is one approach that has been used during COVID-19 [29]. Interventions delivered through technology (ie, telephone or computer) have been found to be effective at reducing loneliness for older adults. One study examined the effectiveness of delivering a web-assisted intervention to older adults with chronic illness or handicap and found that computer and internet use significantly reduced loneliness among older adults [30]. In addition, lower mean levels of loneliness and depressive symptoms were found in a videoconferencing program for older adults in nursing homes after administering the intervention for 3 months [31]. Educational programs aimed at teaching older adults to use computers and the internet have also been found to significantly reduce loneliness [32]. In addition, a recent randomized controlled trial during COVID-19 examining the effectiveness of a web-assisted group intervention via Zoom found that it was effective in reducing loneliness and depressive symptoms among older adults [32]. A qualitative study examining the impact of a web-assisted intervention on loneliness among adults aged 18 to 64 years found that technology was viewed as a means of social connection. Web-assisted interventions have the ability to have a positive impact, as reviewed above. They can present information in a simple format (eg, video, graphics, audio), reach people in their homes and in rural areas, and reduce stigma related to seeking treatment. However, too much use of technology can lead to videoconferencing fatigue, and face-to-face communication is preferred [33].

Cognitive Approach to Loneliness

Theoretical perspectives on loneliness have encompassed a wide range of approaches. Weiss [34] presented an interactionist view of loneliness that focused on the types of relationship deficits in people's social networks. He described 2 types of loneliness: emotional loneliness (absence of a close partner) and social loneliness (absence of friendships and community). Other scholars have advocated for a cognitive approach to loneliness, which emphasizes the discrepancy between individuals' *subjective perceptions* of their social life and their *desired quantity or quality* of social relationships [35]. That is, loneliness is hypothesized to occur when individuals' networks of social relationships do not meet their expectations [35]. Cognition can act as a mediator between perceived loneliness and the intensity of the experience. For example, loneliness is often increased or decreased based on one's thoughts and beliefs about one's social skills. If a person believes that they are awkward and drive other people away, they may view every failed social encounter as their fault and as something that cannot be improved in the future. Thus, the cognitive approach emphasizes causal attributions for social difficulties, as well as behavioral and personality traits.

Based on the cognitive theory of loneliness and past research examining the effectiveness of psychological interventions, a new approach to loneliness is warranted that uses technology to deliver the intervention components. The use of technology (ie, telephone or computer) has been observed to be an effective means of delivering an intervention [27,28]. Psychosocial interventions (ie, reminiscence therapy, social identity interventions, and CBT) have been observed to be effective in reducing the experience of loneliness [27,28]. A systematic review of communication technology interventions suggested a need for further studies in the fields of loneliness and web-based technologies to identify opportunities to reduce loneliness in older people [36]. We propose that ACT, an emerging evidence-based approach to the treatment of emotional distress, is a viable new intervention approach for addressing loneliness among older adults, delivered via computer or the internet [24].

ACT-Based Intervention

The intervention program was developed by drawing upon basic research on loneliness in older adults and using the principles of ACT. ACT is a cognitive-behavioral approach and unified model of human behavior change and psychological growth. ACT interventions focus on developing nonjudgmental present-focused awareness of internal experiences (thoughts, emotions, and memories); willingness to sit with internal experiences that are out of one's control (ie, acceptance); stepping back from negative or critical thoughts and developing greater kindness toward oneself (ie, defusion); discerning what is most important to one's true self (ie, values); and building larger patterns of effective action based on such values (ie, committed action). Compared to traditional CBT, ACT pays greater attention to the context and functions of private events and emphasizes helping individuals respond to them with greater flexibility through strategies such as acceptance and mindfulness rather than directly modifying or removing them per se.

There are several lines of evidence that support the use of ACT with older adults who are socially isolated or having difficulty with social connectedness. First, theories of adult development and successful aging suggest that an ACT approach to treatment could be useful for older adults [37]. It is well established that older adults experience a change in life dynamics due to shifts in gains and losses. Older adulthood has a higher proportion of losses and many of those are out of one's control and unable to be changed [38]. Given that research has consistently shown that loneliness in older adults can be exacerbated by losses such as disability [39,40], decreased mobility [41-43], and widow- or widowerhood [43-45], it may prove fruitful to consider intervention approaches that assist older adults to respond flexibly to these relatively unmodifiable aspects of later life. The use of interventions was proposed to enhance psychological acceptance among older adults in response to findings of higher levels of well-being among older adults who showed greater psychological acceptance [46]. Also, in a study in which treatment response was defined as a reduction in the amount of interference with life due to pain, older people were more likely to respond to ACT compared to CBT [22].

Second, althought CBT approaches have been used with some success, there is reason to doubt their effectiveness for all individuals. Traditional CBT strategies that involve challenging the validity of thoughts may not be beneficial to older adults because the thoughts and feelings that arise after losses, while unhelpful, may not be unrealistic. Moreover, because older adults often have beliefs about aging that have solidified over a long period of time, modifying them may not be an efficient use of time [47].

This is consistent with research on CBT for mental health problems, which has revealed that the cognitive restructuring components of CBT do not significantly improve therapeutic outcomes [48]. Such techniques may be invalidating, futile, or cause iatrogenic effects. For example, there are data to show that cognitions are not directly modifiable and that deliberate attempts to change or suppress thoughts can increase their occurrence and behavioral impact [49]. Furthermore, some evidence suggests that older adults who make active efforts to eliminate problems that cannot be solved are at a higher risk for depression and other negative outcomes, and that disengaging from commitments or goals that are unattainable—followed by choosing an attainable alternative—is associated with better emotional well-being [50,51]. An acceptance approach in which individuals learn to focus on their remaining resources may be more beneficial than an approach in which they are encouraged to modify their thinking about loss or disability.

Third, the goal of an ACT intervention is to live life in accordance with deeply held values. ACT may be particularly appropriate for older adults because individuals experiencing declines associated with aging may limit their goals to those that are most highly valued, work harder to strive toward achieving those goals, and use alternative strategies to compensate for formerly used strategies that may no longer be workable. This perspective is articulated in the Selective Optimization with Compensation Model of successful aging [52]. This is the essence of ACT and psychological flexibility. Such a model of treatment may resonate with older adults, which in turn may make it more likely they will actively engage in treatment. For example, there is some evidence to suggest that attrition rates may be lower among older adults treated with ACT when compared to those who received CBT [22].

In sum, ACT appears well-suited to assist older adults in coping with the challenges of aging, such as losses in functioning and changes in social connections. ACT has been shown to be effective for older adults in other areas, such as reducing depression and anxiety and improving symptoms of chronic pain [53-55]. ACT interventions have been adapted for web-assisted delivery and have been shown to be effective in teaching ACT-based skills to manage conditions such as overweight, fibromyalgia, and stress [56-58]. Recent research indicates even 4 web sessions can have a positive impact [59].

Development of a Web-Based ACT Intervention for Older Adults

Table 1 provides an overview of the ACT intervention program components. The ACT intervention program begins with reconnecting the client with their values, defined as intrinsic reinforcers, which provide a chosen direction for their behaviors and actions despite obstacles faced [60]. First, a list of relationships is provided (friendships, romantic or intimate relationships, family relationships, acquaintances or neighbors, and new people) and participants are asked to indicate how much they value each of those relationships. Importantly, indicating the level of importance means what the participants would like to see in their life, and does not necessarily mean that those relationships are currently matching up with that desired level. Next, a list of potential characteristics and qualities that people often value in their relationships is provided, and the client chooses the 5 that are most important to them. The list includes qualities such as being trustworthy, accepting, spontaneous, kind, open, sincere, forgiving, and loyal. The ultimate goal of the ACT intervention program is to foster flexibility in the participant's behavior so they can behave consistently with their chosen values, rather than becoming locked into a pattern of behavior that is driven by avoiding distress or discomfort.

Table . Acceptance and commitment therapy intervention program modules.

Module	Purpose
(1) Introduction and values	• Education about loneliness and why it is important to address loneliness • Education about values • Identifying and connecting with values and what the older person wants relationships to look like, to enhance motivation
(2) Exploring coping	• Awareness of triggers and consequences • Identifying how one copes with distress • Evaluating the workability of one's coping strategies
(3) Awareness of thoughts	• Learning how the mind works and how thoughts influence behavior • Learning how some people are often sensitive to certain social situations
(4) The impact of thoughts	• Identifying one's own sticky thoughts and how they keep one stuck
(5) Changing the impact of one's thoughts	• Stepping back from thoughts • Labeling thoughts
(6) Changing the impact of ones' thoughts	• Acceptance • Self-compassion
(7) Social stuck points	• Identifying one's interpersonal patterns and identifying where one might need skills • Learning different skills for finding the relationships one wants
(8) Putting it all together	• Integrating education and skills from modules 1-7 • Identifying barriers and setbacks and making a plan for skill use
Homework	• Self-assignments after each module on behavioral tasks to provide exposure to previously avoided situations, with the goal of increasing skill use and increasing adaptive thought patterns

This intervention program is an interactive, dynamic web-based intervention for social isolation and loneliness that delivers ACT over 8 interactive modules. The web-assisted modules are largely self-paced. The ACT intervention includes reading materials, video clips, and activities; each module is followed by a summary and homework assignment, a short quiz to assess learning, and a moderated discussion with a coach. Participants also have access to supplementary materials and email reminders. Participants are instructed to work through the modules in sequential order, approximately one module per week. Each module begins with a brief review of the content from the previous module before introducing a new concept. The homework includes self-assigned behavioral activities to complete each week (eg, "set a specific behavioral goal to engage in this week where you practice the skill learned in this week's module"), and the participant is prompted to enter a description of the self-assignment after the module. Before starting the next module, participants are prompted to complete an "activity recap," where they enter whether or not they completed the behavioral exercise, and to indicate their satisfaction with the exercise. Finally, they are asked to share any challenges that arose while engaging in the activity, and if this kept them from completing it. Participants are sent reminders if they have not logged on to the system for over a week.

The exercises in the first modules of the ACT intervention program attempt to increase clarity about what participants truly value in relationships and social connections, examine the ways in which current behaviors are either helping or hurting these values, and help participants begin to take concrete steps toward behaving consistently with their social values. This is important to set the stage for the rest of the program. All educational and skill-building activities in the ACT intervention program are linked to participants' values, and the module content is aligned with living life in accordance with their own personally chosen values. For example, an increased willingness to experience one's distressing thoughts and emotions (instead of trying to change them) is a skill that is explored as a way to facilitate progress in areas of one's life that provide meaning and personal fulfillment. Participants' self-identified values are also used to set values-consistent goals. For example, if they have an overall goal to have more friendships, their specific goal might be to participate in more social activities where they can meet new people. Most importantly, the homework assignments at the end of each module (ie, self-identified behavioral tasks) are based on what is personally meaningful for each participant. For example, one participant cited being open, friendly, and active as key values. Her homework assignment was to attend the community's senior center game night and talk to a person she had not met previously. Fostering these patterns of committed action is highly important, as this is what helps the participant increase their ability to engage in behaviors consistent with their values and increase social connectedness.

Next, the participants reflect on their use of coping strategies (ie, avoidance and control-based strategies) and evaluate if these are helpful. The goal of this module is to help the participants recognize that avoidance often does not work, and in fact may be their primary problem. For example, isolating oneself at home to control the uncomfortable feelings that arise when attempting to meet new people is an avoidant and unhelpful coping strategy. To address maladaptive coping strategies, participants are guided through several activities to identify positive and active coping strategies. It is even better if their active coping strategies also involve building social connections.

The next several modules focus on thoughts, particularly how the mind works in social situations and how thoughts might influence participants' behavior. These modules also emphasize how some people are vulnerable to experiencing certain thoughts more often, especially in social situations (eg, sensitivity to rejection). Participants identify "sticky thoughts," which are thoughts that tend to stick around and control one's behavior, even when they are unhelpful. For example, a sticky thought might be "Nobody wants to get to know me." Participants are encouraged to increase awareness of how these thoughts get in the way of relationships with other people. Participants are then introduced to several strategies for changing the impact of their sticky thoughts, such as defusion (ie, stepping back from thoughts), acceptance, and self-compassion. One session is then devoted to recognizing social situations in which to use their newly learned skills (eg, when meeting someone new, making conversation with someone, or experiencing conflict with someone). In the final part of the program, participants reflect on their values and set further goals to live their lives according to these values, solving problems related to any perceived barriers.

Several adaptations were made to the program to ensure that it was appropriate for older adults. Changes in cognitive functioning with aging are not universal and older adults show extensive variability, but it is important to make programming flexible and inclusive for all learning abilities and types. Older adults may experience a decline in cognitive speed, working memory, selective attention, and fluid intelligence. Research indicates that for people with cognitive impairment, information should be presented slowly and with frequent repetitions and summaries.

In the ACT intervention program, information is presented in multiple ways, and participants are encouraged to notice what does and does not work for them. To accommodate for a decline in some aspects of executive functioning, such as memory, new information is presented in the context of the previous module's material. Participants can revisit module content at any time, including readings, videos, and assignments. Phone prompts or alarms can remind participants in the program to carry out certain activities, such as behavioral homework tasks.

Conclusion

The desire for fulfilling social connections is a universal need and essential to well-being. Involvement in satisfying social relationships contributes to enhanced emotional and physical health throughout the life span. The fulfillment of this need looks different for older adults, as they navigate the developmental changes of later life and adjust to gains and losses that occur in their social networks. Furthermore, factors such as fear of intimacy, low self-esteem, and behavioral struggles such as difficulty with social skills may exacerbate feelings of loneliness and also make it more difficult to recover from loneliness.

This intervention aims to help participants become more socially connected, less lonely, and more satisfied with their relationships with other people. Researchers and clinicians collaborated on the ACT intervention program, leveraging a behavioral health platform to deliver the intervention. Most existing web-assisted interventions for loneliness that have been tested for efficacy are therapist-based and require extensive involvement by mental health professionals, and they are therefore neither anonymous nor self-directed [27]. Unlike therapist-assisted programs on the web, the ACT intervention program is an interactive, dynamic web-based intervention for social isolation and loneliness that delivers material over 8 modules and can be done largely at one's own pace and anonymously. A trained wellness coach is available to chat (voice or web-assisted) after each module to assist the user with processing program content or answering questions.

The ACT intervention approach is both novel and innovative, as it is based on ACT and leverages a behavioral health web-assisted platform that is flexible and inclusive in its design. The session content of the ACT intervention program is reflective of current knowledge of loneliness presented in the literature, as well as the extant evidence on ACT for older adults.

The emphasis that ACT places on values and living life in accordance with one's values renders it an approach ideally suited to older adults. Furthermore, some of the basic notions of ACT (eg, that pain and suffering are inevitable in human experience and that trying to avoid pain and suffering leads to problems) are highly compatible with this developmental stage of the life span and consistent with basic research on older adults and well-being.

Future studies should include randomized controlled trials of the ACT intervention program that include an attention control group, rater-blind assessments, and a systematic investigation of possible mechanisms of action (eg, acceptance). Measures of treatment adherence will need to be established, and interactions with coaches should be monitored and assessed for treatment fidelity and competency. Using mediator-moderator analyses, physical and cognitive functioning should be evaluated as moderators, and intrinsic motivation and homework adherence as mediators of the ACT intervention program's effectiveness. Additional research may include determination of optimal "dosages" (frequency and duration) of the program for different subgroups of participants. Finally, an examination of treatment components via dismantling studies may reveal the program activities that are most potent in reducing loneliness. For example, the extent to which chat with coaches is essential to the program's success will need to be studied.

Abstract

A healthy lifestyle can be an important prerequisite to prevent or at least delay the onset of dementia. However, the large number of physically inactive adults underscores the need for developing and evaluating intervention approaches aimed at improving adherence to a physically active lifestyle. In this regard, hybrid physical training, which usually combines center- and home-based physical exercise sessions and has proven successful in rehabilitative settings, could offer a promising approach to preserving cognitive health in the aging population. Despite its potential, research in this area is limited as hybrid physical training interventions have been underused in promoting healthy cognitive aging. Furthermore, the absence of a universally accepted definition or a classification framework for hybrid physical training interventions poses a challenge to future progress in this direction. To address this gap, this article informs the reader about hybrid physical training by providing a definition and classification approach of different types, discussing their specific advantages and disadvantages, and offering recommendations for future research. Specifically, we focus on applying digital technologies to deliver home-based exercises, as their use holds significant potential for reaching underserved and marginalized groups, such as older adults with mobility impairments living in rural areas.

physical activity; dementia prevention; cognitive health; hybrid: aging in place; active; exercises; exercising; healthy lifestyle; dementia; dementia onset; dementia care; preventive; prevention; cognitive health; cognition; cognitive; hybrid; hybrid model

Introduction

Dementia is a brain disease that is characterized by an acquired loss of cognitive abilities in different domains which is sufficiently severe to interfere with both activities of daily living and the ability of an individual to live independently [1,2]. As a result, individuals affected by dementia cause high health care expenditures [3-6]. Given the expected worldwide rise in dementia cases from 57.4 million cases in 2019 to 152.8 million cases in 2050 [7], it seems reasonable to assume that the already relatively high health care–related expenditures for dementia (ie, US $1313.4 in 2019 [3]) will dramatically increase in the upcoming years. Thus, preventing dementia should be a priority of public health actions [8,9]. Based on the evidence that the individual dementia risk is substantially influenced by several lifestyle factors (eg, regular engagement in physical activity), a positive modification of these is important to lower the global prevalence and, in turn, the societal and economic costs of dementia [3,8,9]. This assumption is reinforced by the fact that the effectiveness of pharmacological interventions to treat dementia is limited [10,11]. Although lifestyle-related interventions (eg, targeting physical activity, sedentary behavior, diet, or sleep) can be effective and implemented along the entire continuum of dementia [9,12-14], preventive approaches should focus on healthy middle-aged and older adults, and preclinical stages of dementia including adults at-risk (eg, adults with subjective cognitive decline [SCD], mild cognitive impairment [MCI], or with the motoric cognitive risk syndrome [MCR]) [9,15-20] to avoid that cognitive impairment and neurodegenerative changes of the central nervous system become too serious which, in turn, might negatively influence adherence and increase the cost of the implementation of the intervention. At-risk groups for dementia comprise, among others, adults with SCD who have a self-reported or informant-reported worsening of cognitive performance (especially memory) but normal performance on specific clinical cognitive tests [21,22], adults with MCI who have objective cognitive deficits determined by a clinical cognitive test battery [23-25], and adults with MCR who have subjective cognitive complaints and a slow gait speed [17,20,26-28]. SCD, MCI, and MCR are preclinical stages of dementia that are unrelated to an acute event, do not interfere with activities of daily living, and thus allow the individual to live independently [17,20,21,24-27]. Current estimates suggest that worldwide 315 million individuals aged 50 years or older are in a preclinical stage of dementia [29] emphasizing the pressing need to develop and implement appropriate intervention strategies to prevent or at least delay the onset of dementia in the general and at-risk populations.

In the literature, there is some evidence showing that among other factors such as sedentary behavior, sleep, and diet, especially regular physical activity including planned and structured forms such as physical exercise and physical training [6,30-35] can be an important factor to preserve cognitive functions [36-44] and to prevent or at least delay the onset of dementia in older adults [6,9,45,46] although future high-quality randomized controlled trials (RCTs) are required to further substantiate the evidence in this direction [47,48]. Hence, the high prevalence of physical inactivity among the general adult population [6,49] which increases with age [50-52] and low cognitive status [53], necessitates the development of new, more efficient, and sustainable intervention approaches to preserve and maintain cognitive health across the life span, especially in adults-at-risk to develop dementia (eg, adults with MCI) [9,16].

Concerning new approaches to support healthy cognitive aging, there is the opinion in the literature that using digital technologies is a promising and cost-saving option that can support healthy aging in place (eg, by providing lifestyle interventions) [54-56]. In this context, digital technologies can be a valuable instrument to remotely assess and monitor changes in cognitive health [57-63] and to facilitate positive lifestyle changes [57,63-65] by fostering a higher level of regular physical activity (eg, via wearable physical activity trackers [66,67] or via apps or online classes to remotely deliver home-based exercise sessions [64]), which is especially relevant for adults living in rural and remote areas [64,68-71].

Digital technologies can be applied in a wide range of contexts and in recent years they have become a popular instrument for delivering physical exercises and physical training to the general population [64,72-75]. For instance, in center-based exercise sessions, the application of digital technologies encompasses but, is not limited to (1) monitoring and controlling exercise intensity (eg, via wearables recording heart rate) [76-78], or (2) delivering specific physical exercises (eg, via exergames [79-81] or videoconference-based online classes, in which the exercise professional is remotely connected to the groups of trainees being located in a center [82]). However, digital technologies provide also several advantages making them extremely well-situated for delivering home-based exercise sessions. This assumption is supported by the latest editions of the Worldwide Survey of Fitness Trends revealing that digital applications such as wearable technologies, online training, and mobile exercise apps are among the top 20 fitness trends in recent years [72-75]. More specifically, the Worldwide Survey of Fitness Trends also showed that exercising at home is the number 2 trend for 2022 [73] probably due to the consequences of the COVID-19 pandemic (eg, home confinement). Even from a more general point of view, exercising at home provides some benefits for older adults (eg, no need to commute to a training facility) because home-based approaches can help to circumvent frequently mentioned barriers to engaging in planned and structured forms of physical activity (eg, the lack of opportunity or transport [83-86]).

Compared with traditional options, the use of digital technologies can be a promising alternative (1) to remotely recruit and assess a large number of (diverse) participants (eg, in decentralized trials instead of centralized trials) [87], and (2) to deliver home-based interventions (eg, via video capsules instead of booklets) [64]. In particular, remotely delivered home-based interventions via digital technologies can provide several advantages such as better visualization of exercises or gamification (eg, exergames) as compared with nondigital solutions (eg, booklets) [64]. Thus, digital technologies can play an important role in reducing inequalities arising from various reasons (eg, living in a rural area without a driving license) which, in turn, might contribute to increased robustness of the findings of the trials because of the inclusion of larger and more diverse samples of older adults at-risk or with cognitive impairment [87-91]. Further empirical data supporting our claims have been published recently [90-93]. However, using digital technologies and home-based interventions does not come without limitations [87,94]. For instance, home-based physical exercise sessions provided via digital technologies are typically associated with lower levels of supervision, and social interaction (ie, social support and relatedness such as the feelings of belonging to a group) [95] although the level of supervision and social interaction depends on the type of digital technology used for that purpose [64]. Given that the social factors are important for adhering to an intervention [96], the unique characteristics of different types of digital technologies being used for delivering home-based physical exercises should be considered when designing and implementing future trials [87] and suggest that establishing a classification framework to improve the structuring of knowledge is required (eg, as started in [64]) to better inform the application in practical settings.

Since factors such as supervision, social support, and relatedness can be more easily promoted in center-based physical exercise sessions (eg, in clinical settings) because of the interaction with health professionals (eg, certified trainers, physiotherapists) and peers, several studies have combined both center-based physical exercise sessions and home-based physical exercise sessions. For instance, especially in rehabilitative settings such as cardiac rehabilitation [97-99] or orthopedic rehabilitation (eg, hip or knee osteoarthritis [100]) interventions that combine center- and home-based physical exercise sessions are widely used. Such interventions are typically referred to as hybrid. With regard to healthy cognitive aging, hybrid physical training interventions have been somewhat neglected [64] but have been highlighted as a promising option for future studies (eg, for older adults at risk or with cognitive impairment) [87]. Moreover, neither a generally accepted definition nor a classification framework for hybrid physical training interventions is available. As such a classification framework allows for better structuring of knowledge and might foster research in the field of healthy cognitive aging (eg, by increasing the awareness of research in which different types of hybrid physical training interventions exist), this article aims to inform the reader about this intervention approach by providing a definition and classification approach of hybrid physical training and by narratively summarizing the current state of the literature. In accordance with the literature [31-35,101], we use in the forthcoming sections of this article the term “physical training” to refer to chronic forms of planned and structured forms of physical activity. Furthermore, we focus on hybrid physical training approaches that use digital technologies for delivering home-based exercises because their application holds great potential to reach needy but underserved and marginalized groups (eg, older adults with mobility impairments living in rural areas). The latter is related to the facts (1) that reaching and including such cohorts is highly relevant from a public health perspective given the paucity of research in this direction and the existing rural health disparities [68-71,102], and (2) that research in this direction will improve our understanding of whether the effects of physical training on cognitive health typically observed in laboratory setting extend to ecologically valid settings (eg, community-dwelling older adults living in rural areas) for which the evidence base is currently relatively scant [103].

Hybrid Physical Training: A Definition and Classification Approach

Overview

Hybrid interventions have been recently highlighted as a promising option to improve health-related outcomes, especially in rehabilitation settings [87,98,100,104] but, to the best of our knowledge, neither a generally accepted definition nor a classification approach exists. To address this issue and avoid ambiguity which can be a major source of difficulty in scientific communication, we define the term “hybrid physical training” as an intervention that combines center-based physical exercise sessions, that is, conducted in a clinical setting (eg, health care facility) or community setting (eg, local gym) [105] and home-based physical exercise sessions, that is, undertaken inside or within the immediate vicinity of the home (eg, apartment, park) [100,104,105].

To derive a classification approach for different types of hybrid physical training interventions, we orient on recommendations on constructing, conducting, and analyzing physical interventions [105,106] and recent literature in this field [64,107]. In this context, we propose that hybrid physical training interventions can be differentiated based on (1) temporal characteristics, that is, how the center-based exercise sessions and home-based physical exercise sessions are combined, and (2) specific intervention-related characteristics, that is, how center-based physical exercise sessions and home-based physical exercise sessions are delivered.

Temporal Characteristics

Concerning the temporal characteristics, we propose that hybrid physical training can be differentiated as (1) alternating hybrid physical training interventions, and (2) subsequent hybrid physical training interventions (Figures 1A and 1B). First, in alternating hybrid physical training interventions, center-based physical exercise sessions are alternated with home-based physical exercise sessions. While this alternation provides, on the one hand, the advantage that the participant has frequent contact with health professionals and peers fostering higher levels of supervision and social interaction (ie, especially in center-based physical exercise sessions) that might positively influence compliance and adherence to the intervention [108], it is, on the other hand, a clear disadvantage because it demands the participants to commute to attend the center-based physical exercise sessions. However, the alternating hybrid physical training can also unburden the participants because it reduces the number of travels (eg, 1 travel per week if there are 2 sessions per week) and thus allows for a higher frequency (eg, 2 exercise sessions instead of 1 per week), which has been linked to larger improvements of cognitive performance in adults aged 50 years or older [44]. Second, in subsequent hybrid physical training interventions, a phase of center-based exercise sessions is followed by a phase of home-based exercise sessions (Figure 1B). This type of intervention can be further divided into (1) subsequent hybrid physical training interventions with alternating follow-up or (2) subsequent hybrid physical training interventions with home-based follow-up. The advantages and disadvantages of subsequent hybrid physical training interventions strongly depend on the type of follow-up (Figure 1B) and the implementation of the home-based physical exercise sessions (Figure 2B). For instance, subsequent hybrid training interventions with alternating follow-up can enable relatively high levels of supervision and social interactions due to frequent contact with health professionals and peers during the center-based physical exercise sessions. On the downside, to attend center-based physical exercise sessions, the participants are obliged to commute to the training facility, which is in some studies mentioned as a barrier, especially by older women [84]. A home-based follow-up offers the advantage that the participants are not obliged to commute to the training facility but comes at the cost of lower levels of supervision (eg, by the health professional) and limited social interactions (ie, with peers) during the home-based physical exercise sessions in the follow-up, although the latter can be influenced by the implementation (eg, higher levels of supervision and social interaction may be achievable via online classes [64]; Figure 2B).

Figure 1. Overview of possible temporal organizations of hybrid physical training interventions which can be divided into (A) alternating hybrid physical training interventions and (B) subsequent hybrid physical training interventions.

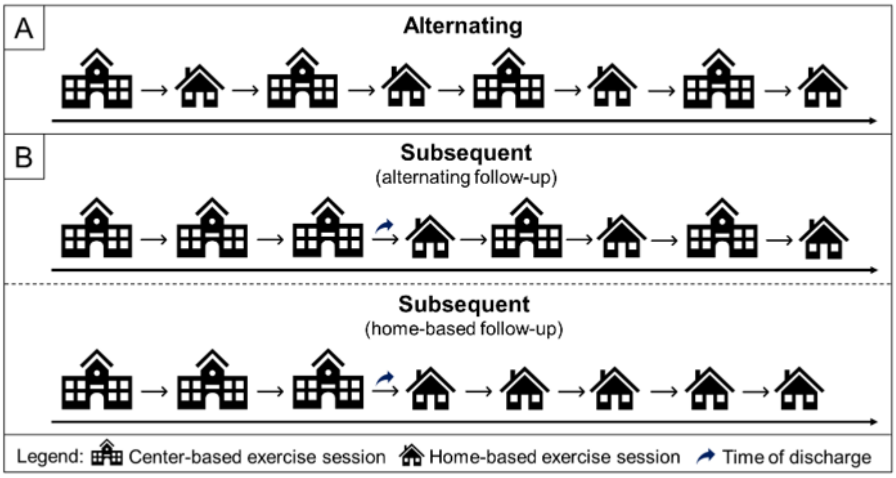

Figure 2. Overview by which means (A) center-based physical exercise sessions and (B) home-based physical exercise sessions can be delivered.

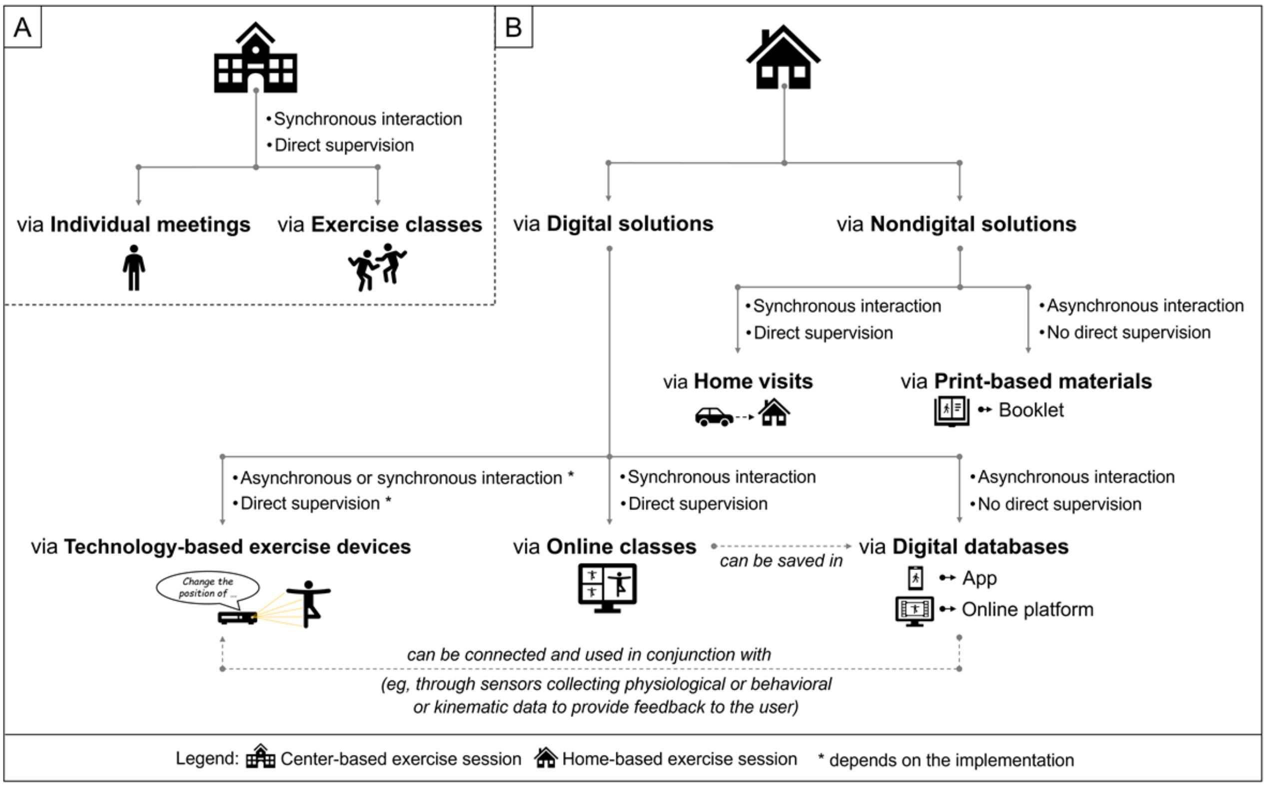

Specific Intervention-Related Characteristics

Based on a recent systematic review of our group, in which we propose a classification approach for digital- and home-based physical training interventions [64], we used the type of interaction and the level of supervision to differentiate between different types of hybrid physical training interventions.

Before we discuss the different types of hybrid physical training interventions and their strengths and limitations in more detail, we provide the reader with a brief description of the different types of interaction and the different levels of supervision.

Regarding the type of interaction, one can distinguish between asynchronous interaction and synchronous interaction. Synchronous interaction refers to an interaction that occurs in real-time, whereas asynchronous interaction refers to a decoupled interaction (eg, at different times) [64,109-113]. Thus, a synchronous interaction allows for the immediate exchange of information (eg, immediate feedback on specific exercises—direct supervision) but is limited concerning time flexibility [64,109]. Vice versa, asynchronous interaction provides the advantage of on-demand information exchange at the convenience of the participating parties but bears—as a consequence of the decoupled communication—the risk that specific information is not received on time (eg, short-term adjustment of a physical exercise session due to quality of exercise execution or acute pain of the trainee is difficult) [64,109].

Regarding supervision, one can distinguish between direct supervision (ie, each exercise session is monitored by a health professional or digitally via sensors allowing for immediate feedback on exercise execution), general supervision (ie, no direct supervision of each exercise session but regular in-person or web-based contact with a health professional to support the trainee; also referred to as “facilitated”), and no supervision (ie, the trainee has no direct contact with a health professional throughout the intervention period; also referred to as “unsupervised”) [64,105]. In general, there is some evidence suggesting that higher levels of supervision (ie, direct supervision) can facilitate adherence to physical training interventions [96,114,115] although, on the downside, higher levels of direct supervision can increase the cost of the intervention (ie, to pay the health professional who supervises the physical exercise sessions) and lower the time flexibility (ie, as result of the synchronous interaction) [96].

As shown in Figure 2A, center-based exercise sessions are typically supervised and are based on synchronous interactions with health professionals and other peers. In addition, center-based exercise sessions can be conducted individually or in a group. Individual meetings provide the advantage that a high level of individualization can be achieved because of close contact with the health professional. In individual meetings, the social interaction with peers, in contrast, to exercise classes, might be somewhat limited. In this context, it is worth noting that in older adults’ social factors such as loneliness are associated with worse cognitive functioning [116-119] and increased risk of dementia [8,120-123]. Furthermore, in a cross-sectional study of older adults with MCI, a higher level of perceived loneliness was observed as compared with age-, sex-, and education-matched controls with slightly less pronounced cognitive deficits [124]. In addition, social factors are also important promotors for regular engagement in specific forms of physical training (eg, sports) [84,125-127] and long-term adherence to interventions [96,128]. Accordingly, promoting social participation (eg, via group-based physical training), especially in at-risk cohorts for dementia (eg, older adults with MCI), seems to be an important factor for fostering adherence to physical training interventions [96,128], preventing cognitive decline, and potentially reducing the risk of dementia [129]. Indeed, there is evidence that in healthy older adults’ group-based physical training interventions can counteract social isolation and loneliness [130,131]. Moreover, there is evidence from cross-sectional studies that older adults who exercise alone and exercise with others (eg, team or partner sports activities) showed better cognitive performance and have a lower risk of cognitive impairment, but that exercising with others is slightly more beneficial than exercising alone [132-134] even after adjusting for important influencing factors (eg, accelerometer-derived physical activity or time spent for other social engagements [133]). Based on these findings, group-based physical training, which can lead to a higher level of social interaction (ie, with peers) and perhaps trigger specific psychosocial-related changes [133] on multiple levels of analysis [129,135-137], might provide some additional benefits to preserve cognitive health as compared with exercising alone or without peers (eg, individual meetings).

The level of social interaction (eg, with peers) depends, among other factors, on the type of digital technology that is used to deliver the home-based physical exercise sessions. As shown in Figure 2B, home-based physical exercise sessions can be broadly categorized based on the instruments being used to deliver and prescribe the physical exercises—namely digital and nondigital solutions.

Nondigital Solutions to Deliver Home-Based Physical Exercise Sessions

We propose that nondigital solutions can be divided into two different types: (1) the term “home visits” refers to physical training interventions in which the health professional provides the physical training at the participant’s home. Although home visits ensure a high level of individualization because of the direct supervision (ie, synchronous interaction), they are relatively costly as the health professional provides 1:1 supervision and needs to commute to the participant’s home [96]; and (2) the term “print-based materials” characterize interventions in which the exercise and training prescription is provided via nondigital solutions such as booklets. This type of intervention provides the advantage that it can be disseminated on a broad scale even in low-resource settings (eg, with limited access to digital technologies). Owing to the asynchronous interaction, this intervention type is, in general, unsupervised, and thus it cannot be controlled for a proper exercise execution [64].

Digital Solutions to Deliver Home-Based Physical Exercise Sessions

In general, digital solutions, as compared with nondigital solutions, can be less costly (ie, online communication in comparison to home visits), allow for better visualization of how the exercises should be conducted (ie, by video instructions which provide more appropriate exercise execution cues than print-based material), allow clinician-based digital care to replace or complement traditional in-person visits in a health care center due to synchronous video or audio visits, and potentially allow for a "gamification" of exercise programs (ie, in comparison to print-based materials) [64]. For instance, there is some evidence that "gamification" can positively influence the promotion of physical activity [138,139]. Because of the aforementioned advantages especially digital solutions to deliver home-based exercise sessions within a hybrid physical training intervention seem to be a promising approach to facilitate the implementation and improve the effectiveness of such an intervention program. In the following, we will discuss in more detail the different types of digital solutions to deliver home-based physical training using a classification approach that has been previously proposed by our group [64]. For a more comprehensive overview of the physical exercise and training characteristics and effectiveness of digital and home-based physical training interventions to improve cognitive functions, we refer the interested reader to a recent systematic review of our group [64].

First, the term "digital databases" comprises digital and home-based physical training interventions that rely on the storage of the exercise prescriptions (eg, via video capsules) on specific digital media platforms (eg, smartphone or tablet-based apps) [64] and thus, can be considered as the digital alternative to print-based materials (eg, booklets). This type of digital and home-based physical training provides the advantage that it can be delivered to a relatively large number of individuals and allows for on-demand training based on asynchronous interaction [64]. A drawback of asynchronous interaction, the inherent feature of digital databases, typically no direct supervision of the single exercise sessions during the home-based training exists [64]. Concerning the implementation of digital databases to support healthy cognitive aging, different digital platforms or applications such as YouTube video capsules [140,141], DVDs [142,143], and tablet-based [144-147] or smartphone-based app [148] have so far been used to deliver a wide range of different types of physical exercises (eg, endurance, resistance, flexibility, or coordinative exercise such balance, or dancing exercises) to diverse cohorts including healthy-middle-aged and older adults [141] or middle-aged and older adults with MCI [144], cardiovascular disorders [140], or Parkinson disease [147,148]. Given that hand-eye coordination, visual acuity, and mental acuity are frequently reported barriers to the use of digital health technologies in older adults [149], commercially available devices with voice-controlled intelligent personal assistants (eg, Amazon Alexa) can be a promising alternative to remotely delivering physical exercises because the voice control helps older adults to access the exercise instructions more easily. Indeed, several small-scale studies (n=15) showed that applying voice-controlled digital solutions to remotely deliver physical exercise instruction and feedback is feasible in older adults [150-152] and is associated with high completion adherence (ie, 100%) and attendance adherence rates (ie, 115% of the prescribed exercise sessions) [152]. Thus, investigating the cognitive health effects of remotely delivered physical training, which uses devices with voice-controlled intelligent personal assistants (eg, Amazon Alexa), seems to be a promising area for further investigation.

Second, the term "online classes" refers to digital and home-based physical training interventions that are characterized by a synchronous and remote interaction of the trainees with the health professional via videoconference software [64]. Hence, it can be considered as some kind of digital alternative to home visits, typically used to supervise a single trainee or a group of trainees who exercise individually at their homes. In this context, it is worth noting that online classes can be delivered via static videoconferencing (eg, PC with camera) or dynamic videoconference (eg, via a mobile telepresence robot [MTR]) [153,154]. MTRs are typically wheeled devices that are remotely controlled by the operator (eg, exercise professional) and which allows them to be present through the robotic embodiment at remote locations, move throughout the environment, and interact with persons (eg, trainee) in the environment by 2-way audio-visual communication [154,155]. Using MTRs to deliver online classes provides the advantage of superior mobility that enables the remote controller (ie, exercise professional) to change the point of view (eg, when the trainee leaves the field of view of the camera) and thus allows for better direct supervision of single trainees or the direct supervision of several trainees exercising as a group at the same location (eg, gym in a retirement home) as compared with static videoconferencing [153,154]. While online classes provide a relatively high level of direct supervision, they are, on the downside, limited with regard to the number of trainees (eg, to ensure an appropriate level of direct supervision) and time flexibility (ie, because of fixed time schedules) [64]. In intervention studies that implement physical training via online classes (ie, static videoconference) to support healthy cognitive aging, different types of directly supervised physical exercises including endurance exercises such as cycling [156], resistance exercises [157], chair-based motor-cognitive exercises [158], or Tai Ji Quan [159] were remotely delivered to healthy older adults [157] or older adults with SCD [156], MCI [159], and Alzheimer disease [158]. In future studies, dynamic videoconference solutions using MTR could be a promising alternative to static videoconference because of their specific advantages over static videoconferencing (eg, the opportunity to change the point of view by moving the robot), and the findings (1) that older adults found MTRs useful, easy to use, and pleasant for remote supervision of physical exercises [153] and (2) that MTRs can be as effective as face-to-face interaction with an exercise professional to learn a new motor cognitive task within a single session [154]. Although these findings are encouraging, future long-term studies are needed to substantiate the evidence on the applicability of MTRs to deliver and supervise physical exercise sessions before they can be unreservedly recommended.

Third, the term “technology-based exercise devices” covers a wide range of instruments that can be used to remind individuals to be physically active (eg, just-in-time adaptive physical activity interventions using real-life data of wearables such as smartwatches or smartphones to provide real-time recommendations for opportunities to be physically active [160-162]) or that are used to conduct physical exercises (eg, virtual reality–enhanced stationary ergometer [163-166]) [64]. Such technology-based exercise devices include but are not limited to exergames. The term “exergames” (ie, also referred to as active video games or gamercizing) is a portmanteau consisting of the terms “physical exercise” and “gaming” [167] and refers to technology-driven physical activities in a gaming environment requiring participants to become physically active to play the game [168-170]. Technology-based exercise devices offer the advantage that they allow for on-demand training, but the level of direct supervision is constrained by the implementation of technical features (eg, integration of different sensors or camera-based information allowing for the assessment of behavioral, physiological, and kinematic data) [64]. In this regard, technology-based exercise devices fulfill the criteria of asynchronous interaction (eg, can be used on-demand) and synchronous interaction (ie, can provide immediate feedback to the user through integrated sensors or camera-based information), although the latter strongly depends on the technological features of the device [64]. Studies aiming to support healthy cognitive aging via technology-based exercise devices typically used specifically designed step-based exergames [171-178] or cycling-based exergames [163-166] in older adults with different health statuses (eg, in healthy older adults [171-175,178], older adults with Parkinson disease [163,164,176], multiple sclerosis [177], or MCI [165,166]), whereas the application of other technology-based exercise devices (eg, wearables such as activity trackers) is less common [64]. Given (1) that wearables (eg, activity trackers) can increase the level of regular physical activity [66,67] and (2) that physical activity is an important factor for preserving cognitive performance [36-44] and lowering dementia risk in older adults [6,9,45,46], wearables (eg, to deliver just-in-time adaptive physical activity interventions [160-162]) may hold some promise to support healthy cognitive aging, although they have so far been underused to prescribe and monitor physical activity in the context of healthy cognitive aging [64].

In summary, we proposed a classification framework and provided definitions for different types of nondigital and digital solutions to remotely deliver home-based physical exercise sessions that can guide future research in the field of healthy cognitive aging. In this context, we wish to acknowledge that in practical and research settings different nondigital and digital solutions (eg, home visits and online classes), different nondigital solutions (eg, home visits and booklet [179]), or different digital solutions (eg, digital database and online classes [180,181]) can be combined to deliver home-based physical exercises but we intentionally refrained from discussing or visualizing all possible combinations (Figure 2) for reasons of clarity and comprehensibility.

Challenges of Implementing Hybrid Physical Training Interventions Using Digital Technologies to Deliver Physical Exercise Sessions Remotely

Digital technologies provide several advantages when they are used to remotely deliver physical exercise sessions (see *Digital Solutions to Deliver Home-Based Physical Exercise Sessions* section) [64]. However, the use of digital technologies in older adults without and with cognitive impairment is also associated with some challenges including but not limited to (1) infrastructural- and device-related factors (eg, absence of stable internet coverage and unequal availability of digital technology or devices in rural or socioeconomically deprived areas), and (2) user-related factors (eg, digital literacy, privacy concerns, perceived usefulness and ease of use of the digital application, support of the social network) [57,94,150,182-188]. In this context, there is, on the one hand, some evidence that older adults with cognitive complaints or decline and who did not regularly use a computer show a lower engagement in a digital intervention aiming to reduce dementia risk through lifestyle changes [189]. On the other hand, several studies provided evidence that digital technologies can be successfully used to remotely deliver physical exercise sessions in diverse cohorts [64] including healthy older adults [142,143,145,171-175,190-192], older adults with MCI [144,159,180] and SCD [146], and even older adults with dementia [193,194]. Although the latter evidence clearly supports the feasibility of such approaches, future studies aiming to implement hybrid physical training interventions by using digital technologies to remotely deliver home-based exercise sessions should consider (1) infrastructural prerequisites (eg, in the absence of a stable internet coverage the application of digital databases instead of online classes to remotely deliver physical exercise sessions) and (2) use a user-centered and participatory approach when designing and tailoring the intervention to the specific needs of older users (eg, group-based physical training to ensure higher levels of social interaction) [57,65,70,91,92,195]. In addition, from a theoretical point of view and compared with a fully remote implementation, hybrid physical training interventions (ie, with alternating center- and home-based physical exercise sessions) provide the advantage that the regular social interaction between health professional, trainee, and peers during the center-based physical exercise sessions might lead to the development of a social network that allows to more easily overcome barriers or difficulties emerging from the use of digital technologies to remotely deliver the home-based physical exercise sessions. For instance, the possibility of receiving social and technological support, if needed, by the health professional and peers during center visits might foster the implementation and adherence to hybrid physical training interventions as compared with fully remote interventions which are characterized by somewhat looser social interactions. This assumption is supported by the fact that the lack of support is often named as a barrier to the use of digital technologies by older adults without and with cognitive impairment [182,185], although future empirical studies are needed to verify (or refute) our idea that such a lack of technological support can be reduced by hybrid physical training interventions.

Another important point that needs to be considered when providing home-based physical training with and without digital solutions is safety. In general, there is evidence that home-based physical training interventions are safe [196] even when using digital solutions [64] or when conducted in vulnerable cohorts such as adults with cardiac diseases [197,198]. In this context, the findings of a recent systematic review and meta-analysis provide evidence that there is no difference in safety-related measures (eg, dropouts) between home- and center-based physical training [196] buttressing the assumption that home-based physical training is a safe alternative to center-based physical training. However, intuitively we suggest that a higher level of direct supervision (eg, online classes) should be used to further minimize the risk of negative health events in vulnerable groups (eg, older adults with chronic diseases and high risk of falls). However, future research studying the influence of different moderators on safety outcomes (eg, level of supervision, specific setting, and trainees' characteristics such as age and health status) is needed to provide evidence-based and more nuanced recommendations in terms of the safety of remotely delivered and home-based physical training.

Current State of Evidence on Hybrid Physical Training Interventions to Support Healthy Cognitive Aging

Overview

Hybrid physical training is a novel and promising form of delivering physical training to support healthy cognitive aging and thus the evidence of its effectiveness is, as far as we know, relatively scant [64] because only a small quantity of trials has been conducted to study the effects of hybrid physical training approaches on cognitive performance [190,199,200]. The characteristics and findings of these studies will be briefly summarized in the following.

Alternating Hybrid Physical Training

In the RCT of Auerswald et al [190] the effect of a 10-week hybrid physical training in alternating mode (Figure 1A) on different health-related outcomes (ie, including cognition) was investigated in a larger sample of healthy older adults (n=551, included in the final statistical analysis). The participants were randomly allocated to a waitlist control group (CG), an intervention group 1 (IG1) that received physical exercise prescription via print-based material or digital database, or an intervention group 2 (IG2) that received physical exercise prescription via digital database and also used a wearable (ie, physical activity tracker) [190]. The physical exercise prescription for the home-based program was individualized based on the individual fitness level of the participants and follows the recommendations of the World Health Organization for regular physical activity in adults [6,201,202] (eg, balance and flexibility exercise 2 times per week, resistance exercises at 2 nonconsecutive days per week, and endurance exercise for at least 150 minutes with moderate intensity) [190]. In IG1 and IG2, the home-based physical exercises were complemented by once-weekly center-based group meetings in which health education and group-based physical exercise sessions were performed [190]. In IG2, the wearable was used to provide the participants with objective feedback on the regular physical activity level [190]. Although the participants in the IG2 and CG showed better executive functions (ie, faster reaction time in the Simon task) in the posttest compared with the pretest, no significant group differences regarding cognitive performance were observed between CG, IG1, and IG2 [190].

Moon et al [200] conducted a 24-week-long RCT in older adults with one or more modifiable dementia risk factors, but no manifest dementia [200]. The participants (n=140, included in the final statistical analysis) were randomized to a CG (ie, receiving general health education), or 1 of 2 multimodal IGs (eg, including elements such as monitoring and management of metabolic and vascular risk factors, cognitive training and social activity, physical exercise, nutritional guidance, and motivational enhancement) that received 3 times a week a 60-minute session of only supervised center-based physical training or alternating hybrid physical training (Figure 1A). The unsupervised home-based physical exercise sessions consisted of endurance, resistance, flexibility, balance, and finger-and-toe exercises that were delivered via booklets or videos (ie, digital database) [200]. In the first 2 months, the hybrid physical training group performed 1 supervised group- and center-based physical exercise session per week (ie, 2 physical exercise sessions per week at home); whereas in the remaining 4 months, 1 supervised group- and center-based physical exercise session was conducted every 2 weeks (ie, 2 home-based physical exercise sessions in a week with a center visit and 3 home-based physical exercise sessions in a week without a center visit) [200]. Regarding cognitive outcomes, the hybrid physical training group showed (1) a better performance in visuoconstruction, attention, and total scale index score in the Repeatable Battery for the Assessment of Neuropsychological Status, and (2) a better score in the Prospective Retrospective Memory Questionnaire (ie, both as compared with the CG) [200].

Subsequent Hybrid Physical Training With Home-Based Follow-Up

In the randomized controlled pilot study of Wiebking et al [199], which can be classified as subsequent hybrid physical training with home-based follow-up (Figure 1B), a 12-week long intervention (ie, 3 weeks center-based and 9 weeks home-based; 3 exercise sessions per week each lasting 30-40 minutes) was conducted in a small sample (n=21, included in the final statistical analysis) of middle-aged adults with chronic unspecific low-back pain. The participants were randomly allocated to the CG receiving usual care, a unimodal intervention group receiving sensorimotor training (SMT) consisting of stability and resistance exercises, and a multidisciplinary intervention group receiving sensorimotor training supplemented by behavioral therapy (SMT+BT) that includes cognitive distraction during sensorimotor exercises, psychoeducation, and a body scan [199]. The center-based physical exercise sessions were group-based and directly supervised by an exercise professional, whereas the home-based physical exercise sessions were delivered via a digital database (ie, DVD) [199]. Concerning cognitive measures, a faster processing speed (ie, assessed via Trail Making Test A) was observed after the intervention and at the 3-month follow-up only in the SMT+BT group but not in the SMT or the CG group [199].

Interim Summary

Collectively, the findings of the aforementioned studies suggest that hybrid physical training is a promising approach to fostering healthy cognitive aging. However, the limited number of trials that have studied the effect of hybrid physical training on cognitive performance in the aging population does not allow for drawing more nuanced conclusions (eg, which type of hybrid physical training is most suitable for a specific context and setting). Thus, future research is needed to derive more robust and nuanced conclusions on the effectiveness of specific types of hybrid physical training to support healthy cognitive aging. In this context, our classification framework of hybrid physical training interventions provides researchers with an orientation that can help them to (1) structure findings and knowledge and (2) elucidate which type of hybrid physical training is most suitable for the specific context and setting. In prompting the direction of future research, we provide in the next section recommendations for research priorities concerning hybrid physical training and healthy cognitive aging.

Recommendations for Future Research

Considering the facts that (1) hybrid physical training interventions, especially those that use digital solutions to provide home-based physical exercise sessions, have been underused to promote planned and structured forms of physical activity in healthy middle-aged and older adults and adults at higher risk to develop dementia (eg, adults with MCI) [64] and (2) hybrid physical training provides some specific advantages depending on their implementation (see Interim Summary section for a detailed discussion), we recommend that future research should aim to answer the following research questions:

- Do the positive effects of physical training on cognitive health and dementia risk, as seen for traditional physical training intervention approaches, extend to hybrid physical training interventions?
- Is the potential effectiveness of hybrid physical training interventions influenced by their implementation (eg, temporal and intervention-related characteristics)?
- Do hybrid physical training interventions, as compared with traditional physical training approaches, improve measures of adherence?
- Are hybrid physical training interventions using digital technology feasible, safe, and effective in special populations with lower digital health literacy (eg, older adults with MCI)?

In the context of the aforementioned research questions, we propose that future studies should especially focus on, but are not limited to, measures of cognitive performance (eg, global cognition and memory), dementia-related risk factors and biomarkers (eg, blood-based parameters), ability to live independently (eg, activities of daily living, life-space mobility), adherence (eg, attendance and completion adherence [64,203,204]), social interaction (eg, social isolation, social connectedness), and cost use. To get a more comprehensive understanding of the neurobiological mechanisms that drive the positive effects of physical activity on cognitive health and to gain a deeper understanding of how physical training interventions can be effectively tailored to fit the individual needs of healthy middle-aged and older adults, and older adults with existing health conditions (eg, MCI), future studies should (1) use a rigorous study design [205-207] including a transparent reporting of the intervention-related characteristics [34,35,106,208], (2) conduct analysis on multiple levels (ie, level 1: changes on a molecular and cellular level, level 2: functional and structural brain changes, and level 3: socioemotional changes) [36,38,64], and (3) consider potential moderators such as sex or genetic status [209-213].

Conclusions

Hybrid physical training interventions, which consist of both center-based physical exercise sessions and home-based physical exercise sessions, can be a promising option to better tailor physical training-based approaches aiming to promote healthy cognitive aging to the individual needs of a person because they combine the strengths of a center-based approach (eg, supervision and social contact) and a home-based approach (eg, on-demand training), which, in turn, may increase the efficacy of such a form of intervention. To advance research in this direction, this article (1) provides a definition of hybrid physical training, (2) proposes a classification approach of different types of hybrid physical training interventions, (3) discusses the specific advantages and disadvantages of the different types of hybrid physical training interventions, and (4) provides recommendations for future research on hybrid physical training interventions in the context of healthy cognitive aging.

Abstract

Background: Myocardial injury after noncardiac surgery (MINS) is an easily overlooked complication but closely related to postoperative cardiovascular adverse outcomes; therefore, the early diagnosis and prediction are particularly important.

Objective: We aimed to develop and validate an explainable machine learning (ML) model for predicting MINS among older patients undergoing noncardiac surgery.

Methods: The retrospective cohort study included older patients who had noncardiac surgery from 1 northern center and 1 southern center in China. The data sets from center 1 were divided into a training set and an internal validation set. The data set from center 2 was used as an external validation set. Before modeling, the least absolute shrinkage and selection operator and recursive feature elimination methods were used to reduce dimensions of data and select key features from all variables. Prediction models were developed based on the extracted features using several ML algorithms, including category boosting, random forest, logistic regression, naïve Bayes, light gradient boosting machine, extreme gradient boosting, support vector machine, and decision tree. Prediction performance was assessed by the area under the receiver operating characteristic (AUROC) curve as the main evaluation metric to select the best algorithms. The model performance was verified by internal and external validation data sets with the best algorithm and compared to the Revised Cardiac Risk Index. The Shapley Additive Explanations (SHAP) method was applied to calculate values for each feature, representing the contribution to the predicted risk of complication, and generate personalized explanations.

Results: A total of 19,463 eligible patients were included; among those, 12,464 patients in center 1 were included as the training set; 4754 patients in center 1 were included as the internal validation set; and 2245 in center 2 were included as the external validation set. The best-performing model for prediction was the CatBoost algorithm, achieving the highest AUROC of 0.805 (95% CI 0.778 - 0.831) in the training set, validating with an AUROC of 0.780 in the internal validation set and 0.70 in external validation set. Additionally, CatBoost demonstrated superior performance compared to the Revised Cardiac Risk Index (AUROC 0.636; *P*<.001). The SHAP values indicated the ranking of the level of importance of each variable, with preoperative serum creatinine concentration, red blood cell distribution width, and age accounting for the top three. The results from the SHAP method can predict events with positive values or nonevents with negative values, providing an explicit explanation of individualized risk predictions.

Conclusions: The ML models can provide a personalized and fairly accurate risk prediction of MINS, and the explainable perspective can help identify potentially modifiable sources of risk at the patient level.

Introduction

Myocardial injury after noncardiac surgery (MINS), a prominent postoperative cardiovascular complication, occurs in approximately 8% to 22% of patients overall [1]. The Vascular Events in Noncardiac Surgery Patients Cohort Evaluation (VISION) study showed that MINS was the second most common cause of short-term mortality among 8 perioperative adverse events [2,3]. MINS is also reportedly an independent predictor of 1-year or long-term mortality [4]. Nevertheless, 90% of the MINS events are unrecognized because most patients are not presenting ischemic symptoms, and a minority of MINS cases are diagnosed by electrocardiogram abnormalities, involving typical chest pain symptoms [5]. Therefore, early prediction and identification of patients at higher risk for MINS is critically important for enhancing the outcomes of these underappreciated complications in older patients.

The most common prediction tool available to identification of high-risk patients is Revised Cardiac Risk Index (RCRI) [6], a universally used screening tool due to ease of use but with poor performance in other validation sets. American College of Surgeons National Surgeons Quality Improvement Program (NSQIP) [7] and Myocardial Infarction or Cardiac Arrest (MICA) surgical risk calculators [8] were subsequently developed with higher accuracy than RCRI, designed to predict more severe outcomes, including death and myocardial infarction, instead of predicting MINS. Another prediction model was derived from the MANAGE cohort [9], using 3 preoperative risk factors and not considering intraoperative factors. ML has been proven more powerful than conventional logistic regression because it can overcome the limitations of statistical methods and even create personalized risk predictions [10]. Recently, two novel ML models were reported to predict the occurrence of MINS. Oh et al [11] developed a machine learning (ML) model and achieved an area under the receiver operating characteristic (AUROC) curve of 0.78 using 12 variables. However, the population heterogeneity and lack of external validation may limit its generalization to older patients. Nolde et al [12] applied single-layer and multiple-layer variables to different models and achieved the highest AUROC of 0.77 and accuracy of 0.70. Despite comprehensive included variables, anesthesiologists and surgeons are unable to distinguish modifiable risk factors and make targeted interventions to improve outcomes.

Currently, no validated and accurate risk prediction tools for MINS are in use. Therefore, the purpose of our research was to develop and validate an ML model that predicts MINS risk based on surgery data available at admission and during the intraoperative period. The model also used Shapley Additive Explanations (SHAP) method to interpret results, allowing for targeted interventions to modify risk factors and support clinical decision-making.

Methods

Patient Cohort

We collected data anonymously from our electronic health record (EHR) system, which was an integrated clinical database containing data on all patients who were admitted to hospitals. The data set was derived from older patients (defined as aged ≥65 years) undergoing noncardiac surgery from January 2017 to August 2019, and the internal validation data set was derived from patients enrolled from July 2020 to July 2021 in center 1 (Chinese People's Liberation Army General Hospital in northern China). We also included patients who had noncardiac surgeries in center 2 (Nanfang Hospital of Southern Medical University in southern China) from January 2021 to October 2021 as an external data set. The uniform exclusion criteria were as follows: excluding patients with the American Society of Anesthesiologists (ASA) grade V, a short operation interval (scheduled for more than 1 surgery within a week), with nongeneral anesthesia, low-risk surgery (eg, outpatient surgery, hysteroscopic surgery, or body surface surgery), and a short surgery duration (≤30 min). Patients undergoing either elective or emergency surgery were eligible for participation.

Ethical Considerations

The study was approved by the Ethics Committee Board of the First Medical Center of Chinese People's Liberation Army (S2019-311-02), and the requirement for informed consent was waived because this was an observational study with minimal risk for patients. This study conforms to the principles outlined in the Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis (TRIPOD) statement.

Data Processing

Variables from the following categories were collected: demographics, preoperative comorbid conditions and medications, preoperative laboratory results, vital signs, and intraoperative information. For laboratory testing variables with multiple measurements, we used only the last preoperative measurements taken within 1 week before surgery for analysis. A total of 118 variables from the electronic database were extracted and listed in Table S1 in Multimedia Appendix 1. Additional extraction details are displayed in supplementary material 1 in Multimedia Appendix 1. The least absolute shrinkage and selection operator (LASSO) method, which could solve high dimensionality and multicollinearity between variables was used. After the initial screening, recursive feature elimination (RFE), combined with 5-fold cross-validation, was adopted to rescreen and select the best hyperparameters [13]. After final screening, missing values were imputed using multiple imputation [14].

Outcome

The primary end point was the incidence of MINS within the first 30 days after surgery. According to the scientific statement from the American Heart Association [15], MINS was defined as at least 1 postoperative high-sensitivity troponin T of 20 to <65 ng/L with an absolute change ≥5 ng/L or a high-sensitivity troponin T concentration ≥65 ng/L; or at least 1 postoperative measurement of troponin I concentration exceeding the uniform 99th percentile due to a presumed ischemic etiology irrespective of the presence or absence of clinical symptoms and electrocardiographic changes within the first 30 days after noncardiac surgery.

ML Models

Linear and nonlinear ML models were applied, including category boosting (CatBoost) [16], random forest [17], logistic regression [18], naïve Bayes [19], light gradient boosting machine (LightGBM) [20], extreme gradient boosting (XGBoost) [21], support vector machine [22], and decision tree [23,24]. The above algorithms were implemented using the Scikit-learn, LightGBM, XGBoost, and CatBoost Python packages. Each method is described in detail in supplementary material 2 in Multimedia Appendix 1.

Model Performance and Evaluation

Because of the imbalance between the positive and negative events, the random under-sampling technique was used to avoid overfitting by the rationale of eliminating samples from the majority class to make the majority class equal to the minority class, which is a simple but effective way to treat imbalanced data sets. Eight ML models with final indicators were developed to predict outcomes. The AUROC was used as the evaluation standard of the model performance, and classifiers with larger AUROCs were considered to have better prediction efficiency, and the best-performing ML model was chosen by its AUROC. We also calculated the 95% CIs for each model using the advanced bootstrap method. Similarly, the related sensitivity, specificity, and accuracy were assessed in models conducted. Appropriate figures were produced for these metrics in the best fitting model, including a precision-recall curve and calibration curve, to show the average precision and difference between the predicted risk and actual risk. The AUROCs were also calculated in the validation sets and in the RCRI model to compare the efficacy.

Model Interpretation

The SHAP method [24] was used to analyze the importance of features in the model because of the limited interpretability in the ML algorithm. SHAP was used as a scoring metric for feature contributions, through determining the difference between the predicted values with and without each feature for all combinations. The greater the influence a particular value of a sample has on the composition of the model, the farther that point deviates from 0 on the x-axis. Using SHAP values and a summary plot, it is thus possible to determine which features have a significant effect on the prediction and whether this contribution is positive or negative. Moreover, SHAP facilitates individual-level risk prediction and stratification, which is straightforward and understandable by doctors.

Statistical Analysis

For the baseline data analysis, continuous characteristics were evaluated by the Shapiro-Wilk normality test and analyzed by either the 2-tailed *t* test for normally distributed variables or the Mann-Whitney *U* test for skewed data and were reported as means or medians. Categorical variables were compared using the chi-square test or Fisher exact test and were reported as proportions. As this was a retrospective exploratory study, no attempt was made to estimate the sample size of the study; instead, all eligible patients in the database were included to maximize the statistical power. For all analyses, a 2-sided *P* value <.05 was considered statistically significant. All analyses were performed using Python (version 3.6; Python Software Foundation).

Results

Characteristics

In total, we retrospectively enrolled 12,464 patients (median age 69, IQR 67-74 years; n= 6793, 54.5% male) who met the inclusion criteria in center 1 from January 2017 to August 2019 as the training data set. Finally, 884 (7.1%) patients developed postoperative 30-day MINS among 12,464 patients. The flowcharts of patient enrollment in the training data set are shown in Figure 1. In the training data set, patients with postoperative MINS tended to be older; have more chronic conditions, such as hypertension, diabetes mellitus, and cerebrovascular diseases; and have more abnormal laboratory test values. The differences in the demographics and other characteristics between patients with and without MINS are summarized in Table 1. The flowcharts of validation data sets are shown in Figure S1 in Multimedia Appendix 1.

Table . Baseline characteristics of patients with or without myocardial injury after noncardiac surgery (MINS) at center 1 in the training set.

Variable		Non-MINS (n=11,580)	MINS (n=884)	Total (n=12,464)
Age (years), median (IQR)		69 (67-73)	72 (68-78)	69 (67-74)
Hypertension, n (%)		5225 (45.1)	500 (56.6)	5725 (45.9)
Coronary heart disease, n (%)		1282 (11.1)	206 (23.3)	1488 (11.9)
Cerebrovascular disease, n (%)		836 (7.2)	140 (15.8)	976 (7.8)
Renal insufficiency, n (%)		117 (1)	50 (5.7)	167 (1.3)
β-blockers, n (%)		944 (8.2)	140 (15.8)	1084 (8.7)
Diuretics, n (%)		578 (5)	120 (13.6)	698 (5.6)
Anticoagulants, n (%)		845 (7.3)	164 (18.6)	1009 (8.1)
Hemoglobin (g/L), median (IQR)		131 (120-142)	122 (105-136)	131 (120-142)
RBC[a] (10^9), median (IQR)		4.32 (3.96-4.65)	4.04 (3.54-4.45)	4.3 (3.94-4.64)
SCr[b] (umol/L), median (IQR)		71.2 (60.9-82.9)	78.9 (64.8-98.175)	71.6 (61.1-83.7)
RDW[c] (%), median (IQR)		12.8 (12.3-13.4)	13.3 (12.6-14.4)	12.8 (12.3-13.4)
Albumin (g/L), median (IQR)		40.15 (37.8-42.7)	38.2 (34.7-41.1)	40 (37.6-42.6)
Blood glucose (mmol/L), median (IQR)		5.08 (4.62-5.85)	5.46 (4.77-6.63)	5.1 (4.63-5.9)
Lymphocyte count (10^9), median (IQR)		0.3 (0.24-0.36)	0.24 (0.18-0.32)	0.3 (0.24-0.36)
Surgery duration (min), median (IQR)		144 (90-205)	180 (120-260)	145 (93-210)
ASA [d] grade, n (%)				
	I	116 (1)	6 (0.7)	122 (1)
	II	9380 (81)	485 (54.9)	9865 (79.1)
	III	2034 (17.6)	340 (38.5)	2374 (19)
	IV	50 (0.4)	53 (6)	103 (0.8)
Emergency surgery, n (%)		207 (1.8)	76 (8.6)	207 (1.8)
Colloid input (mL), median (IQR)		500 (0-500)	500 (0-1000)	500 (0-500)
Crystalloid input (mL), median (IQR)		1600 (1100-2100)	2000 (1300-2600)	1600 (1100-2100)
Blood loss (mL), median (IQR)		100 (30-200)	150 (50-300)	100 (50-200)
Blood transfusion, n (%)		1044 (9.0)	222 (25.1)	1266 (10.2)
Duration of intraoperative hypotension (min), mean (SD)		16.85 (37.8)	29.91 (57.6)	17.78 (42.3)

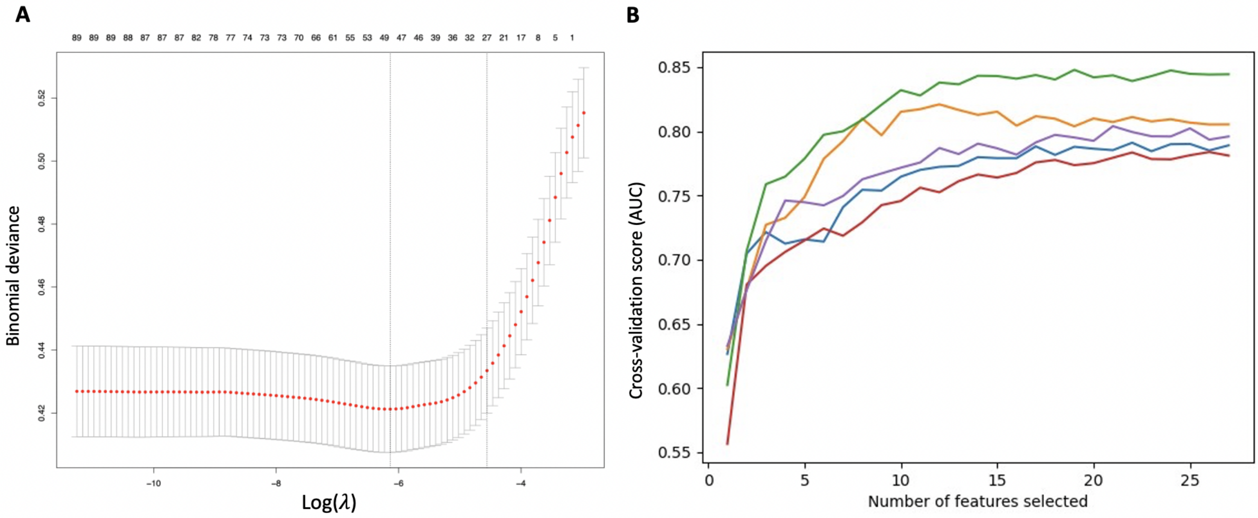
Feature Selection

Through LASSO, we found that the optimal number of features for model prediction was 27 (Figure 2A). The RFE method was used to repeat the model building and feature selecting procedure, finally resulting in 25 features by excluding myocardial infarction history and facility (Figure 2B). The features selected by LASSO and RFE are listed in the supplementary material 1 in Multimedia Appendix 1.

Figure 2. Feature selection by least absolute shrinkage and selection operator (LASSO) and recursive feature elimination (RFE) with 5-fold cross-validation. (A) Through LASSO, the filtered variables were as follows: renal insufficiency, diuretics, cerebrovascular disease, β-blockers, anticoagulants, hypertension, blood transfusion, coronary heart disease, colloid, blood pressure monitoring method, American Society of Anesthesiologists grades, crystalloid, hemoglobin, surgery duration, sodium, age, lymphocyte, anesthesia duration, duration of intraoperative hypotension, red blood cell, glucose, red blood cell distribution width, blood loss, albumin, serum creatinine, facility, and myocardial infarction. (B) Recursive feature elimination with a 5-fold cross-validation method filtered features again and removed 2 parameteres (facility and myocardial infarction), leaving 25 parameters as mentioned above. AUC: area under the curve.

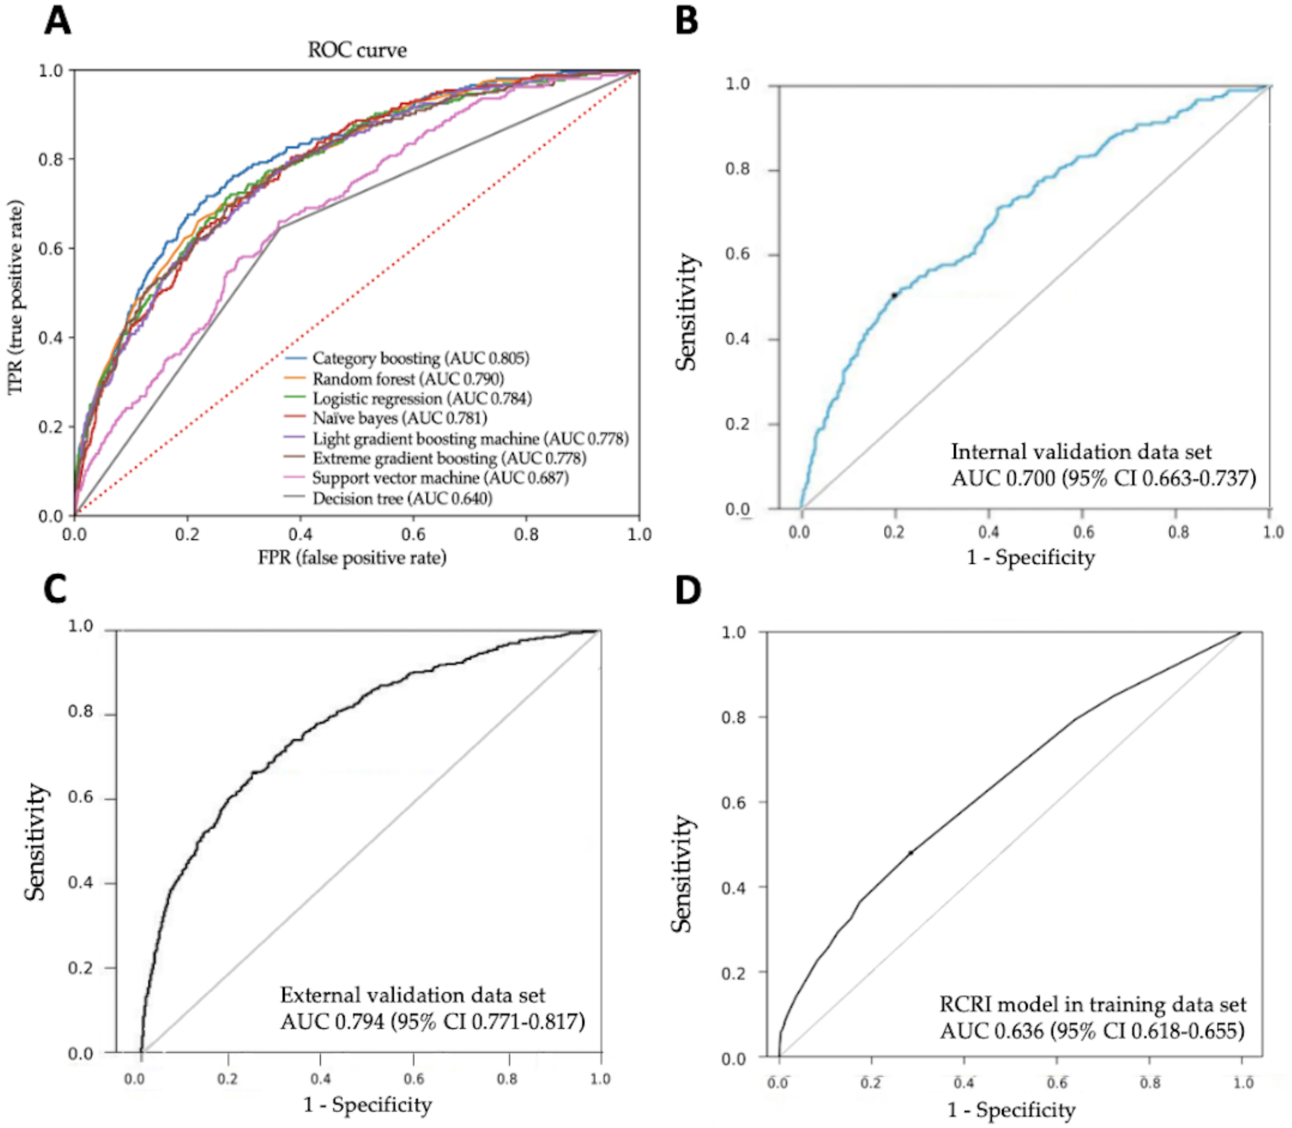


Model Performance and Comparison

The training data set from center 1 was used to develop the forecast models, and MINS was predicted with an AUROC of 0.805 (95% CI 0.778 - 0.831) by the best-performing CatBoost method, compared with the other 7 algorithms. CatBoost revealed a relatively high accuracy (0.730, 95% CI 0.716 - 0.745), sensitivity (0.747, 95% CI 0.694 - 0.797), and specificity (0.729, 95% CI 0.714 - 0.744). The overall AUROC by all algorithms is shown in Figure 3A. The average accuracy, sensitivity, and specificity calculated by all the algorithms are summarized in Table S2 in Multimedia Appendix 1. The model was well calibrated with a Brier score loss of 0.18; its calibration plot is depicted in Figure S2 in Multimedia Appendix 1.

To verify the stability of our model, prediction was validated with an AUROC of 0.794 in the internal validation set of center 1 and 0.70 in the external validation set of center 2, by the method of CatBoost, and their AUROCs are displayed in the Figure 3B and 3C. Incorporating the 6 parameters in the RCRI model into the validation data set, we observed a poor prediction performance, with an AUROC of 0.636, which was inferior to that of our machine learning models (*P*<.001) (Figure 3D).

Figure 3. The receiver operating characteristics curve of different models. (A) Eight different machine learning prediction models for myocardial injury after noncardiac surgery using the training data set from center 1. (B) Model performance in the internal validation data set from center 1. (C) Model performance in the external validation data set from center 2. (D) Performance of 6 indicators from Revised Cardiac Risk Index (RCRI) in the training data set. AUC: area under the curve. ROC: receiver operating characteristic.



Model Interpretation

Assisted by the development of explainable ML models, the SHAP values for the prediction of MINS were calculated. Figure 4A shows the 20 most influential factors ranked by the average absolute SHAP value, and Figure 4B shows their effect values and interpretations. In the graph, the red dots represent high risk, and the blue dots represent low risk. A higher serum creatinine, higher red blood cell distribution count, older age, increased blood loss, higher blood glucose concentration, higher ASA grade, longer duration of intraoperative hypotension, longer surgery duration, greater infusion of crystalloids or colloids, lower red blood cell count, lower lymphocyte count, lower albumin, lower sodium, and lower hemoglobin were associated with a higher predicted probability of postoperative MINS. Invasive arterial pressure monitoring, blood transfusion, preexisting coronary heart disease, and preexisting hypertension also increased the event risk.

In addition, a visualization method [25] was used to make patient-level prediction interpretations of the model. We provided 2 examples to illustrate this in Figure 5. An 81-year-old patient with ASA grade III underwent surgery with a nearly 2.5-hour duration of anesthesia and developed MINS. His preoperative laboratory test values are listed in Figure 5A. The arrows indicate the influence of each feature on prediction; the red arrows suggest an increased risk of the outcome, and the blue arrows suggest a decreased risk. The predicted score of MINS (approximately 3.11) was 30 times higher than the base value predicted by the model (approximately 0.1). Conversely, the second patient, with preoperative normal laboratory measurements, intraoperative blood transfusion, blood loss of 400 mL, and intraoperative short hypotension, did not experience MINS, with a predicted score of −0.72, lower than the base value of 0.1.

Figure 4. The model’s interpretation. (A) Bar summary of the most important 20 features according to the mean Shapley Additive Explanations (SHAP) values. A higher value of a feature has a greater effect on the model’s composition, indicated by how far a point deviates from 0 on the x-axis. (B) Summary of the most impactful features with interpretation. The red dots represent the high-risk value, and the blue dots represent the low-risk value. ASA: American Society of Anesthesiologists; Na: sodium; HGB: hemoglobin; BP: blood pressure; GLU: glucose; RDW: red blood cell distribution width; SCR: serum creatinine.

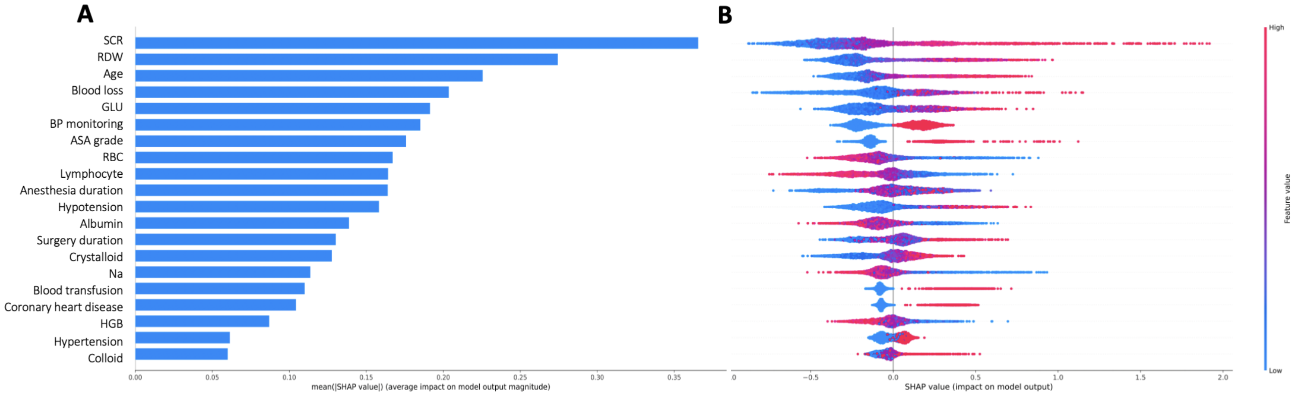


Figure 5. The composition risk of individualized predictions for 2 patients. A blue arrow indicates that a factor reduced the risk of myocardial injury after noncardiac surgery (MINS), whereas a red arrow indicates it increased the risk. (A) An 81-year-old patient with American Society of Anesthesiologists (ASA) grade III underwent surgery with a nearly 2.5-hour duration of anesthesia and developed MINS. (B) A patient with preoperative normal laboratory measurements, with intraoperative blood transfusion, blood loss of 400 mL, and intraoperative short hypotension did not have MINS. ASA: American Society of Anesthesiologists; BP: blood pressure; GLU: glucose; MAP: mean artial pressure; RBC: red blood cell; RDW: red blood cell distribution width; SCR: serum creatinine.

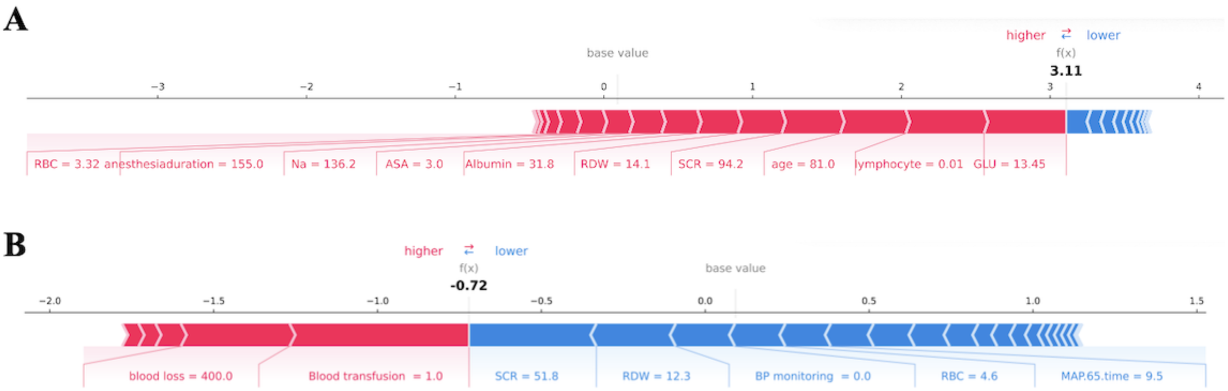

Discussion

Principal Findings

In this cohort study, we used ML approaches with multiple demographic and clinical data from EHR to predict the occurrence of postoperative myocardial injury. The CatBoost algorithm achieved the best predictive performance in the training data set and was validated in both the internal and external data sets, with high sensitivity and specificity, also superior to the classic RCRI model. The SHAP method also provided information on the contribution of each variable toward an event or nonevent, quantifying the association between variables and patient outcomes of a single patient. Our results aim to assist in the accurate and timely identification of older patients at high risk of postoperative myocardial injury, enhancing clinical decision support.

The RCRI is considered a conventional predictive model and has been widely used for more than 20 years [6]. Although it has the merit of simplicity with 6 indicators, its use is limited in clinical practice because of its low discriminative ability and lack of specific and sensitive biomarkers for MINS [26]. In our study population, the RCRI model could only achieve an AUROC of 0.636, significantly lower than our model projections. The NSQIP and MICA surgical risk calculators were validated to better estimate cardiovascular risk compared to the RCRI; however, the NSQIP and MICA scores provided only fair discrimination with a C-statistic of 0.70 for postoperative myocardial infarction and MINS outcomes in another external validation research [27]. Our study did not compare our models with the NSQIP surgical risk calculator and MICA as several key indicators needed to be collected prospectively and were not available in our data. Another prediction model by logistic regression was derived from the MANAGE cohort, using only 3 preoperative risk factors, not accounting for intraoperative factors, which might be important contributors to adverse outcomes [9]. Therefore, neither of these widely used assessment tools performed by logistic regression statistics has yet been shown to have sufficient predictive strength and applicability.

Recent work has highlighted the strengths of ML algorithms for predicting postoperative complications compared to classic statistical analyses because they can eliminate nonlinear interactions between clinical variables and resolve the imbalance problem. Oh et al [11] developed the prediction model using extreme gradient boosting algorithm and achieved an AUROC of 0.78 through 12 variables. There were 5 variables coinciding in Oh's model and ours: operation duration, age, history of chronic kidney disease, history of coronary artery disease, and intraoperative red blood cell transfusion. Other inconsistent variables were due to medication differences, uncollected variables, and number of events. Furthermore, there were 6811 patients selected from 43,019 patients, and the high exclusion rate (84%) and high incidence of MINS (22%) caused a high risk of selection bias in the study. The potential risk factors in Oh's study may not be generalizable to our data set, which is including older patients. Another ML model was developed by Nolde et al [12], through applying single-layer and multiple-layer variables to different models and achieving the highest AUROC of 0.71. However, the model with optimal prediction efficacy also included information of postoperative vital parameters and oxygenation within 1 - 4 days, making it more challenging for anesthesiologists to identify high-risk patients after procedures immediately. Moreover, despite the presentation of variable importance ranking, anesthesiologists and surgeons are were still unable to distinguish modifiable risk factors and make targeted interventions to improve outcomes.

In our study, we used several ML approaches based on different principles and noticed that the prediction efficacy of each approach did not greatly differ from each other, suggesting the promising performance of all advanced ML algorithms for the relatively small and low-dimension data. Logistic regression, representing the simplest of all classifiers, was chosen to create a reference model against the performance of other machine models. Based on this principle, the CatBoost and random forest demonstrated relatively good prediction results in our data set and CatBoost was chosen for further analysis. We also noticed that the naïve Bayes algorithm provided the highest accuracy but with the disadvantage of worse classification performance. The reason for this result might be due to different models dealing with sample classification in different ways. The accuracy index considered only the percentage of correct classification, whereas the AUROC index reflected the ability of a classification model to discriminate between positive and negative samples, taking into account the set threshold's influence on prediction results. Although similar accuracy can be achieved, the discrimination of being misjudged was not considered while the AUROC index was used as a complementary measure. Based on these points, we conclude that the CatBoost algorithm demonstrates a better predictive effect for MINS due to its highest AUROC, much faster speed, and using default parameters.

In addition, our model not only achieved good predictive effect for MINS but also explored a model-agnostic interpretation technique on how potential variables contribute to adverse outcomes, which was not explored in previous studies. The SHAP values confirmed the importance of variables, reflecting their positive or negative roles. The top important features contributing to adverse cardiovascular complications included preoperative renal dysfunction, inflammatory status, glucose metabolism, anemia, and electrolyte disturbances. The intraoperative hemodynamic and other physiological changes are also important contributors to the occurrence of MINS, including more blood loss, prolonged surgery duration, hypotension, greater infusion of fluids, and blood transfusion [28-34]. The SHAP plot presentats predictions for a single sample in which each feature is a value that increases or decreases the prediction efficacy and its contribution level, providing intuitive explanations for what led to a patient's predicted risk and quantitative prediction at individual levels. For example, in our first sample patient, we recognized that his high preoperative blood glucose concentration played the greatest negative role in the development of complications. Similarly, in the second sample, intraoperative blood transfusion was considered the strongest risk factor for postoperative MINS. Although the complications are unavoidable mainly due to patients' comorbidities and surgical stimuli, some variables are modifiable. Identifying specific patient characteristics that predispose them to at-risk status can prompt early targeted prevention or treatments, such as administering insulin to patients with a high blood glucose concentration or taking measures to reduce intraoperative blood loss, which may improve the prognosis. The individual risk estimates may provide the modifiable factors through the SHAP method, which was clinically meaningful and can be used in multiple surgical scenarios.

Limitations

There are limitations to our study. While the model showed with high accuracy, it was highly dependent on data from EHR. When one indicator was missing, the true risk of adverse outcomes for the patient could not be reflected. Second, the surgical patient data were obtained retrospectively from 2 hospitals, which may have introduced bias, as some potential candidates' data may not be collected in the EHR. Although external validation was conducted in our model, more validation centers are warranted to support the extrapolation and creditability. Third, some variables were excluded before feature selection, especially those laboratory tests not rountinely measured, such as brain natriuretic peptide and C-reactive protein, leading to omission and neglect of important indicators. Lastly, this study only enrolled older Chinese patients who had noncardiac surgeries from 1 northern center and 1 southern center, and whether the results can be extrapolated to other populations remains uncertain.

Conclusions

These findings suggest that the ML technique, combining the preoperative and intraoperative variables for predicting MINS with a model-agnostic interpretation, is a potentially efficient management tool for practitioners to guide their postoperative care planning and management.

Abstract

Background: Geriatric comanagement has been shown to improve outcomes of older surgical inpatients. Furthermore, the choice of discharge location, that is, continuity of care, can have a fundamental impact on convalescence. These challenges and demands have led to the SURGE-Ahead project that aims to develop a clinical decision support system (CDSS) for geriatric comanagement in surgical clinics including a decision support for the best continuity of care option, supported by artificial intelligence (AI) algorithms.

Objective: This qualitative study aims to explore the current challenges and demands in surgical geriatric patient care. Based on these challenges, the study explores the attitude of interviewees toward the introduction of an AI-supported CDSS (AI-CDSS) in geriatric patient care in surgery, focusing on technical and general wishes about an AI-CDSS, as well as ethical considerations.

Methods: In this study, 15 personal interviews with physicians, nurses, physiotherapists, and social workers, employed in surgical departments at a university hospital in Southern Germany, were conducted in April 2022. Interviews were conducted in person, transcribed, and coded by 2 researchers (AU, LB) using content and thematic analysis. During the analysis, quotes were sorted into the main categories of geriatric patient care, use of an AI-CDSS, and ethical considerations by 2 authors (AU, LB). The main themes of the interviews were subsequently described in a narrative synthesis, citing key quotes.

Results: In total, 399 quotes were extracted and categorized from the interviews. Most quotes could be assigned to the primary code *challenges in geriatric patient care* (111 quotes), with the most frequent subcode being *medical challenges* (45 quotes). More quotes were assigned to the primary code *chances of an AI-CDSS* (37 quotes), with its most frequent subcode being *holistic patient overview* (16 quotes), then to the primary code *limits of an AI-CDSS* (26 quotes). Regarding the primary code *technical wishes* (37 quotes), most quotes could be assigned to the subcode *intuitive usability* (15 quotes), followed by *mobile availability and easy access* (11 quotes). Regarding the main category *ethical aspects of an AI-CDSS*, most quotes could be assigned to the subcode *critical position* toward *trust in an AI-CDSS* (9 quotes), followed by the subcodes *respecting the patient's will and individual situation* (8 quotes) and *responsibility remaining in the hands of humans* (7 quotes).

Conclusions: Support regarding medical geriatric challenges and responsible handling of AI-based recommendations, as well as necessity for a holistic approach focused on usability, were the most important topics of health care professionals in surgery regarding development of an AI-CDSS for geriatric care. These findings, together with the wish to preserve the patient-caregiver relationship, will help set the focus for the ongoing development of AI-supported CDSS.

Introduction

Older adults represent a large proportion of patients in hospitals, and numbers will be increasing [1]. Treatment of these patients can be challenging, due to complex medical conditions including deficits in multiple geriatric domains [2,3]. Therefore, identification of geriatric patients with complex needs is needed and should be followed by comprehensive geriatric assessments to capture needs and resources in multiple domains such as cognition, nutrition, physical functioning, comorbidities, frailty, and others [4].

An additional challenge is determining the best discharge destination for these patients, also referred to as transition of care or continuity of care (COC) [5]. Multiple options exist in most high-resource countries, such as rehabilitation with geriatric or orthopedic specialization, specialized acute geriatric departments or hospitals, short- or long-term care in nursing homes, or ideally a direct discharge home with or without further support [6]. In Germany, social services assist with organizing adequate COC. Ideally, the decision is discussed by physicians, patients, relatives, nurses, therapeutic, and social service staff. Barriers to optimal COC decisions have been observed and include staffing shortages, difficulties to assess the potential of geriatric patients in an acute stress situation, difficulties to communicate with relatives and team members in a structured way, and an insufficient alignment between bed capacity and the demand in the target facilities [5,7,8].

The involvement of geriatric specialists in the treatment of geriatric patients on surgical wards has been shown to improve relevant clinical outcomes [9]. However, a shortage of geriatric specialists prevents the widespread implementation of geriatric comanagement [10]. To address this problem, the SURGE-Ahead project (supporting surgery with geriatric comanagement and artificial intelligence [AI]) aims to develop an AI-enhanced clinical decision support system (AI-CDSS) to support geriatric comanagement and COC decisions in surgical departments without a resident geriatrician [11]. SURGE-Ahead started in July 2021 and is a multidisciplinary project funded by the Federal Ministry of Education and Research. For this purpose, the SURGE-Ahead AI-CDSS system collects patient data from the hospital information system (HIS) including central laboratory parameters, diagnoses, and operation procedures. In addition, relevant scores for comprehensive geriatric assessments domains, such as mobility, cognition including delirium, and medication appropriateness, will be registered, calculated, and presented to the surgical staff. Furthermore, a suggestion for the most suitable COC destination will be given based on decision trees and machine learning algorithms. To develop the algorithm, the ground truth (optimal discharge decision) will be provided by experts for geriatric medicine.

The use of an AI-CDSS in health care delivery raises ethical questions [12-14]. While it could improve communication with patients and contribute to increased quality of the diagnostic and therapeutic process [15,16], it also carries risks such as overlooking patients' individual wishes and needs. Other issues, such as decreased trust in accuracy and usability of the system because of errors, technical problems, or overalerting, may result in the product not being used in everyday clinical practice [12,17]. It has been shown that a cocreation process with end users helps improve the development of targeted new digital health applications [18]. We therefore conducted qualitative expert interviews with different health care professionals to capture current challenges on surgical wards, requirements for an AI-CDSS, and ethical considerations. In detail, we aimed to cover the following 3 main categories:

1. Challenges and need for support in geriatric patient care.
2. Technical and general wishes regarding the development of an AI-CDSS for geriatric patient care in surgery.
3. Expected ethical challenges using an AI-CDSS with respect to the 4 core medico-ethical principles of autonomy, beneficence, maleficence, and justice [19].

Methods

Participants

We included 15 health care professionals involved in the inpatient surgical care of geriatric patients. Three senior physicians, 3 assistant physicians, and 3 nurses from the departments of urology, visceral surgery, and traumatology (all 3 departments are recruitment centers for the SURGE-Ahead project), as well as 2 senior physicians from the emergency department, 2 physiotherapists, and 2 social service workers, all responsible for surgical patients, agreed to participate. None of the interviewees were involved in the SURGE-Ahead project or in the development of the AI-CDSS.

Participants were recruited at Ulm University Medical Center in Southern Germany. The department of orthopedic trauma surgery has been certified as an AltersTraumaZentrum (center for geriatric traumatology) DGU in cooperation with a local geriatric clinic in 2019. This model of care entails medical visits by a geriatrician on trauma wards. Furthermore, a senior surgeon visits the geriatric clinic. Thus, an exchange exists between the 2 hospitals regarding the care for geriatric trauma patients. Currently, this model exists only for orthopedic trauma surgery and not for other surgical departments.

Interviews

An interview guideline with 12 questions corresponding to the 3 main topics was prepared by a multidisciplinary research team consisting of geriatricians, surgeons, public health specialists, and ethicists. The questions were formulated on the basis of a prior literature research, the guidelines for conduct of qualitative interviews [20,21], and professional experience of the researchers. The number of questions was limited to 12 due to the expected short time available to our interview partners. Interviews were conducted in a semistructured way. While the preformulated questions set the focal point, ad hoc questions provided a possibility to clarify statements or focus on particularly important issues mentioned by the interviewees [22,23].

Interviews were conducted in person in April 2022 in German. Potential interview partners were contacted personally or via email. If willing to participate, interviewees received a short information sheet about the SURGE-Ahead project.

Ethical Considerations

Ethical approval was waived by the ethics committee of Ulm University, because no information on personal data, health-related data, or data on sexuality of the interviewees was collected (March 21, 2022). All interviewees declared their consent after being informed about the aim of the study, their rights, potential risks, and data protection. Interviewees did not receive any compensation for participation in the study.

Data Analysis

Interviews were recorded and transcribed by an external transcription service provider (abtipper.de). After transcription, the interviews were anonymized. Transcripts were checked for accuracy against the recordings by 2 authors (AU, LB) to avoid bias. Occurring flaws in transcription were resolved by mutual agreement.

The statements of the interviewees were coded, extracted, and sorted into main categories, primary codes, and subcodes according to usual procedures of qualitative analysis [24] and thematic analysis [25,26] using the software MAXQDA (VERBI GmbH). Total numbers of the extracted categories and codes are presented. Representative quotes that illustrate various themes were translated from German into English by 2 researchers independently (AU, MLF), compared, and then unified into a final version. Based on these representative quotes, a narrative synthesis of the results was written. Finally responses across categories were also stratified according to the most significant hopes and fears of participants [27]. The final manuscript was written based on COREQ (Consolidated Criteria for Reporting Qualitative Research) [28].

Results

Interview Participants

In total, 14 interviews were conducted with 15 professionals. The mean duration of the conducted interviews was 13:51 minutes. The interviewees' professional experience ranged from 2 to 43 years with a median duration of 15 years. Median time of affiliation with the department (8 years) differed between professions. Nursing management had the longest affiliation of 22 years, and senior physicians in the emergency department had the shortest median affiliation of 1.5 years. For details, see Table 1.

Table . Interviewed experts[a].

ID	Profession	Professional experience (years)	Department	Affiliation with the department (years)
1	Social service	32	Social counseling service	2
2	Social service	8	Social counseling service	8
3	Assistant physician	4	Visceral surgery	1
4	Nursing management	43	Urology	40
5	Senior physician	19	Traumatology	19
6	Physiotherapy	22	Physiotherapy surgery	22
7	Senior physician	21	ED[b]	1
8	Physiotherapy	34	Physiotherapy surgery	34
9	Nursing management	37	Traumatology	22
10	Assistant physician	2	Urology	2
11	Senior physician	15	ED	2
12	Assistant physician	6	Traumatology	6
13	Nursing management	8	Visceral surgery	8
14	Senior physician	10	Visceral surgery	9
15	Senior physician	13	Urology	13

[a] Identification numbers (ID) are assigned to the interview partners according to the chronological order of the interviews. In the narrative synthesis of the statements below, these IDs are assigned to the corresponding quotes.

[b] ED: emergency department.

Qualitative Analysis of Interviews

Overview of Themes

Interview data were categorized into three major themes: (1) geriatric patient care, (2) use of an AI-CDSS in geriatric care, and (3) ethical challenges of using an AI-CDSS in geriatric care. Table 2 gives an overview of all extracted main categories (1-3), primary codes, and subcodes. A narrative synthesis of interview statements corresponding with the primary codes and their subcodes is represented thereafter. Key quotes are integrated into the text and additional quotes are listed in Multimedia Appendix 1 (selected quotes for each category).

Table . Main categories (1-3), primary codes, and subcodes emerging from inductive analysis of the interviews.

Main topic, primary codes, and subcodes			Number of quotes
1. Geriatric care			
	Challenges in geriatric patient care		111[a]
		Medical challenge	45
		Discharge management	27
		High workload	20
		Communication	14
		Lack of technical solutions	6
	Solutions for challenges in geriatric patient care		60[a]
		Patient-centered care	22
		Communication (patients, colleagues, and relatives)	21
		Social service	11
		Cooperation with geriatric hospital	6
	Wishes for geriatric patient care		20[a]
		Geriatric expertise	10
		Improved communication and availability of information	7
		Human resources and assistive devices	3
2. Use of an AI-CDSS[b] in geriatric care			
	General wishes for an AI-CDSS[c]		53[a]
		Electronic health record	30
		Work support	22
		No added workload	1
	Chances of an AI-CDSS[c]		37[a]
		Holistic patient overview	16
		Improvement of geriatric patient care	13
		Acceleration of processes	5
		Decision support	3
	Technical wishes for an AI-CDSS		37[a]
		Intuitive usability	15
		Mobile availability and easy access	11
		Automatic transfer of HIS[d] data into AI-CDSS	8
		Other	3
	Limits of an AI-CDSS		26[a]
		Decision-making authority remains with humans	9
		Preservation of individual and personal patient care	9
		Technical affinity and time constraints	7

Main topic, primary codes, and subcodes			Number of quotes
		Information overload	1
3. Ethical aspects of an AI-CDSS in geriatric care			
	Critical assessment of AI-CDSS recommendations		23[a]
		Respecting the patient’s will and individual situation	8
		Beneficence	5
		Data protection	4
		Scientific validation	3
		Loss of professional autonomy	2
		Legal responsibility	1
	Trust in an AI-CDSS		15[a]
		Critical position	9
		Ambivalent position	4
		Rejection	2
	Preserving the patient-caregiver relationship		17[a]
		Responsibility remains in the hands of humans	7
		Inform patients about the use of an AI-CDSS	4
		Preservation of patient-caregiver relationship	3
		Use AI-CDSS without informing patients	3

[a] The total sum of quotes belonging to the subcodes.

[b] AI-CDSS: artificial intelligence–supported clinical decision support system.

[c] In the following section, wishes for and chances of an AI-CDSS are presented together due to their overlapping subcodes.

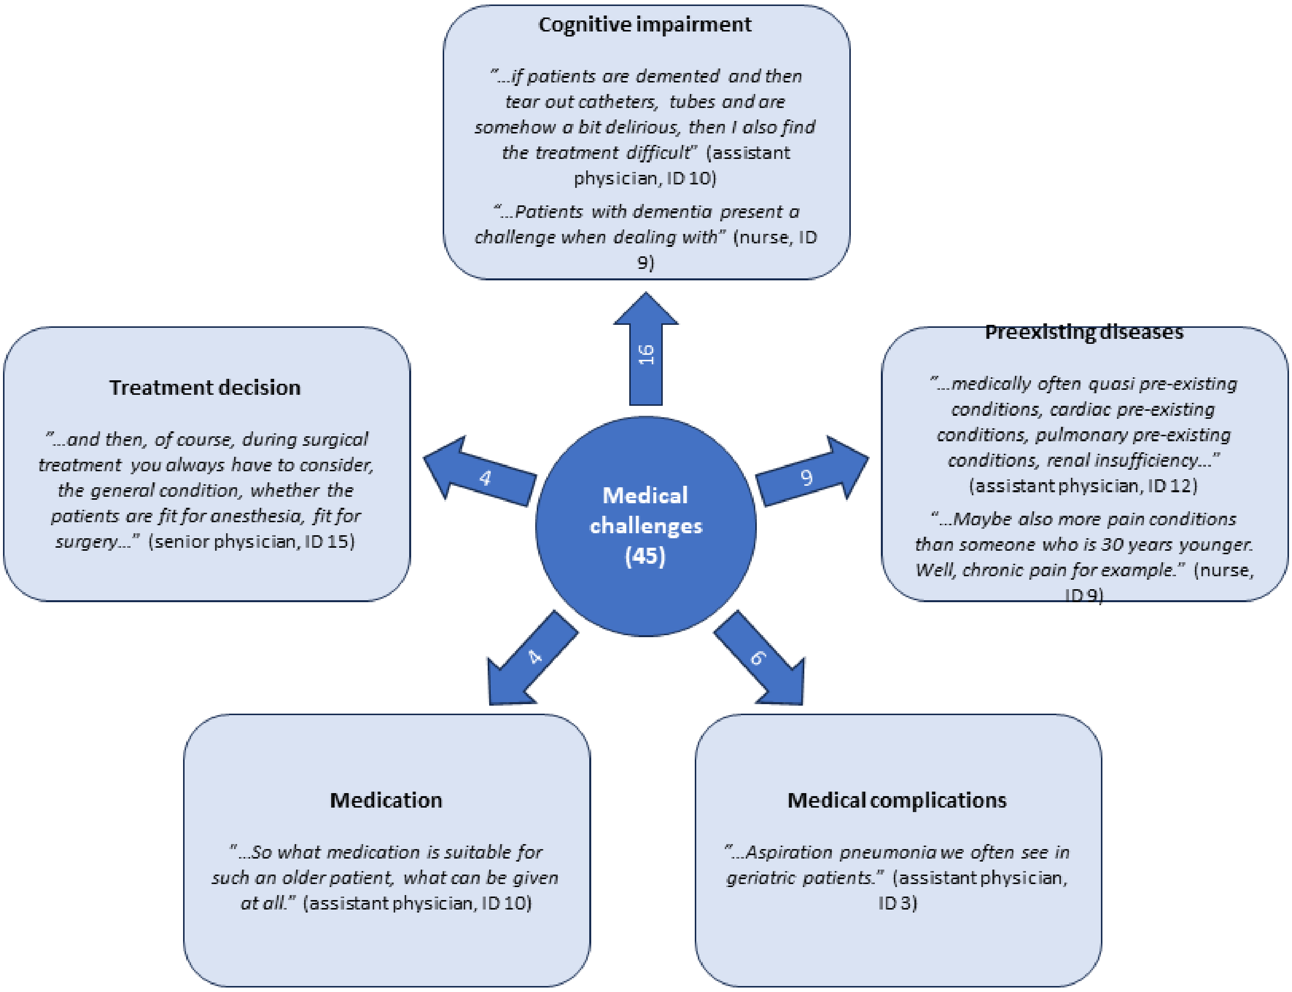
[d] HIS: hospital information system.

Geriatric Care

Challenges

Physicians, nurses, and physiotherapists mentioned multiple medical challenges when caring for geriatric patients on surgical wards such as medical complications, preexisting diseases, and cognitive impairment. Figure 1 shows this primary code and its associated subcodes including key quotes.

Figure 1. Numbers in the inner circle and the outgoing arrows show the number of citations for each subcode and the primary code. Further mentioned challenges were drainages (3 citations), reduced mobility (3 citations), slower regeneration (2 citations), and legal support (1 citation).



Cognitive impairment

”...if patients are demented and then tear out catheters, tubes and are somehow a bit delirious, then I also find the treatment difficult” (assistant physician, ID 10)

“...Patients with dementia present a challenge when dealing with” (nurse, ID 9)

Treatment decision

”...and then, of course, during surgical treatment you always have to consider, the general condition, whether the patients are fit for anesthesia, fit for surgery...” (senior physician, ID 15)

Preexisting diseases

“...medically often quasi pre-existing conditions, cardiac pre-existing conditions, pulmonary pre-existing conditions, renal insufficiency...” (assistant physician, ID 12)

“...Maybe also more pain conditions than someone who is 30 years younger. Well, chronic pain for example.” (nurse, ID 9)

Medication

”...So what medication is suitable for such an older patient, what can be given at all.” (assistant physician, ID 10)

Medical complications

”...Aspiration pneumonia we often see in geriatric patients.” (assistant physician, ID 3)

In addition to medical challenges, discharge management was stressed especially by social service members as highly challenging in clinical routine due to the need to organize the best possible follow-up care for each geriatric patient (Multimedia Appendix 1, quote 1), alongside a high patient turnover and the resulting high workload in acute surgical hospitals. Social service members also stated the lack of a person having the main responsibility for the COC decision as an issue.

> *…each day we have on average 25 to over 30 registrations. And you have to manage that for a start. And that is what is actually almost not possible.* [Social service member, ID 1]

Physicians mentioned that they have difficulties to find the best place for the patient after discharge, because they do not feel properly educated about it (Multimedia Appendix 1, quote 2). Physicians, nurse management, and social service mentioned that staff shortage and high work density can impact the quality of care, which can be aggravated by economic pressure (Multimedia Appendix 1, quotes 3 and 4). Finally, interviewees still relied on telephone, fax, and email as the only technical solutions facilitating geriatric patient care and especially discharge management (Table S1 in Multimedia Appendix 1, quotes 5 and 6).

Solutions

Patient-centered care involving patient contact and diagnostic examinations, for example, in radiology or the laboratory, as well as exchanging ideas with colleagues and experts, are commonly cited strategies in geriatric patient care. While physicians, nurses, and physiotherapists see the social service as a crucial partner for organizing discharge of patients, social service members stated that they find value in involving relatives and having conversations with them. Interviewees also expressed that cooperation with the geriatric hospital is an important aspect in geriatric patient care on surgical wards.

> *…, so you try to find a solution with the social service or, depending on the illness, together with ambulant palliative care (Brückenpflege), together with the relatives to find a solution. Bethesda (acute geriatric hospital) is of course also always a welcome solution.* [Nurse ID 4]

Wishes

The main wish expressed by physicians, nurse management, and social service was an improved cooperation with geriatric experts.

> *…perhaps if we had…people here who are more familiar with geriatric disease patterns. After all, we all rather come from the acute care, acute hospital.*

> *We all don't really have a background in geriatric care, there are other basics involved in our training. So, if you could mix it up a little, it would probably be good for everyone, yes.* [Nurse ID 13]

Nurses, physicians, and social service employees stressed the need for better communication, also across institutions, and timely availability of information (Multimedia Appendix 1, quotes 7 and 8). Further frequent wishes to improve geriatric patient care on surgical wards were improved awareness about drug interactions and side effects especially regarding geriatric patients (assistant physician) and improved management of delirium (senior and assistant physicians). More frequent mobilization of patients through physiotherapy (assistant physicians) and the establishment of a geriatric ward in the department for trauma surgery (senior physician) were mentioned by singular interviewees.

Use of an AI-CDSS

General Wishes for and Chances of an AI-CDSS

All interviewees expressed a desire for an electronic health record (EHR) to gain a holistic picture of the patient's situation, accelerate processes, and reduce resource expenses.

> *…so I see a chance to shorten my time expenditure because I already have a medical history that I can access with a few clicks. Which might otherwise cost me a lot of time.* [Social service ID 2]

Cognition, frailty, mobility, medication, substance abuse, social history, and laboratory values were mentioned as important aspects, which should be integrated in an AI-CDSS (Multimedia Appendix 1, quote 9). Primarily requested by physicians were features that could increase awareness for needs and pitfalls of geriatric patient care but could also give constructive solutions, for example, for drug interactions, delirium management, or discharge management (Multimedia Appendix 1, quotes 10 and 11). The capacity of the AI-CDSS to advance treatment effectiveness through faster evaluation of large amounts of data was mentioned (Multimedia Appendix 1, quote 12). Finally, the application should not increase the existing workload (Multimedia Appendix 1, quote 13).

Technical Wishes for an AI-CDSS

Intuitive usability was mentioned most frequently by all interviewees when asked about technical wishes for an AI-CDSS.

> *So I think it should be intuitive. That's always difficult to define. So it should be a clear program that I can access from anywhere. Maybe not only from fixed PCs, but also from tablets and so on…But it should be kept relatively simple so that everyone can understand it. And can use it without much prior knowledge.* [Assistant physician ID 12]

Mobile and easy access for all involved caregivers were additional desirable features (Multimedia Appendix 1, quote 14). Physicians emphasized the importance of a regular and automatic data transfer from the HIS to the new AI-CDSS to avoid redundancy and additional workload due to the need for double entries (Multimedia Appendix 1, quotes 15 and 16). Some physicians also proposed linking the application with external hospitals for better networking and some suggested incorporating functions such as showing the availability of free beds, for example, in external rehabilitation hospitals (Multimedia Appendix 1, quote 17).

Limits of an AI-CDSS

The main concern expressed by interviewees regarding the use of an AI-CDSS was that the final decision-making authority should always stay with humans. They emphasized that the doctor-patient relationship cannot be replaced by a computer. In addition, some interviewees worried about losing sight of the individual patient's needs when relying on an AI-CDSS:

> *Limitations of course, it is and will remain a human being and not a material in quotation marks. That one does not forget this and that this is still considered and not forgotten, that there is no text-book and no cookie-cutter approach….* [Assistant physician ID 12]

Several interviewees also raised concerns about the implementation of new technology in health care settings, particularly regarding the handling and operation of such systems. One interviewee mentioned that operating an AI-CDSS might be challenging in a busy clinical environment due to the already existing high workload (Multimedia Appendix 1, quotes 18 and 19). One senior physician mentioned that it might be difficult to make decisions about interventions, such as new medications, due to the theoretical risks and complications presented by the system (Multimedia Appendix 1, quote 20). Interestingly, 2 assistant doctors did not see any risks in incorporating such a new technology.

Ethical Aspects of an AI-CDSS

Critical Assessment of AI-CDSS Recommendations

Many interviewees stated that they had no concerns about—and would even appreciate—the use of an AI-CDSS in geriatric patient care as a supporting tool. However, an underlying condition should be informing patients about the use of a CDSS and considering the patient's individual situation. Interviewees stressed that the will of patients or relatives should be at the core of clinical decisions and COC decisions.

> *So, the patient's wishes should be considered. Or, if the patient can no longer decide for themselves, the relatives in any case.* [Nursing ID 9]

In this regard, interviewees mentioned that it might be difficult for an AI-CDSS to capture all facets of geriatric patients (Multimedia Appendix 1, quote 21). One of the respondents described it as "*putting patients in a box*" (physiotherapist, ID 8).

According to the respondents, such a system would require solid scientific validation prior to integration into routine care and adhere to all data protection requirements (Multimedia Appendix 1, quote 22 and 23). Some concerns of the interviewees also raised the question of accountability and reliance on the decisions made by an AI-CDSS. Strong reliance on the technology might lead to a loss of autonomy and professional identity of caregivers. Moreover, the question of professional and legal responsibility for the decisions taken was raised (Multimedia Appendix 1, quote 24).

Trust in an AI-CDSS

The majority of interviewees were unsure whether they would fully trust the AI-CDSS and emphasized the need for medical professionals to critically evaluate all suggestions made by the system.

> *So, I can imagine that it could well be trustworthy and reliable. However, I would not rely on that alone. So would say, it is…a recommendation. So not a strict default. So I think you still have to examine and evaluate the individual case from a human or medical point of view to see whether it really makes sense and whether it is in the best interests of the patient or their relatives. But as a supportive tool, I think it's very good. And then it would also be reliable for me.* [Senior doctor ID 5]

Preserving a Patient-Caregiver Relationship

Regarding the patient-caregiver relationship, most interviewees remarked that it is crucial to openly communicate the use of an AI-CDSS (Multimedia Appendix 1, quote 25) and to emphasize that the main responsibility for clinical decisions remains in the hands of humans. Preservation of the physical and emotional relation between caregivers and patients was also mentioned by interviewees as an important factor for a trusting relation.

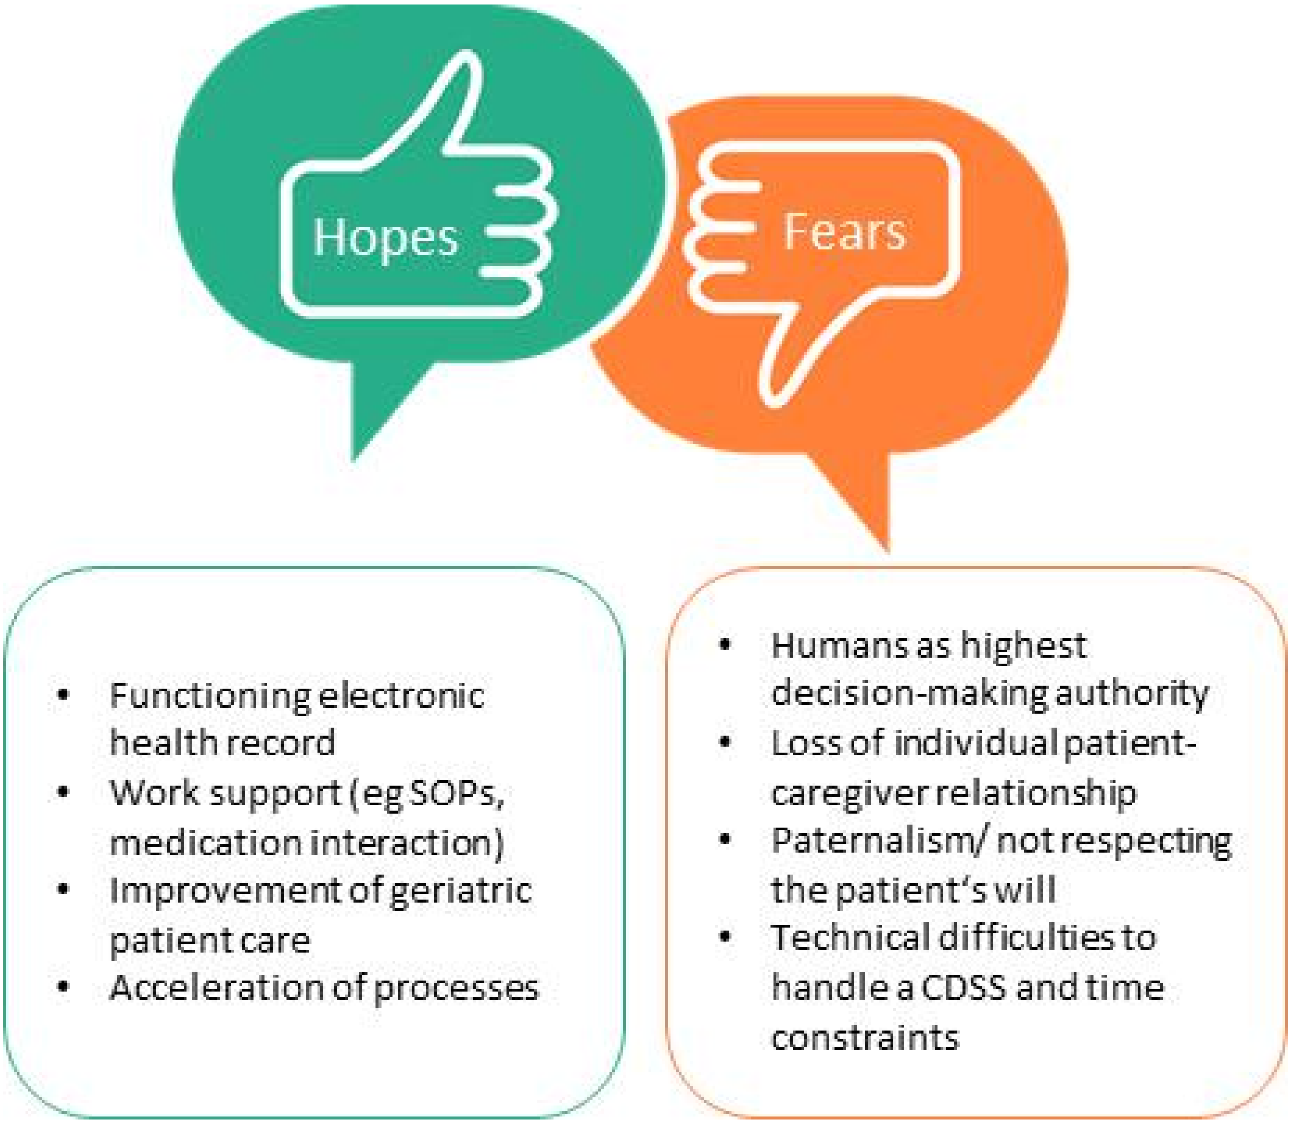
> *…by always clarifying, that the final medical decision always lies with a person or a doctor. I think that is very, very important for the patient, but also for the doctor himself…So I think, the independent decision for medical matters must remain with the doctor. And of course you can't replace the doctor-patient-relationship with a computer, so to speak.…So it must always be clear that the doctor ultimately makes the decision, so to speak, and the machine supports him in making the right one. I would say that the machine processes a complexity of information that the doctor would otherwise not be able to process.* [Senior doctor ID 7]

In contrast, 1 interviewee feared an adverse result for the patient-caregiver relationship if openly communicating about the use of an AI-CDSS and another interviewee proposed not to inform patients about the use of it (Multimedia Appendix 1, quote 26).

Fears and Hopes

In order to summarize all answers and for a quick and clear overview, responses were stratified according to the biggest fears and hopes that could be extracted across all categories and codes as displayed in Figure 2.

Figure 2. Main hopes and fears expressed by interviewees about an AI-CDSS for surgical patient care. CDSS: clinical decision support system; SOP: standard operating procedure.



Discussion

Study Overview

In this qualitative study, we analyzed the status of geriatric care and the expectations for an AI-CDSS supporting patient care by interviewing physicians, nurses, physiotherapists, and social service members. Results were summarized in 3 main categories covering geriatric patient care, the use of an AI-CDSS, and ethical considerations regarding an AI-CDSS. While the biggest hope was that such an application could improve geriatric care including the handling of medical geriatric challenges within a functioning digital service, the loss of individual patient-caregiver relation and a lack of usability were the biggest fears.

AI-CDSS to Support Geriatric Care

Provision of an EHR by an AI-CDSS was the most frequent subcode extracted from the interviews. Currently, health professionals must gather information about patients from different sources (eg, HIS, paper documents, and telephone calls), which is time consuming. One of the biggest advantages of a CDSS could be an overview of relevant individual clinical and social information. However, a higher workload was feared due to the task of entering data. Physicians already spend up to 35% of their time on documentation [29,30]. Because of these shortcomings low acceptance of EHR and CDSS is a common phenomenon in clinical practice [31,32]. Therefore, the involvement of future users in the development of the application [32], ensuring seamless integration with existing clinical information systems, minimizing the need for manual data entry, and designing applications as close as possible to the existing systems have been found to be important for the acceptance of CDSS [17,33].

Interviewees also emphasized how challenging it is to care for geriatric patients due to complex medical conditions and impairments such as cognitive impairment. It has been shown that a multidisciplinary approach is favorable for geriatric patient care and COC decisions [34-37]. Considering the lack of geriatricians [10], geriatric expertise is something the AI-CDSS could provide, and support clinical work, by highlighting relevant issues such as medication interactions or factors increasing the risk for delirium.

The lack of knowledge of optimal COC was considered relevant by all professionals. The discharge destination can have a profound effect on long-term outcomes. A discharge to nursing homes has been associated with lower survival than a discharge home [5]. COC placement suggestions by an AI-CDSS could fill a gap in care for geriatric patients in surgery. Some interviewees even expressed the wish that an AI-CDSS should enable reservation of beds in rehabilitation clinics. For this purpose, new software options for hospitals have already been established and are currently being implemented in several regions in Europe [38].

Organizational and Technical Challenges of an AI-CDSS

Time and resource constraints could inhibit overall feasibility and practicality. Some interviewees were concerned whether all health care professionals will have the technical affinity to operate the AI-CDSS, potentially limiting the acceptance of the system [17]. Acceptance of an AI-CDSS is closely connected to explainability, accountability, and trust [39]. Increasing transparency of AI-systems leads to more trust in these systems and thus increases their acceptance [32]. If medical professionals cannot fully understand the recommendation of an AI-CDSS, it might result in conflicting situations [40]. This becomes evident considering the current legislation stating that even when using an AI-CDSS, medical professionals are responsible for the decisions [41]. However, this might change in the future with a CDSS improving and potentially even outperforming health care professionals [42].

In addition, professional caregivers need to be able to explain the use and functionality of the AI-CDSS to patients and their relatives [40,43,44]. In this context, the concept of digital divide seems important, which describes a decreased ability of older adults to use modern technologies compared with their younger counterparts [45]. However, a recent study could not detect interviewed geriatric patents' reservation toward the use of smart sensors [46].

Ethical Challenges of an AI-CDSS

Regarding the 4 core medico-ethical principles [19], the protection of patient autonomy seemed the most important, which reflects the current consent in medical practice about shared decision-making between patients and clinical professionals [47]. Although an AI-CDSS could support this, the identification of a patient's values, beliefs, and aims is a prerequisite [48-50]. Overreliance on the AI-CDSS might lead to premature and rigid categorization of the patients according to preprogrammed categories, which are not sublime enough to catch intrinsic differences in a patient's individual situation. Interviewees emphasized that all recommendations of an AI-CDSS must be reviewed critically by medical professionals to protect the patient's will and autonomy.

Another central ethical code was the importance of preserving the caregiver-patient relationship—an aspect related to the principle of beneficence [19]. Interviewees demanded that they would not want the AI-CDSS to prejudge a patient. Patient-caregiver relationships were considered important for the recovery and self-efficiency of patients because of associated emotions and their trust-building effect [13]. Research about placebo effects also supports this position [51]. Fear of losing their professional identity was mentioned by some interviewees [52]. The best way to maintain professional identity and a trustful patient-caregiver relationships was seen in an open communication with the patient about the use of a CDSS, followed by informed consent.

Albeit only mentioned by a few participants, data protection and scientific evaluation of a new AI-CDSS are essential regarding the medico-ethical concept of nonmaleficence [53,54]. Especially, data protection seems to be crucial from an ethical perspective to protect sensitive personal patient data from theft, manipulation, or access by third parties [49,55]. In case of geriatric patients, who are often overwhelmed by modern processes of data gathering, storage, and processing, special responsibility falls on the developers of AI-CDSS and clinical professionals collecting the data.

A last aspect of medico-ethical reflection is justice, which was superficially touched upon only during the interviews. It has been argued that developing and maintaining a CDSS is cost-intensive and therefore could be afforded only in high-resource countries with a well-functioning health system and in big hospitals, such as university hospitals [13,56].

Limitations

One limitation of the study was the rather low number of experts and an unproportionate distribution of health care professionals, with a higher representation of physicians. This does not allow for generalization of the results in a wider perspective. However, 15 interviewees should allow to capture about 85% (17/20) of possible topics, a phenomenon called "thematic saturation" [57], and in a smaller sample of interviewees, it is possible to focus on individual perspectives.

In addition, our information sheet did not explain the term AI to the interviewed health care professionals, so the reflections might have depended a lot on the individual knowledge. We, however, did not want to anticipate too much to broaden perspectives. Finally, the unique clinical information system, the status of hospital readiness for IT, and overall clinical structures could make it difficult to compare the findings with those from other hospitals, both nationally and internationally.

Conclusions

An AI-CDSS was mostly considered to be beneficial, especially by providing health care professionals with an easily accessible data platform focused on geriatric needs and supporting geriatric comanagement and COC decisions. The most common concerns focused on maintaining the patient's autonomy and preserving the patient-caregiver relationship, as well as smooth integration into existing workflows without extra tasks. Therefore, careful consideration must mainly be given to address technical demands (intuitive usability and easy access for all caregivers involved) and ethical challenges (maintaining the patient's autonomy, explainability, and supportive character) during the development and implementation of a new AI-CDSS for geriatric patients in surgical departments.

Acknowledgments

This study was supported through a grant by the German Federal Ministry of Education and Research for the project SURGE-Ahead (grant number 01GY2101). The authors would like to thank all participants for taking the time to talk to them and sharing their valuable insights and opinions.

Authors' Contributions

The study was planned by AU, MLF, CL, TDK, MO, FS, and MD. Participants were recruited by AU. Interviews were conducted by AU and LB. Data analysis was performed by AU, LB, AHA, and MLF. The manuscript was written by AU, MD, and MLF. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Correction of: https://aging.jmir.org/2022/2/e28260

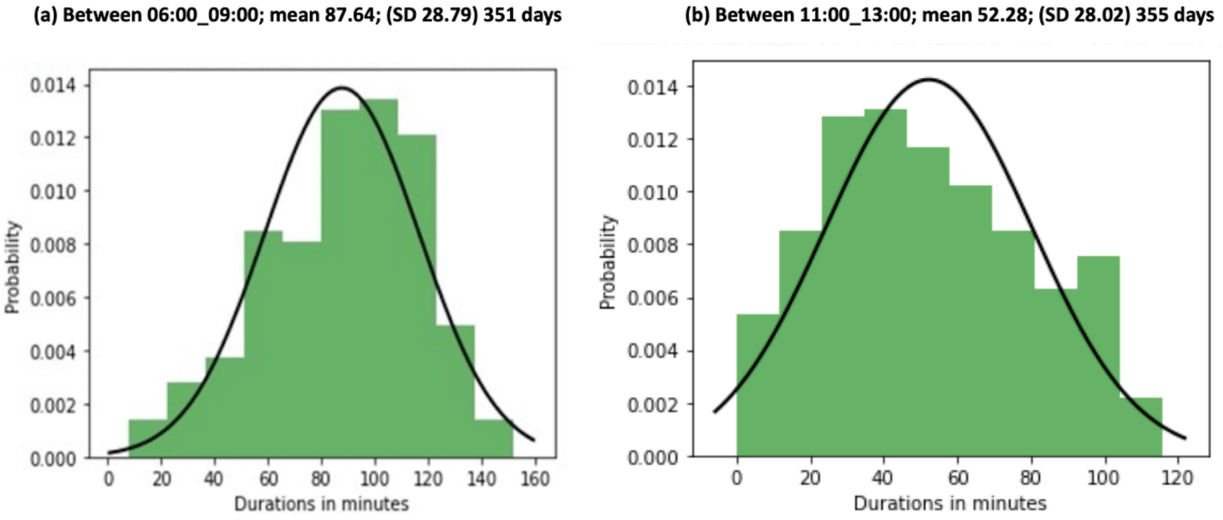
(JMIR Aging 2024;7:e58394) doi:10.2196/58394

In Detecting Anomalies in Daily Activity Routines of Older Persons in Single Resident Smart Homes: Proof-of-Concept Study (JMIR Aging 2022;5(2):e28260), the authors noticed one error.

In the orinally published article, a duplication error occured in Figure 5. The original Figure can be viewed in Multimedia Appendix 1.

Figure 5 has been corrected as follows:

Figure 5. Probability distribution with mean (SD) for 351 days in the kitchen between (a) 6:00 and 9:00 and (b) 11:00 and 13:00 in apartment 1.



(a) Between 06:00_09:00; mean 87.64; (SD 28.79) 351 days

(b) Between 11:00_13:00; mean 52.28; (SD 28.02) 355 days

The correction will appear in the online version of the paper on the JMIR Publications website on April 30, 2024, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Abstract

Background: Social media may be a useful method for research centers to deliver health messages, increase their visibility in the local community, and recruit study participants. Sharing examples of social media–based community outreach and educational programs, and evaluating their outcomes in this setting, is important for understanding whether these efforts have a measurable impact.

Objective: The aim of this study is to describe one center’s social media activities for community education on topics related to aging, memory loss, and Alzheimer disease and related dementias, and provide metrics related to recruitment into clinical research studies.

Methods: Several social media platforms were used, including Facebook, X (formerly Twitter), and YouTube. Objective assessments quantified monthly, based on each platform’s native dashboard, included the number of followers, number of posts, post reach and engagement, post impressions, and video views. The number of participants volunteering for research during this period was additionally tracked using a secure database. Educational material posted to social media most frequently included content developed by center staff, content from partner organizations, and news articles or resources featuring center researchers. Multiple educational programs were developed, including social media series, web-based talks, Twitter chats, and webinars. In more recent years, Facebook content was occasionally boosted to increase visibility in the local geographical region.

Results: Up to 4 years of page metrics demonstrated continuing growth in reaching social media audiences, as indicated by increases over time in the numbers of likes or followers on Facebook and X/Twitter and views of YouTube videos (growth trajectories). While Facebook reach and X/Twitter impression rates were reasonable, Facebook engagement rates were more modest. Months that included boosted Facebook posts resulted in a greater change in page followers and page likes, and higher reach and engagement rates (all $P \leq .002$). Recruitment of participants into center-affiliated research studies increased during this time frame, particularly in response to boosted Facebook posts.

Conclusions: These data demonstrate that social media activities can provide meaningful community educational opportunities focused on Alzheimer disease and related dementias and have a measurable impact on the recruitment of participants into research studies. Additionally, this study highlights the importance of tracking outreach program outcomes for evaluating return on investment.

(JMIR Aging 2024;7:e51520) doi:10.2196/51520

KEYWORDS

education; social media; outreach; recruitment; Alzheimer’s disease; Alzheimer disease

Introduction

With the aging of the population, the number of individuals living with dementia globally is expected to triple by 2050 [1]. Disseminating reliable information on topics related to healthy aging and Alzheimer disease and related dementias (ADRD) is particularly important given modifiable lifestyle factors may play a role in dementia risk reduction [2], receiving an early diagnosis requires identifying the signs and symptoms of memory loss, and persons and families affected by dementia may benefit from information about ADRD. Connecting the public with education and resources related to these topics is aligned with national and international initiatives that emphasize the importance of healthy aging, dementia awareness, risk reduction, diagnosis and services, and caregiver support [3,4]. Social media content aimed at older adults may provide a mechanism for sharing resources, research findings, and available services related to healthy aging and ADRD. Social media may also generate increased interest in research participation, in addition to the in-person approaches that have been used for many years.

Research centers specializing in aging and ADRD use several approaches for community outreach, education, and volunteer recruitment for research studies. This includes a variety of in-person events, such as providing educational presentations in the community, hosting resource tables at community events, and organizing conferences in collaboration with community organizations, among others. Centers also use a range of web-based activities including newsletters, websites, and social media platforms such as Facebook, X (formerly Twitter), YouTube, and Instagram. While social media may be a potentially important method of delivering health messaging and recruitment [5], the types of activities used, and the outcomes of social media outreach efforts, are not well understood.

Social media has become a primary source of information for the general public hoping to “seek and share health-related information” [6]. Recent estimates indicate that 73% of middle-aged and 45% of older adults in the United States use social media, with Facebook and YouTube being two of the most common among these age groups [7,8]. This suggests that key age demographics for messaging may be reached through social media, providing a platform for research centers to become trusted web-based sources of information on topics related to healthy aging and memory loss, ADRD, and caregiving in their local communities.

Studies incorporating social media activities into community outreach and recruitment in the context of aging and memory loss have covered a broad range of topics. For example, studies have examined the role of social conversations in providing advice related to cognitive decline [9]; described social media activities in targeted dementia awareness campaigns [10-12]; and evaluated the use of social media advertisements to drive traffic to educational resources [13] or to recruit into aging or ADRD research studies [14-16]. Moreover, prior research has demonstrated the feasibility of using a digital community-engaged research approach (which included a social media component) for reaching individuals from racially diverse backgrounds [17]. More broadly, studies analyzing dementia content on social media have also suggested that these platforms have the potential to deliver health information on this topic, raising awareness and facilitating communication with the public [18-20].

Prior studies in this area have not, to our knowledge, described aging and memory loss educational programs across multiple social media platforms and reported on their impact on research recruitment. To address this gap, this study describes the social media approaches, aimed at community outreach and education related to aging and ADRD, implemented by one research center. Importantly, the objective was not to compare social media to other approaches but to describe the social media activities implemented to date and evaluate the outcomes of these activities using up to 4 years of metrics, including success in reaching members of the community and impact on recruitment.

Methods

Overview

The Johns Hopkins Alzheimer’s Disease Research Center (JHADRC) has used 3 social media platforms over the past 4 years: Facebook, Twitter (rebranded as X in 2023), and YouTube. Each platform was launched with a different set of goals.

Facebook

The primary goal of the *Johns Hopkins Memory & Aging* Facebook page is to provide education and resources, as well as information about community events and research opportunities, related to healthy aging, brain health, memory loss, and dementia. The content primarily targets members of the community and community partners. Content is posted to this page 3-5 times per week. This page was launched in January 2019.

Twitter

The goals of the *Johns Hopkins Memory & Aging* Twitter account are 3-fold. The first goal is consistent with those of the Facebook page: to provide education, resources, and information about community events and research opportunities related to healthy aging, brain health, memory loss, and dementia. This includes promoting the visibility of Johns Hopkins (JH) aging and ADRD researchers, clinicians, and staff. The second goal is to serve as an information hub for local aging and ADRD researchers by sharing academically focused content such as recent research publications, information about social determinants of health for underserved populations (eg, Black Americans, Hispanics, and the LGBTQ+ community), funding and training opportunities, professional development opportunities, and upcoming conferences. Where possible, content is shared (ie, retweeted) through related JH Twitter accounts, such as the Center on Aging and Health and Geriatric Medicine and Gerontology, to expand views of the content. The third goal is to strategically network with community partners engaged in activities related to aging and ADRD. This includes making a concerted effort to share the events, activities, and accomplishments of these groups. Given these 3 broad goals, the target audience includes community audiences and community partners, as well as researchers and health professionals. A communications specialist spends approximately 1-3 hours per weekday identifying, sharing, and retweeting content of relevance to the abovementioned audiences, and approximately 6-8 hours monthly creating original content. This account was launched in July 2020.

Readers should note that the Facebook and Twitter pages are branded with the name *Johns Hopkins Memory & Aging*. This name was selected to be intentionally broad in order to demonstrate relevancy to topics related to aging, memory loss, and ADRD, and to resonate with the general public, particularly the target audience of middle-aged and older adults.

YouTube

The primary goal of the *Johns Hopkins ADRC* YouTube page is to serve as a repository for outreach content, including center-produced resources, recordings of web-based community outreach events, and activities developed in collaboration with the JHADRC's community advisory board, known as the Memory and Aging Community Advisory Board (MACAB). The page primarily targets members of the community, with content uploaded as needed. This page was launched in October 2020.

All social media pages are overseen by members of the JHADRC's Outreach, Recruitment, and Engagement (ORE) Core. The ORE Core worked with the Johns Hopkins Medicine Strategic Marketing and Outreach team to set up the page and get approval for the use of the institutional name. The web-based recruitment materials of the JHADRC were approved by the Johns Hopkins Medicine institutional review board (IRB).

Description of Content

The majority of content shared through the Facebook and Twitter pages highlights topics broadly related to ADRD, consistent with the goals of these pages. This includes educational content related to healthy aging, brain health, and risk factors for memory loss; information about Alzheimer disease and other types of dementia; resources for caregivers; information about clinical research and research findings; social determinants of health; and local events of relevance to these topics (both our own and those of our community partners). During the first year of the COVID-19 pandemic, many posts included COVID-19–related health and support resources.

The shared information includes content developed by JH staff (described below) and content from external sources such as news articles, website pages, infographics, and blog posts from trusted outlets. For example, we frequently share content from the National Institute on Aging, the Alzheimer's Association, our local Alzheimer's Association Chapter, the American Association of Retired Persons (AARP), a website known as MindCrowd, and major news outlets. We also make a concerted effort to share news articles and web-based resources that quote or feature JH staff, researchers, or clinicians, as well as materials that highlight recent research findings from studies that include JH researchers. As noted above, our Twitter page also shares content of relevance to academic audiences and health professionals, such as funding and conference announcements and professional development opportunities.

Internally Developed Social Media Content and Programs

Social Media Series

To date, we have developed 3 educational series consisting of a collection of posts on specific topics, including general information about AD, brain health, and research awareness (see Table 1 for details). Posts within each series are branded with a hashtag, allowing the topic to be indexed and searchable on social media platforms. Although developing a series of posts requires time up-front, the approach provides a library of original content that can be released over several months or more, and are available to be reposted in the future. This also allows for content to undergo IRB review prior to use if needed (eg, Research Awareness Series). Having prepared content on-hand has been particularly helpful given the multiple responsibilities that compete for staff effort.

Table 1. Overview of social media series about aging and ADRD[a].

Series name (social media hashtag)	Goal of content and distribution timeline	Description of content	Posts, n
Alzheimer's awareness series (#JHAlzAwareness)	• Increase awareness of AD[b] • Developed and posted in 2020; some content reposted 2021 and 2022	Two categories of content: (1) education about AD (eg, definitions, prevalence, signs and symptoms, stages, effect on the brain, and importance of research) and (2) risk factors and symptom management (eg, risk factors, risk reduction, genetics, diagnosis, treatments, and caregiving)	31
Brain health series (#JHBrainHealthMatters)	• Share expert recommendations and practical tips from the reports developed by the AARP's[c] Global Council on Brain Health • Developed and posted in 2020; plans to repost some content in future	Content and infographics from Global Council on Brain Health reports: (1) The Brain-Sleep Connection; (2) The Brain-Body Connection; (3) Engage Your Brain; (4) Music on Our Minds; (5) The Brain-Heart Connection; (6) Brain Food; (7) The Real Deal on Brain Health Supplements; (8) Preserving Your Brain Health During Illness or Surgery; (9) Brain Health and Mental Well-Being; and (10) The Brain and Social Connectedness	89 (7-10 posts per topic)
Research awareness series (#JHMemoryResearch)	• Increase awareness of the importance of memory loss research and ongoing research activities to facilitate recruiting participants into JHADRC[d]-affiliated research studies • Developed in 2021, posted 2022-2023	Topics covered: (1) goals of research and different types of research studies (observational, interventions, or clinical trials); (2) examples of research procedures and what's learned (eg, brain imaging and fluid biomarkers); (3) importance of diversity in research; (4) examples of JHADRC-affiliated research studies; (5) benefits of research participation; (6) participant, staff, and researcher spotlights; (7) study recruitment flyers	86

[a] ADRD: Alzheimer disease and related dementias.

[b] AD: Alzheimer disease.

[c] AARP: American Association of Retired Persons.

[d] JHADRC: Johns Hopkins Alzheimer's Disease Research Center.

Web-Based Talks About Memory Loss and Brain Health on Social Media

We have developed brief web-based presentations designed to reach new audiences in the local community. Web-based presentations on the topics of memory loss ("What you should know about memory loss") or brain health ("A brain healthy lifestyle matters for healthy aging") are given by ORE Core Community Outreach Coordinators. Individuals register through Zoom and registrants must attend to receive the content (ie, presentations are not recorded). One week prior to the presentation date, modest funds (US $30-US $150) are used to boost the post on Facebook, targeting middle-aged and older adults in the Greater Baltimore area. These presentations, organized approximately every quarter, have been advertised 11 times to date, at various times of day (eg, noon "lunch & learn"; evening "dinner table discussion"). Typically, more individuals register than actually attend. On average, 19 individuals, representing approximately 25% of those registered, attend each presentation.

Educational Videos Posted to YouTube

A web-based talk series, titled *Memory Matters*, was developed to provide brief research updates on topics related to aging, memory loss, and ADRD. These approximately 15-minute presentations are designed to share recent research findings that may be of particular interest to lay audiences, such as sleep, hearing loss, and physical activity (see the " Growth Trajectories and Page Visibility" section for details). To ensure that the presentations are targeted to a lay audience, presenters are asked to include an overview slide, make their slide content as simple and clear as possible, include a summary slide that recaps main points, conclude with actionable takeaway messages, and share publicly available resources. They also receive a document entitled "Tips and Examples for Effective Science Communication to a Lay Audience." Presenters are given a template for the first and last slide to provide uniformity to the talks within the series. To date, these talks have been given by junior faculty who are given feedback in advance of the video recording by center faculty (CP and MA). Thus, this talk series also provides an opportunity for science communication mentorship to junior investigators, including guidance on effectively communicating complex scientific topics with lay audiences. Talks within this series are branded with the hashtag #JHMemoryMatters. Once recorded and edited, they are posted to YouTube and the JHADRC website and shared through Facebook and Twitter.

A *Community Views* (#CommunityViews) web-based interview series features short (6-7 minutes) one-on-one interviews with members of the community. The goal of these videos is to provide members of the lay community an opportunity to advocate for topics of personal importance to them. Members of the JHADRC ORE Core work with the interviewee to collaboratively develop a set of interview questions, as well as a short set of slides to support the interview content and provide uniformity to the talks within the series. Once recorded and edited, the interviews are posted on YouTube and shared through Facebook and Twitter. To date, the interviews have been with members of the MACAB. Two interviews have been recorded: the first on the importance of educating the youth about dementia and the second on empowering older adults and caregivers to maintain their brain through physical activity and self-care. These programs are ongoing.

Twitter Chats and Webinars

A series of Twitter chats and webinars have been developed to promote the goals of a coalition of stakeholders in the brain health and dementia community. This collaboration consists of 2 research centers internal to Johns Hopkins University (the JHADRC and the Johns Hopkins Alzheimer's Disease Resource Center for Minority Aging Research), as well as external partners including the Global Council on Brain Health convened by the American Association of Retired Persons, the Greater Maryland Chapter of the Alzheimer's Association, and 2 strategically targeted audience stakeholder organizations, both local alumnae chapters of the Delta Sigma Theta Sorority, Inc. Branded as #BrainMatters, the goal has been to develop dialog, engagement, and educational programs for sharing evidence-based information about brain health, health disparities, memory loss, and ADRD at the grassroots level. This approach aligns with the recognized importance of developing equitable community partnerships for reaching individuals from diverse backgrounds [5].

Prior to each scheduled event, the program organizers communicate via email and meet virtually (typically 3-5 times) to make collaborative decisions about program timing, format, content, and invited participants. For Twitter chats, this involves identifying the specific questions to be sequentially asked during the scheduled web-based conversation; questions are answered by both invited guests and the Twitter users at large. For webinars, this involves deciding on the topic and event flow (eg, speaker presentations vs moderated conversations). To date, Twitter chat topics have included (1) brain health, (2) achieving brain health equity, and (3) the state of research on memory loss and dementia, and webinar topics have included (4) dementia caregiving and caregivers and (5) the relationship between community, social connection, and cognitive decline. Event promotion occurs predominantly on Twitter (which allows us to tag guest speakers) and Facebook, and is shared by the coalition's stakeholders. The product of the Twitter chats remains on Twitter indefinitely as a resource to the public, and webinars have been recorded and uploaded to YouTube, thus, generating a marketable product that can also be shared after the event. In 2023, the #BrainMatters leadership made the decision to pivot toward webinars over Twitter chats, as it was determined that this format would better reach the target audiences.

Overarching Strategies

Research Recruitment

When the Facebook and Twitter accounts were first launched, we strategically decided not to emphasize clinical research recruitment (eg, study flyers, information about ongoing studies). Our goal was to first build a modest base of followers and develop a presence as a source of information before discussing research participation. Information about ongoing clinical research studies was not consistently posted until approximately 3 years after the Facebook page was launched. To date, this has been accomplished primarily through our Research Awareness Series (described above and in Table 1).

Diversity and Inclusion

We take care to ensure the visuals we post are representative of individuals from diverse communities. This includes evaluating the pictures posted in association with existing website links, as well as making a concerted effort to ensure that stock photos reflect individuals from diverse racial and ethnic backgrounds.

Boosting Facebook Posts

We have boosted occasional Facebook posts to increase the reach of our content and enhance the local visibility of our efforts, our Facebook page, and our center more broadly. This involves paying Facebook to more prominently display specific posts in users' feeds. To help reach new local audiences who may be interested in our content, boosted posts targeted middle-aged and older adults (eg, 55 years and older) in the Greater Baltimore area (ie, approximately 25- to 50-mile radius of Baltimore, MD) using the Age and Locations fields of Meta Business Suite's Boost Post settings. This strategy relied on Meta's "Audience" settings, which allow users to define who will see their advertised posts by targeting audiences whose profiles match specific characteristics, such as demographics. Each time content is boosted, we make a concerted effort to invite individuals who like the posts to like or follow our Facebook page, to help expand our followership. Boosted content has most frequently included talks on social media, as well as posts from our educational series (eg, the Research Awareness Series) and information about center-organized events (eg, the MACAB's Annual Holistic Health Seminar on Memory Loss). To date, our expenditures have been modest, ranging from US $30 to US $200 per boosted post. In years 2 and 3, we boosted 1 post approximately every other month; from year 4 onwards, we boosted 1 post almost every month.

Measures and Outcomes

In order to track our social media activities, at the start of each new month, members of the ORE Core record metrics from the prior month using data from each platform's native analytics dashboards.

For Facebook, the following metrics were tracked through the Meta Business Suite's Professional Dashboard: number of posts made during the month; the average reach of that month's posts, reflecting the number of people who saw that month's post at least once (calculated as the total [sum] reach of all posts within the month divided by the total number of posts); and the average engagement with that month's posts, reflecting the number of times people engaged with that month's posts through reactions, comments, shares, and clicks (calculated as the total [sum] engagement with that month's posts divided by the total number of posts). Note that all posts within a given month were included in these monthly analytics; therefore, the data reflect both organic and paid reach and engagement. The number of page likes and page followers was additionally recorded. Facebook metrics were missing for 2 months in year 2.

For Twitter, the following metrics were tracked through Twitter's monthly Analytics report: number of Tweets; Tweet impressions, reflecting the number of times that month's Tweets were displayed to users; profile visits; mentions; and new followers. The number of account followers and the number of accounts that we follow were additionally recorded. Two Twitter metrics (the number of account followers and the number of accounts we follow) were missing for 5 months in year 1, 2 months in year 2, and 2 months in year 3.

In this report, we summarize metrics for both Facebook and Twitter. This includes monthly data on the number of likes and followers to assess page growth trajectories (presented in 6-month intervals), which has previously been described as an indicator of success [5]. Monthly metrics were additionally used to calculate average reach rates and average engagement rates for Facebook, and average impression rates for Twitter. These were calculated by dividing each month's average reach, average engagement, or average impressions by that month's total number of page followers, then multiplying the quotient by 100. Annual reach, engagement, and impression rates were calculated for all years (excluding year 1) by averaging over all available months within a year, for year 2 onwards. Year 1 metrics were excluded because they appear inflated due to high engagement from a limited number of followers, as the pages were being established and accruing audiences. Note that the analytics for posts made at the end of the month may be slightly underestimated, given posts may have received continued views after the data were recorded. For videos posted to YouTube, we report the number of views over time.

The number of individuals who expressed interest in participating in research after engaging with our social media activities was tracked through a secure, web-based REDCap database hosted at Johns Hopkins [21,22]. This database is designed to track the outreach activities that result in recruitment, including how an individual learned about our studies, whether they were referred to a center-affiliated research study, and the outcomes of those referrals. Database entries that provide results related to social media come from 2 sources of information. The first reflects individuals who complete an IRB-approved "Participate in Research" webform on the JHADRC website and indicate on that form that they learned about us through social media. The second pertains to entries of individuals who contact us (eg, by phone) to express interest in research after viewing web-based programming, indicating that they learned about our programs through social media while completing their phone screen; these individuals were entered into the database by members of the ORE Core.

Statistical Analysis

The data reported below reflect outcomes and metrics between page launch (as noted by the dates above) and the time of manuscript writing (April 2023). Time-based outcomes (such as growth trajectories and video views) are reported as months since launch, to describe, for example, how long the content or programs have been available. Where relevant, continuous variables are summarized as mean (SD) and categorical data are summarized as n (%). Average annual reach, engagement, and impression rates are calculated as percentages (as described above), with differences between months with versus without boosted posts assessed by Mann-Whitney *U* tests. Analyses were run in SPSS (IBM Corp; version 29.0).

Social media data pertaining to this report are available by qualified investigators upon request to the corresponding author.

Ethical Considerations

The data for this report come from 2 recruitment procedures implemented by the JHADRC, both of which have been approved by the Johns Hopkins Medicine IRB (protocol NA_00045104). First, the JHADRC website includes a section labeled "Participate in Research." This section includes a web form that asks individuals interested in learning more about research to complete an electronic form. The first item on the webform asks that the individual respond "yes" or "no" to the following statement: "I understand that by submitting this form I am providing consent to be contacted about research studies related to aging and memory loss by staff affiliated with the Johns Hopkins Alzheimer's Disease Research Center, and that this information will be stored in a secure database." Second, members of the JHADRC also administer an IRB-approved phone screen, which includes questions similar to those in the web form. The first item on the phone screen includes the following statement "Before we begin, I should point out that the possible risk to your answering questions is that you will be revealing confidential information to us. We promise to keep all such information strictly confidential. You do not have to answer any questions that might make you uncomfortable. Your participation is voluntary. If you do not agree, this will not affect your care, if you are a patient at Johns Hopkins, in any way. If you are not interested, please let me know." The anonymized, group-level demographic data included in this study are based only on outcomes from individuals who responded "yes" to the statement at the beginning of the web form or completed the phone screen and indicated willingness to be contacted about research. Participants were not compensated for completing these optional forms and outcome data are reported in aggregate to protect participant privacy and confidentiality.

Results

Outcomes and Indicators of Success

Growth Trajectories and Page Visibility

Growth trajectories for our Facebook and Twitter pages are shown in Figure 1. Both accounts have demonstrated continued increases in the number of new followers since the account launch, suggesting that it takes years to build a modest audience. The total number of Facebook followers exceeds 500; this includes a clear uptick in the trajectory of Facebook page followers around 24 months when we started boosting occasional Facebook posts. Notably, months that include a boosted Facebook post resulted in a greater change in page followers and page likes (mean change in page followers 13.7, SD 9.2; mean change in page likes 19.0, SD 12.3), compared with months that did not include boosted posts (mean change in page followers 6.2, SD 4.5, *U*=294.5, *P*<.001; mean change in page likes 8.0, SD 5.0, *U*=285.0, *P*=.002), suggesting our efforts to invite individuals to like or follow the page were successful. The total number of Twitter followers exceeds 2000. Additionally, the talks within the *Memory Matters* web-based talk series have received over 3000 views, whereas views of the *Community Views* interviews have been less (Table 2); both of the #BrainMatters webinars hosted to date attracted >100 registrants with >50 individuals attending.

Average annual reach and engagement rates (Facebook) and average annual impression rates (Twitter) for year 2 onward are shown in Table 3. As anticipated, for Facebook, average reach and engagement rates were significantly higher for months that included boosted posts (mean reach rate 136.2%, SD 87%; mean engagement rate 10.7%, SD 6.1%) compared with months that did not include boosted posts (mean reach rate 34.7%, SD 26%, *U*=332.0, *P*<.001; mean engagement rate 5.1%, SD 4.3%, *U*=297.0, *P*<.001).

Figure 1. Growth trajectories in social media followers for Facebook (left; launched January 2019) and Twitter (right; launched July 2020), shown in 6-month intervals.

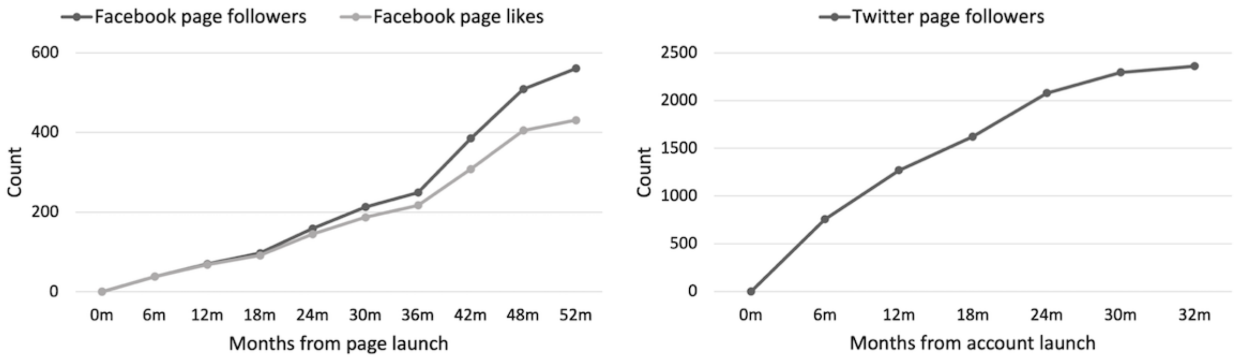

Table 2. Overview of educational videos posted to YouTube, including Memory Matters web-based talk series (#JHMemoryMatters) and Community Views (#CommunityViews) interview series.

Talk title	Months since launch, n	Views to date, n
***Memory Matters* web-based talk series**		
Dementia and cognitive decline: a brief overview	42	658
Vascular risk factors for cognitive decline and dementia	41	430
Changes in sleep and circadian rhythms in aging and memory loss	22	414
Hearing loss and dementia: what’s the connection?	17	1629
The importance of brain donation for Alzheimer’s disease and related disorders	5	90
Physical activity and cognitive health	1	74
***Community Views* interview series**		
Educating the youth about dementia	24	95
Empowering older adults and caregivers	3	35

Table 3. Visibility metrics over time for Facebook and Twitter. Values reflect mean (SD) and ranges.

Year[a]	Facebook				Twitter	
	Average annual reach rate		Average annual engagement rate		Average annual impression rate	
	Mean (SD), %	Range	Mean (SD), %	Range	Mean (SD), %	Range
All years (except year 1)	80.1 (79.1)	8.0-355.3	7.6 (5.8)	1.2-29.2	1260.3 (1076)	559.4-4152.9
Year 2	50.2 (30)	26.7-113.9	8.2 (4.7)	4.1-16.5	1564.9 (1319.6)	559.4-4152.9
Year 3	52.5 (37.7)	13.5-128.9	5.4 (2.7)	2.1-11.2	803.4 (195.6)	573.5-1141.6
Year 4	138.4 (111.4)	11.6-355.3	10 (8.3)	1.4-29.2	—[b]	—
Year 5	62.8 (61)	8.0-122.5	5.7 (5.3)	1.2-12.0	—	—

[a] Metrics exclude each platform's first year of data because these metrics appear inflated due to high engagement from a limited number of followers, as the pages were being established and accruing followers. For Facebook (launched in January 2019), year 2: January 2020-December 2020; year 3: January 2021-December 2021; year 4: January 2022-December 2022; year 5 (partial, n=4 months): January 2023-April 2023. For Twitter (launched in July 2020), year 2: August 2021-July 2021; year 3 (partial, n=8 months): August 2022-March 2023.

[b] Not available.

Research Recruitment Resulting From Social Media Activities

Social media activities have resulted in 89 individuals expressing interest in participating in center-affiliated clinical research studies over the past 2 years, the majority coinciding with boosted social media content (eg, posts from the #JHMemoryResearch series or web-based talks advertised on social media). This includes 76 individuals who indicated that they came to the JHADRC website after viewing social media content, when completing the "Participate in Research" website form (mean age 66.2, SD 10.4 years; 67/76, 88% female; 12/76, 16% self-reporting non-White race or Hispanic/Latino ethnicity). Of these, 46 (61%) have been referred to an ongoing research study, 22 (29%) were not referred, and 8 (11%) have phone screens pending (see Table 4 for additional details). In addition, 13 individuals expressed interest in participating in research after attending a web-based talk advertised on social media (mean age 64.3, SD 4.4 years; 13/13, 100% female; 3/13, 23% self-reporting non-White race). Of these, 12 (92%) have been referred to an ongoing research study; 1 (8%) was not referred (Table 4).

Table 4. Recruitment outcomes: breakdown of participant referrals for those expressing interest in participating in research after learning about the Johns Hopkins Alzheimer's Disease Research Center through social media activities.

	Webform indicates social media as a source for engagement (n=76), n (%)	Attended a social media-advertised web-based talk (n=13), n (%)
Referred to a center-affiliated research study		
Enrolled in a center-affiliated research study	6 (8)	5 (38)
Enrollment pending (referral sent, outcome pending)	26 (34)	6 (46)
Not enrolled (eg, ineligible; study coordinator unable to contact)	9 (12)	1 (8)
Referred to another ADRC or online registries (eg, lives out of state; unable to travel)	5 (7)	0 (0)
Not referred to a center-affiliated research study		
Phone screen pending	8 (11)	0 (0)
Contacted but no longer interested	3 (4)	1 (8)
Unable to contact	19 (25)	0 (0)

Discussion

Principal Findings

This study describes one center's social media strategy for community outreach and recruitment. Four years of page metrics and recruitment data suggest that the content and programs provide educational resources, increase the visibility of the center's activities, and result in the recruitment of participants into center-affiliated research studies.

Given the increased use of social media among middle-aged and older adults, these platforms can serve as one method by which the JHADRC provides reliable education and resources to members of the local community, networks (on the web) with local community organizations, and shares information about the important work (research studies, research findings, events, etc) being done by center-affiliated faculty and staff. Based on these data, it appears that these efforts, including boosting occasional Facebook posts, have increased the visibility of the JHADRC in the local geographic area and have provided opportunities to reach individuals who we may not have encountered through in-person community outreach. Importantly, these activities can be achieved primarily through staff time, with minimal additional cost to center budgets. Using creative digital approaches to serve as a public source of reliable information on topics related to aging, memory loss, and ADRD provides an additional opportunity for centers to meet critical community engagement goals, including building trust and creating better communication with members of the community [23,24].

These findings also demonstrate that social media activities have been a source of participant recruitment. Potential participants (ie, middle-aged and older adults) learned about our research program through social media–advertised talks as well as social media post content, including our Research Awareness Series. This allowed us to increase the number of participant referrals to center-affiliated studies, supporting the promise of social media as a low-cost method of recruiting potential research participants [16,25,26]. Additional follow-up is needed to determine whether these participants have different demographics and retention characteristics than individuals recruited through in-person community outreach or other activities.

Our evidence suggests that innovative social media activities can also provide novel opportunities for the scientific community. For example, although our web-based *Memory Matters* talk series was primarily designed to share recent research findings with the lay community, it simultaneously provided professional development opportunities. Through this series, junior investigators receive mentorship on the principles and importance of science communication, specifically communicating science-related topics with the public [27,28]. Engaging staff and investigators in the development of social media content, such as writing accessible descriptions of their research programs and findings, can also provide science communication opportunities. This highlights an additional possible benefit of social media for centers or programs that may be considering whether to develop a social media presence or those exploring ways in which they might expand their programming.

Moreover, providing education and resources for adults in the local community, including individuals living with cognitive impairment and caregivers, is in alignment with international efforts promoting healthy aging, ADRD education and support, and dementia risk reduction [3,4]. While most of our educational content to date focused on these broad topics, future content could include materials that address ageism and ableism, and promote age-friendly [29] and dementia-friendly [30] activities and resources that ensure inclusive environments, empowerment, and sustained engagement with issues related to age and disease.

Limitations

This study has limitations. First, this is a retrospective account of one center's social media activities and their outcomes, and the number of individuals following the social media pages is still modest. Additional work is needed to understand the long-term impact of these activities on community education, center visibility, and clinical research recruitment, and to evaluate the types of content that lead individuals to express interest in participating in center-affiliated research studies. Second, we do not have data on the demographics of our social media followers to evaluate whether our content reached the target audience or the extent to which we are reaching individuals living with cognitive impairment. However, the recruitment metrics indicate that those expressing interest in participating in research were in the target age range. Social media and internet use is reportedly lower among the oldest-old, as well as individuals with cognitive impairment and poorer subjective health [31-36]; these groups may, therefore, be less likely to engage with these platforms. Third, we did not compare the efficacy of the 3 social media platforms described, although we believe that each allows us to reach unique audiences in different ways. Fourth, the individuals who have expressed interest in research have been predominantly female; additional efforts are needed to understand how to similarly reach males, as well as a greater proportion of individuals from diverse racial and ethnic backgrounds. Fifth, although our reach and impression rates are promising, our Facebook engagement rates are relatively low. Because this metric is an indicator of how, and the degree to which, our audience interacts with our content, these data suggest that much of our social media outreach may be unidirectional (ie, low levels of likes, comments, and content sharing). Future efforts should strive to improve this. Additionally, these measures were collected as monthly averages, which limited our ability to assess the impact of individual posts or specific content types. Furthermore, engagement data were not collected for Twitter. Finally, we describe the efforts of one Alzheimer's Disease Research Center; the extent to which similar approaches generalize to other types of centers or programs remains to be determined.

Although social media may be an effective means for raising awareness about dementia, dispelling stigma, and highlighting positive aspects of clinical research [37], it is only one method within a wide range of strategies needed for engaging communities, individuals with cognitive impairment, and families on topics related to aging and ADRD [5,24]. Social media may supplement in-person community outreach, engagement, and partnerships, the latter of which have been reported to be important for building trust, particularly in minoritized communities [38-40]. It will furthermore be important to continually monitor use trends among target demographics, and evaluate the addition of, or migration to, other emerging platforms. We, nonetheless, hope these activities—or a subset thereof—may serve as an exemplar for other centers or programs, or provide ideas for new initiatives that can be implemented and improved upon.

Conclusions

These data suggest that social media activities may have a measurable impact on the outreach, visibility, and recruitment activities of research centers, including National Institute on Aging–funded ADRCs. They also highlight the importance of tracking the success of outreach programs for evaluating outcomes. These data provide evidence of return on investment and support the continued use of social media for the above-mentioned purposes. Given the public's use of social media as a source of health information [6], this may be an important means by which centers can present themselves as a reliable educational resource, educate the community, and share research findings with community stakeholders. Incorporating additional activities designed to test the efficacy of different approaches for attracting research participants is an important future direction.

Combating Barriers to the Development of a Patient-Oriented Frailty Website

Abstract

This viewpoint article, which represents the opinions of the authors, discusses the barriers to developing a patient-oriented frailty website and potential solutions. A patient-oriented frailty website is a health resource where community-dwelling older adults can navigate to and answer a series of health-related questions to receive a frailty score and health summary. This information could then be shared with health care professionals to help with the understanding of health status prior to acute illness, as well as to screen and identify older adult individuals for frailty. Our viewpoints were drawn from 2 discussion sessions that included caregivers and care providers, as well as community-dwelling older adults. We found that barriers to a patient-oriented frailty website include, but are not limited to, its inherent restrictiveness to frail persons, concerns over data privacy, time commitment worries, and the need for health and lifestyle resources in addition to an assessment summary. For each barrier, we discuss potential solutions and caveats to those solutions, including assistance from caregivers, hosting the website on a trusted source, reducing the number of health questions that need to be answered, and providing resources tailored to each users' responses, respectively. In addition to screening and identifying frail older adults, a patient-oriented frailty website will help promote healthy aging in nonfrail adults, encourage aging in place, support real-time monitoring, and enable personalized and preventative care.

(JMIR Aging 2024;7:e53098) doi:10.2196/53098

frailty; frailty website; patient-oriented assessment; community-dwelling older adults; internet security; privacy; barrier; barriers; development; implementation; patient-oriented; internet; virtual health resource; community dwelling; older adult; older adults; health care professional; caregiver; caregivers; technology; real-time; monitoring; aging; ageing

Introduction

Technological advances, principally computer-aided assessments and electronic health information exchanges, have enormous promise to promote healthy aging. Fortunately, older adults (ie, those aged ≥65 years) are open to using new technologies [1]. Thus, health care is adopting technologies that support real-time monitoring to promote personalized and preventative care [2].

Frailty is an age-related dynamic state characterized by deficits across multiple physiologic systems with increased vulnerability to stressors [3,4]. Consensus guidelines state that early detection of frailty is key to its management [5,6]. To this end, technology-based frailty tools have allowed health care professionals to screen, assess, identify, and develop care plans for frail persons [7-11]. Yet, physician-oriented frailty screening tools are resource intensive.

A patient-oriented frailty website is the next step in frailty care [12]. In Canada, approximately 23% of community-dwelling older adults are frail [13]. Although primary care frailty screening tools used by health care providers show promise in the identification and management of frailty [14], many community-dwelling older adults do not have the ability to undergo in-person frailty screening. Therefore, patient-oriented frailty screening tools in the form of websites and apps should be developed and implemented.

The concept of a patient-oriented frailty website is straightforward. Individuals go to a secure frailty website where they answer a series of health-related questions. The website, in turn, generates a frailty/health summary and score based on the user's responses. In addition to a score, the website could also inform the user of their frailty status and whether they should seek medical counsel. Upon consent, users can share their responses and score with their care provider. In this capacity, a patient-oriented frailty website could identify those that are frail or at an increased risk of becoming frail. The website would be inclusive and encourage *all* older adults, regardless of health status, to participate. For healthy older adults that show no signs of frailty, the website would promote and reinforce their current healthy lifestyle and serve as a baseline. In this way, a frailty website is similar to the standard practice of well-baby visits—periodic examinations that screen for potential developmental health complications [15]. Therefore, well-baby visits and web-based frailty assessments are tools for the prevention and treatment of health issues that occur early and late in life, respectively.

To understand the interest in a patient-oriented frailty website, we conducted a planning project consisting of 2 components. In May 2023, we held a web-based educational symposium on frailty [16]. Experts in frailty spoke on the importance of frailty assessment and identification, approaches to preventing and mitigating frailty, frailty in primary care, and factors common to those who age gracefully beyond the age of 85 years. Recruitment for symposium audience and discussants was done via posters, which were distributed and published in local health authority newsletters, at academic institutions, and at a volunteer recruitment site for health research using REACH BC (the *Ethical Considerations* section provides more details). The audience was Canadian clinicians, researchers, caregivers, and community-dwelling older adults. Before and at the symposium, we invited interested audience members to participate in a discussion session scheduled 2 weeks later; individuals were excluded if they had not seen the symposium. Interested care providers, caregivers, and community-dwelling older adults returned to 1 of 2 discussion sessions. One discussion session included 7 caregivers and care providers, whereas the other session included 6 community-dwelling older adults; sample sizes were determined by best practices [17-19]. In contrast to a traditional qualitative research where findings are summarized then supplemented with participants' quotes, in this viewpoint paper, we summarize the main findings of the discussion groups, highlighting the major barriers to developing a patient-oriented frailty website. To benefit other researchers developing similar health websites, we also provide potential solutions as observed throughout the literature and discuss caveats to those solutions, as summarized in Table 1.

Table . Barriers, their potential solutions, and caveats to those solutions regarding the implementation of a patient-oriented frailty website.

Barriers and solutions	Caveats
Completing a frailty assessment on the web is restrictive to frail persons.	
Caregiver assists or completes assessment on frail person's behalf.	Not all frail older adults will have a caregiver.
Distribute low-tech (ie, paper) frailty assessments.	Requires a set of complex steps a frail person cannot do.
There are privacy and security concerns.	
The website needs to be hosted from a reputable source with clear intent on its use.	It is unknown how users will perceive the trustworthiness of a frailty website.
Users may restrict researchers from health data analyses.	
Implement federated learning.	Federated learning is still relatively novel and may be susceptible to attacks.
Users want to complete the assessment quickly.	
Reduce the number of frailty questions.	Fewer questions may compromise the clinical usefulness of the assessment.
Health care providers need to know how to interpret and apply the information to care for frailty.	
Develop models to treat frailty; implement training for health professionals.	This solution requires significant resources.
Being labeled as frail is counterproductive to combating frailty.	
Educate users on frailty and reframe frailty in a more positive light (eg, well-being).	It is unknown how users will respond to their (potentially negative) scores.
Users want health resources tailored to them in addition to a frailty/health assessment.	
Provide additional resources tailored to users' responses.	Users may be deterred from seeking the expertise of medical professionals.

Ethical Considerations

This planning project received an exemption from the Fraser Health Research Ethics Board as it fell under quality improvement and evaluation studies. Stakeholders provided informed consent prior to the discussion session for review, following the Fraser Health guidelines. All stakeholders had the ability to opt out at any time for any reason and were reminded of this right prior to the start of the discussion session. Both discussion sessions were recorded for the purpose of transcription offline. Videos of the 2 discussions are stored on a secured drive that is both password protected and can only be accessed by approved Fraser Health employees. Stakeholders were compensated CAD $25 (US $18.27) for engaging in the symposium and 1 discussion session.

A Website That Assesses Frailty Is Restrictive to the Frail

The most substantial issue involving the implementation of a patient-oriented frailty website is its restrictiveness. A website targeting a subpopulation assumes that the targeted audience can access the website. On average, internet use among Canadian older adults is 68%, but it is only 41% for those aged ≥80 years [20]. In addition to age, health and frailty status are also related to internet and computer use. For example, 73% of Canadian older adults in excellent or very good health use the internet, whereas 62% of older adults in fair or poor health use the internet [20]. Likewise, another group found that the frailer a person was, the less likely they were to use a computer [21]. Thus, attempting to reach frail older adults through a website is a major hurdle.

A seemingly simple solution to this barrier is targeting caregivers (eg, partners, family members, friends, colleagues, or neighbors) and having caregivers assist or complete the questions on the frail person's behalf. However, this solution only works for those with caregiver support. In one study based in the Netherlands, having a primary caregiver was reported in 32% of older adults who visited the emergency department [22]. This figure may be slightly lower in Canada. It is estimated between 23% [23] and 28% [24] of older Canadian adults have caregivers. Consequently, there is a chance that most frail community-dwelling older adults would not have assistance using a computer, navigating to the frailty website, and answering a series of health-related questions. Clearly, increasing caregiver support is one approach to increasing internet access among frail older adults.

Another solution to combat the restrictiveness of a frailty website is to also provide a paper version to frail older adults. Despite acknowledging the importance and benefits of digital screening tools, older adults have suggested that low-tech alternatives should also be available [25]. It would be convenient to make a paper pamphlet that has the same information and questions as a frailty website. This way, both paper and web-based frailty assessments would be interchangeable, allowing for conversion from one medium (ie, paper) to the other (ie, website) and vice versa. Pamphlets can be widely distributed and made available at family physicians' and nurse practitioners' offices, wellness and health clinics, pharmacies, and even mailed directly to older adults (eg, using Canada Post's Precision Targeter). However, there are concerns regarding this approach as well. Assuming frail community-dwelling older adults obtained access to the frailty pamphlet survey, they would still need to fill it out (accurately), return it, schedule an appointment, and visit a health care professional. Some of these barriers can be mitigated by including a return address with free postage, using free door-to-door shared ride services, or scheduling a telehealth appointment. However, this process requires a series of complicated steps and older adults with mild cognitive impairment will be unable to complete them [26]. Other means of reaching frail persons are needed, but without significant assistance, it is unlikely that these individuals will be screened for proper frailty care.

Older Adults Have Internet Privacy Concerns

Despite a positive attitude toward web-based health services [27], older adults are concerned about privacy, especially when it is unclear by whom or how their medical data will be used [28]. For example, the probability of being identified was the single most important attribute when older adults considered internet privacy, even though sharing their medical data was viewed positively if it was to be used for science and the development of novel care and treatment [29]. The hesitancy of older adults to share their medical data reveals the need for clearly communicating how their information will be used—if they are to be comfortable consenting to its wider use. Similarly, a previous study found that older adults were more willing to share their data (eg, demographics, family relations, economic status, physical and mental illnesses, family history, medication, and health care service use) with family and hospitals compared to researchers or government agencies [30]. Public trust in the government is complex. For example, despite only 19% of Americans trusting the federal government, 70% viewed the US Food and Drug Administration and US Centers for Disease Control and Prevention favorably [31]. Thus, hosting a patient-oriented frailty website on a health authority or a particular branch of government, as opposed to a commercial site, with the clear intent to promote health, may increase the likelihood of the widespread adoption of a web-based frailty assessment tool among older adults. However, more work is needed to fully understand the actual adoption (as opposed to the hypothetical adoption) of a frailty website among older adults and how to securely transfer a user's medical responses to a health authority without compromising privacy if the user consents.

Users' Restriction of Their Data May Limit Health Data Analyses

The reluctance for individuals to share their health data for research purposes is understandable and may dictate the use of a frailty website. Researchers and health authorities may bemoan the decision for users to protect their data, which, in turn, may restrict our understanding of frailty. For example, knowing the frailty status and location of older adults who completed a web-based frailty assessment could reveal concentrated areas of frail older adults, suggesting environmental or societal risk factors and the need for additional services to be deployed to those locations. Realistically, this type of analysis can only be done with a user's location and health data. Still, it is important to remember that the personal health data acquired from any website belongs to the user. It is at the discretion of the user (assuming they have the cognitive faculties to consent in the first place, a topic not discussed in our sessions) whether to share their data.

Hence the success of a frailty website is contingent upon the implementation of a privacy-first approach. A privacy-first approach underscores the users' ownership of their data, using dynamic identifiers and storing data locally (ie, on a smartphone or computer), as opposed to a data-first approach, which prioritizes the retention and distribution of data, typically in a centralized location [32]. However, a happy medium exists where users can keep and protect their data while researchers and health authorities can advance frailty care through modern analysis.

New advances in data analysis [33] have been developed and used to underscore privacy-first approaches. Federated learning, for example, is a machine learning model that aggregates training results from multiple sources to create a consensus model without the need for data to leave a given device or system. A recent study found federated models achieved the same accuracy, precision, and generalizability as standard centralized statistical models using a variety of health data [34]. As a specific example, federated learning was used to predict treatment response in breast cancer patients using data behind a hospital's firewall [35]. Emerging technologies and analyses have made it possible to have a patient-oriented frailty website that both ensures the privacy of the user and allows for analyses that will usher in better frailty care. A caveat to this is that federated learning is relatively new and will take time to implement across health authorities, and it may be prone to specific types of attacks [33].

Users Want to Complete a Frailty Assessment Quickly

A frailty website needs to be efficient and user-friendly [12] while adequately collecting health information that can assess frailty [3,4]. After the user completes a series of health-related questions on a frailty website, the website should produce a score (eg, "Your frailty score is 42/100, consider making an appointment with your doctor" or "Your biological age is 71, 6 years older than your actual age of 65"). One scoring approach could be a multisystem deficit-accumulation frailty index [36,37], which subscribes to the idea of an accumulation of deficits and is scored between 0 and 1, with 0 being no deficits present and 1 being all deficits present and fully expressed (in reliaty, the score seldom exceeds 0.7, a limit of deficit acculation); this approach has acceptable validity, reliability, and diagnostic test accuracy [38]. One benefit of a frailty score derived from a frailty index is that it can be interpreted by nonexperts. However, because the accumulation deficit model subscribes to the idea that frailty is a multisystem state, ideally a frailty website that adopts this approach would require 30 to 40 questions [39] across multiple domains (ie, physical, cognitive, psychological, and social). Research has shown that people are more likely to complete a survey if it takes 15 minutes or less [40]. In the context of a frailty website, completing 30 to 40 questions in 15 minutes would require users to spend 23 to 30 seconds on each question. Therefore, inaccurate responses and the respondent feeling rushed, frustrated, and stressed can be a concern.

In an attempt to make the website user-friendly, the number of questions would have to be reduced, potentially compromising its clinical utility [41]. A frailty index comprising fewer than 30 variables and questions can still be useful. In one study, researchers found that a frailty index constructed using 23 variables was just as accurate as one constructed using 70 variables [42]. An alternative approach to written multiple-choice questions may be a pictorial frailty assessment. The Pictorial Fit-Frail Scale [43] was recently developed for this purpose. It is fast (it took patients 6 minutes to complete) and comprehensive (the assessment covered 14 domains). However, agreement rates among Canadian and UK health care professionals were low (32% agreement for social, 44% agreement for mood, and 59% agreement for function), and it is unclear how patients understood each domain (averages were taken across 146 patients, caregivers, health care professionals, and general public participants) [43]. In contrast to the frailty index with precise grading of frailty, the phenotype model of frailty includes only 5 variables. Yet, the phenotype model requires grip strength and walking speed, measures that cannot be easily tested and may not be safe for many older adults to complete in their own homes. A methodological consensus regarding the definition of a frailty index, the variables that comprise it, and how they are scored has been encouraged [44-46].

Frailty Score Needs to Be Interpretable

In addition to a methodological consensus, output from a patient-oriented frailty website must be sufficient and interpretable for all health care professionals irrespective of location. For example, health care professionals across Canada would need to know what a frailty score of "42/100" means and how to prescribe the appropriate care. Our modern health care system is well designed for treating diseases but not for embracing the unique challenges of frailty among older adults, a population that experiences complex health issues [47].

Fortunately, the development of novel models [48] and guidelines [49] that address frailty in primary care is already underway. Moreover, frailty training would be required for physicians to prescribe appropriate frailty care. A systematic review found that there were limited frailty training programs for health professionals; however, the programs that did exist effectively increased frailty knowledge and competence in frailty assessments [50]. Although this would require significant resources, postponing or reducing frailty would result in a significant reduction in health care costs [51] and would pay for itself.

Being Labeled Frail Is Counterproductive to Combating Frailty

Numerous studies have agreed that there is a stigma around the concept of frailty and being labeled as frail. In one study, community-dwelling older adults reported that frailty was perceived as "approaching the end of their lives, malnourished and highly dependent on care" [52]. This same study also found that older adults are likely to reject the concept of frailty even when an objective measure may define them as frail [52]. Hence, a frailty website that labels a user frail may be counterproductive to the purpose of preventing and managing frailty.

In addition to education, another solution to combat the negative perceptions of frailty is to reframe the concept of frailty in a more positive light, using terminology such as "healthy aging" or "well-being" [52,53] or, within the context of a fit-frail score, "well-being score." It should be noted, however, that positive output from a web-based frailty assessment (eg, a low fit-frail score, or a low biological age relative to chronological age) could also be counterproductive and have the same consequences as a negative output, deterring older adults from seeking medical care. Nevertheless, at least 1 study suggests otherwise. Among older adults who avoided medical care, 36% did so out of fear of a serious illness, and the likelihood of avoidance was greater in those who self-reported a poorer health status [54]. Ultimately, it is unknown how users will respond to negative or positive outputs from a frailty website, and more research is needed to understand the potentially complicated reactions older adults will have after receiving their personalized health score and summary. Regardless, it is of the utmost importance that older adults are comfortable, feel safe, and are motivated (not discouraged) when using a frailty website.

Frailty Websites Should Provide Additional Health Resources

A frailty website should offer resources in addition to a health score and summary. A patient-oriented frailty website that gathers health information can be of great use for health care providers. It should also produce personalized resources based on the user's responses [55,56]. For example, if a community-dwelling older adult is deemed to be at risk of becoming frail and their deficits are primarily in a physical domain (ie, they are slightly overweight, sleep less than 6 hours a night, drink >6 alcoholic drinks a week, and have hypertension but are cognitively normal), the website ought to provide links to resources to meet those care needs. In this scenario, the website could suggest resources such as how to start and maintain an exercise program and provide best sleep hygiene practices in addition to recommending that the user make an appointment with their physician to manage hypertension.

Self-management is a potentially viable, low-cost approach to addressing frailty, but this is a relatively unexplored topic in frailty care [53]. Additionally, caution must be exercised with self-management. For instance, individuals that are provided resources may be lulled into a false sense of security and feel that their health can be managed without regular check-ups by the expertise of trained medical professionals. On the other hand, older adults may be unmotivated to complete a series of health-related questions if a website does not provide any immediate, clear feedback other than a score. There needs to be a happy medium where older adults are motivated to use a frailty website but also supplement the website with a medical expert's opinion. Future studies need to understand where that happy medium exists and incorporate it into frailty website development.

Limitations

This viewpoint paper is not without limitations. One such limitation is the lack of quotes from discussants. While quotes are typically included in qualitative research to strengthen findings, our viewpoint explicitly draws attention to barriers and potential solutions to the development of a patient-oriented frailty website. Further, traditional focus group studies that include theme discovery supplemented with quotes will be needed to better understand and address these barriers. Another limitation is the omission of technological barriers, which have been published elsewhere [12,57]. One important technological barrier is search engine optimization—a process of making modifications to a website to increase its visibility. Well-tuned site optimization strategies increase traffic to health websites, whereas poor search engine optimization can affect older adults' experience in frailty assessment and health interpretation simply due to a missing hyperlink to the website. Finally, the barriers reported here may not generalize to populations outside of Canada. However, some of the barriers reported here also exist for older adults in Switzerland [26] and the United Kingdom [53,56]. Future studies should attempt to recruit samples representing broader geographical regions to promote equity in global health care.

Conclusion

A frailty website that can be used by the community to screen and identify older adults at an increased risk of frailty and health decline is an important step in geriatric care and public health. However, several barriers must be addressed in future research before the development of such websites. While some barriers have potential solutions, they come at a cost (eg, resources required for optimizing frailty models in primary care and patient-oriented frailty assessment training and support). Other potential solutions (eg, caregiver assistance and an accompanying paper-based frailty assessment) have their own challenges. Regardless, addressing these barriers, even partially, is a worthy goal. The early detection and management of frailty can lead to significant inroads to integrated care, benefiting the quality of life of older patients and their caregivers and the health of the aging population.

Acknowledgments

The authors sincerely acknowledge the distinguished speakers who generously shared their expertise during the educational symposium: Kenneth Rockwood, MD; John Muscedere, MD; Barry Clarke, MD; Grace Park, MD; Belinda Robinson, MD; and Angela Brooks-Wilson, PhD. The full recording of the symposium is available at the eFI-CGA (Electronic Frailty Index Based on the Comprehensive Geriatric Assessment) website [16]. We would also like to express our appreciation to the Fraser Health Authority Department of Evaluations and Research Services for research administrative support, the eFI-CGA IT support team for their valuable consultation in hosting the symposium materials on the website, and REACH BC for their assistance during the participant recruitment phase. We acknowledge the significant contributions of Alia Januwalla, BA, from the BC Support Unit for her knowledge translation inputs and support, and we extend our thanks to Hilary Low, BA, for administrative assistance. Finally, we would like to acknowledge all focus group participants for their time, commitment, and invaluable insights.

This planning project was supported by a planning and dissemination grant from the Canadian Institutions of Health Research (CIHR-PCS-185525). Additional funding for research operating and training came from a Canadian Institutions of Health Research project grant (CIHR PJT156210 eFI-CGA) and a Surrey Hospitals Foundation training award (FHG 2017-001).

Abstract

Background: The rise in life expectancy is associated with an increase in long-term and gradual cognitive decline. Treatment effectiveness is enhanced at the early stage of the disease. Therefore, there is a need to find low-cost and ecological solutions for mass screening of community-dwelling older adults.

Objective: This work aims to exploit automatic analysis of free speech to identify signs of cognitive function decline.

Methods: A sample of 266 participants older than 65 years were recruited in Italy and Spain and were divided into 3 groups according to their Mini-Mental Status Examination (MMSE) scores. People were asked to tell a story and describe a picture, and voice recordings were used to extract high-level features on different time scales automatically. Based on these features, machine learning algorithms were trained to solve binary and multiclass classification problems by using both mono- and cross-lingual approaches. The algorithms were enriched using Shapley Additive Explanations for model explainability.

Results: In the Italian data set, healthy participants (MMSE score≥27) were automatically discriminated from participants with mildly impaired cognitive function (20≤MMSE score≤26) and from those with moderate to severe impairment of cognitive function (11≤MMSE score≤19) with accuracy of 80% and 86%, respectively. Slightly lower performance was achieved in the Spanish and multilanguage data sets.

Conclusions: This work proposes a transparent and unobtrusive assessment method, which might be included in a mobile app for large-scale monitoring of cognitive functionality in older adults. Voice is confirmed to be an important biomarker of cognitive decline due to its noninvasive and easily accessible nature.

cognitive decline; speech processing; machine learning; multilanguage; Mini-Mental Status Examination

Introduction

According to “The 2021 Ageing Report by the European Commission,” life expectancy has shown a continuous trend over the past years [1]. As life expectancy increases, so does the number of people with dementia worldwide. Dementia is a neurodegenerative disease, which entails a long-term and gradual decrease in cognitive functionality, resulting in the reduction of patients’ autonomy and well-being, as well as worsening of the quality of life of their caregivers. The management of the increased number of older adults at risk of developing severe cognitive decline is a big challenge for health care systems, with the annual global cost expected to rise to US $2 trillion by 2030 [2]. These pathologies start silently up to 20 years before clear cognitive symptoms. However, there is increasing evidence that pharmaceutical interventions may be most effective at milder stages of dementia [3]. Thus, it is fundamental to find strategies that may anticipate the diagnosis [4-6]. Current diagnostic procedures require a thorough examination by medical specialists. The most employed tool for the first screening of cognitive function is the Mini-Mental Status Examination (MMSE). It is based on 30 questions that address short and long-term memory, attention span, concentration, language, and communication skills, as well as the ability to plan and understand instructions [7]. A score of 26 or higher is usually classified as normal. If the score is below 25, the result highlights a possible cognitive impairment, which may be classified as mild (21≤MMSE score≤26) or moderate to severe (MMSE score≤20). Although this test has high sensitivity and specificity (87% and 82%, respectively) [8] and can be quickly administered, its employment is restricted within primary care facilities. Thus, faster, noninvasive, and automatic methods are needed to provide digital biomarkers for large-scale monitoring of cognitive functions in real-life scenarios [9].

In recent years, voice has been one of the most studied digital biomarkers since it allows cheap, noninvasive, ecological, rapid, and remote assessment of several aspects of a patient’s health status, such as the functionality of the respiratory system, cognitive decline, emotions, and heart dysfunctions [7,10-12]. Speech and language capacity is a well-established early indicator of cognitive deficits [13,14]. In the early phase of dementia, participants show alterations in the rhythm, resulting in a higher number of pauses, probably due to word-finding problems (ie, anomia and semantic paraphasia), worsening of verbal fluency [15-17], low speech rates, and decrease in the length of voiced segments [18-20]. Several studies have addressed the possibility of identifying signs of cognitive decline from voice recordings. Martínez-Sánchez and colleagues [21] analyzed the temporal parameters of reading fluency to discriminate between Spanish-speaking asymptomatic participants and those with Alzheimer disease (AD), and they were able to differentiate between patients with AD and healthy controls with an accuracy of 80% based on the speech rate. However, using a reading task introduces the possibility that participants’ fluency is affected by other factors such as educational level or visual impairment. Konig et al [22] demonstrated that it is possible to differentiate between dementia and mild cognitive impairment (MCI) in English-speaking participants based on voice features extracted from different tasks, for example, verbal fluency, picture description, counting down, and free speech, with a classification accuracy of 86%. Toth et al [23] showed that acoustic parameters such as speech rate, hesitation ratio, number of pauses, and articulation rate yield good results in discriminating between Hungarian-speaking participants with MCI and healthy controls. They analyzed a movie recall task and achieved an F_1-score of 78.8%. Calzà et al [2] were able to discriminate between Italian-speaking healthy controls and participants with MCI by using random forest and support vector machine (SVM) with an F_1-score of 75% by employing natural language processing. Finally, Bertini et al [24] achieved high performance (accuracy of 93% and F_1-score of 88.5%) based on acoustic features extracted from spontaneous speech from a corpus of English-speaking participants, that is, Pitt Corpus, by using deep learning techniques. Nevertheless, natural language processing and deep learning require the analysis of raw data, thus having access to the recordings’ information content and endangering the participants’ privacy. Most previous works [2,21-24] aimed to distinguish participants with a proper diagnosis of AD or MCI from healthy participants. However, as far as we know, there are no studies investigating whether machine-learning algorithms based on voice features can identify early signs of functional cognitive decline detected by a decrease in the MMSE score.

In a previous study of our group [25], voice features automatically extracted from recordings of episodic storytelling could discriminate between Italian-speaking participants with normal cognitive functions (MMSE score≥27) and participants with mild cognitive decline (20≤MMSE score≤26) with an accuracy of 73%. Starting from this preliminary study, our study exploits acoustic features automatically extracted from spontaneous speech and machine learning techniques to support the early identification of cognitive function decline, meant as a reduction of the MMSE score. The main novelties involve the extension of a number of features, reduction of the computational time for feature extraction, and the multilanguage approach since both Spanish- and Italian-speaking participants were considered.

Methods

Participants and Data Collection

A sample of older adults were recruited in Italy (Lombardy region) and Spain (Extremadura region). In Italy, participants were recruited based on direct contact with the Geriatric Unit of the Foundation Scientific Institute for Research, Hospitalization and Healthcare (IRCCS) Ca’ Granda Ospedale Maggiore Policlinico (day hospital, ambulatory, and gymnasium). In Spain, people were recruited based on direct contact with professionals working in health care belonging to the Extremadura Health Ecosystem.

The essential requirement for participation was a good knowledge, at least oral, of the language of the country where the audios were recorded. Exclusion criteria were nonnative-speaking participants, clinically unstable participants, terminal illness (life expectancy <6 months), severe hearing or visual deficits, aphasia, and a score on the 30-item Geriatric Depression Scale >9. After providing informed consent to participate in the study, participants were met individually and they underwent the MMSE performed by health care professionals (geriatrician in Italy and neuropsychologist in Spain). Afterward, they were asked to tell 3 stories about their life for 2 minutes each without interruptions (positive, negative, and episodic) and to provide a 2-minute description of the "Cookie-Theft picture" of the Boston Diagnostic Aphasia Examination [26]. For each task, voice signals were recorded in separate .WAV files (16 kHz) by using an ad-hoc toolbox developed in MATLAB (MathWorks), through an external USB microphone. Participants were divided into 3 groups based on the MMSE score:

1. Group 1: MMSE score≥27, that is, healthy participants
2. Group 2: 20≤MMSE score≤26, that is, participants with mild impairment of cognitive function
3. Group 3: 11≤MMSE score≤19, that is, participants with a moderate to severe impairment of cognitive function

The choice of the MMSE score for separation among the groups was employed since the aim was to detect the earliest symptoms of cognitive decline in the prediagnostic phase.

Ethics Approval

This study was approved by the ethics committee of Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico in Italy (ref: 1272018, approval date: March 15, 2018) and by the Comité Ético de Investigaciòn Clìnica de Badajoz in Spain (approval date: April 11, 2018).

Feature Extraction and Statistical Analysis

Data preprocessing and features extraction were performed employing an automatic algorithm implemented in MATLAB [25]. A positive speech polarity was imposed, and voice recordings were standardized. Afterward, the acoustic features described in Table 1 were extracted [20,21,23,27,28]. The features were grouped into 4 macrocategories according to their information content: voice periodicity, shimmer-related, syllabic, and spectral features. Feature extraction was repeated 3 times for voice segments lasting 5 seconds, 10 seconds, and 15 seconds to assess whether different time lengths can capture specific patterns. For each voice segment length, voice features extracted from the 4 audio recordings were substituted by their mean and standard deviation or their median and interquartile range, based on data set distribution, assessed by the Anderson-Darling normality test. Thus, each participant was represented by a single entry in the final data set, and 138 acoustic features (23 features × 3 segments length × 2 statistics) were computed for each entry. A 1-way analysis of variance for independent samples was applied to compare the 3 groups in terms of age. Due to their categorical nature, the Kruskal-Wallis test was applied to compare years of education and MMSE scores among groups. A Pearson chi-squared test was instead used for gender. Finally, generalized linear mixed models were defined in SPSS Statistics (version 28; IBM Corp) to evaluate whether acoustic features were significantly different among groups. Specifically, the mean (or median) values of the 23 acoustic features extracted from the 15-second segments were considered as the target for each model following a gamma regression distribution with a log link to the linear model. If significant differences were found, post hoc analysis with Bonferroni correction was also performed.

Table 1. Overview of the extracted features.

Domain, feature description	Feature code
Voice periodicity	
Unvoiced percentage, that is, percentage of aperiodic parts in the audio segment	F1
Duration of voiced and unvoiced segments, that is, mean, median, 15th and 85th percentiles of the parts of the signal with (voiced) and without (unvoiced) periodic nature	F2-F9
Percentage of voice breaks computed on the number of distances between consecutive pulses longer than 1.25 divided by the pitch floor (70 Hz) [27]	F10
Shimmer	
Shimmer, that is, random cycle-to-cycle temporal changes of the amplitude of the vocal fold vibration [28]	F11
Syllabic and pauses features	
Speech rate, that is, number of syllables per second [21]	F12
Percentage of phonation time, that is, the intrasyllabic and intersyllabic nuclei time <250 ms divided by the total speech time [20,21]	F13
Articulation rate, that is, the number of syllables divided by the phonation time without pause [20,21]	F14
Mean duration of intersyllabic pauses >250 ms [21]	F15
Mean duration of syllables [20,21]	F16
Number and mean duration of pauses of the audio segment [23]	F17-F18
Spectral features	
Mean (SD) of pitch	F19-F20
Standard deviation of third formant (F3-SD)	F21
Speech temporal regularity, that is, temporal structure of the audio segment	F22
Centroid, that is, location of the center of mass of the spectral signal	F23

Feature Selection and Classification

Machine learning algorithms were trained to solve multiclass and binary classification problems (group 1 vs group 2 and group 1 vs group 3) starting from the extracted voice features, which were preliminary normalized.

Classifiers

SVM [29], logistic regression (LR), and CatBoost classifier (CAT) [30] were used. SVM is robust to noise in training data, since SVM decisions are only determined by the support vectors, while CAT represents the state of the art of boosting algorithms based on decision trees, and it has been proven to be very effective with small data sets with a high number of features. LR was investigated due to its simplicity and low computational cost. To achieve robust estimations despite the relatively small number of samples, the performance of each classifier was evaluated using stratified nested 10-fold cross-validation, which leads to the construction of an ensemble model via soft voting starting from each fold, obtaining a macromodel composed of 10 models trained on different subsets of data [31]. The classifier was selected according to the accuracy obtained in validation. Finally, a Kruskal-Wallis test was performed to determine whether there was a statistically significant difference between different classifiers in terms of accuracy.

Parameter Setting

Hyperparameter tuning was performed to limit overfitting with the nonlinear classifier. The following parameters were tuned for CAT through a randomized search method: bagging temperature, tree depth, l2 leaf regularization, and random strength. SVM was employed with a linear kernel and default parameters, and LR was also considered with default parameters. All the experiments were implemented using scikit-learn Python libraries, Catboost library, and Shapley Additive Explanation (SHAP).

Feature Selection

Due to the high dimensionality of the features set, the selection of the most informing features was performed through SHAP [32]. For each fold, starting from the entire set of features, the training was performed iteratively by computing the accuracy and the feature importance via SHAP for that specific iteration. At the end of each iteration, the 2 least significant features were removed until the minimum number of 6 features was reached. Therefore, the best model, that is, the one that achieved the best accuracy, was selected for each fold of the outer loop, and the model parameters were tuned for the identified set of features. As a result, 10 models trained on 10 different folds, each characterized by a different set of parameters and exploiting a different set of features, were obtained. The algorithm related to a single fold of the outer loop is summarized in Textbox 1. Finally, the ranking of the most informing features was implemented by summing up the unweighted mean of the Shapley values obtained at the end of the training of each fold for each feature.

Textbox 1. Algorithm of feature elimination with Shapley Additive Explanations.

```
1: Train algorithm with whole set of features
2: Calculate model performance

Results

Characteristics of the Participants

Table 2 shows the characteristics of the recruited participants. A total of 266 participants were recruited: 133 Italian-speaking and 133 Spanish-speaking older adults. In the Italian data set, most participants in all groups were females. In contrast, in the Spanish data set, participants were balanced for gender in group 1 and unbalanced in favor of females in the other 2 groups. Overall, significant differences in terms of age (P=.03 and P=.001 for the Italian and Spanish data sets, respectively), MMSE scores (*P*<.001 for both data sets), and years of education (only for the Italian data set, *P*<.001) were found among the 3 groups, with people with severe impairment of the cognitive function being characterized by an older age in both data sets and by fewer years of education in the Italian data set.

Table 2. Characteristics of the participants.

	Group 1[a]	Group 2[b]	Group 3[c]	*P* value	*P* value group 1 vs group 2	*P* value group 2 vs group 3	*P* value group 1 vs group 3

Acoustic Feature Characteristics

Table 3 reports the results of the statistical analysis comparing acoustic features for the Italian and Spanish data sets. Voice periodicity features, particularly those related to unvoiced segments, were found to be significantly different among groups (P<.001 for mean, median, and 85th percentile of duration of unvoiced segments). Indeed, from group 1 up to group 3, a significant increase (P<.001 for mean and 85th percentile and P=.004 for median) in the unvoiced duration was found. Significant differences were found also for some syllabic features such as duration of pauses and syllables, which significantly increased with the decrease in the MMSE score, as expected from literature [20]. The results of the statistical analysis comparing acoustic features for the Italian and Spanish data sets separately are reported in Multimedia Appendix 1 (Tables S1 and S2).

Multiclass Classification

Table 4 reports the results of the multiclass classification in terms of accuracy for 3 data sets: only Italian, only Spanish, and combination of Italian and Spanish participants. Overall, CAT achieved the best scores on the validation sets for the 3 data sets, but its performance considerably worsened when applied to the test sets. From the Kruskal-Wallis test, it can be seen that CAT achieved significantly better performance than LR for all data sets (P=.005, P=.02, and P=.03 for the Italian, Spanish, and Italian&Spanish data sets, respectively). A significant difference was also highlighted between SVM and CAT for the multilanguage data set (P=.01) and between SVM and LR for the Spanish data set (P=.003). Since there was no substantial difference in the accuracy between SVM and CAT, SVM was selected for its simplicity and further metrics, that is, receiver operating characteristic (ROC) curves, confusion matrices, and feature rankings are also reported (Figures 1-2). Overall, ROC curves (Figures 1A, 1C, and 1E) show a better trend for groups 1 and 3, whereas for group 2, the curve almost overlaps the bisector. The macro and micro averages of the areas under the curves achieved a fair score. The confusion matrices in Figures 1B, 1D, and 1F confirm this trend, with group 2 being the most misclassified in all 3 cases. For the Italian data set (Figure 1B), the model mainly misclassifies the participants from group 2 with those belonging to group 3, whereas for the Spanish data set (Figure 1D), participants from group 2 were mainly misclassified with participants from group 1.

The feature rankings obtained from SHAP (Figure 2) show the contribution of the most important features, ranked from the most to the least informing. It can be seen that the most important features changed depending on the considered language. For the Italian data set (Figure 2A), the spectral features (in purple), and those related to voice periodicity (in green) were among the most important features, whereas within the Spanish data set (Figure 2B), features related to syllables and pauses (in blue) and shimmer (in yellow) became more important. For the Italian&Spanish data set, the resulting ranking was a combination of the previous two, as displayed in Figure 2C.

Binary Classification

Tables 5 and 6 report the performance achieved for the binary classification, respectively, to distinguish group 1 (MMSE≥27) and group 2 (20≤MMSE≤26) and group 1 and group 3 (11≤MMSE≤19). SVM achieved the best scores on the validation sets compared to CAT and LR for the Italian&Spanish data sets in the discrimination between group 1 and group 2. However, the discrimination between group 1 and group 3 achieved a substantial equivalence among the 3 algorithms. As expected, better performance was obtained in the discrimination between healthy participants and those with severe impairment. As for the multiclass scenario, the accuracy of the test sets worsened in all data sets, with the Spanish data set experiencing the largest decrease.

ROC curves, confusion matrices, and feature rankings for the Italian&Spanish data set were shown for SVM, which achieved the best performance, at least in distinguishing group 1 from group 2. Regarding ROC curves, the results were poor for the classification between healthy participants and those with mild impairment, with an area under the curve score of 0.65 (Figure 3A), as it can be noticed also by the confusion matrix in Figure 3B. Fair results were obtained for the ROC curve concerning the distinction between healthy participants and participants with impairment, with an area under the curve score of 0.77 (Figure 4A). Moreover, the confusion matrix (Figure 4B) shows a smaller number of misclassified participants. Feature rankings showed that the most informing features were mainly spectral features and features related to voice periodicity for the classification between healthy participants and participants with mild impairment (Figure 5A). In contrast, features related to syllables and pauses (in blue) were more important for classifying between healthy and older adults with severe impairment (Figure 5B). ROC curves, confusion matrices, and feature rankings related to binary classifications of the Italian&Spanish data sets are reported in Multimedia Appendix 1.

Discussion

An artificial intelligence–based classification pipeline has been implemented to evaluate the possibility of using voice analysis as a prescreening tool for detecting the impairment of cognitive function in a single and multilanguage approach. Multiclass and binary classification were performed on 3 data sets (Italian, Spanish, and a combination of Italian and Spanish data sets). For the multiclass tasks, the models obtained an accuracy of 57%, 53%, and 54% on the test set with SVM on the Italian, Spanish, and multilanguage data set, respectively. Regarding the binary classification, an accuracy of 80%, 59%, and 65% in the test set was achieved on the Italian, Spanish, and multilanguage data set, respectively, when distinguishing between healthy participants and those with the first symptoms of cognitive decline and an accuracy of 86%, 73%, and 78% for the classification between healthy participants and those with an MMSE score≤19. The ROC curves in the multiclass task underlined how the participants with mild symptoms of cognitive decline are the most misclassified. This outcome aligns with expectations since participants belonging to this group exhibit mild impairment, indicated by an intermediate MMSE score. When having a deeper look into the misclassifications results (confusion matrices in Figure 1B and 1D), we observed that for the Italian data set, the model mainly misclassified participants from group 2 with those belonging to group 3, while for the Spanish data set, participants from group 2 were mainly misclassified with participants belonging to group 1. This result is in line with the results of the statistical analysis for the 2 data sets separately, which are reported in Multimedia Appendix 1 (Tables S1-S2): the statistical analysis highlighted a higher number of significantly different acoustic features between group 1 and group 2 for the Italian data set, while for the Spanish data set, there was a higher prevalence of acoustic features, which significantly differed between group 2 and group 3. A possible confounding factor might be the different distributions between the 2 data sets in terms of years of education, with a difference of 5 years between group 1 and group 2 for the Italian data set and a difference of only 1 year for the Spanish data set (Table 2).

The overall differences in the performance between the 2 languages may be explained by the heterogeneous demographic characteristics between the 2 data sets. Indeed, the distribution of participants in terms of gender, which highly affects acoustic features such as pitch [33], differed between the Italian and Spanish data set. In the Italian one, the distribution was more similar among the 3 groups, with a prevalence of females in each group, whereas for the Spanish data set, there was a prevalence of females in group 2 and group 3 compared to group 1, in which there was a balance between the 2 genders. Furthermore, the overall lower performance obtained on the Spanish data set may be related to the distribution of the MMSE scores among the groups. Indeed, there was a sharper separation among the 3 groups in the Italian data set, with a median MMSE score of 30 in group 1 and a median MMSE score of 24 in group 2, whereas the distribution of the scores in the Spanish data set was shrunk, with more participants being borderline among the groups (see Table 2).

The results highlighted that different sets of features are relevant depending on the considered language and the specific task. Indeed, shimmer was shown to be more relevant in Spanish-speaking participants, suggesting that an amplitude variation is predictive of a decline in cognitive function, whereas spectral features and those related to the voiced and unvoiced parts of speech were more important for predicting cognitive decline in Italian-speaking participants. The feature rankings of the classification tasks obtained with the multilanguage data set showed that the most informing features were a combination of those achieved for the 2 languages, when considered individually. This variability in the ranking of the features may be due to the change in prosody and accents of the languages themselves. Indeed, the Italian language is characterized by a wider spectral range compared with Spanish [34], which might explain why spectral features are predominant in the prediction of cognitive decline for the Italian data set. Nevertheless, these speculations need to be further explored in future studies.

Compared to that achieved by Calzà et al [2], we achieved slightly higher performance in the binary classification for distinguishing participants with mild cognitive decline from healthy participants when only the Italian data set was considered. Indeed, we achieved a test accuracy of 80%, while Calzà and colleagues [2] obtained an F_1-score of 75% on a manually checked corpus. However, there are several differences between these 2 studies. First, they considered not only acoustic features extracted from free speech but also lexical and syntactic features extracted with natural language processing as well as the demographic characteristics of the participants, such as age and years of education, which are considered important indicators of cognitive decline [35]. Conversely, we exploited only acoustic features automatically extracted from free speech, without considering any demographic features, to evaluate the possibility of exploiting this method for longitudinal monitoring. Moreover, in their work, Calzà and colleagues [2] recruited participants with a diagnosis of MCI based on a neuropsychological assessment, while in our work, we focused on the prescreening phase before an eventual diagnosis of MCI, and indeed, our groups were discriminated only based on the MMSE score. In another work [24], Bertini et al achieved instead higher performances, that is, 93% after data augmentation with a 20-fold cross-validation with acoustic features extracted from spontaneous speech from a corpus of English-speaking participants, that is, the Pitt Corpus, by applying deep learning techniques on a graphics processing unit. In their study, patients had a diagnosis of AD with the mean MMSE scores of the healthy control group of approximately 29 versus the AD group characterized by a mean score of 18. The lower performances of our model (accuracy of 86% to discriminate between group 1 and group 3 in the Italian data set) may be due to the use of the MMSE score only to distinguish between groups, which may have resulted in misclassification problems. Toth et al [23] achieved 75% accuracy from a binary classification task on Hungarian-speaking participants to distinguish healthy controls from those with MCI by using leave-one-out cross-validation on a set of 88 participants. Our results slightly outperformed their results on the Italian data set (accuracy of 80%), while we achieved lower performances on the Spanish and the multilanguage data sets (accuracy of 62% and 65%, respectively). However, as in the previous studies [2,24], but differently from our study, Toth and colleagues [23] recruited participants with a diagnosis of MCI based on a neuropsychological assessment. Martínez-Sánchez et al [21] classified dementia among Spanish-speaking participants with an accuracy of 80%. The analysis was conducted to distinguish between 35 patients with AD and 35 healthy participants. They stated that fluency is an important aspect of cognitive decline from spontaneous speech, which was confirmed in our work by Figure 1D since the duration of syllables, phonation percentage, and articulation rate are in the top 5 most important features for the multiclass classification of the Spanish data set.

Our approach is based on acoustic features that can be automatically extracted on-the-fly on short speech segments. The satisfactory accuracy achieved with this approach to distinguish healthy participants from those with mild impairment (80% for the Italian data set) makes our results promising toward the design of a mobile app. Leveraging on this tool, an ecological and transparent mass screening of the early signs of cognitive decline can be performed, for example by analyzing free speech during phone calls. Moreover, since there is no need to store raw data and the information content of the speech is not exploited, this tool would preserve the speaker's privacy.

This work has some limitations. The performance of the models on unseen data, that is, on the test set, worsened overall, probably due to the lack of the generalization power of the model; therefore, there is the need for larger data sets to have more robust classification models. Furthermore, regarding the Spanish data set, another limitation was the lower number of years of education of the recruited participants. Previous studies recruited only participants with more than 6 years of primary education to ensure that participants were fully literate [27]. Another limitation was the use of the MMSE score as the only method to allocate participants into different groups, without collecting information about an eventual diagnosis of MCI or AD, which might have brought to misclassification issues. Furthermore, as reported by Yancheva et al [36], MMSE is affected by a within-participant interrater standard deviation of 3.9 [37,38], which may have resulted in a further wrong group assignment for some participants. Finally, the MMSE test was administered by 2 different professional roles in the 2 recruitment sites—a geriatrician in Italy and a neuropsychologist in Spain, which may have introduced further differences between the 2 data sets.

This work confirmed that it is possible to detect early symptoms of cognitive function decline from the automatic analysis of acoustic features, exploiting a multilanguage approach. Overall, good performances by considering only acoustic features to discriminate between participants with different MMSE scores were achieved. The results obtained on the classification tasks are promising for the development of a screening tool for large-scale monitoring of cognitive function in community-dwelling older adults.

Abstract

Background: Frailty is a widespread geriatric syndrome among older adults, including hospitalized older inpatients. Some countries use electronic frailty measurement tools to identify frailty at the primary care level, but this method has rarely been investigated during hospitalization in acute care hospitals. An electronic frailty measurement instrument based on population-based hospital electronic health records could effectively detect frailty, frailty-related problems, and complications as well be a clinical alert. Identifying frailty among older adults using existing patient health data would greatly aid the management and support of frailty identification and could provide a valuable public health instrument without additional costs.

Objective: We aim to explore a data-driven frailty measurement instrument for older adult inpatients using data routinely collected at hospital admission and discharge.

Methods: A retrospective electronic patient register study included inpatients aged ≥65 years admitted to and discharged from a public hospital between 2015 and 2017. A dataset of 53,690 hospitalizations was used to customize this data-driven frailty measurement instrument inspired by the Edmonton Frailty Scale developed by Rolfson et al. A 2-step hierarchical cluster procedure was applied to compute e-Frail-CH (Switzerland) scores at hospital admission and discharge. Prevalence, central tendency, comparative, and validation statistics were computed.

Results: Mean patient age at admission was 78.4 (SD 7.9) years, with more women admitted (28,018/53,690, 52.18%) than men (25,672/53,690, 47.81%). Our 2-step hierarchical clustering approach computed 46,743 inputs of hospital admissions and 47,361 for discharges. Clustering solutions scored from 0.5 to 0.8 on a scale from 0 to 1. Patients considered frail comprised 42.02% (n=19,643) of admissions and 48.23% (n=22,845) of discharges. Within e-Frail-CH's 0-12 range, a score ≥6 indicated frailty. We found a statistically significant mean e-Frail-CH score change between hospital admission (5.3, SD 2.6) and discharge (5.75, SD 2.7; *P*<.001). Sensitivity and specificity cut point values were 0.82 and 0.88, respectively. The area under the receiver operating characteristic curve was 0.85. Comparing the e-Frail-CH instrument to the existing Functional Independence Measure (FIM) instrument, FIM scores indicating severe dependence equated to e-Frail-CH scores of ≥9, with a sensitivity and specificity of 0.97 and 0.88, respectively. The area under the receiver operating characteristic curve was 0.92. There was a strong negative association between e-Frail-CH scores at hospital discharge and FIM scores (r_s=–0.844; *P*<.001).

Conclusions: An electronic frailty measurement instrument was constructed and validated using patient data routinely collected during hospitalization, especially at admission and discharge. The mean e-Frail-CH score was higher at discharge than at admission. The routine calculation of e-Frail-CH scores during hospitalization could provide very useful clinical alerts on the health trajectories of older adults and help select interventions for preventing or mitigating frailty.

Introduction

Switzerland’s current declared health care policy and its overall national system both aim to support older adults who wish to age healthily in their own homes. Recent statistical trends show increasing numbers of older adults who are multimorbid being hospitalized, thus putting age-related diseases and chronic health conditions at the forefront of the many concerns facing acute health care systems [1,2]. There is growing evidence that frailty syndrome may be a relevant acute hospital care clinical alert to predict complications associated with adverse outcomes [3-6]. Although there is a consensus on the definition of frailty—but perhaps not always on how to measure it—it is widely considered to be a dynamic geriatric condition characterized by an increased vulnerability to external dysfunction, a complex etiology, and intrinsic difficulties distinguishing it from normal aging [7,8]. Frailty is a preclinical state not directly associated with any disease or disability. The scientific literature documents a phenotypical approach to identifying frailty. It uses 3 or more of Fried 5 criteria (unintentional weight loss, exhaustion, low energy expenditure, slowness, and weakness) to recognize prefrailty and the deficit accumulation approach based on Rockwood Clinical Frailty Scale engineering theory [9]. In the phenotypical approach, 3 or more of Fried 5 criteria (unintentional weight loss, exhaustion, low energy expenditure, slowness, and weakness) are used to recognize prefrailty. In Rockwood deficit accumulation approach, frailty is associated with known comorbidities and disabilities, polypharmacy, and the relative risks of adverse drug reactions, rehospitalization, health services use, age-associated sensory deficits, and a lack of social support [9].

Routine hospitalization data stored in patients’ electronic health records (EHRs), including social, clinical, medical, and pharmacy data, could be important sources of frailty detection information during hospitalization and for assessing and comparing the different phases of hospitalization, such as in admission and discharge [10,11]. However, EHRs do not currently enable the construction of a standard reference measure of frailty for clinical and research purposes—they require customization. Researchers would require different data types (eg, diagnoses, clinical data, and health service codes) collected over specified periods using specific, discriminating coding methods [10,12]. Indeed, the length of the assessment period during which codes were measured could affect the measure’s accuracy when capturing certain chronic conditions. Another challenge is that coding systems and medical practice can change over time or across geographical regions. Switzerland’s different regional health care systems all use the *ICD-10* (*International Classification of Diseases, Tenth Revision*), as their medical coding system [13]. New billing codes are generated for new health care procedures (in the *ICD-11* [*International Classification of Diseases, Eleventh Revision*]) and services (eg, SARS-CoV-2 vaccination), and numerous codes are withdrawn each year [14]. Therefore, how well the frailty measures routinely collected by health care professionals perform should be evaluated periodically using updated datasets [15]. Developing a frailty measure from patients’ EHRs requires restricting the population to individuals with high rates of data completeness within the system to avoid bias due to missing data [16]. Few studies have explored customizing database-derived frailty measures using EHRs from a hospital register [10,12,16,17]. Measures using EHRs focus on investigating exposure to the risks of a particular outcome (such as syndromes, death, or reoccurrences of a disease) based on the selection of a group of patient characteristics and using a statistical model to explore the effectiveness of interventions and treatments among hospitalized inpatients [18]. However, any model’s usefulness and relevance depend on its accuracy. Few studies have investigated the robustness of frailty measures taken from routinely collected datasets using 2 approaches to frailty simultaneously [10]. Indeed, the Fried phenotypic approach has found a correlation of 0.6-0.7 between hospital EHRs and retrospective medical assurance data; the Rockwood deficit-accumulation approach has found correlation coefficients of 0.2-0.6 [10]. In particular, a recent study by Kim et al [19] showed that a frailty index, estimated using data routinely collected by health care professionals for older adults’ medical assurance claims (equivalent to Medicare claims), performed better than a comorbidity index for predicting disability, mobility impairments, recurrent falls, and days spent in a skilled nursing facility [19]. However, an e-Frailty Index >0.19, a threshold for frailty developed in the United Kingdom, had a positive predictive value of 0.11 (R^2) for death in the next 3 months among primary care patients in that country [19]. Nevertheless, a database-derived measure of frailty might be able to provide a clinical alert of frailty across older adults, although it would be less readily interpretable deterministically for a particular individual. A cutoff point for positive screening can be determined according to percentile distributions (eg, top 5%), to sensitivity and specificity to a state of frailty (eg, 90% sensitivity for detecting a frailty phenotype), or to predefined, clinically relevant thresholds (eg, ≥0.2 according to a deficit accumulation frailty index) after considering clinical contexts (eg, inpatient or preoperative screening) and the resources available for detailed assessments and care management [20].

Few studies to date have used a database-derived frailty measurement score as a clinical alert (ie, change in frailty levels over time) to estimate the effects of an intervention (medical and medication treatment) or hospitalization (length of stay). In addition, frailty measures’ responsiveness to improvements or deteriorations in health status is still under investigation, as is the minimum clinically significant change they can recognize. Most of the research done in North America, Western Europe, and Asia has explored measures of frailty developed from primary care EHRs [10,11,21,22]. The items of clinical knowledge selected for these measures used data relevant to frailty’s overall clinical picture [23]. This paper’s overall aim is to demonstrate that data from hospital registers, which collect clinical and administrative information (for billing), can be used to identify a clinical alert of frailty among patients at the time of their hospital discharge. We hypothesized that the e-CH-frailty (Switzerland) clinical alert would significantly increase hospital discharges compared to the e-CH-frailty scores at hospital admission.

Methods

Study Design

We conducted a register-based study of patients' routinely collected EHR data to customize a database-derived frailty measure. Data came from a large, longitudinal EHR dataset extracted from the register of a multisite public teaching hospital in Switzerland [24]. Once a database-derived frailty measure is developed, the critical next step is validating it against a reference standard, 1D, or multidimensional measure of frailty [20]. Due to the lack of any routine frailty assessment tool within our database, we selected the multidimensional Functional Independence Measure (FIM) [25], recommended by Dodds et al [25], Carlson et al [26], and De Saint-Hubert et al [27], as an alternative means of convergent validation [19,20].

Study Population and Variables

The dataset comprised the Valais Hospitals' sociodemographic, clinical, medical, and drug data. Valais Hospitals is a multisite public hospital in Switzerland serving a population of almost 360,000. It recorded over 40,000 hospitalizations and 650,000 ambulatory visits in 2023, mainly at its 2 primary hospital centers, 1 in each of the canton's 2 distinct linguistic regions [25]. The EHR dataset included all inpatients aged 65 years or older admitted or readmitted between January 1, 2015, and December 31, 2017 (N=53,690). Incomplete records with more than 20% missing health data or records without sociodemographic data were excluded (excluded records numbered 6947, 12.93%). This study did not consider older adult inpatients who were admitted to the emergency department but returned to their homes within 24 hours. These 3 years were selected based on the availability of systematic, well-coded patient data. Without unique patient identifiers, the number of different patients and their readmission rates could not be explored. Per this study's aims, we included the sociodemographic variables of age, gender, prehospital provenance, and discharge destination or death during hospitalization (Table 1). For patients' physical status, we included the variables of general mobility, mobility for changing position, gait, balance disorders, fall risk, exhaustion, independence in upper- and lower-body care, upper- and lower-body dressing or undressing, and bladder continence (Multimedia Appendix 1). Unfortunately, the EHR did not include data on the older adult inpatients' nutritional status for the selected period (January 2015 to December 2017). For their cognitive status, we included the variables of alertness or consciousness, orientation, concentration, verbal expression, capacity and skills to react to the demands of daily life, and ability to learn (Table 2). In addition, we noted the number of comorbidities calculated at each hospitalization (using *ICD-10*) [28].

Variable Selection for the e-Frail-CH Measurement Instrument

Following a literature review on frailty instruments, the authors were inspired by the selection of clinical data and variables reported in the dimensions covered by the Edmonton Frail Scale (EFS; Table 2) [29]. The EFS assessment tool comprises 10 items [29]. Considering this study's retrospective nature, EHR data on the risk of falls replaced a physical assessment of mobility. The EFS has been validated against the comprehensive geriatric assessment tool and was shown to be reliable and feasible for routine use by nongeriatricians [30,31]. Rolfson et al [29] described scores ranging from 0 (not frail) to 17 (severely frail), with scores of 8 or above defining patients as frail [29]. We selected data associated with the clinical features of frailty measured by the EFS to compute a data-driven frailty measure [29]. Using this approach, the clinical variables of frailty were defined as (1) the presence of any of the selected codes (no=not present; yes=present) or (2) the proportion of the codes present (0=not present or good health; 1=sometimes present or moderate health; 2=always present or bad health).

We constructed our instrument using clinical information from the following 9 dimensions of frailty: cognition (0=no errors, 1=minor errors, or 2=other errors), general health status (0=good health, 1=1-2 hospital visits, or 2=more than 2 hospital visits), functional independence (0=0-1 activities of daily living [ADLs] requiring help, 1=2-4 ADLs require help, or 2=5-8 ADLs require help), informal social support (0=always present, 1=sometimes present, or 2=never present), medication use (0=no polypharmacy or adherence problems, or 1=polypharmacy or adherence problems), nutrition (0=no weight loss or 1=substantial weight loss of >10%), mood (0=no depression or 1=depression), continence (0=no urine incontinence or 1=urine incontinence), and self-supported performance (0=able to do heavy work, walk upstairs, or walk 1 km; or 1=not able to do heavy work, walk upstairs, or walk 1 km). Scores of 0-7 were considered "not frail." Scores of 8-9, 10-11, and 12-17 were considered "mild frailty," "moderate frailty," and "severe frailty," respectively [32].

Construction of the Data-Driven Frailty Measure Based on the EHR

The inpatient EHR dataset extracted included each older adult hospitalization between January 1, 2015, and December 31, 2017—3 years selected based on the availability of systematic, well-coded patient data. In addition, variables were selected according to this study's aim and as closely as possible to the EFS, which we used as a reference instrument to create the e-Frail-CH for this study.

Description of the Data

We selected the 8 dimensions of frailty listed in Table 2 (column 1), their indicators (column 2), their aggregated response categories (column 3), and their corresponding codes (column 4). We used them to construct the clusters for each dimension. Columns 5 and 6 present each response category's distribution (as a percentage) within its respective dimension at hospital admission and discharge (when available). Note that the dimension of nutrition was not included in the e-Frail-CH instrument due to high numbers of missing values (92.7% missing at admission and 83.8% missing at discharge). Overall, patients at discharge presented with higher levels of dependency than at admission. In the dimension of functional independence, patients' ability to self-care for their upper body increased (62.11% to 63.42%) between admission and discharge. The same result was noted for mood, with more participants feeling exhaustion at admission than at discharge (18.6% fell to 17.39%), and for an indicator of continence, with more urine drainage devices used at admission than at discharge (9.59% improved to 9.39%). Finally, for the dimension of cognition, the evaluation of patients' states of consciousness found that 97.38% were fully alert at admission, 2.39% were in a state of drowsiness or stupor, and 0.19% were comatose. These proportions were 95.49%, 3.49%, and 0.99% at discharge, respectively. Table 2 presents all these data extracted from the Valais Hospitals' register and used to construct the e-Frail-CH instrument. Almost all the differences between admission and discharge shown in Table 2 (last column) were highly significant ($P<.001$). However, the distributions of only 2 indicators were not significantly different, namely upper body self-care skills and having a urine drainage device.

Data Analysis

In total, 2 experienced data managers (BW and HV) inspected the EHR dataset for extraction errors, missing values, and data consistency. Missing values were not replaced. Data were then imported into SPSS software (version 29, IBM Corp), for analysis. The e-Frail-CH instrument was constructed using hierarchical cluster analysis. This statistical technique involves grouping patients with similar characteristics in the dataset, such as similar diagnosis codes, clinical features, or self-reported performances. After examining the characteristics of each group derived from the hierarchical cluster analysis, a group with 6 or more diagnoses indicative of frailty was identified as the "frailty group." For most of the dimensions of frailty, such as cognition, functional status, social support, and self-reported performance, we created clusters of variables based on an exploratory algorithm that uses the SPSS TwoStep Cluster Analysis procedure—a flexible, adaptable tool for clustering data. This exploratory procedure is designed to reveal natural groupings (or clusters) within a dataset that would not otherwise be apparent. Its algorithm has several advantages over traditional clustering techniques: (1) it can create clusters based on both categorical and continuous variables, (2) the number of clusters can be selected automatically or manually, and (3) it can analyze large data files efficiently. The TwoStep Cluster Analysis procedure handles categorical and continuous variables using a likelihood distance measure that assumes that variables in the cluster model are independent. The number of clusters to be formed is based on the Schwarz-Bayesian information criterion [33]. The higher the coefficient, the better the corresponding algorithm, as this coefficient is akin to a correlation coefficient [34]. Based on a Kolmogorov-Smirnov analysis, all the data included in the cluster analysis showed normal distributions, and the e-Frail-CH scores at admission and discharge were compared using a 2-tailed paired *t* test.

SPSS TwoStep Cluster Analysis Algorithm for the e-Frail-CH Instrument

The 2-step procedure's first step is constructing preclusters to reduce the matrix size and the distances between all the possible pairs of data points. Preclusters are simply clusters of the original cases that are used in place of the raw data in the hierarchical clustering. As a case is read, the algorithm decides, based on a distance measurement, whether the current case should be merged with a previously formed precluster or start a new precluster. In the second step, SPSS uses the standard hierarchical clustering algorithm on the preclusters. This refines the initial estimate by finding the most significant change in distance between the 2 closest clusters in each hierarchical clustering step. Forming clusters hierarchically allows us to explore a range of solutions with different numbers of clusters. At this point, the algorithm can propose a number of clusters, on an experimental basis, using the Schwarz-Bayesian information criterion, but the number of clusters can also be defined in advance. Our top-down, divisive approach groups all the observations into 1 cluster and then splits it recursively as we move down the hierarchy. The divisive coefficient varies from 0 (a poor coefficient) to 1 (a strong coefficient) across the observations [34,35]. Summing all the subcluster scores to create an overall frailty score made our strategy as close as possible to that used in the EFS framework and enabled us to count the score attributed to each of our different subdimensions. The scores of certain dimensions of frailty were defined directly in an affirmative manner, without clustering. This included the dimensions of general health status (defined by the number of *ICD-10* and CHOP [Swiss classification of surgical procedure] surgery intervention codes at discharge), medication (defined by the number of medicines prescribed at admission and discharge), mood (defined by the presence or absence of exhaustion or depression), and continence.

Validity Analysis

We performed a validity analysis to explore the e-Frail-CH instrument's sensitivity, specificity, and cut point accuracy between nonfrail and frail. The sensitivity analysis was constructed using hospital discharge data. We analyzed receiver operating characteristics (ROCs) to reveal the e-Frail-CH instrument's trade-off between sensitivity and specificity [36]. The instrument was structurally validated using the multidimensional FIM as described by Naschitz et al [37] and Stuck et al [19,20,25,37,38]. The FIM instrument includes measures of independence in self-care, including sphincter control, transfers, locomotion, communication, and social cognition. It is an 18-item, 7-level, ordinal scale sensitive to the changes occurring during a comprehensive inpatient medical rehabilitation program. Its total score ranges from 18 (entirely dependent) to 126 points (completely independent), using the levels of assistance individuals need to grade their functional status between the extremes. The instrument can assess a patient's level of disability or a change in their status in response to rehabilitation or a medical intervention. Our sample population's scores were recorded as dependent patients (FIM scores of 18-53), patients with modified independence (54-107), and independent patients (scores from 108 to 126).

Ethical Considerations

The Human Research Ethics Committee of the Canton of Vaud (2018-02196) gave its ethics approval, which enabled the research team to partner with the hospital's data warehouse to access the appropriate dataset. Given the retrospective data source, obtaining consent from the patients concerned was impossible or posed disproportionate difficulties. This study respects the legal requirements for research projects involving data reuse without consent, as set out in Article 34 of Switzerland's Human Research Act. As per Switzerland's Federal Act on Data Protection, which is regulated at the federal and cantonal levels, patients' sensitive personal data, such as their date of birth, address, educational level, and profession, were excluded from the dataset [39]. However, this study's participants had signed a general consent form based on informed consent, in which they agreed that their data could be used for research purposes.

Results

e-Frail-CH Sample

Of the 53,690 hospitalization lines in the dataset, 46,743 and 47,361 met our inclusion criteria for computing 2-step hierarchical clustering for hospital admission and discharge, respectively. About 5.58% (2646/47,361) of the sample died during the hospitalization period selected and thus could not be considered at discharge.

Constructing the e-Frail-CH Admission and Discharge Measurement Instrument

At the beginning of its construction, the e-Frail-CH measurement instrument's 8 basic dimensions were selected based on the available EHR data that closely matched the EFS dimensions (Table 3, column 1). The selected dimensions' clustering quality was computed and assessed using the SPSS TwoStep Cluster Analysis procedure (column 2). Column 3 presents each cluster-construction item's score. In contrast, column 4 indicates the conditions used to attribute different variables to different hospital admission assessment categories, either in an exploratory way or manually, by using the order of the indicators in Table 2. Finally, column 5 presents the relative distributions (as percentages) of each dimension's score at hospital admission. Columns 6 and 7 used the same information for hospital discharge.

The intermediate category for cognition indicators, coded 1, was attributed to patients admitted awake and conscious, displaying full capacity regarding temporal-spatial orientation but a limited ability to acquire knowledge or function in the ADL. The worst state of cognition, coded 2 at hospital admission, corresponded to any other indicator configuration. This clustering solution presented excellent summarizing quality, with a score of 0.8 on a scale from 0 to 1 (Table 2). The dimension of general health status (the same measure at hospital admission and discharge) was not clustered but defined in an affirmative manner based on the number of *ICD-10* and CHOP codes at hospital discharge only. The best health status, coded 0, was given to patients with just 1 *ICD-10* or CHOP code (2.39% of cases); the intermediate score, coded 1, was given to patients with 2 *ICD-10* or 2 CHOP codes (6.21% of cases), while the worst score, coded 2, was given to people with more than 2 *ICD-10* or CHOP codes (91.39% of cases; Table 3).

Table 3. Distribution of frailty scores at admission (n=46,743) and discharge (n=47,361).

e-Frail-CH[a] score	Distribution at hospital admission, n (%)	Distribution at hospital discharge, n (%)	Relative difference in e-Frail-CH distribution from admission to discharge (%)
0 (no frail)	268 (0.57)	226 (0.47)	–0.1
1	1040 (2.22)	782 (1.65)	–0.5
2	5078 (10.86)	2784 (5.87)	–5
3	6871 (14.69)	6710 (14.16)	–0.5
4	7297 (15.61)	7350 (15.51)	–0.1
5	6546 (14)	6664 (14.07)	0.1
6	5438 (11.63)	5766 (12.17)	0.6
7	4373 (9.35)	5249 (11.08)	1.7
8	3436 (7.35)	3900 (8.23)	0.8
9	2670 (5.71)	2677 (5.65)	0
10	1878 (4.01)	2008 (4.23)	0.2
11	1488 (3.18)	2511 (5.30)	2.1
12 (severely frail)	360 (0.77)	734 (1.54)	0.7
Total	46,743 (100)	47,361 (100)	N/A[b]

Cut Points Between the e-Frail-CH and FIM Scores at Hospital Discharge

Functionally unimpaired patients (with FIM scores ≥107) had optimal e-Frail-CH cutoff scores ≥6, with an excellent sensitivity cut point of 0.82, a specificity cut point of 0.88, and an area under the ROC curve of 0.85. Patients with the lowest FIM scores (18-53, n=272, 0.01%), indicating severe dependence, had optimal e-Frail-CH cutoff scores ≥9, with an excellent sensitivity cut point of 0.97, a specificity cut point of 0.88, and an area under the ROC curve of 0.92.

Prevalence of Frailty Among Admitted and Discharged Patients

Based on the e-Frail-CH instrument and considering equivalent cutoffs based on the FIM score of 6, a total of 42.02% (n=19,643) of older adult patients were considered frail at admission, whereas 48.23% (n=22,845) were frail at discharge. e-Frail-CH scores are constructed by summing an individual's scores for each dimension of frailty at hospital admission and discharge (Table 3). The theoretical score range is 0-12, with 0 meaning no frailty and 12 representing the highest state of frailty. The distribution approached normality for both scales with a slight positive skew. The mean hospital admission score (5.30, SD 2.59) was lower than at discharge (5.75, SD 2.65), indicating deterioration in most cases. The difference between the mean e-Frail-CH admission and discharge scores was significant: $t_{60,651}$=0.45, 95% CI 0.44 to 0.48, *P*<.001).

Association Between the e-Frail-CH and the FIM at Hospital Discharge

A strong negative association was found between e-Frail-CH scores and FIM scores at hospital discharge. Calculating a Spearman rank correlation (r_s) of –0.844 (*P*<.001) showed that they were oriented in opposite directions.

Discussion

Principal Findings

Using routinely collected clinical and medical information, this research study developed a data-driven measurement instrument to compare older adult frailty at admission and discharge from Valais Hospitals' multiple acute care sites. Frailty was measured using a cumulative approach, incorporating 8 dimensions of inpatients' diagnostic, health, and clinical characteristics. These characteristics were very similar to those in prior studies measuring the prevalence of frailty based on accumulations of *ICD-10* diseases [28,40]. They were also similar to those in the studies by Hilmer et al [32] and Liang et al [28], which concluded that frailty appears to be a good predictor of adverse health outcomes and should be used as a health indicator in acute clinical practice to help formulate care and discharge plans and improve shared decision-making [32,41,42].

To transform frailty into a health indicator, we used hierarchical cluster analysis, a statistical technique that groups together individuals in a dataset whose measured characteristics are similar. These characteristics could be diagnosis codes or social, clinical, and medical data reported during a specified period [43,44]. However, hierarchical cluster analysis can require significant computing power for large datasets and yield different clusters in different datasets. Inspired by the components of EFS and Hilmer et al [32], this study tried to overcome the latter limitation by conducting its cluster analysis on a subset of a large hospital's overall clinical dataset and developing a model to predict patients' membership of different frailty groups [29]. Although our approach identified frail older adult individuals without requiring a dataset with a reference standard frailty measure, how the number of groups in the cluster analysis (anything other than a single, large frailty group) should be determined is open to interpretation. Frail older adult individuals will likely not all be classified into 1 group. For example, frail patients with cancer and frail patients with heart disease may be classified into different groups despite similar levels of frailty [40]. Our e-Frail-CH measurement instrument used information available within patients' EHRs to identify their varying degrees of frailty. The 2-step hierarchical clustering strategy demonstrated robust results, with divisive coefficients between 0.5 and 0.8 fitting well with the results reported in similar studies [45,46]. e-Frail-CH's high sensitivity, specificity, and areas under the ROC curve confirmed the instrument's robustness. The EHR dataset included more than 45,000 valid hospitalizations or rehospitalizations used to construct the e-Frail-CH measurement instrument's clusters. This should be considered an extremely big set of routinely collected data, especially when compared to the smaller samples used in the studies by Horn et al [47] and Pronk et al [47,48].

The summing of preclustered components enabled us to develop a clinical frailty score for older adults at acute hospital admission and discharge. Routinely identifying potentially frail older adult inpatients opens the way to targeted needs assessments and clinical alerts, better integrated care coordination, and coordinated planning to deliver necessary interventions during older adults' health care trajectories and follow-up [18,20].

Our innovative approach aligns with a recent investigation in Spain by Orfila et al [40], who created and validated an electronic frailty score based on hospitalized patients' clinical EHR data [40]. This study has the advantages of being inexpensive and transferable to other health care settings, especially in Switzerland. However, e-Frail-CH is not a clinical diagnostic tool—it is a population risk stratification tool that identifies groups of people likely to live with varying degrees of frailty. It cannot categorize specific individuals. Consequently, longitudinal assessments should take place to support the diagnosis when e-Frail-CH identifies an individual with potentially severe or moderate frailty. This study showed a 0.45-point mean increase in the frailty score between hospital admission and discharge. Although this value is essential for research purposes, the magnitude of such an e-Frail-CH score change might have clinical implications for individuals.

The e-Frail-CH instrument can be used as a clinical alert instrument in longitudinal retrospective studies and tested as a continuous variable. However, although it is suitable for acute care settings, the e-Frail-CH instrument's screening effectiveness should be tested and compared against instruments screening for frailty in specific diseases or among preoperative patients. On the other hand, the EFS, the inspiration for our frailty scale, has recognized good psychometric properties [29,49,50]. The e-Frail-CH measurement instrument provides new insights into the potential for data-driven frailty assessments and comparisons of patient frailty during acute hospital trajectories [51,52]. Frailty remains complex, often undetected or confounded with other geriatric conditions or comorbidities [53]. To respond positively to frailty and its challenges, acute health care institutions need to be prepared for it: they should attempt tertiary preventive measures to take care of people exhibiting frailty and, where possible, report frailty scores for optimal hospital care planning. This could lead to targeted assessments and person-centered care plans being developed as the condition progresses to severe frailty. Alternatively, e-Frail-CH could guide optimized integrated care planning to help reverse emerging frailty among at-risk older adults [47,54]. Other investigations on data-driven electronic frailty indicators [8,39,55] corroborate our ideas about the e-Frail-CH measurement instrument. However, our investigation of frailty at acute hospital admission and discharge presents the added value of allowing an evaluation of changing frailty scores between these 2 critical points in a care trajectory. Additionally, e-Frail-CH enables patients who are frail to be distinguished from fit ones. Recent clinical guidelines recommend that inpatients be screened for frailty using a validated clinical alert instrument appropriate to the clinical setting, whether it is data-driven or not [53].

Strengths and Limitations

One of this study's main strengths was its innovative use of hospital register data-driven frailty detection or clinical alert indicator in acute care. To the best of our knowledge, few studies have investigated frailty using hospital registers. Another strength was using an approach that hierarchically clustered existing data to show frailty at hospital admission and discharge. Using an existing large-scale dataset and coding from patients' EHRs was a crucial advantage because we did not have to solicit busy clinicians or patients who are frail and already weakened by multiple health conditions.

Nevertheless, this study had some limitations, notably its retrospective design and use of routinely collected hospital admission and discharge data. However, this could be considered a strength based on the clinical relevance of data in real-life hospital trajectories. As a result, we were unable to include data on patient nutrition due to that variable's absence in the database for the selected period; nutrition is an essential dimension in assessing frailty [29]. Additionally, we could not control for potential data assessment errors made by health care staff during admission and discharge hospitalization. We could not suggest that our CH-e-frailty indicator was in a causal relationship with hospitalization trajectories, merely that it might serve as a clinical alert that could be communicated to other health care professionals (such as in a discharge letter) taking over responsibilities for older inpatients. Without a unique, encrypted patient identifier, we were unable to track inpatients who might have undergone multiple hospitalizations from 2015 to 2017, including some who died during their stay. The absence of data on patients' functional status preadmission meant that we could not assess changes to that status during hospitalization or the influence of improving or deteriorating functional and cognitive impairments. Furthermore, using the FIM as an instrument for making comparisons should be carried out cautiously as it does not measure frailty directly but rather the level of disability. Further research should be conducted to reveal the profiles of older adult inpatients at risk of frailty. This means we must be careful about the external validity of our results and their interpretations. Finally, our findings should be considered with care because it was impossible to detect rehospitalizations, which may be a confounding factor in measuring frailty during hospital trajectories.

Conclusion

The e-Frail-CH measurement instrument developed in this study could be applied widely across Switzerland to make the most of the routinely collected data on older adult inpatients in its acute care hospitals. This study demonstrated that patients' EHRs contain easily extractable data that can be used to identify frail inpatients and to compare measures of frailty at admission and discharge. Furthermore, by using the e-Frail-CH measurement instrument, frailty could easily be identified using broader sociodemographic data and patients' EHRs. Introducing a routine estimation of potential frailty among older adults via automated e-Frail-CH measurements could be a valuable way of identifying at-risk patients or clinical indicator and managing their frailty along their health trajectories. Further research could be carried out by using the e-Frail-CH measurement instrument score as both a long-term outcome and a patient-reported outcome [56].

Abstract

Background: Transcatheter aortic valve replacement (TAVR) is a commonly used treatment for severe aortic stenosis. As degenerative aortic stenosis is primarily a disease afflicting older adults, a frailty assessment is essential to patient selection and optimal periprocedural outcomes.

Objective: This study aimed to enhance frailty assessments of TAVR candidates by integrating real-world structured and unstructured data.

Methods: This study analyzed data from 14,000 patients between January 2018 and December 2019 to assess frailty in TAVR patients at the University of Florida. Frailty was identified using the Fried criteria, which includes weight loss, exhaustion, walking speed, grip strength, and physical activity. Latent Dirichlet allocation for topic modeling and Extreme Gradient Boosting for frailty prediction were applied to unstructured clinical notes and structured electronic health record (EHR) data. We also used least absolute shrinkage and selection operator regression for feature selection. Model performance was rigorously evaluated using nested cross-validation, ensuring the generalizability of the findings.

Results: Model performance was significantly improved by combining unstructured clinical notes with structured EHR data, achieving an area under the receiver operating characteristic curve of 0.82 (SD 0.07), which surpassed the EHR-only model's area under the receiver operating characteristic curve of 0.64 (SD 0.08). The Shapley Additive Explanations analysis found that congestive heart failure management, back problems, and atrial fibrillation were the top frailty predictors. Additionally, the latent Dirichlet allocation topic modeling identified 7 key topics, highlighting the role of specific medical treatments in predicting frailty.

Conclusions: Integrating unstructured clinical notes and structured EHR data led to a notable enhancement in predicting frailty. This method shows great potential for standardizing frailty assessments using real-world data and improving patient selection for TAVR.

KEYWORDS

transcatheter aortic valve replacement; frailty; cardiology; machine learning; TAVR; minimally invasive surgery; cardiac surgery; real-world data; topic modeling; clinical notes; electronic health record; EHR

Introduction

Degenerative severe aortic stenosis is estimated to affect 3.4% of the older population [1]. It results in reduced cardiac output, which reduces activity tolerance and often restricts the ability to perform activities of daily living [2,3]. This stage is associated with high short-term mortality [4]. The most common treatment that helps many patients resume an active lifestyle is transcatheter aortic valve replacement (TAVR), a less invasive procedure than open-heart surgery that replaces the diseased or damaged aortic valve [5]. Unfortunately, about 25% to 35% of patients either die or achieve no functional, morbidity, or mortality benefit from TAVR [6,7]. To optimize patient selection and postsurgical outcomes, accurate tools to acquire personalized, pertinent health data for TAVR candidates can provide valuable insights for patients and their clinicians to make informed decisions in presurgical clinics [6,8].

The American College of Cardiology's guidelines [9], along with various clinical studies [8,10,11], have identified frailty as a risk factor for post-TAVR mortality and morbidity. In a systematic review, Sepehri et al [12] demonstrated the relationship between frailty and adverse postsurgical outcomes in the cardiac population. In addition, research in health economics has shown that frail patients undergoing cardiac procedures incur higher hospitalization costs than nonfrail patients [13]. Given the clinical and economic implications of the TAVR procedure, there is a need to standardize the frailty assessment. This can aid in formulating strategies to enhance post-TAVR outcomes in frail patients. Such strategies may include partnering with geriatricians, opting for monitored anesthesia care, and employing 2 surgeons for complicated procedures, among several others [14].

Existing risk scores, such as the Society of Thoracic Surgeons score and the European System for Cardiac Operative Risk Evaluation, are commonly used for patients referred for cardiac surgery. These scores are useful, but they are stratified into lower-risk patient groups referred for cardiac surgery and do not meet the specific needs of TAVR patients [15-17]. The current methods of assessing frailty in patients undergoing TAVR have significant limitations. A wide variety of tests and instruments are used across studies, many of which have not been robustly evaluated for this specific patient population [15,18]. For example, some studies use subjective methods such as the eyeball test, which relies on visual assessments to gauge frailty but lacks standardization and objective criteria [15]. Other instruments like the Katz Index of Independence in Activities of Daily Living [19] and the Kansas City Cardiomyopathy Questionnaire [20] are often employed in TAVR clinics to assess functional dependency in older individuals, focusing on daily living activities like feeding, bathing, and dressing. While these assessments are valuable in evaluating different aspects of frailty, they vary significantly in their focus and methodology, leading to inconsistencies in frailty classification among TAVR patients. Additionally, they are not specific to the TAVR population. The Fried frailty phenotype [21] and the Rockwood Frailty Index [22] are well-established and validated frailty assessments. However, these assessments require a detailed physical examination, patient interviews [21], and the completion of surveys [22], which may be time consuming and resource intensive. For example, the Fried frailty phenotype assessment takes 15 - 20 minutes [23], and the Rockwood Frailty Index requires answering a 70-item questionnaire [22], which can burden health care providers and patients, hindering the adoption of frailty assessments and raising concerns about their feasibility, particularly in high-volume and resource-limited settings.

The goal of this study is to create a novel method that utilizes both structured and unstructured real-world data, along with machine learning (ML) techniques, to construct a frailty index that is specific to patients with aortic stenosis who are scheduled to undergo a TAVR procedure.

Methods

Ethical Considerations

This retrospective study utilized perioperative data collected from January 2018 to December 2019, as part of a federal study (R01 AG055337, CP) approved by the institutional review board of the University of Florida, with a waiver for Health Insurance Portability and Accountability Act compliance and an honest broker for medical record retrieval. The research adhered to the Declaration of Helsinki and followed all the institutional protocols. Participants provided written informed consent at the time of data collection.

Study Population

The study extracted data on 14,000 patients from a deidentified historical database. A specific subset, the TAVR cohort, was identified using the Current Procedural Terminology code 33361, which narrowed the focus to 131 patients. All these patients had aortic stenosis as one of their symptoms.

Frailty Phenotype and Target Variables

A person is classified as frail if they meet 3 or more of the following conditions: (1) unintentional weight loss of 10 pounds or more over the past 6 months; (2) a sense of persistent exhaustion, characterized by a moderate feeling that normal activities were strenuous over the past week or a moderate inability to initiate activities; (3) a reduced pace in walking, as assessed by a nurse; (4) diminished grip strength, determined by a gender-specific T-score below −2.5, based on the highest grip strength recorded across 3 attempts using a Jamar hydraulic hand dynamometer (Model J00105, Lafayette Instrument Europe); and (5) a self-reported decrease in physical activity, gauged by the Duke Activity Status Index [24]. The scoring range is from 0 to 5; individuals meeting fewer than 3 of these criteria are considered nonfrail. This frailty assessment is documented in electronic health records (EHRs) to assist in planning perioperative care. In the preoperative anesthesia clinic, both the nursing staff and anesthesia professionals undergo training to perform frailty assessments, guided by published criteria [21,25], alongside documenting educational background and conducting cognitive evaluations.

Topic Modeling

Latent Dirichlet allocation (LDA) is a statistical model used in the field of natural language processing to uncover the hidden thematic structure in extensive collections of documents. We used LDA to generate 150 topics on clinical notes collected 60 days before surgery. A total of 543,520 clinical notes from 18,513 patients were collected. We removed preoperative evaluation notes that documented the results of the Fried frailty phenotype score to avoid information contamination. During data preprocessing, we found that some clinical notes contained similar information about the patients. To overcome this issue, we calculated the similarity between clinical notes that share the same NOTE_KEY using cosine distance and removed the notes with a similarity score greater than 80%. Special characters were removed, and all uppercase letters were converted to lowercase. Three types of words from the clinical notes were removed: (1) high-frequency words that were not closely related to medical symptoms, (2) words with a frequency less than 30, and (3) common stop words. We further performed stemming to reduce the words to their root form to simplify and standardize the vocabulary. After the data preprocessing, a total of 170,731 notes from 18,012 patients were included. Topic modeling was based on 50,000 randomly selected clinical notes. Topics of the remaining clinical notes were predicted and aggregated to the individual level to represent if the patients had a mention of a certain topic.

Structured EHR Data

Preoperative attributes extracted from structured EHR data encompassed patient details available up to 6 months prior to their frailty evaluation. These included sociodemographic data (like age, gender, race, and years of education), medical history and severity (such as cancer history and the American Society of Anesthesiologists [ASA] physical status classification [26]), along with the latest biochemical markers typically recorded in preoperative settings (eg, hemoglobin and hematocrit levels).

Sociodemographic attributes captured information such as the patient's age at frailty evaluation, gender, race, marital and employment status, and educational attainment. We divided age into 3 categories: under 70 years, between 70 and 79 years, and over 80 years. Education level was quantified by the total years of formal education [27], with each year of progression counted and repetitions not contributing to the total. For instance, completion of high school was marked as 12 years, a bachelor's degree as 16 years, and so on. Medical history and acuity features included various medical conditions, the ASA physical status score, and the type of clinical encounter.

Medical conditions were binary indicators based on whether a patient had certain conditions, with the *International Classification of Diseases and Related Health Problems, Tenth Revision*, diagnosis codes condensed into Clinical Classifications Software categories for a more clinically relevant summarization. Conditions appearing in at least 10% of a broader cohort were selected as features for the ML models. The ASA score, ranging from 1 to 5, assessed patient health, with scores 1-2 indicating low-risk or mild systemic disease, and scores 3 and above signaling serious systemic illness.

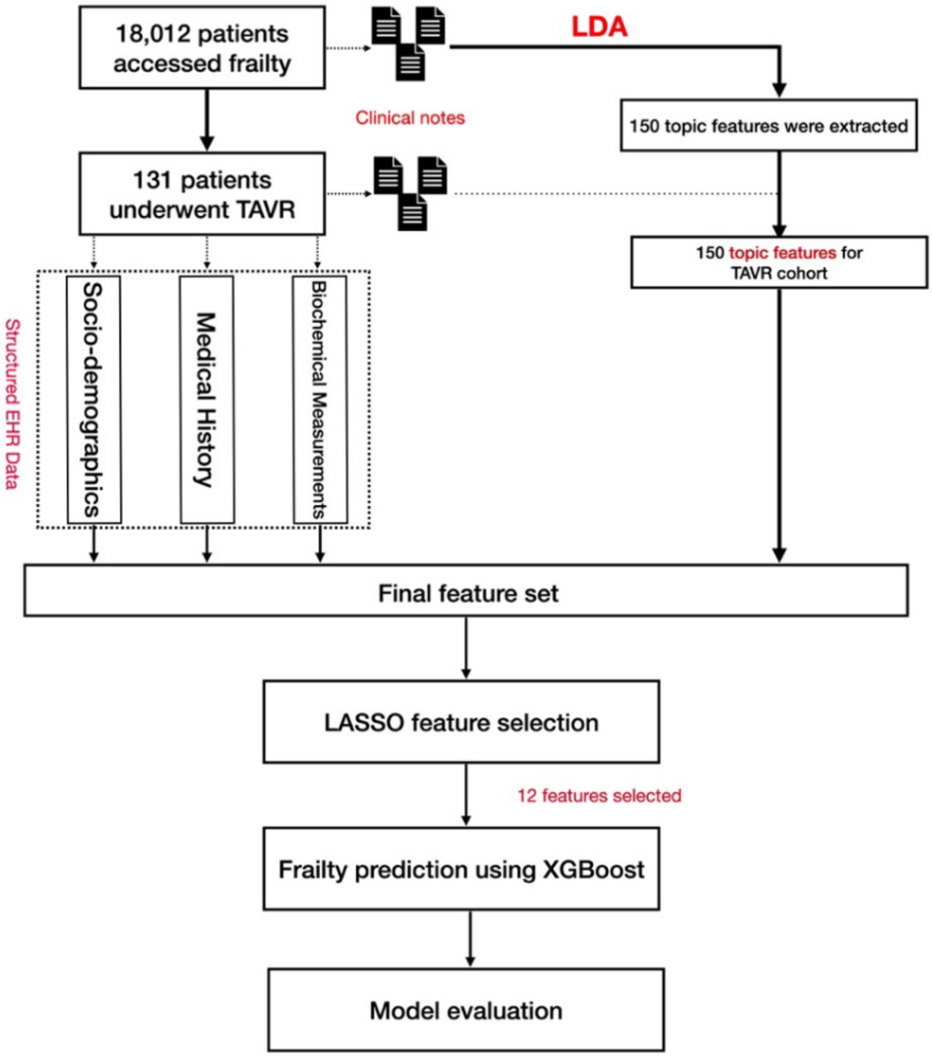
Biochemical features included hematocrit, hemoglobin, and platelet count, with hemoglobin and hematocrit levels recommended for evaluation in older patients (65 years and above) undergoing significant surgery or those with a history of severe anemia undergoing minor surgery.

Integration of Topic Features and Structured EHR Features

We manually reviewed topics generated from topic modeling and removed those that were not related to medical findings, resulting in 121 topic features in total. TAVR patients without clinical notes were removed (n=34), resulting in 97/131 patients in the training and evaluating ML models. Table S1 in Multimedia Appendix 1 compares the demographics between patients who were removed due to the absence of clinical notes and those who were used for modeling. After combining features generated from topic modeling and those from structured EHR data, we performed least absolute shrinkage and selection operator (LASSO) regression to reduce the feature space. Different parameters for regularization strength were examined, and the one that achieved the highest area under the receiver operating characteristic curve (AUC) for predicting frailty was selected for feature selection. We further applied Extreme Gradient Boosting (XGBoost) on features selected from LASSO to predict frailty. XGBoost is an ensemble learning method that uses decision tree frameworks. It creates models to improve the efficacy of preceding trees by diminishing errors through gradient descent. The resulting frailty index from XGBoost is a continuous score between 0 and 1, representing the probability of a patient being predicted as frail; high scores indicate a greater likelihood of frailty in TAVR patients.

To assess the additive value of topic features derived from clinical notes, we also evaluated the performance of XGBoost on predicting frailty using only features from structured EHR data. We used the k-nearest neighbor imputation technique to impute missing values in numerical features with the mean value from the k-nearest neighbors (k=5) found in the training dataset. Missing values in categorical features were imputed as a new label (unknown). Numerical features were scaled to 0-1, and categorical features were encoded before training the ML model. Figure 1 illustrates the overview of the analytic pipeline.

Figure 1. Overview of the analytic pipeline. EHR: electronic health record; LASSO: least absolute shrinkage and selection operator; LDA: latent Dirichlet allocation; TAVR: transcatheter aortic valve replacement; XGBoost: Extreme Gradient Boosting.



Model Performance and Evaluation

We employed a 5×5 nested cross-validation technique to evaluate our ML models. This technique consisted of 5 outer and 5 inner folds. During each outer fold, we set aside one-fifth of the patient records as an independent testing set, while the remaining four-fifths formed the training set. This outer training subset was then split into 5 inner folds for further validation. Each inner fold served as a stand-alone validation set, while the other 4 acted as the training set for the inner loop. The inner loop was responsible for training the models and fine-tuning the hyperparameters, taking a methodical approach in searching for the model's ideal hyperparameter settings. Meanwhile, the outer loop estimated errors and evaluated generalization capabilities. To optimize hyperparameters, we utilized a grid search strategy to systematically explore various combinations of predefined hyperparameters to train our models. We calculated and reported the mean and SD for metrics like AUC, accuracy, sensitivity, and specificity across the 5 outer folds. This thorough approach boosts confidence in the models' generalizability and scalability.

Model Interpretation and Feature Ranking

We used the Shapley Additive Explanations (SHAP) method to explain how our trained ML models work. SHAP is a widely used model-agnostic explanatory approach that helps in understanding the outputs of ML models. We created a SHAP summary plot to demonstrate the importance of features and their impact on the outcome. This impact is shown through a sign and magnitude: the SHAP value's sign indicates the direction of the feature's impact on the outcome (eg, a positive SHAP value indicates that the feature in question increases the likelihood of frailty), while its magnitude reflects the feature's predictive influence.

Statistical Analysis

Categorical features between the frail and nonfrail cohorts were compared using a χ^2 test for features with expected cell counts greater than 5 and a Fisher exact test for features with expected cell count less than or equal to 5 (ie, race). Age differences between the frail and nonfrail cohorts were compared using a Wilcoxon rank sum test. The significance level was set at *P*<.05.

Results

Table 1 compares patient characteristics between frail and nonfrail patients who underwent TAVR. The most significant difference observed was that frail patients were older and had lower hematocrit and hemoglobin levels compared to nonfrail patients. However, there were no significant differences in other characteristics such as gender, race, marital status, education, ASA score, or employment status.

Table . Comparison of patient characteristics between frail and nonfrail TAVR[a] patients.

Features	Frail (n=46)	Nonfrail (n=51)	*P* value
Age (years), mean (SD)	80.22 (7.45)	77.31 (6.05)	.04
Hematocrit (%), mean (SD)	36.16 (5.38)	39.93 (4.99)	<.001
Hemoglobin (g/DL), mean (SD)	12.14 (1.89)	13.4 (1.78)	.002
Platelet count (platelets/mL), mean (SD)	199.95 (86.34)	202.12 (51.91)	.88
Gender, n (%)			.69
Female (n=37)	19 (51.4)	18 (48.6)	
Male (n=60)	27 (45)	33 (55)	
Race, n (%)			.54
White (n=93)	43 (46.2)	50 (53.8)	
Others (n=4)	3 (75)	1 (25)	
Marital status, n (%)			.32
Married (n=65)	28 (43.1)	37 (56.9)	
Others (n=32)	18 (56.3)	14 (43.7)	
Years of education, n (%)			.41
Greater than 12 (n=58)	25 (43.1)	33 (56.9)	
Less than or equal to 12 (n=49)	21 (53.8)	28 (46.2)	
ASA[b] physical status score, n (%)			.47
Less than or equal to 3 (n=21)	8 (38.1)	13 (61.9)	
Greater than 3 (n=76)	38 (50)	38 (50)	
Employment status, n (%)			.79
Retired (n=76)	35 (46.1)	41 (53.9)	
Not retired (n=21)	11 (52.4)	10 (47.6)	

[a] TAVR: transcatheter aortic valve replacement.

[b] ASA: American Society of Anesthesiologists.

Table S2 in Multimedia Appendix 1 shows the number of features selected by LASSO alongside corresponding performance metrics across different regularization parameter values. Lower regularization parameter values (ie, inversed regularization strength) correspond to increased penalization of coefficient magnitudes and reduced features retained in the final model. Specifically, an inversed regularization strength of 0.25 imposed the highest penalty, leading to the smallest feature selection. Comparatively, an inversed regularization strength of 0.5 resulted in 12 selected features and achieved the highest AUC (0.67) and accuracy (0.65).

Table S3 in Multimedia Appendix 1 and Figure 2 show the performance of the ML models in identifying frailty. Results showed significant enhancement in the predictive performance when topic features derived from clinical notes were integrated with structured EHR data, compared to when only structured EHR data were used. Specifically, the combined topic + EHR model demonstrated a superior AUC of 0.82 (SD 0.07), indicating a robust ability to distinguish between frail and nonfrail individuals. This was a notable improvement over the EHR-only model, which achieved an AUC of 0.64 (SD 0.08).

Figure 3 shows the rank of features in predicting the frailty phenotype based on their SHAP values. Notably, the treatment and management of congestive heart failure (CHF) with carvedilol, spondylosis, intervertebral disc disorders, and other back problems and the treatment and management of atrial fibrillation (AFib) were found to have the strongest influence. These features exhibited high SHAP values, suggesting they strongly predict the frailty phenotype. Other significant factors included musculoskeletal symptoms, anemia, and age ≥80 years.

Figure 2. Receiver operating characteristic curves of frailty prediction using structured EHR data only and an integration of structured EHR data and topic features. Structured EHR features included sociodemographics, medical history and severity, and biochemical measurements. Topics features included features derived from clinical notes using latent Dirichlet allocation. The final features used were the ones selected from least absolute shrinkage and selection operator logistic regression. AUC: area under the receiver operating characteristic curve; EHR: electronic health record.

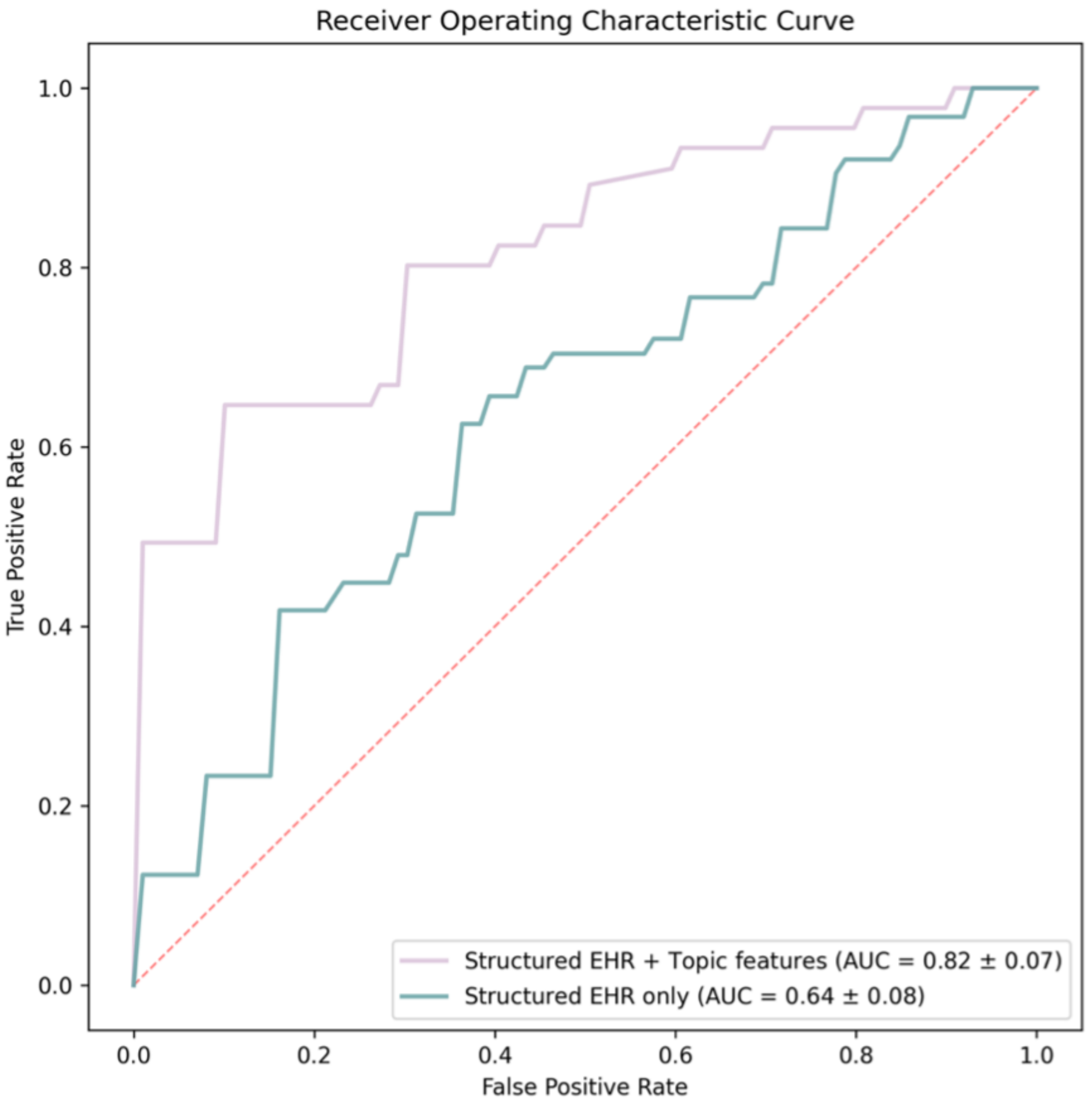


Figure 3. The rank of features in predicting the frailty phenotype. SHAP values greater than 0 (towards the right) contributed to predicting frailty, whereas SHAP values less than 0 contributed to predicting nonfrailty. For diagnosis and topic features, red dots indicate the presence, while blue dots indicate the absence of the condition. Red dots in “Years of education” represent patients with less than 12 years of education. Red dots in “Age >= 80” represent patients aged over 80 years old. SHAP: Shapley Additive Explanations.

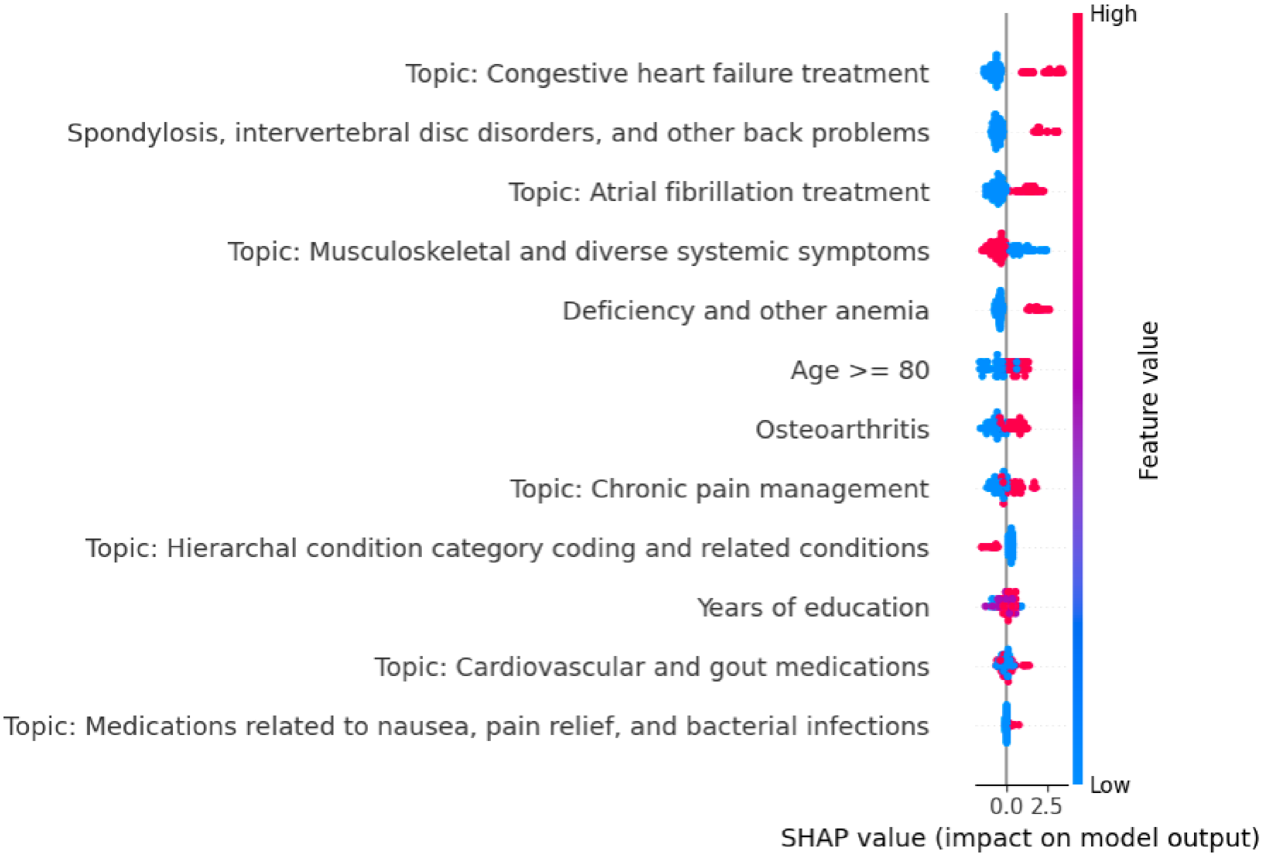

Table 2 presents 7 topics identified through LDA of clinical notes and further selected by LASSO. Of these, 5 topics related to the treatment and management of specific medical comorbidities in the cohort. The LDA algorithm identified underlying topics by clustering co-occurring terms across the clinical corpus. Each topic’s top 10 weighted terms indicated which terms appeared most prominently within a given cluster. Higher term weights represented stronger associations between the term and the topic. For instance, the medications “Carvedilol” (term weight 0.097) and “Coreg” (term weight 0.094) had the highest weights within the first topic. Based on the prominence of these cardioprotective drugs, the topics were interpreted as medical treatment and management of CHF.

Table . Topics selected by least absolute shrinkage and selection operator regression for predicting the frailty phenotype in transcatheter aortic valve replacement patients, along with the top associated terms (stemmed) and their respective weights. The topics and terms listed are critical factors identified by the least absolute shrinkage and selection operator model that contribute to the prediction of frailty. The weights indicate the strength and direction of each term’s association with the frailty phenotype, providing insights into the underlying factors influencing patient outcomes.

Discussion

Principal Findings

This study developed a frailty index using ML techniques by combining structured and unstructured real-world data. Incorporating the features obtained from unstructured clinical notes and structured EHR data significantly improved the model’s performance in identifying frailty. SHAP revealed that cardiovascular conditions, specifically CHF and AFib, as well as musculoskeletal disorders, were the primary factors that predict frailty among patients. This is consistent with the mainstream of clinical evidence [28-30]. The prominence of age as a predictor supports the well-established association between advancing age and increased vulnerability to frailty and limited quality of life improvement post TAVR [31]. The impact of years of formal education on frailty prediction was relatively lower (ranked 10th in importance), indicating that while socioeconomic factors contribute to health outcomes, clinical characteristics are more determinative in the context of frailty. This clinical ML application can easily be integrated into pre-TAVR settings to guide perioperative management, heart team discussions, and resource utilization. Our model provides actionable and semiquantitative insights and can potentially highlight targets for optimization (eg, anemia). In addition, the data processing and derivation pipeline we practically demonstrate allows ML model retraining to accommodate updates in practice and interinstitutional context differences.

Structured real-world data that contain rich historical and current information across various domains (eg, diagnoses, procedures, demographics) have been leveraged to predict frailty. Segal et al [32] constructed ML models using medical claims data to predict the Fried frailty phenotype, achieving an AUC of 0.76 with a gradient boosting machines algorithm. Similarly, Le Pogam et al's [33] exploration using inpatient discharge data obtained an AUC of 0.71, while Bai et al [34] harnessed structured EHR data to predict preoperative frailty, achieving an AUC of 0.74 using XGBoost. Notably, a considerable amount of information contained within EHRs exists as unstructured text. Recent advancements in ML and natural language processing have enabled researchers to harness this valuable resource, which traditionally posed substantial challenges for manual analysis. For instance, Shao et al [35] used topic modeling to extract frailty-related topics from clinical notes and defined frailty using the number of frailty-related topics present. This frailty index was associated with a 2-fold increased risk of the composite outcome combining 1-year hospitalization and mortality. Further, Chen et al [36] and Martin et al [37] developed deep learning models to predict sentences indicating geriatric syndromes or actionable frailty aspects and achieved an F_1-score of 0.61 and a scaled Brier score of 0.52. Despite these advances, a gap remains in the literature concerning the integration of structured and unstructured real-world data for frailty prediction. Moreover, the development of frailty indices tailored to preoperative contexts, especially for TAVR patients, remains unexplored.

Our results demonstrated that clinical notes serve as a complement to structured EHR data in predicting preoperative frailty. Incorporating features extracted from clinical notes significantly improved the model's performance over using only structured EHR data, with the integrated model using only 12 features achieving an AUC of 0.82 compared to 0.64 for the EHR-only model in the test set. This performance is superior to the one-size-fits-all statistical models such as the Society of Thoracic Surgeons score, which has an AUC of 0.64-0.7 in risk stratifying patients [38-40].

Identifying the key topics and associated terms provides actionable insights into understanding and managing frailty-associated factors. For instance, knowing that the patient has heart failure requiring cardiac medications and contributing to frailty may trigger putting the patient on a more intensive pre- and post-TAVR optimization pathway, such as right heart catheterization, to optimize heart failure therapy preprocedures. Similar approaches can be applied to other cardiovascular conditions or musculoskeletal disorders that are partially correctable with focused pre- or postprocedural conditioning. The topic of CHF treatment and management, with high-weight terms like "Carvedilol," can highlight high systemic vascular resistance hemodynamic phenotypes, systolic heart failure, or arrhythmia requiring beta blockade. Similarly, the topic focusing on AFib management, with terms like "Eliquis" and "Apixaban," highlights the need to evaluate and manage arrhythmias, which are risk factors for stroke and also are associated with obesity, hypoventilation, and chronically low physical and cardiopulmonary conditioning. The specificity of terms and their weights in each topic provides a framework for health care professionals to identify and prioritize areas of concern in pre-TAVR patients, ensuring a comprehensive and tailored approach to frailty assessment. Identifying "high-risk candidates" is crucial in determining a patient's readiness for TAVR and optimizing postprocedural outcomes by addressing the multifaceted aspects of frailty and medical complexity in this vulnerable patient population [41,42]. A considerable advantage to using ML models is that they are translatable to new TAVR techniques, adaptable to clinical settings and automated facilitating implementation, and updatable to accommodate shifts in populations and practices.

Compared to the traditional frailty measurements, a key advantage of our developed method is its applicability to newly admitted patients with severe aortic stenosis being considered for TAVR. The model can process a patient's available information, including both structured EHR data and unstructured clinical notes, to generate a frailty index score once the patient is admitted. This assessment provides an objective measure of a patient's frailty status, which has the potential to enhance the clinical shared decision-making between physicians and the patient. By offering an early and timely indication of a patient's frailty status, this approach allows for a more informed discussion about the risks and benefits of TAVR, potential alternative treatments, and the need for additional preoperative interventions and postoperative care plans, ultimately improving the care of TAVR patients.

This study, while insightful, acknowledges specific limitations. It utilizes retrospective EHR data, a method that provides a valuable foundation for analysis despite its inherent limitations, such as the potential for minor reporting inconsistencies, recall variations, and lead time considerations. The study's focus on frailty, although a topic of ongoing discussion due to its varied definitions and intersection with medical complexity, enriches the discourse by offering a nuanced view of its implications. Additionally, while our ML approach effectively integrates structured and unstructured real-world data to predict frailty, it does not extensively address potential confounding factors such as comorbidities, medications, or socioeconomic status. This focus on predictive modeling, rather than causal analysis, may limit the ability to fully account for these variables. Furthermore, this study has not undergone external validation; however, this aspect is mitigated by the rigorous internal review processes, which reduce the risk of overfitting and ensure the model's preliminary reliability. Rather than significantly limiting, these considerations underscore the study's contribution to ongoing research and its potential as a springboard for further investigation and external validation efforts.

Conclusion

This study demonstrates the effectiveness of combining unstructured clinical notes with structured EHR data to assess frailty in TAVR patients. This approach can potentially improve risk stratification for TAVR, adding insight into targets for perioperative optimization and potentially improving TAVR outcomes. Future efforts should integrate these models into clinical settings to improve TAVR planning and patient care, emphasizing continuous medical education and innovation.

Acknowledgments

We wish to acknowledge and thank the preanesthesia clinical staff who perform frailty assessments as part of routine care, the coordinators who worked diligently for the institutional review board and data cleaning, and Ron Ison, MS, PMP, Application Developer Analyst III, who provided expertise in data management with the honest data broker. Support was provided by the University of Florida's Claude D. Pepper Older Americans Independence Center (P30AG028740, MM) and the National Institutes of Health (R01AG055337, K07AG066813, CP).

Abstract

Background: Visual impairment (VI) is a prevalent global health issue, affecting over 2.2 billion people worldwide, with nearly half of the Chinese population aged 60 years and older being affected. Early detection of high-risk VI is essential for preventing irreversible vision loss among Chinese middle-aged and older adults. While machine learning (ML) algorithms exhibit significant predictive advantages, their application in predicting VI risk among the general middle-aged and older adult population in China remains limited.

Objective: This study aimed to predict VI and identify its determinants using ML algorithms.

Methods: We used 19,047 participants from 4 waves of the China Health and Retirement Longitudinal Study (CHARLS) that were conducted between 2011 and 2018. To envisage the prevalence of VI, we generated a geographical distribution map. Additionally, we constructed a model using indicators of a self-reported questionnaire, a physical examination, and blood biomarkers as predictors. Multiple ML algorithms, including gradient boosting machine, distributed random forest, the generalized linear model, deep learning, and stacked ensemble, were used for prediction. We plotted receiver operating characteristic and calibration curves to assess the predictive performance. Variable importance analysis was used to identify key predictors.

Results: Among all participants, 33.9% (6449/19,047) had VI. Qinghai, Chongqing, Anhui, and Sichuan showed the highest VI rates, while Beijing and Xinjiang had the lowest. The generalized linear model, gradient boosting machine, and stacked ensemble achieved acceptable area under curve values of 0.706, 0.710, and 0.715, respectively, with the stacked ensemble performing best. Key predictors included hearing impairment, self-expectation of health status, pain, age, hand grip strength, depression, night sleep duration, high-density lipoprotein cholesterol, and arthritis or rheumatism.

Conclusions: Nearly one-third of middle-aged and older adults in China had VI. The prevalence of VI shows regional variations, but there are no distinct east-west or north-south distribution differences. ML algorithms demonstrate accurate predictive capabilities for VI. The combination of prediction models and variable importance analysis provides valuable insights for the early identification and intervention of VI among Chinese middle-aged and older adults.

KEYWORDS

visual impairment; China; middle-aged and elderly adults; machine learning; prediction model

Introduction

Visual impairment (VI) represents a significant global public health challenge. Over the period from 1990 to 2019, the burden index of VI has escalated for individuals aged 50 - 74 years and individuals aged 75 years and older, shifting from the 20th and 16th positions to the 19th and 15th positions, respectively [1]. The global increase in VI prevalence is primarily attributed to cataracts and uncorrected refractive errors, accounting for 55% of blindness cases and 77% of VI cases among adults aged 50 years and older in 2015 [2]. This trend is further exacerbated by population growth and aging [2]. According to the National Bureau of Statistics of China's January 2022 report, adults aged 60 years and older accounted for 18.9% of the total population by the end of 2021.

Meanwhile, adults aged 65 years and older exceeded 200 million, representing 14.2% of the total population [3]. It is projected that during the "14th Five-Year Plan" period, the total number of adults aged 60 years and older will surpass 300 million, accounting for over 20% of the population, indicating a transition into the moderate aging phase. By around 2035, China is anticipated to enter the severe aging phase [3]. Older adults with VI are at a heightened risk of falls [4], potentially leading to fractures and severe outcomes such as cerebral hemorrhage. Furthermore, VI can hinder social engagement among older adults, possibly giving rise to more profound mental health issues, including depression and anxiety [5]. As the population ages, the prevalence of VI is expected to increase dramatically. However, half of all VI cases are estimated to be preventable or treatable [6]. Hence, bolstering screening efforts and enhancing risk prediction for VI is paramount in stemming the tide of this growing concern.

In response to the crises posed by VI and to improve public visual health, the China National Health Commission has released the 14th Five-Year National Eye Health Plan (2021 - 2025). The plan focuses on enhancing eye health information platforms and promoting the harmonious integration of big data, artificial intelligence, and ophthalmology services to advance the early detection of eye diseases [7]. Through the development of machine learning (ML) prediction models for VI, the precise determination of VI risk and identification of influencing risk factors can be achieved. ML could offer new insights for early detection and timely intervention of retinopathy, as well as for the integrated management of ocular health in older adults, ultimately enhancing the overall eye health status of the population.

Artificial intelligence has experienced swift progress in recent years, resulting in extensive use of diverse ML algorithms in clinical research [8,9]. Compared with traditional statistical methods, ML algorithms can handle more complex nonlinear relationships, interactions, and multiple covariances, significantly improving the predictive ability of artificial intelligence models [10,11].

Despite the advantages of ML algorithms, there is an absence of the use of ML algorithms to predict the risk of VI in the general middle-aged and older adult population in China. Previous studies on predicting VI have focused on various topics, including examining trends in the incidence of VI among populations [12,13]; assessing the risk of VI in specific groups, such as those with congenital cytomegalovirus infection [14-16]; and further predicting the risk of developing particular types of VI [17]. However, these studies have not focused on predicting the individual risk of VI among the general population. In current research on predicting individual risk of VI among the general population, three studies [18-20] based on traditional statistical methods and two studies [21,22] based on ML algorithms have achieved good predictive performance. Among these, two studies [20,21] lacked Chinese populations, with the studied populations being mainly from the United States and Singapore; one focused on Chinese children [22]; one was a single-center study [18]; and one [19] had a small sample size of 133 participants. To date, no research has yet been conducted on using ML algorithms to predict VI in Chinese middle-aged and older adults. Therefore, our objective was to develop an individual risk prediction model for VI, which could be used to assess the risk of VI among China's general middle-aged and older population. Additionally, we aimed to identify key predictors of VI. Our findings could be used to provide personalized intervention guidance for health care professionals, aiming to reduce and delay the onset of retinal diseases among middle-aged and older adults.

Methods

Analytic Sample

The data used in our study originate from the China Health and Retirement Longitudinal Study (CHARLS), a longitudinal survey that represents a nationally diverse cohort of Chinese adults aged 45 years and older. This survey strives to establish a comprehensive public database documenting Chinese adults' social, economic, and health statuses, thereby bolstering scientific investigations conducted by the National Development Institute of Peking University. The CHARLS project executed a nationwide baseline survey between 2011 and 2012, with subsequent follow-up visits occurring biennially [23]. The CHARLS baseline survey encompassed 450 villages and neighborhoods spread across 150 counties in China. The sampling process encompassed multiple levels, including counties, villages, households, and individuals, culminating in interviews with 10,257 households and broadly reflecting the general Chinese middle-aged and older adult populace. We used 25,538 observations from 4 waves of surveys between 2011 and 2018. Excluding ages younger than 45 years (n=4079) and missing information on self-reported vision conditions (n=2457), 19,047 participants were included in this study. More details of the sampling process are shown in Figure S1A in Multimedia Appendix 1.

Predictors of VI

Drawing on existing literature and expert insights, 42 predictors were used for ML algorithm training. The predictors were categorized as follows: self-reported questionnaire, physical examination, and blood biomarkers. The self-reported questionnaire included (1) demographic factors (gender, age, and region), [24] (2) lifestyle (night sleep duration, smoking, and drinking), (3) health status factors (pain, weight change, health status during childhood, and self-expectations of health status), [25] (4) disease factors (depression, hearing impairment, hypertension, dyslipidemia, diabetes, liver disease, heart disease, stroke, kidney disease, stomach or other digestive disease, memory-related disease, arthritis or rheumatism, menopause, and prostatic diseases), (5) living environment factors (house structure, heating energy, cooking energy, and room temperature), and (6) socioeconomic factors (standard of living and education level). Measurement parameters included (1) physical examination data ([26] hand grip strength, waist, and BMI) and (2) blood biomarker data (white blood cell, platelets, glycated hemoglobin, glucose, total cholesterol, triglycerides, high-density lipoprotein cholesterol, and low-density lipoprotein cholesterol). The characteristics of the predictor distribution in the study are displayed in Table S1 in Multimedia Appendix 1.

Measurement of VI

Vision encompasses both far and near eyesight. VI in our study was assessed using the following questions from the CHARLS questionnaire: (1) “How well do you see things in the distance? For example, can you recognize a friend across the road (even with glasses on)? Is it excellent, very good, good, fair, or bad?” and (2) “How well do you see things close up? For example, can you read a newspaper with your glasses on? Is it excellent, very good, good, fair, or bad?” Respondents who answered “not good” to any of the questions were categorized as having a VI, while those who answered “excellent” to “fair” were considered to have no VI [27].

Statistical Analysis

We used R (version 4.3.1), developed by the R Core Team of the R Foundation for Statistical Computing, for statistical analysis and model development. The summary of continuous variables involved the use of the median and IQR (25th and 75th percentiles), and categorical variables were summarized by providing the count (n) and proportion (%) for each category. We used the R H2O package to construct various ML predictive models for a dichotomous outcome of VI [28]. H2O supports a wide range of ML models, including deep learning (DL), gradient boosting machine (GBM), distributed random forest (DRF), and more. In our study, we chose the generalized linear model (GLM) as our benchmark model, representing logistic regression. The study process is shown in Figure S1B in Multimedia Appendix 1. As per the No Free Lunch Theorem [29], no algorithm can outperform a linear enumeration of the search space or a purely random search algorithm. Thus, we split the dataset into training (n=14,286) and testing (n=4761) datasets at a 75:25 ratio. The training dataset was used to develop various models, including a GLM with regularization to prevent overfitting and enhance the model’s predictive accuracy. GBM uses decision trees as weak learners and boosts their predictions iteratively [30]. DRF incorporates both DRF and extremely randomized tree approaches to ensure diversity and robustness in the ensemble [31]. The DL model consists of a fully connected multilayer artificial neural network trained with backpropagation to capture complex nonlinear relationships [32,33]. A stacked ensemble combines the predictions of these individual models as input features for the ensemble’s meta-learner. The meta-learner then outputs a final prediction based on the learned weights of each base model’s contribution, enhancing overall prediction performance [34]. The random forest algorithm was used to impute missing values, while the continuous variables were normalized. In this study, the ratio of positive to negative outcomes in the target variable was 1:2, indicating an imbalanced dataset. To address data imbalance, random oversampling of the minority class was initially used [35]. Furthermore, to mitigate overfitting and enhance model generalization [36], external 5-fold cross-validation was implemented. However, the model’s performance did not show improvement compared with the no-resampling, blending mode. Therefore, we trained the stacked combinations using the no-resampling and blending mode, plotted the receiver operating characteristic (ROC) curves, and constructed the confusion matrix. We used the area under the curve (AUC) to evaluate the best model, with an acceptable AUC of 0.7 - 0.8, a good AUC of 0.8 - 0.9, and an excellent AUC of >0.9 [37]. We calibrated the probabilities predicted by the models to the actual occurrence level in the testing dataset using a logistic function and calculated the Brier score to assess the reliability of the prediction of VI [38]. The Brier score takes values from 0 to 1, and at a predicted probability of 50%, the Brier score is 0.25 [39]. A model score between 0 and 0.25 indicates a correct prediction, and a score closer to 0 indicates better model effectiveness. Additionally, we used models with acceptable AUCs for variable importance analysis. This enabled us to quantitatively assess the contribution of each feature towards model predictions, thereby allowing us to evaluate and compare the significance of various features.

Ethical Considerations

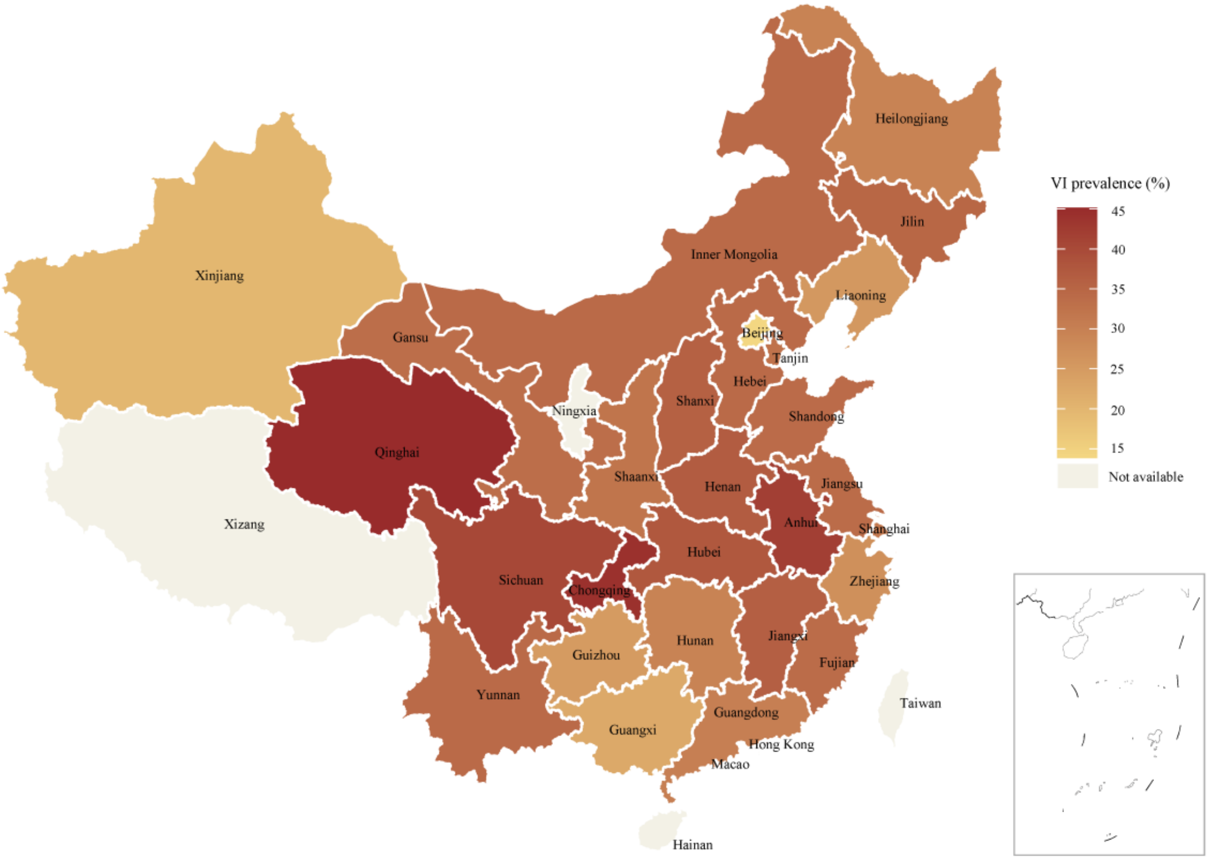
The Peking University Institutional Review Board (IRB) granted ethical approval for all waves of the CHARLS. The IRB approval number for the self-reported questionnaire (including physical examination measurements) was IRB00001052-11015; the IRB approval number for the biomarker collection was IRB00001052-11014.

Results

Geographical Distribution of VI

Figure 1 presents the prevalence of VI by province in China, based on data from the 4 waves of the CHARLS conducted between 2011 and 2018. Qinghai, Chongqing, Anhui, and Sichuan provinces reported a high prevalence of VI, with rates exceeding 40% (69/153, 45.1%; 117/265, 44.2%; 390/930, 41.9%; and 654/1619, 40.4%, respectively). In contrast, Xinjiang and Beijing had a low prevalence of VI, with rates below 20% (23/116, 19.8% and 14/101, 13.8%, respectively). The remaining provinces, municipalities, and autonomous regions exhibited a moderate prevalence of VI, ranging from 20% to 40%. Additional information regarding the prevalence of VI in each province is presented in Table S2 in Multimedia Appendix 1.

Figure 1. The prevalence of VI by province in China from the China Health and Retirement Longitudinal Study (2011 - 2018) 4 waves. VI: visual impairment.



Characteristics of the Study Participants

A total of 33.9% (6449/19,047) of participants reported VI, divided between the training dataset (n=4837) and the testing dataset (n=1612). Among the cases of VI, 58.8% (3795/6449) were female, and 41.2% (2654/6449) were male. The age group with the highest prevalence of VI was 55 - 65 years, accounting for 39.1% (2520/6449), followed by those aged 65 years or older at 31.4% (2025/6449) and 45 - 55 years at 29.5% (1904/6449). The selected characteristics of the study participants are shown in Table 1. The full characteristics of the predictor distribution in the study are shown in Table S1 in Multimedia Appendix 1.

Table . Selected characteristics of study participants among Chinese adults older than 45 years as drawn from the China Health and Retirement Longitudinal Study (2011 - 2018; N=19,047).

Characteristic		Overall (N=19,047), n (%)	Non-VI[a] (n=12,598), n (%)	VI (n=6449), n (%)	*P* value[b]
Sex					<.001
	Female	9927 (52.1)	6132 (48.7)	3795 (58.8)	
	Male	9120 (47.9)	6466 (51.3)	2654 (41.2)	
Age (years)					<.001
	45 - 55	7279 (38.2)	5375 (42.7)	1904 (29.5)	
	55 - 65	6794 (35.7)	4274 (33.9)	2520 (39.1)	
	≥65	4974 (26.1)	2949 (23.4)	2025 (31.4)

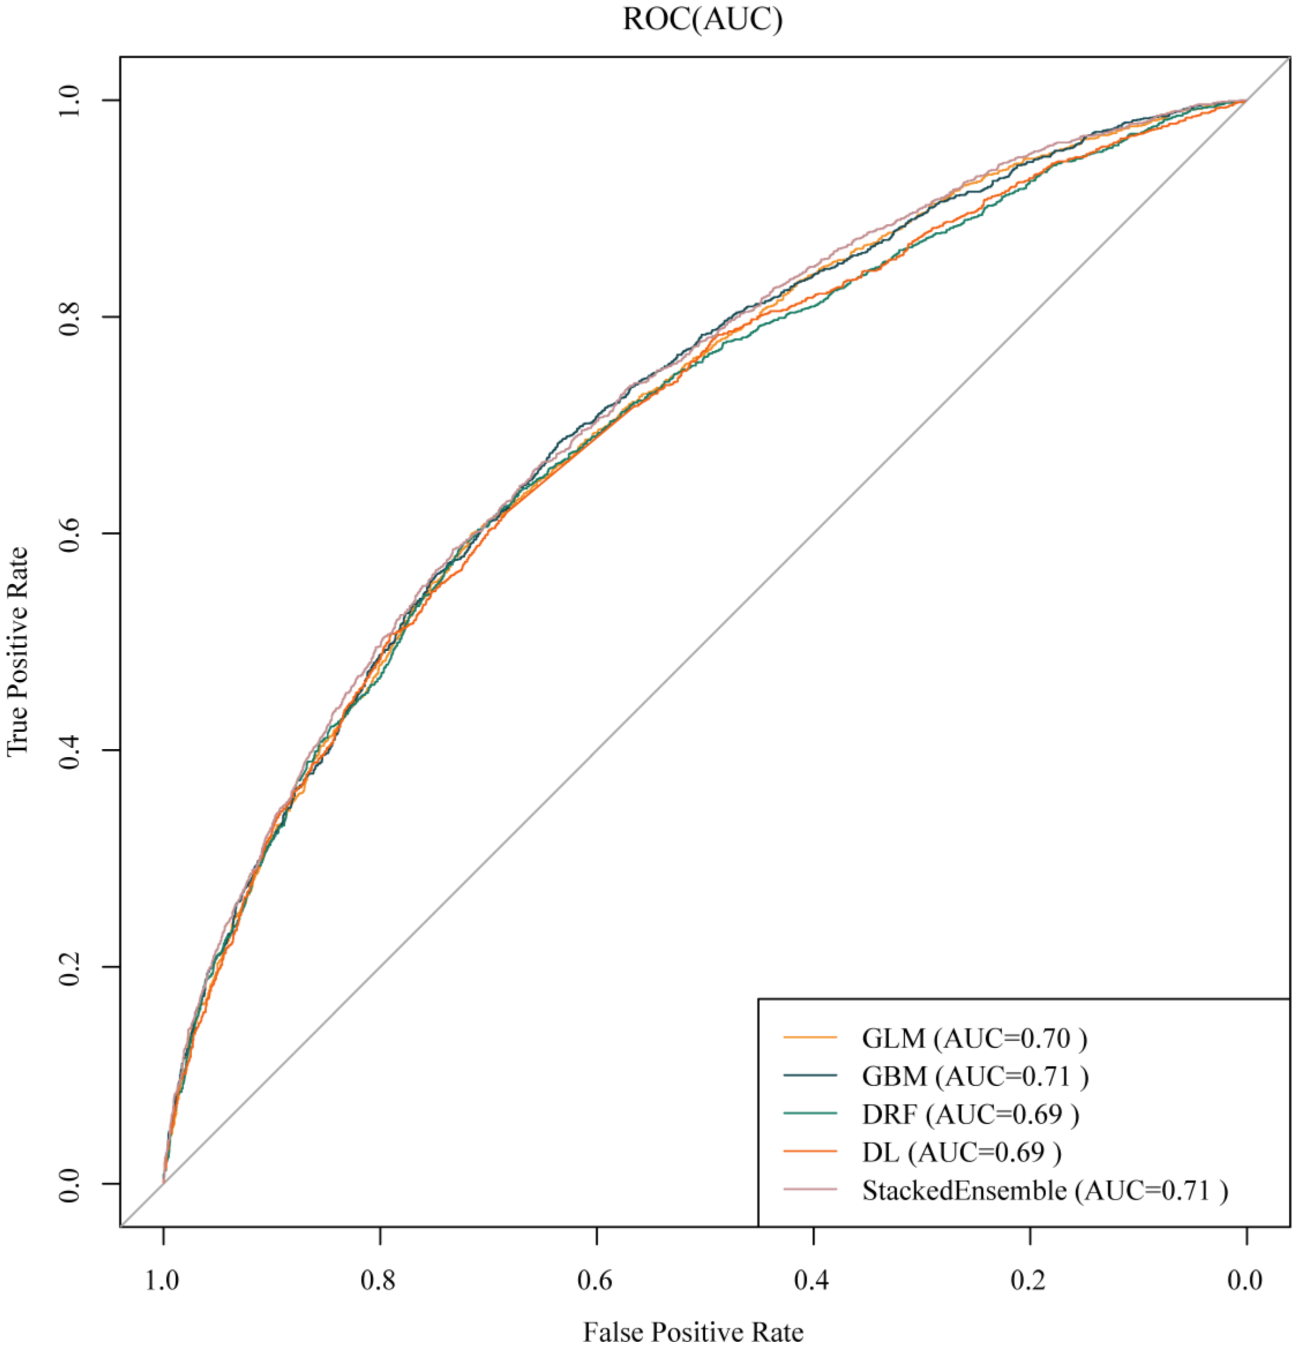
[b] Pearson χ^2 test.

VI Prediction

We applied the trained models to the testing dataset. The distribution of predictor variables between the testing and training datasets is detailed in Table S3 in Multimedia Appendix 1. The results indicate that the ensemble model demonstrates superior predictive performance compared with individual ML models. Three algorithms, namely the GLM, GBM, and stacked ensemble model (GBM-XGBoost-GLM-DL-DRF), achieved acceptable AUC values 0.706, 0.710, and 0.715, respectively. The ensemble model exhibited the best performance. However, the DRF and DL models did not meet the acceptable AUC threshold of 0.70, achieving an AUC of 0.698. Detailed evaluation metrics for all models on the testing dataset are provided in Table S4 in Multimedia Appendix 1. Figure 2 depicts the ROC curves for all the models. The hyperparameters used in model training are summarized in Table S5 in Multimedia Appendix 1. ROC curves of all VI prediction models on the training dataset are shown in Figure S2 in Multimedia Appendix 1.

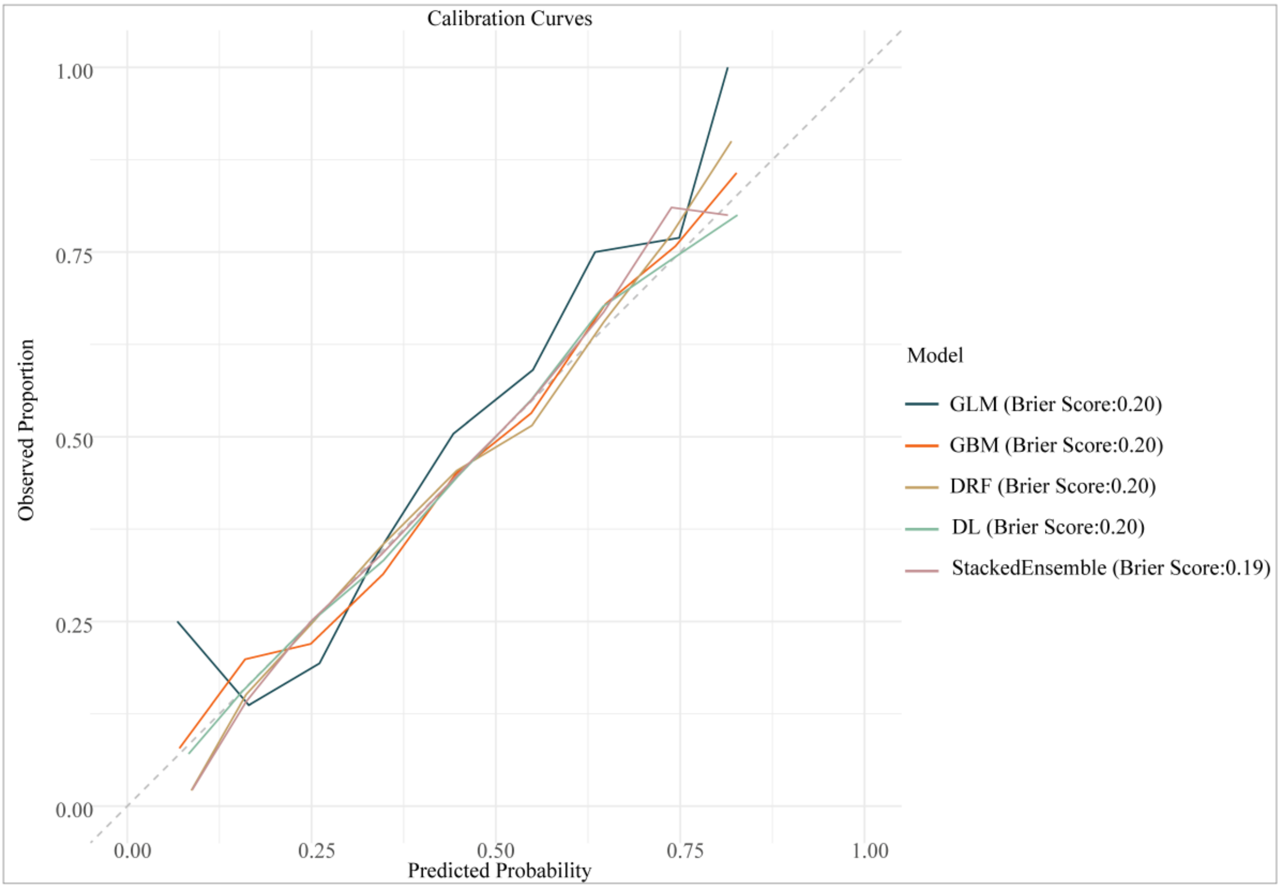
Figure 2. Receiver operating characteristic curves of all visual impairment prediction models on the testing dataset. AUC: area under the curve; DL: deep learning; DRF: distributed random forest; GBM: gradient boosting machine; GLM: generalized linear model; ROC: receiver operating characteristic; StackedEnsemble: GBM-XGBoost-GLM-DL-DRF.



Assessing the Efficacy of ML Models for VI Prediction

Figure 3 presents the calibration curves of all the models on the testing dataset. These curves illustrate the agreement between each model’s predicted probabilities and VI’s observed probabilities in the testing data. The results indicated that all models accurately predicted VI, as evidenced by their Brier scores being less than 0.25.

Figure 3. The calibration curves of all visual impairment prediction models on the testing dataset. DL: deep learning; DRF: distributed random forest; GBM: gradient boosting machine; GLM: generalized linear model; StackedEnsemble: GBM-XGBoost-GLM-DL-DRF.



Determinants of VI

Table 2 presents the importance of predictors for VI in models with acceptable AUCs. The top 10 important predictors for VI were identified by the GLM, including hearing impairment, pain, depression, hand grip strength, standard of living, education level, age, self-expectation of health status, night sleep duration, and arthritis or rheumatism. For GBM, the top predictors for VI were hearing impairment, self-expectation of health status, pain, age, hand grip strength, depression, night sleep duration, hemoglobin, high-density lipoprotein cholesterol, and arthritis or rheumatism. Notably, hearing impairment, self-expectation of health status, pain, age, hand grip strength, depression, night sleep duration, and arthritis or rheumatism have emerged as common predictors for these models.

Table . Variable importance analysis was performed by the generalized linear model (GLM) and gradient boosting machine (GBM), sorted in descending order.

Rank	GLM	GBM
1	Hearing impairment	Hearing impairment
2	Pain	Self-expectations of health status
3	Depression	Pain
4	Hand grip strength	Age
5	Standard of living	Hand grip strength
6	Education level	Depression
7	Age	Night sleep duration
8	Self-expectations of health status	Hemoglobin
9	Night sleep duration	High-density lipoprotein cholesterol
10	Arthritis or rheumatism	Arthritis or rheumatism

Discussion

Principal Results

To our knowledge, this study is the first attempt to predict the risk of VI among middle-aged and older adults in China using ML algorithms. The findings indicated that ML algorithms could accurately identify individuals at risk of VI among this demographic. Our results also showed that ensemble algorithms proved superior to individual ML models. Furthermore, we calculated the prevalence of VI and presented it through regional visualization. The results indicated the existence of regional disparities in the prevalence of VI among Chinese middle-aged and older adults, with varying rates across provinces. However, it is worth noting that we did not find any significant north-south or east-west directional differences in prevalence. Based on these results, gaining a more intuitive understanding of the regional distribution of VI is possible. Additionally, our prediction model can be leveraged to develop a risk assessment tool for early detection of VI. Predictors' importance could help guide personalized early interventions for middle-aged and older individuals at risk of VI.

Comparison With Prior Work

Our study showed that GBM outperformed logistic regression in predicting VI among middle-aged and older Chinese adults. Previous ML studies on VI prediction have predominantly relied on single algorithms without comparing the predictive performance across multiple algorithms. In contrast, our work used various ML algorithms for VI prediction and assessed their comparative effectiveness. Furthermore, our findings highlighted the superior performance of ensemble algorithms over individual learning models despite an accuracy of 0.625. This is due to the imbalanced nature of our dataset, where accuracy may not fully reflect the model's ability to predict VI. We chose AUC as the primary metric and found that the ensemble model had the highest AUC, indicating its overall superior ability to rank positive and negative samples.

The calibration curves showed satisfactory calibration but moderate discrimination, indicating the models' ability to assess the overall risk for VI in the population effectively. This finding has significant implications for designing resource allocation strategies in clinical and public health settings. While the models' discriminatory power was not exceptional, they could be used as supplementary tools in broader clinical or public health assessment frameworks, providing valuable insights for early screening of VI risk. Nevertheless, we acknowledged and considered the limitations of these models when applying them in practice. Consequently, our research contributed significantly to future investigations of ML algorithms for VI prediction by providing a comprehensive evaluation of multiple algorithms and emphasizing the advantages of ensemble methods. Additionally, our work offers technical guidance for the primary prevention of VI by identifying the most effective predictive models.

Our study has the following strengths compared with previous ML models for VI prediction. First, our model is more adept at identifying potentially modifiable risk factors. Unlike prior studies that primarily relied on image or video data as predictors [21,22], our approach incorporates easily accessible everyday information, such as lifestyle factors like night sleep duration. Second, our predictive model holds greater representativeness and general applicability for the middle-aged and older adult Chinese population. Previous domestic studies on VI prediction tended to focus on specific disease groups (stroke patients) or particular types of VI (anterior retinal VI) [14,15]. Our study, based on a national sample, includes individuals from the middle-aged and older adult demographics, and our results pertain to general types of VI.

We found that the important predictors of VI included hearing impairment, self-expectation of health status, pain, age, hand grip strength, depression, night sleep duration, high-density lipoprotein cholesterol, and arthritis or rheumatism. This finding aligns with those documented in prior research [24,25,40-42]. Significantly, our study newly highlighted the crucial role of hearing impairment, self-expectation of health status, and pain in predicting VI. Although hearing impairment does not directly affect vision, its underlying causes may be associated with ocular or neurological disorders. For instance, neurofibromatosis occurring near the inner ear and optic nerve can potentially lead to concurrent hearing and VI [43]. The eyes and ears share a common neuroectodermal origin and exhibit similar genetic networks [44]. When pathogenic mutations occur in these shared genes, they can concurrently affect the functions of both the eyes and ears, leading to dual sensory loss. For instance, defects in the development of inner ear hair cells and photoreceptor cells may underlie the pathogenesis of Usher syndrome, the most prevalent syndromic form of retinitis pigmentosa [45]. In addition, self-expectation of health status reveals one's attitudes towards personal health. High expectations often lead to proactive health behaviors, such as regular ophthalmologic check-ups for vision issues. In contrast, lower expectations, possibly due to comorbid chronic conditions [25], may cause psychological stress affecting vision [46]. For example, depression is more prevalent in patients with VI [47]. Additionally, pain serves as a vital physiological indicator, revealing certain discomforts or underlying ailments in the body. Prolonged pain can keep an individual in a constant state of stress, disrupting the normal functions of the immune and endocrine systems, thereby indirectly impacting vision. Our findings enhance comprehension of the mechanisms underlying the development of VI, enabling early identification of high-risk groups and the implementation of targeted interventions for these individuals. Moreover, our findings provide a valuable reference for selecting variables in constructing VI prediction models. Nevertheless, to ensure the accuracy and credibility of our findings, further studies are required to validate these associations.

Limitations

This study has several limitations that should be acknowledged. First, the assessment of VI relied on self-reported data, which may be subject to recall bias or subjectivity in responses. The qualitative nature of the VI assessment responses lacks the numerical precision of a quantitative evaluation, potentially affecting the accuracy of the outcome variable. Second, while environmental and lifestyle factors were considered, VI is also influenced by genetic factors, which were not included in the model due to the absence of such information in the database. Incorporating genetic data could potentially enhance the model's predictive performance. Finally, the data were sourced from the CHARLS, which only represents the Chinese population aged 45 years and older. Consequently, the model's generalizability to other age groups or populations outside of China remains uncertain. Further validation studies are necessary to evaluate the model's effectiveness in diverse populations across different countries and age ranges.

Conclusions

The prevalence of VI was notably high among middle-aged and older Chinese adults, displaying regional disparities but no significant variances between north-south or east-west regions. Our study is the first to use ML algorithms in predicting VI among China's general middle-aged and older population. The findings demonstrate that ML algorithms can accurately predict VI among this demographic. Ensemble algorithms outperform individual learning models in predicting VI. Variable importance analysis highlighted the importance of considering factors such as hearing impairment and individuals' self-expectation of health status when predicting VI risk. By incorporating these predictors, our study facilitates the early identification of individuals at high risk for VI, enabling timely interventions and preventive measures to mitigate the development and progression of VI.

Acknowledgments

This document uses data from 4 waves of the China Health and Retirement Longitudinal Study (CHARLS) from 2011 to 2018. We thank the CHARLS research team and each respondent for contributing to this study. We are grateful for funding from the Traditional Chinese Medicine research project of the Shanghai Municipal Health Commission (2024QN108), Shanghai University of Traditional Chinese Medicine in 2021 (2021LK008), and Shanghai University of Traditional Chinese Medicine in 2024 (KECJ2024019).

Authors' Contributions

XX and LM conceived and designed the study. LM and XX cleaned the data and built the models and codes. LM wrote the first draft and edited the manuscript. LM and XX contributed to data cleaning. HS, HZ, and XX contributed to data validation and supervision. YZ, LL, MS, HS, HZ, and XX contributed to data interpretation and manuscript revision. All authors contributed to the preparation of the manuscript and approved the final manuscript.

Conflicts of Interest

None declared.

Multimedia Appendix 1

Supplementary tables and figures containing further data on participant characteristics, visual impairment prevalence, predictive factors, model performance, hyperparameters, the sampling and study processes, and receiver operating characteristic curves of prediction models on the training dataset.

Abstract

Background: The number of older people with unmet health care and support needs is increasing substantially due to the challenges facing health care systems worldwide. There are potentially great benefits to using the Internet of Things coupled with artificial intelligence to support independent living and the measurement of health risks, thus improving quality of life for the older adult population. Taking a co-design approach has the potential to ensure that these technological solutions are developed to address specific user needs and requirements.

Objective: The aim of this study was to investigate stakeholders' perceptions of independent living and technology solutions, identify stakeholders' suggestions on how technology could assist older adults to live independently, and explore the acceptability and usefulness of a prototype Internet of Things solution called the NEX system to support independent living for an older adult population.

Methods: The development of the NEX system was carried out in 3 key phases with a strong focus on diverse stakeholder involvement. The initial predesign exploratory phase recruited 17 stakeholders, including older adults and family caregivers, using fictitious personas and scenarios to explore initial perceptions of independent living and technology solutions. The subsequent co-design and testing phase expanded this to include a comprehensive web-based survey completed by 380 stakeholders, encompassing older adults, family caregivers, health care professionals, and home care support staff. This phase also included prototype testing at home by 7 older adults to assess technology needs, requirements, and the initial acceptability of the system. Finally, in the postdesign phase, workshops were held between academic and industry partners to analyze data collected from the earlier stages and to discuss recommendations for the future development of the system.

Results: The predesign phase revealed 3 broad themes: loneliness and technology, aging and technology, and adopting and using technology. The co-design phase highlighted key areas where technology could assist older adults to live independently: home security, falls and loneliness, remote monitoring by family members, and communication with clients. Prototype testing revealed that the acceptability aspects of the prototype varied across technology types. Ambient sensors and voice-activated assistants were described as the most acceptable technology by participants. Last, the postdesign analysis process highlighted that ambient sensors have the potential for automatic detection of activities of daily living, resulting in key recommendations for future developments and deployments in this area.

Conclusions: This study demonstrates the significance of incorporating diverse stakeholder perspectives in developing solutions that support independent living. Additionally, it emphasizes the advantages of prototype testing in home environments, offering crucial insights into the real-world experiences of users interacting with technological solutions.

Introduction

The world is witnessing a rapidly aging population. Population aging can be seen as one of the greatest successes of public health, as a longer life brings opportunities, not only for older people and their families, but also for societies as a whole [1]. The extent of these opportunities and contributions however depends heavily on one factor: healthy and positive aging [1]. Therefore, mechanisms that support healthy and positive aging are essential to ensure older people can enjoy physical and mental health and well-being to their full potential. Globally, health care policies including Ireland's "Sláintecare" [2] are focusing on extending the ability of older people to continue to live independently at home. This entails maintaining quality of life as well as working to reduce the costs of an older person's care. This presents a grand challenge to ensure that older adults receive adequate and individualized care and support to maintain their health, well-being, and safety whilst living independently [3].

The Internet of Things (IoT) and artificial intelligence (AI) offer significant benefits for supporting older adults in living independently, through enhanced health monitoring, improved home safety, and increased social connection, which in turn can improve health-related quality of life [4,5]. In this context, IoT refers to a network of physical devices that communicate and exchange data, while AI-based systems use algorithms and machine learning to process and analyze this data. Wearable IoT devices like smartwatches and fitness trackers monitor vital signs such as heart rate, blood pressure, and blood glucose levels, providing critical data to health care providers [6-8]. Smart home devices and AI-powered digital assistants can also mitigate risks by detecting hazards like fires and intruders, as well as alleviating loneliness and managing chronic conditions such as diabetes and hypertension [9-11]. Previous system-based approaches such as The HABITAT system [12] aim to support the independence of older adults by integrating technologies like radio frequency identification, wearable electronics, wireless sensor networks, and AI to enhance daily living environments. However, the deployment of these technologies comes with challenges, notably privacy and security risks that could expose older adults to cybercrimes and unauthorized access to sensitive health data [13,14]. Addressing these concerns is crucial to ensure the safe and accepted use of IoT technologies in this population.

The NEX system is an advanced IoT platform designed to support the independent living of older adults by monitoring their daily activities unobtrusively. It integrates various technologies such as smartwatches, voice-activated assistants, contact sensors, and smart plugs to gather comprehensive data on users' activities and environments. This system uses AI and machine learning algorithms to analyze this data, enabling the detection and prediction of changes in the routines of older adults, known as activities of daily living (ADLs). The objective is to offer prompt and customized support to improve the quality of life and safety of older adults living at home. By unobtrusively monitoring for changes in routine behavior, such as a notable decrease in daily step count, the NEX system enables caregivers to respond quickly and provide necessary interventions. To address privacy and security concerns related to these technologies, the NEX system was designed to be highly customizable, giving users autonomy over the components they chose to use. Users were fully informed about the data each technology component collected and its purpose.

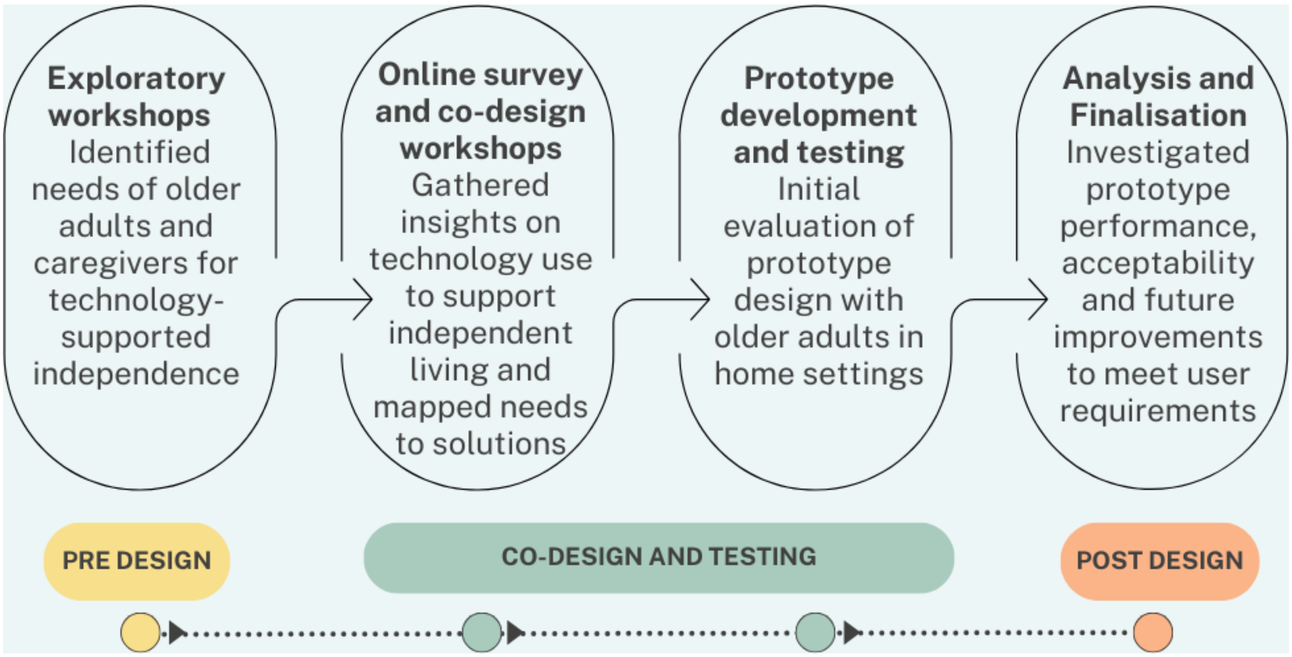
Despite the mounting evidence of the role of technology in supporting older adults to live independently at home [4,15,16], evidence in the literature suggests that end user's acceptability and usability of technology are often neglected [17] and the literature calls for a shift in emphasis from focusing on product design to the user perspective. Co-design is essential in developing technology for older adults, as it engages end users directly in the design process to ensure that solutions align with their specific needs and preferences and enhances the relevance, usability, and acceptance of technology [18]. This research describes the comprehensive co-design approach used in the development of the NEX system, which integrates the perspectives and insights of multiple stakeholders [19]. By involving a diverse array of stakeholders including older adults, caregivers, and health care professionals, the project ensures that the system addresses the real-world needs and preferences of its end users. This participatory approach enhances the relevance and usability of the system in order to foster greater acceptance and effectiveness. Furthermore, the development process includes rigorous prototype testing in the homes of older adults, providing authentic insights into how the system functions in everyday home-based settings. This iterative process, characterized by real-world testing and stakeholder involvement, is fundamental to creating effective and sustainable health technology solutions.

Methods

Overview

A user-centered design approach [20] was used to identify user needs and requirements. This co-design approach focuses on partnering with end users to design technology with them and not for them. This paper describes the use of a generative co-design framework for health care innovation [21] to inform the design of the NEX system. Figure 1 illustrates the adapted framework used to co-design the NEX system.

Figure 1. Co-design framework for the NEX system.



Recruitment and Participant Profile

The recruitment process for the study involved multiple phases, starting with exploratory workshops aimed at older adults and family caregivers, who were recruited through Dublin City University Age Friendly network, social media, and local newspaper advertisements. The study's co-design phase further expanded recruitment through a web-based survey targeting older adults, family caregivers, and health and social care professionals. This survey was advertised through social media and local council Age Friendly coordinators throughout Ireland. The final phase of recruitment occurred during the prototype development, where participants were those who had engaged in the web-based survey and expressed interest in further research participation. To ensure diverse participant recruitment a range of strategies were used ranging from web-based recruitment to recruiting and hosting one of the workshops at an older adults' club in Dublin's inner city. The recruitment for workshop and focus group activities ceased when thematic saturation was reached, indicating that sufficient data to robustly inform the design process was collected. Participants in the predesign and co-design workshops received a €20 (US $22) One4All voucher as compensation for their time and effort. Those who participated in the 10-week prototype testing phase were compensated with a €60 (US $66) One4All voucher.

The research engaged diverse participant groups across different phases. In the exploratory workshops, 17 participants including 15 older adults aged 60 years and older and 2 family caregivers participated. In the web-based survey, 380 respondents participated, comprising 235 older adults, 77 family caregivers, 47 health care professionals, and 21 homecare support staff. The majority were female (304/380, 80%) and well-educated with 58% (n=220) having completed tertiary education. The mean age of the cohort was 62.5 years (SD 11.5 years). Twenty-nine individuals including 15 older adults, 4 family caregivers, 4 health care professionals, and 6 home support workers participated in web-based workshops to discuss the utility and concerns regarding the various technology solutions proposed as part of the co-design phase. Lastly, 7 healthy older adults, aged 63 to 87 years, participated in a 10-week prototype testing of a system in their own homes. This sample size is based on population sizes from other published prototype testing studies in this area [22]. This group consisted of 5 women and 2 men, all living alone across Ireland, predominantly in urban areas. Living independently was a requirement for testing the prototype version of the system to ensure that most of the sensor data collected was attributable solely to the participant, not co-inhabitants. Due to COVID-19 restrictions limiting the movement of older adults, participants in the prototype testing self-installed the system with remote assistance from technical support over the phone. Future research will explore solutions for older adults living with caregivers or family. All described their health as "very good" or "excellent," with most having chronic conditions. They were all regular smartphone users, and all had home broadband.

Ethical Considerations

Ethical approval for the study was granted by the Dublin City University (DCU) Research Ethics Committee. The study adhered to strict data protection and ethical guidelines throughout its phases, from exploratory workshops to prototype testing. Participants' contributions, whether in workshops or web-based surveys, were conducted with a focus on confidentiality and informed consent. Participation was voluntary, and oral and written information was provided to participants regarding the purpose of the study and how their data would be used in the research. The academic partners completed a data sharing agreement and conducted a data protection impact assessment to guarantee the protection and responsible use of participant data. While the industry partners had access to participants' names and home addresses for technology installation purposes, they were restricted from accessing any health assessment data or any other personal information. To further ensure data security, all study-related data were securely stored on a designated drive at DCU. Ethical approval for conducting the predesign and co-design phases of this research was obtained from the DCU Research Ethics Committee under the reference DCUREC2019223, and for the prototype testing under the reference DCUREC2020180.

Data Collection

Data collection methods varied across the study's phases. In the predesign phase, exploratory workshops were conducted with potential end users (n=17), including older adults and family caregivers, to identify their needs and explore how technology could support their independence. These workshops were audio recorded and later transcribed to facilitate the exploration of the real-world needs and scenarios of users, setting a solid foundation for future technology design. Moving into the co-design and testing phase, a web-based survey (n=380 responses) was developed and disseminated using LimeSurvey platform to gain broader insights into older adults' and stakeholders' attitudes toward using technology for independent living. A user needs mapping exercise followed, linking these identified needs to potential technological solutions. Co-design workshops (n=29 participants) involving older adults, family caregivers, health care professionals, and home support workers facilitated in-depth discussions on these solutions, gathering feedback on their utility and acceptability. This phase also included the development of a prototype system that integrated various technologies, all tailored to the specific needs identified earlier.

The proposed prototype design consisted of contact sensors on entry and exit doors to the home and contact sensors on drawers and cupboards in the kitchen to detect activity around the house; smart plugs for kitchen appliances; 6-in-1 sensors to detect motion within rooms in the home alongside temperature and humidity; a Sony mWatch (smart watch device) as an alert system (call for assistance) and for measurement of sleep duration and step count; and an Amazon Echo Show 8 voice-activated assistant for entertainment or leisure use and reminder functionality. The prototype was subsequently tested in a real-world environment, with older adults (n=7) testing the prototype in their home environments for a period of 10 weeks. Participants also completed a process evaluation interview with a researcher via Zoom providing critical feedback on usability, acceptability, and technical performance, aiding in further refinement. In the postdesign phase, the feedback and data collected from the testing were analyzed to extract key insights, which were instrumental in refining the technology and finalizing the design, ensuring it aligned with the users' needs and requirements effectively.

Data Analysis

Quantitative survey responses were analyzed using descriptive statistics in SPSS (IBM Corp). Thematic analysis, as outlined by Braun and Clarke [23], is a qualitative research method used to systematically identify and analyze patterns or themes within data. This approach was applied to workshop and interview transcripts to uncover key themes and insights using NVIVO (Lumivero) qualitative data analysis software. The findings from this analysis were integral to the iterative design process, guiding the development of prototypes and informing the final design and functionality of the NEX system.

Results

Exploratory Workshop

Three broad themes emerged from the thematic analysis of the transcripts from the exploratory workshops based on the aims: loneliness and technology, aging and technology, and adopting and using technology (Table 1).

Table . Key themes from predesign workshops.

Theme	Key findings	Participant quotes
Loneliness and technology	Loneliness is a significant issue for older adults, particularly postretirement, and may lead to mental health concerns. Technology can potentially mitigate some aspects of loneliness by providing means of communication and maintaining social connections.	*If you could have some kind of a system, it is probably technology that could link a person who is isolated at home with some kind of community group or something.* [Family caregiver 01]
Aging and technology	Participants recognized technology's role in supporting independent living for older adults. They discussed the challenges associated with aging, such as the risk of falling, and how technology can offer solutions for home safety and security.	*And also I suppose falling, maybe if there is a stairs in the house, at the top of the stairs, an alert that would come on, say if you were at the top of the stairs, be careful or something. It happened to me, that is why I am conscious of it.* [Older adult 01]
Adopting and using technology	Adoption and ongoing use of technology are hindered by a lack of familiarity and reluctance to use new devices. Participants expressed the need for gradual introduction of technology, appropriate training, and the importance of nonstigmatizing technology that adapts to their changing needs.	*I have a friend, she is older and she has the tablet she won't even open it, even to do a text, it is easy, I will sit and show you. She is very intelligent and that but she has no interest.* [Older adult 02]

Web-Based Survey and Web-Based Workshops

Web-Based Survey

The findings from the survey responses are reported elsewhere [19]. In brief, there was a high level of willingness reported across all groups (202/235, 86% older adults; 71/77, 91% family caregivers; 45/47, 96% health care professionals; and 16/21, 76% homecare staff) to use technology in the future to support older adults to live independently. Additionally, the analysis highlighted that key areas identified by older adult stakeholders where technology could assist in living independently were: home security (77/235, 33%), falls (69/235, 30%), reduced mobility (55/235, 23%), and loneliness (54/235, 23%). Thematic analysis of free text responses for other stakeholder groups highlighted that there were differences in which technology could best assist with independent living. The key areas that were identified were: remote monitoring of family members (family caregivers), communication with clients (health care professionals), and falls (homecare workers). The main disadvantages were considered to be the ability of some older adults to use the technologies, limited access to broadband, impaired cognition limiting the ability to use the technology, and the ability to interpret the data. Older adults perceived the main advantages of the technologies presented to be security or safety potential, the use of these devices to provide independence, and the ability to monitor their own health. Older adults reported the financial investment required and privacy concerns over data collected as the main disadvantages of these devices.

Web-Based Workshops

Participants of the web-based workshops discussed the potential value and concerns related to technology solutions identified by the technology partners. The findings are summarized in Table 2.

Table . Summary of technology types and participant value and concerns from the NEX web-based workshops.

Technology	Value for older adults	Concerns for older adults	Value for other stakeholders	Concerns for other stakeholders
Voice-activated assistant	Communication, entertainment, and activity	Dependency, privacy/intrusion, and data security	Reminders, social connections, entertainment, emergency calls, and promotes confidence	Dependence, disembodied voice, annoying accent, and issues for those with speech impediments
Ambient sensors	Confidence, falls prevention, security, and information for objective assessment	Intrusion/tracking and false alarms	Fall prevention, home security, emergency response activation, clinical benefits, person-centered monitoring, and value for caregivers	Maintenance, false alarms, complex data interpretation, and additional services required for monitoring
Wearables	Emergency response, falls detection, monitoring, and sleep	Stigma and forgetting to wear	Fall detection, reassurance, rehabilitation, and goal setting	Stigma, limited range (geofencing), cumbersome, aesthetically unpleasing, interferes with daily activities, and may forget to wear
Overall system	Reassurance and fosters independence	Trust issues, readiness, and burden on family	Favorable perception and substantial monitoring and information	Ability to adapt to different contexts and tailoring system to individual needs and preferences

Prototype Testing

Overview

In the prototype testing, participants interacted with 4 types of technology: a wearable device (Sony mWatch), a voice-activated assistant (Amazon Echo 8), ambient sensors (Aeotec door and window sensor 6), and smart plugs (Samsung SmartThings smart plugs) installed in their home environment for a 10-week period. At the end of the testing phase, participants completed an evaluation interview. Although the small participant group size made it difficult to generalize the acceptability results, there appeared to be clear trends in the feedback from the prototype testing. The most salient findings from the thematic analysis of transcribed interviews in relation to users' experiences of the prototype are outlined in Table 3 below.

Table . A summary of user experiences from prototype testing.

Technology	User feedback	Participant quotes
Wearable device	Participants were generally disappointed with the watch due to its large, chunky, and masculine design. They found it less attractive compared with other smartwatches like Fitbit, noted issues with its functionality including lack of step history, and frequent need for recharging.	• *I didn't like the watch, I didn't like the style, it wasn't a bit feminine.* [Participant 01] • *I've seen watches that would give you yesterday's and today's steps but there was no history on this watch.* [Participant 04]
Voice-activated assistant	The response was mixed: some participants appreciated the device for its ability to provide companionship, access to music, and international radio stations. However, others viewed it as gimmicky and raised privacy concerns related to data sharing with Amazon.	• *I felt it was a bit of company, to have a voice coming back at you…you could have a conversation with it...I just think it's a wonderful piece of equipment. I live on my own.* [Participant 01] • *If I was lonely, it was quite nice to have someone to talk to and who wouldn't get cross with you.* [Participant 03]
Ambient sensors and Smart plugs	Participants quickly adapted to these technologies, noting a high level of comfort with their presence. Participants appreciated the sensors for their nonintrusive nature and the sense of security they provided, with minimal behavior modification observed.	• *I forgot all about them, except occasionally I might notice the green light flashing if I opened the door.* [Participant 01] • *… great to be able to know what state people are in and what they are doing without necessarily a camera being on them.* [Participant 03]

Post Design Analysis

To consider the implications of the co-design process on the final NEX system design, discussion workshops between the NEX team members (academic and industry project partners) were conducted. A public and patient involvement panel which was established at the outset of the project was also consulted at each stage of design to give expert opinion and advice on how to consider the findings at each iterative phase. The discussion workshops were based on (1) the findings of the pre- and co-design phases, and (2) an investigation of the technical performance of the system during prototype testing (Table 4).

Table . Key findings and recommendations from post design analysis phase.

Aspect	Key issues identified	Recommendations for future deployments
Participant experience	One participant withdrew due to the self-installation process.	Install the NEX system in participant's homes by a technical expert.
Device use	Sony mWatch was found to be unsatisfactory.	Discontinue Sony mWatch and switch to an alternative wearable for data collection.
System performance	Battery life issues, configuration of sensors, system crashes, and missing data.	Implement automatic system data checks to reduce data losses.
Sensor configuration	Issues with battery life, participant-led installation, and devices turned off.	Review and use next-generation devices with longer battery life.
Data integrity	Missing data attributed to device and installation issues.	Use only pretested Smart Plugs and improve ground truth data collection.
Technical analysis	Front-end usability issues and back-end issues like memory use.	Deploy a larger range of sensors and smart plugs, and collect more frequent ground truth data.
ADL[a] detection	Need for improved accuracy in ADL detection.	Deploy a broader range of sensors and smart plugs alongside more frequent ground truth data collection to enhance ADL detection accuracy.

[a] ADL: activities of daily living.

Discussion

Principal Findings

The results of this research have implications for researchers, practitioners, and digital health organizations who are aiming to design and implement technology-based solutions for health care. The co-design process used in this research facilitated the consideration of the needs and requirements of the proposed NEX system through a dynamic design process and design tool selection in response to a range of stakeholder perspectives.

Barriers and Facilitators to Co-Designing Technology to Support Independent Living

In the development of the NEX system, a structured co-design methodology was used, incorporating a series of distinct phases that gathered and integrated insights from a diverse group of stakeholders. Initially, exploratory workshops and web-based surveys provided a broad array of perspectives from older adults, caregivers, health care professionals, and home care staff. These early phases captured essential needs and expectations, which were then analyzed in subsequent co-design sessions focused on refining the prototype. Discussion workshops between researchers and industry partners with input from a public and patient involvement panel were crucial for consolidating the findings from each phase. This process ensured that diverse insights were synthesized into a cohesive design strategy.

A systematic review [18] on co-designing technology for aging in place emphasizes the significant benefits of involving stakeholders in developing technological solutions for older adults, such as enhanced acceptance and adoption. However, the review also identifies that a lack of knowledge among participants can lead to unrealistic expectations, which may impede the design process. This knowledge gap poses a substantial barrier, particularly when co-designing with older adults who may not be familiar with the functionalities of smart devices. The challenge of addressing gaps in understanding the capabilities and benefits of technology was actively addressed during the NEX system's co-design process. Due to COVID-19 constraints, at the early co-design stages (web-based focus groups and surveys) participants were not able to interact with some of the proposed technological solutions. To overcome this, technology images, descriptions of technology use, and demonstration videos were developed to showcase each of the potential technology solutions and their functionality. The images and text descriptions were embedded in the survey to assist with responses relating to the usefulness of technology and the demonstration videos were played via web-based focus groups to aid discussions.

Technology Acceptability and Usability

The exploratory workshops and web-based surveys from the predesign phase underscored the critical importance of using technology to enhance the safety and security of older adults living independently. Interestingly, in the prototype testing, of all of the different technology types that make up the NEX system, ambient sensors were the most widely accepted technology among participants. Additionally, ambient sensors collected the most valuable data to assist with automated identification of ADL [24] which has been implicated as an important approach for supporting continued autonomous living for older adults in the future [25]. A smartwatch was also incorporated into the prototype design to address these needs with features like step count motivation for promoting a healthy lifestyle and emergency response capabilities for safety. However, the smartwatch was not well-received mainly due to its aesthetic features (interfered with clothing) and some technical issues with the GPS emergency response feature, rendering it less effective. Participants did appreciate the step count feature of the smartwatch. These findings prompted further exploration of alternative solutions for safety and security in the home environment for future iterations of the NEX system. Moore et al [26] note that older adults generally enjoy wearable devices that monitor steps, track location, log activities, measure health metrics, and offer automatic emergency contact features. However, continued use of devices requires more than just useful features; it necessitates a support system that motivates users, encourages social interaction, and adjusts to their preferences.

Consistent with the observations of Moore et al [26], the NEX system prototype testing revealed that research participants initially demonstrated high levels of engagement with new technology, but their engagement and potential interest can lessen over time [27]. This has been evidenced by others [28,29] who have investigated motivation among long-term users of assistive technologies. As part of the NEX project, the authors explored the intentions of older adults to adopt and use smart home technologies using the Theoretical Domains Framework, the results of which are reported elsewhere [30]. This work highlighted that unless methods to increase intrinsic motivation are considered in the design of such systems, long-term adherence is unlikely to be achieved. This is an important point of consideration for future research to promote consistent engagement by participants for the collection of data to support their well-being.

Recommendations for Future Deployments

The results of the post design phase highlight the iterative nature of technology development in the context of IoT systems for older adults, emphasizing the need for continuous refinement and user-centered design to address practical challenges effectively. The withdrawal of a participant due to challenges with the self-installation process underscores the importance of user-friendly setup procedures. The recommendation for future deployments to include installation by a technical expert will ensure that participants are not burdened by technical complexities. Participants from the predesign phase also discussed the need for training and support to develop the digital literacy skills required to adopt technology to support independent living. Jiménez et al [31] outline the benefits of an iterative training approach for supporting older adults in the development of these skills. This approach involves a continuous process of training and support, allowing older adults to gradually build their digital literacy skills and confidence in using technology. This approach was subsequently implemented as part of the action research cycle which explored the feasibility and acceptability of NEX in a larger population of community-dwelling older adults. Another key observation from the prototype testing was the need for improved accuracy in detecting ADLs which is a critical aspect of the system's functionality. The recommendation to deploy a broader range of sensors and collect more frequent ground truth data reflects an ongoing commitment to enhancing the precision and effectiveness of the system in real-world applications. Ghayvat et al [22] suggest larger numbers of sensor placements (approximately 30) for effective detection of ADLs in the homes of older adults however the acceptability of the placement of this number of sensors in the home environments of older adults needs to be explored further.

Limitations

As for many other research projects, the COVID-19 pandemic and subsequent restrictions on movement limited the way the research teams could engage with participants and may have had implications for both co-design and prototype testing in this study. For aspects of the co-design process, focus groups were conducted via the web using Zoom as it was not possible to meet in person due to national COVID-19 guidelines. It is possible that richer discussions and opinions on how individual technology types may support independent living might have been achieved during in-person focus groups. Additionally, the prototype testing of NEX occurred during a time when restrictions on movement were in place and therefore the technician could not install the prototype in the homes of participants. Although participants self-installed the technology with the remote support of a technician, there were instances where technology failed (due to battery life) and data was lost, impacting the assessment of the technical performance of NEX. However, these adapted research approaches did facilitate the progression of this research during difficult circumstances.

Conclusion

The co-design process described by the authors enabled the project team to use an agile approach and consider a range of stakeholders' opinions in the design of this system. Although COVID-19 restrictions prevented face-to-face co-design research activities, the research team adapted research methods to facilitate web-based data collection and remote real-life testing. In terms of the research methodology, the authors presented an approach for a comprehensive co-design process involving older adults experiencing technology to support independent living over a sustained period in their own homes rather than conducting experiments and analyzing results based on limited exposure and assessment. The findings from this co-design process highlight that early participant engagement in the design process is necessary to ensure that the system meets the needs of stakeholders, which in turn supports technology adoption and cultivates motivation to use technology. An appreciation of the role of co-design and stakeholder opinions in terms of user needs and requirements by industry partners and clear and frequent communication channels were key attributes of a successful academic-industry collaboration in the area of digital health innovation.

Acknowledgments

This project was funded under the Disruptive Technologies Innovation Fund administered by Enterprise Ireland (project grant DT-2018-0258). The authors are grateful to all participants for their involvement in this research and support of the DCU's Age Friendly University initiative and local council Age Friendly networks.

Abstract

Background: Interventions and care that can evoke positive emotions and reduce apathy or agitation are important for people with dementia. In recent years, socially assistive robots used for better dementia care have been found to be feasible. However, the immediate responses of people with dementia when they are given multiple sensory modalities from socially assistive robots have not yet been sufficiently elucidated.

Objective: This study aimed to quantitatively examine the immediate emotional responses of people with dementia to stimuli presented by socially assistive robots using facial expression analysis in order to determine whether they elicited positive emotions.

Methods: This pilot study adopted a single-arm interventional design. Socially assistive robots were presented to nursing home residents in a three-step procedure: (1) the robot was placed in front of participants (visual stimulus), (2) the robot was manipulated to produce sound (visual and auditory stimuli), and (3) participants held the robot in their hands (visual, auditory, and tactile stimuli). Expression intensity values for “happy,” “sad,” “angry,” “surprised,” “scared,” and “disgusted” were calculated continuously using facial expression analysis with FaceReader. Additionally, self-reported feelings were assessed using a 5-point Likert scale. In addition to the comparison between the subjective and objective emotional assessments, expression intensity values were compared across the aforementioned 3 stimuli patterns within each session. Finally, the expression intensity value for “happy” was compared between the different types of robots.

Results: A total of 29 participants (mean age 88.7, SD 6.2 years; n=27 female; Japanese version of Mini-Mental State Examination mean score 18.2, SD 5.1) were recruited. The expression intensity value for “happy” was the largest in both the subjective and objective assessments and increased significantly when all sensory modalities (visual, auditory, and tactile) were presented (median expression intensity 0.21, IQR 0.09-0.35) compared to the other 2 patterns (visual alone: median expression intensity 0.10, IQR 0.03-0.22*;* *P*<.001; visual and auditory: median expression intensity 0.10, IQR 0.04-0.23; *P*<.001). The comparison of different types of robots revealed a significant increase when all stimuli were presented by doll-type and animal-type robots, but not humanoid-type robots.

Conclusions: By quantifying the emotional responses of people with dementia, this study highlighted that socially assistive robots may be more effective in eliciting positive emotions when multiple sensory stimuli, including tactile stimuli, are involved. More studies, including randomized controlled trials, are required to further explore the effectiveness of using socially assistive robots in dementia care.

Introduction

The number of people with dementia is increasing globally, and it is estimated that it will reach 152 million by 2050 [1]. The provision of adequate social care for people with dementia is a major public health concern in many countries. The neurodegenerative nature of dementia affects memory, cognitive function, and more, resulting in a range of noncognitive symptoms, including changes in behavior, emotion, and social functioning. The most frequent changes include agitation, depression, and apathy. These emotional changes are reported as the most challenging aspect of dementia care by many caregivers [2]. On the other hand, positive emotions such as joy or comfort are relatively preserved until the terminal stage of the disease [3,4]. Previous studies suggest that the arousal of positive emotions may enhance cognitive function, presumably through amygdala activation; therefore, stimuli with a positive valence may enhance the effect of the rehabilitative approach for patients with dementia [3,5]. Considering these facts, interventions and caregiver involvement that can evoke positive emotions and suppress negative psychological responses are important strategies that should be actively implemented in long-term care for people with dementia to maintain residual functions and alleviate the burden of care.

As examples of emotion-related interventions, music therapy [6,7] and occupational therapy [8,9] have been shown to be effective in terms of emotional control. However, due to the rapid increase in the number of people with dementia and the shortage of dementia caregivers [1,10,11], there is a lack of staffing power to provide such nondrug therapies broadly and equally. In recent years, clinical applications of socially assistive robots have been used to provide high-quality emotional support and companionship [12-14]. Socially assistive robots are machines designed to provide assistance in the caregiving process through social rather than physical means and are equipped with a social interface to enable interaction with the user [15-17]. One systematic review and meta-analysis, as well as one scoping review, found that Paro, a baby seal–shaped socially assistive robot, has significant effects on agitation and depression [12,18], while another systematic review and meta-analysis concluded that there is little evidence that people with dementia derive benefits from socially assistive robots for cognition or neuropsychiatric symptoms when considering various types of robots, although they are feasible and acceptable [11]. On the other hand, one small between-groups comparison study reported that a certain type of socially assistive robot showed a negative effect in participants with cognitive decline, based on an examination of immediate neurophysiological changes [19].

When using socially assistive robots in clinical practice, one important aspect to consider is the immediate response of persons with dementia. In general, when confronted with a new robot or technology, a relatively positive immediate response known as the novelty effect [20] tends to be observed. In contrast, in people with cognitive decline, the immediate response to robots is reported to be somewhat stressful rather than positive [19]. These findings suggest that people with dementia, or those with memory and other cognitive impairments, may have a different immediate response compared to the general public. For example, people with dementia have a reduced ability to process multiple sensory stimuli [21]; therefore, they might have difficulty accepting and integrating multiple unfamiliar stimuli (eg, shapes, lights, sounds, and touch) provided simultaneously by the robot in the first interaction. Since they are prone to mental stress when they do not understand a situation [22], these stimuli from the robots could cause a tense or negative response. Nonetheless, no studies have verified how socially assistive robots are perceived by people with dementia from the perspective of having to process multiple sensory modalities. Moreover, an immediate response from the person with dementia is crucial in clinical settings because it helps care providers confirm the effectiveness of the robot on the spot and make precise decisions about whether to continue using the robot. Therefore, it is beneficial for clinical applications to focus on understanding the immediate responses of people with dementia when they are given multiple sensory modalities from socially assistive robots.

For an objective and better understanding of these issues, the signs of emotional responses should be quantified using appropriate techniques. Given that verbal skills tend to be impaired in people with dementia [23,24], it is important to use not only self-reported outcomes but also objective measures that can be obtained with minimal burden. For example, in the field of psychology, facial expression is considered a differentiated indicator of inner emotions [25,26]. According to recent reports, analysis of facial imaging using facial expression analysis software is able to quantify facial expressions and estimate emotions with good validity [27,28]. Applying these technologies to the investigation of the use of socially assistive robots among people with dementia will enable detailed and empirical verification of their effects, such as responses to the different sensory stimuli mentioned above, which are difficult to detect with subjective scales.

In this context, this study aimed to quantitatively evaluate the psychological and emotional reactions evoked in people with dementia to stimuli derived from socially assistive robots using facial expression analysis of facial video clips. In particular, we investigated how immediate responses changed as the modalities of sensory stimulation provided by the robot increased. Furthermore, from the perspective of eliciting positive emotions, which are beneficial to dementia care, this study also examined the differences in the emotion of joy elicited by the different types of robots.

Methods

Ethical Considerations

The study protocol was approved by the institutional ethics committee of the National Center for Geriatrics and Gerontology (1539) and prospectively registered in the UMIN Clinical Trial Registry (UMIN000046256). All participants with a Clinical Dementia Rating (CDR) scale [29] score of 0 or 1 provided informed consent themselves in accordance with the Declaration of Helsinki. For those who were considered to have an insufficient capacity to consent due to cognitive decline equivalent to CDR 2 and 3, informed consent was obtained from their family members, and the procedures were explained to the participants in plain language to obtain their approval. To comply with ethical principles, all data collected were anonymized and stored in a locked file or on a password-protected computer.

Study Design and Setting

This pilot study was conducted as a single-arm, self-controlled, interventional study. Two local nursing care facilities that had no previous experience implementing socially assistive robots were selected as the experiment sites.

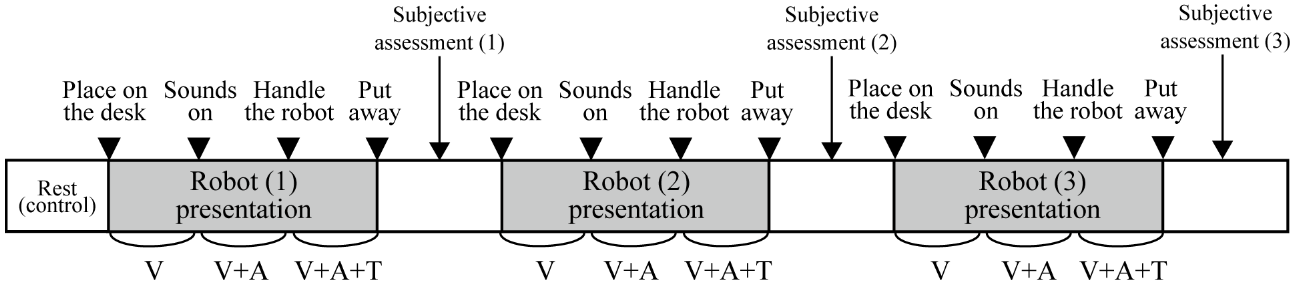
Participants

Participants were recruited among the residents of the 2 nursing homes. The inclusion criteria were as follows: a significant decline in cognitive function interfering with independence in the performance of everyday activities, the ability to maintain a sitting position for 15 minutes or more, the ability to communicate using simple words, and the ability to follow 2-step instructions. These criteria were first assessed by nursing home staff members through assessments performed as part of daily nursing care procedures. Regarding cognitive decline, candidates either had a previous formal diagnosis of dementia from their physician or received a diagnosis from one of the researchers (EO, a physician); they also had confirmed evidence that cognitive decline was present and that the decline was not due to delirium or other mental disorders. Ultimately, all the participants met the diagnostic criteria for dementia in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*). Those with unstable physical or mental conditions or evident higher cognitive dysfunction due to causes other than dementia were excluded.

Procedures

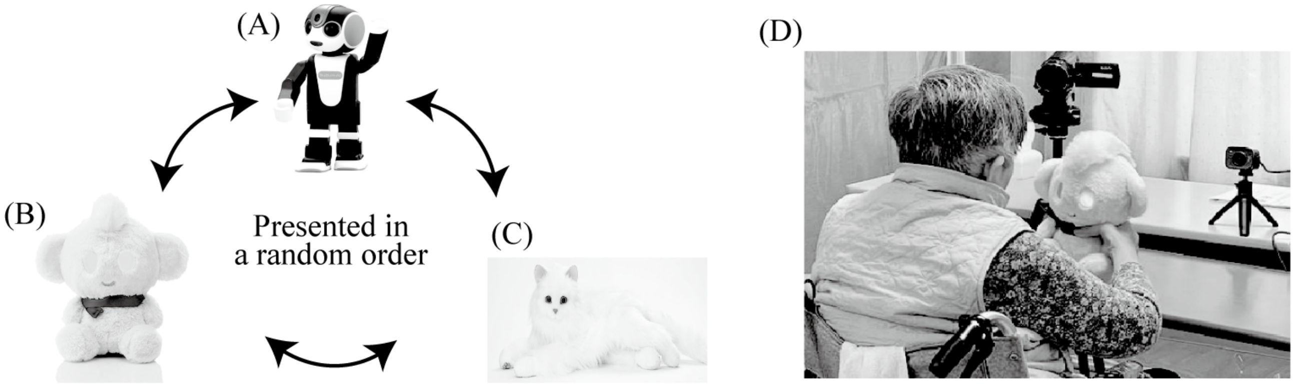
The participants were taken to a private room or a place with minimum environmental noise, and their faces were recorded in a resting state for 30 seconds. This was referenced as the control image for calibrating the facial expression analysis (to be described below). Next, the socially assistive robots were presented to the participant by a familiar staff member in 1 session using a predetermined 3-step procedure. The staff explained in advance that they wanted the participants to share how they felt after experiencing the robots. In the first step, the robot was placed on a desk in front of the participant (visual stimulus). In the second step, the robot was manipulated to produce a gentle voice or meow (visual and auditory stimuli). In the third step, the participant was encouraged to touch the robot (visual, auditory, and tactile stimuli) and was able to handle it freely, including petting and holding. The 3 patterns of sensory stimulus produced by the robots were presented for approximately 30 seconds in the context of assessing the participant's immediate responses unless the participant refused (Figure 1).

Figure 1. The flow of robot presentation to the participant. V: visual stimulus only; V+A: visual and auditory stimuli; V+A+T: visual, auditory, and tactile stimuli.



Each participant was presented with 3 types of commercially available robot with typical characteristics—a humanoid-type robot capable of voice communication (RoBoHoN; Sharp Corp), a doll-type robot with the appearance of a stuffed toy and a voice recognition and reproduction system (Chapit; RayTron Inc), and an animal-type (cat-shaped) robot that can meow, move its tail, and recognize sound (Amaenbou-Nekochan; Digirect Co, Ltd)—resulting in 3 sessions per participant. The order of presentation, which was determined in advance using a random number table, differed for each participant (Figure 2).

Figure 2. Socially assistive robots used in this study. Each participant was presented with these 3 types of robots with typical characteristics, resulting in 3 sessions per participant. The order of presentation was determined in advance using a random number table. (**A**) Humanoid-type, (**B**) doll-type, and (**C**) animal-type robots; (**D**) video recording while the participant is touching the robot.



Assessments of Emotional Responses

Subjective Assessment

At the end of each robot presentation session, the degree of subjective feelings (happy, sad, angry, surprised, scared, and disgusted) was recorded using a 5-point Likert scale (1: not at all; 2: very little; 3: so-so; 4: somewhat; 5: very much). The participants were shown a scale with words corresponding to each of the 5 points of the scale and were asked to select the point that best described their current feelings. This was assessed a total of 3 times (ie, once at the end of each robot presentation).

Video Recording and Facial Expression Analysis

For the study procedures, a video camera (Logicool StreamCam; Logitech Inc) was configured on a desk to capture the participants' faces from the front. In case this camera's view was blocked by arm movements or the robot, another camera (Handycam HDR-CX470, Sony Corp) was fixed on a tripod positioned 30 degrees diagonally in front of the participant.

The videos were recorded continuously during the session in full HD (1920 × 1080 pixels) at 60 frames per second. To optimize the sensitivity and accuracy of the facial expression analysis, we segmented the video clips such that each clip contained 1 sensory stimulation pattern (visual only; visual and auditory; or visual, auditory, and tactile), and then cropped them to a suitable resolution that focused on the facial region. If necessary, the brightness of the video clips was minimally adjusted.

We used commercially available software for quantifying facial expressions (FaceReader; version 7; Noldus Information Technology Inc). This software was developed based on a quantitative evaluation method called the Facial Action Coding System [30], which describes visually identifiable facial muscle movements as "action units," identifies the intensity of a basic emotional state, and outputs time-series data sets comprising expression intensity values from 0 to 1 for each of the 7 facial expression elements (ie, neutral, happy, sad, angry, surprised, scared, and disgusted) on a continuous scale with high accuracy [27,31,32]. This method is advantageous in that it can quantitatively evaluate facial expressions conveniently with good reproducibility, unlike subjective evaluations, as discussed previously [33]. The software provides 5 face models (General, General61, Children, East Asians, and Elderly) that correspond to the data sets used in the algorithm training. We used the East Asian face model according to the software specifications.

Additionally, we used the calibration function provided by the software to minimize person-specific biases due to facial wrinkles or light effects. The reference manual of FaceReader explains that this function removes biases in the 7 facial expression elements but does not increase the intensity. For each participant, the resting facial image in the first part of recording was used as the calibration image for all the video clips of the participant. In cases where certain facial expression elements were detected in the neutral control image, those expression elements were corrected in the images to be analyzed. The degree of successful face recognition was evaluated for every video clip, and the session was excluded from further analysis if both images from the 2 cameras had a low proportion of successful frames (<20%), with reference to previous studies [32,34].

Clinical Assessments

In addition to basic characteristics, overall cognitive function was assessed using the Japanese version of the Mini-Mental State Examination (MMSE-J) [35] and the Japanese version of the Montreal Cognitive Assessment (MoCA-J) [36]. The Barthel index was used to assess performance on 10 basic activities of daily living (ADL), which tend to deteriorate in people with dementia. The total score ranges from 0 (worst; all dependent) to 100 (best; all independent). The Dementia Behavior Disturbance Scale (DBDS) [37,38] was used to assess the severity of neuropsychiatric symptoms. The scale evaluates a total of 28 items on a 5-point scale from 0 (not at all) to 4 (always) in terms of the frequency of the behavioral disturbances typically seen in persons with dementia, such as wandering, agitation, and aggression, and is scored from 0 (best) to 112 (worst). The questionnaire format allowed caregivers to answer the questions easily. Finally, to assess hearing disability, which may affect the response to auditory stimulation, 10 items from the Questionnaire on Hearing [39] were surveyed to score the severity of hearing loss in daily life. These 10 questions set up specific situations of hearing speech or environmental sounds in daily life and were to be answered on a 5-point scale from 1 (always able to hear) to 5 (never able to hear). The total score ranges from 10 (best) to 50 (worst).

The MMSE-J and MoCA-J were administered by skilled occupational therapists on different days. The Barthel index, DBDS, and the Questionnaire on Hearing were scored by nursing home staff members who were sufficiently familiar with the participants.

Statistical Analyses

The averages of the emotions expressed in response to the robot (ie, happy, sad, angry, surprised, scared, and disgusted) were compared to each other using the nonparametric Wilcoxon signed-rank test, with the *P* values multiplied by the number of tests according to the Bonferroni method. The correlations between subjective and objective emotional assessments were also examined using Spearman correlation coefficients. The average expression intensity values during the 30 seconds for each sensory stimulus obtained by facial expression analysis were compared for all 3 patterns (visual only; visual and auditory; or visual, auditory, and tactile) using the Friedman test with the Wilcoxon signed-rank test as a post hoc test. The average of the 3 robot presentation sessions was used in this part of the analysis. Additionally, focusing on positive emotions, the expression intensity values for “happy” were compared between the different types of robots using the Friedman test with the Wilcoxon signed-rank test as a post hoc test. Statistical analyses were performed using STATA/SE (version 13.1; StataCorp). Any *P* value less than .05 was considered statistically significant.

Results

Table 1 presents the demographic characteristics of the participants. Eleven participants (38%) had been diagnosed with Alzheimer disease by their physician, 5 (17%) had dementia with Lewy bodies, and 13 (45%) met the criteria for major neurocognitive disorder in the *DSM-5*, but the etiology was not specified. All the participants had cognitive decline when compared with the cutoff value of 26 on the MoCA-J [36].

Table . Overall participant characteristics (N=29).

Characteristics		Values
Age (years), mean (SD; range)		88.7 (6.2; 71-98)
Gender, n		
	Male	2
	Female	27
Type of disease, n		
	Alzheimer disease[a]	11
	Dementia with Lewy bodies[b]	5
	Not specified	13
Years of education, mean (SD; range)		9.7 (2.2; 6-13)
MMSE-J[c], mean score (SD; range)		18.2 (5.1; 11-28)
MoCA-J[d], mean score (SD; range)		11.8 (4.9; 2-24)
Barthel index, mean score (SD; range)		66.0 (24.8; 10-95)
10 items from the Questionnaire on Hearing, mean score (SD; range)		26.6 (8.6; 14-50)
DBDS[e], mean score (SD; range)		13.4 (9.6; 0-40)

[a] A total of 4 patients were taking medication for dementia.

[b] A total of 2 patients were taking medication for dementia.

[c] MMSE-J: Japanese version of Mini-Mental State Examination.

[d] MoCA-J: Japanese version of Montreal Cognitive Assessment.

[e] DBDS: Dementia Behavior Disturbance Scale.

The average subjective emotional assessments (5-point Likert scale) and objective expression intensity values for the expression elements across all of 3 types of robots are shown in Table 2. Facial analysis failed to detect any action units or emotional elements in 1 of the 29 participants. Also, 1 video clip was excluded from the analyses because of a low proportion of successful frames (participant 13; doll-type robot; visual, auditory, and tactile stimuli presented). After excluding these video clips, the overall percentage of the video frames analyzable by the software was 81.4%. Among the self-reported emotions, “happy” was significantly the most common (happy vs surprised: *P*=.01; happy vs sad, angry, scared and disgusted: *P*<.001), and facial analysis–detected emotions showed the same trend in that the values of “happy” were significantly the most common among the 6 emotional elements assessed (happy vs all others: *P*<.001). Additionally, the correlations between subjective and objective emotional assessments were significant for “happy,” “sad,” and “surprised,” though the correlation coefficients were interpreted as slight or low. Taking the value of “happy” as an example, as shown in Figure 3, there were cases where the objective value was detected as high even when the subjective feelings were reported as low.

Table . The relationship between subjective and objective emotional assessments.

	Subjective (5-point Likert scale; n=29)		Objective (expression intensity values; n=28)		ρ	*P* value
	Mean (SD)	Range	Mean (SD)	Range		
Happy	3.6 (1.0)	1-5	0.18 (0.16)	0-0.73	0.21	<.001
Sad	2.1 (0.8)	1-5	0.07 (0.09)	0-0.61	0.14	.03
Angry	1.9 (0.8)	1-4	0.07 (0.11)	0-0.77	0.06	.31
Surprised	3.1 (1.1)	1-5	0.09 (0.11)	0-0.62	0.29	<.001
Scared	1.9 (0.7)	1-5	0.03 (0.05)	0-0.36	0.05	.42
Disgusted	2.0 (1.0)	1-5	0.05 (0.06)	0-0.34	0.08	.21
Neutral	N/A[a]	N/A	0.46 (0.13)	0.14-0.85	N/A	N/A

[a] N/A: not applicable.

Figure 3. Comparison of the objective expression intensity for “happy” at each grade of subjective emotional assessment (5-point Likert scale). Error bars indicate SDs, the lines within the boxes indicate medians, and the dots indicate outliers that were more than a quarter of the range × 1.5 away from the first or third quartile.

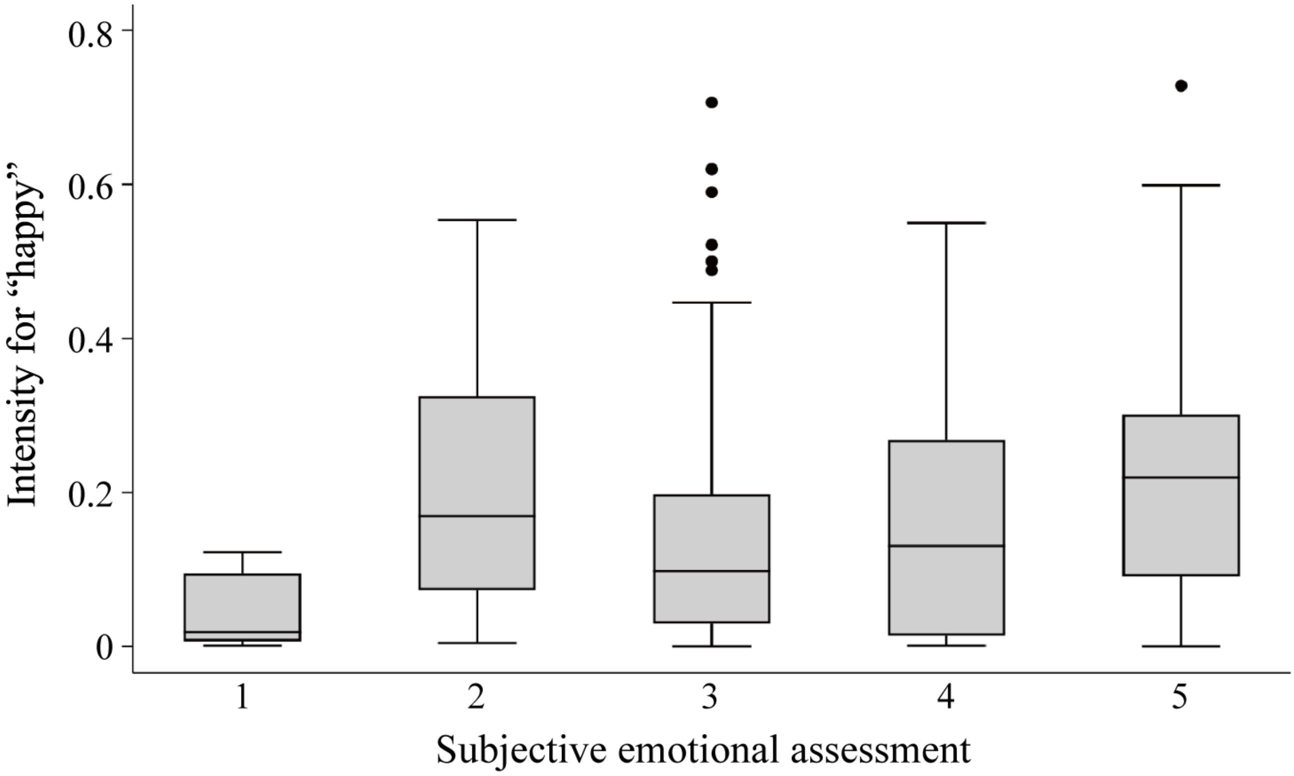


Figure 4 shows a comparison of 3 different patterns of sensory stimuli among all participants. There were significant differences in the values for “neutral” (*P*<.001), “happy” (*P*<.001), “sad” (*P*=.001), “scared” (*P*=.04), and “disgusted” (*P*<.001) among the 3 patterns. Post hoc analyses revealed that the values for “happy” significantly increased in the pattern with visual, auditory, and tactile stimuli (median score 0.21, IQR 0.09-0.35) compared to the patterns with visual stimulus only (median score 0.10, IQR 0.03-0.22; *P*<.001) and with both visual and auditory stimuli (median score 0.10, IQR 0.04-0.23; *P*<.001). The values for “sad” (with visual, auditory, and tactile stimuli: median score 0.05, IQR 0.01-0.11) and “disgusted” (with visual, auditory, and tactile stimuli: median score 0.04, IQR 0.02-0.10) exhibited the same trend, though both of these values were significantly smaller than those for “happy” (*P*<.001). In contrast, the values for “neutral” and “scared” significantly decreased in the pattern with visual, auditory, and tactile stimuli compared with the other 2 patterns. However, the intensity of each emotional element did not change linearly over time.

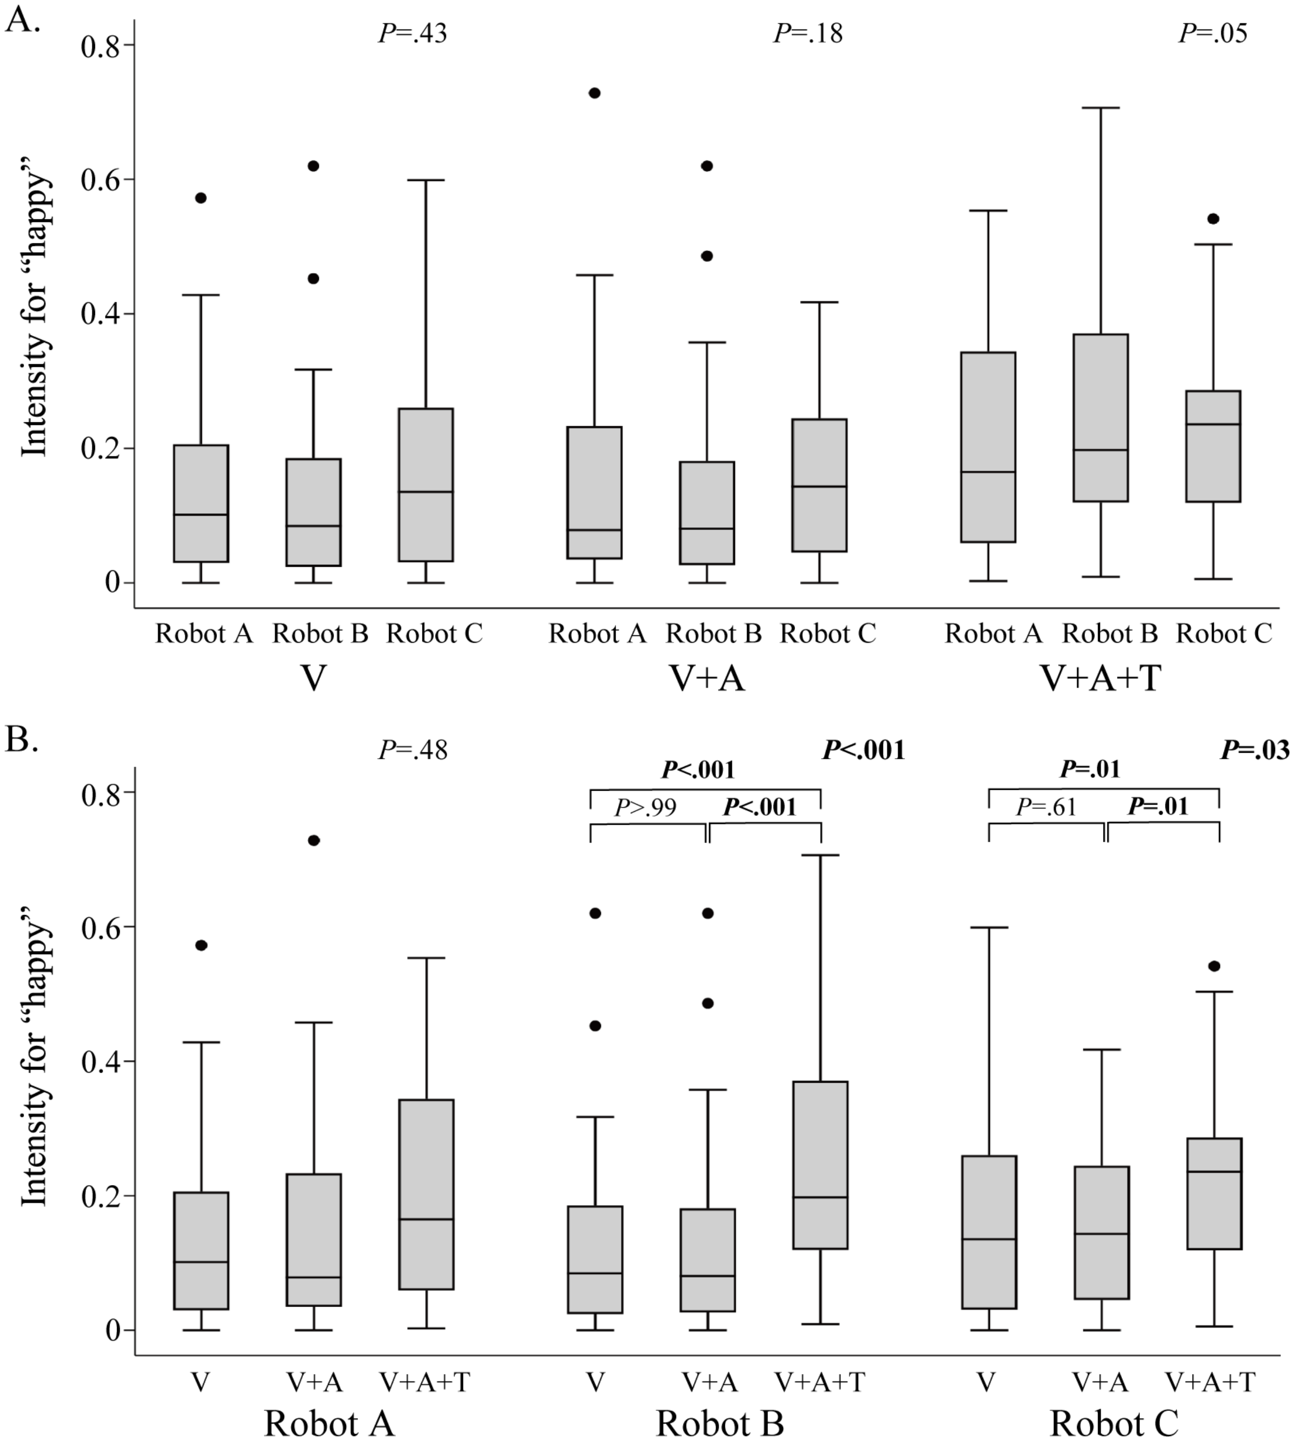
Figure 4. Comparison of all the expression intensities under the 3 different patterns of sensory stimulation. Error bars indicate SDs, the lines within the boxes indicate medians, and the dots indicate outliers that are more than a quarter range × 1.5 away from the first or third quartile. The values in the upper right of each group represent the overall *P* values in the Friedman test. The values above the boxplots for the nonresponder group represent the *P* values in the post hoc test (the Wilcoxon signed-rank test). *P* values less than .05 are denoted in bold. V: visual stimulus only; V+A: visual and auditory stimuli; V+A+T: visual, auditory, and tactile stimuli.

When comparing the expression intensity values for "happy" between the different types of robots for the same participants and the same sensory stimuli, no statistical differences were found, as depicted in Figure 5A. When comparing the expression intensity values for "happy" between the different sensory stimuli for the same robot type, no statistically significant differences were found for robot A (humanoid-type*;* *P*=.48), while robot B (doll-type*;* *P*<.001) and robot C (animal-type*;* *P*=.03) had large, significant values in the pattern with visual, auditory, and tactile stimuli compared with the other 2 patterns, as shown in Figure 5B.

Figure 5. Comparison of the expression intensity for "happy" between the different types of robots. (A) Comparison between 3 types of robots with the same pattern of sensory stimulation. (B) Comparison within each robot type using the 3 different patterns of sensory stimulation. Error bars indicate SDs, the lines within the boxes indicate medians, and the dots indicate outliers that are more than a quarter of the range × 1.5 away from the first or third quartile. The values in the upper right of each group represent the overall *P* values from the Friedman test. The values above the boxplots for robots B and C represent the *P* values from the post hoc test (the Wilcoxon signed-rank test). *P* values less than .05 are denoted in bold.



Discussion

Principal Results

This study aimed to quantitatively evaluate the psychological and emotional responses of people with dementia to complex sensory stimuli provided by socially assistive robots. To summarize, the values for “happy” were found to be the largest in the overall response to the robots among the emotional elements in both the self-recorded assessment and objective facial expression analysis. However, correlations between the subjective and objective emotional assessments were found to be relatively low or insignificant. When comparing the 3 different patterns of sensory stimulation, there was a significant increase in some of the expression intensity values when all stimuli (visual, auditory, and tactile) were presented. In the comparison between different types of robots, focusing on “happy,” there was a significant increase when all stimuli were presented by a doll-type robot and by an animal-type robot but not by a humanoid-type robot.

The emotional responses revealed by the objective facial expression analysis showed the same trend as the participants’ subjective assessment, with happy emotions having the largest values in both assessments. This result suggests that the facial expression analysis system can successfully detect the expressions that emerge in people with dementia, which is consistent with a previous study [40].

However, considering that the facial expression intensity was detected as relatively high in some cases where the subjective rating was moderate, the facial expression analysis may be able to capture emotions that are not sufficiently represented by a subjective 5-point Likert scale. In fact, a previous study supports the appropriateness of facial expression analysis as a nonverbal pain assessment for people with dementia when they lack the ability to self-report [41]. Therefore, facial expression analysis may also be useful as an accurate nonverbal assessment of emotions for people with dementia.

Although some studies have already demonstrated positive responses in people with dementia when presented with socially assistive robots [42,43], this study is the first to objectively and quantitatively describe emotional responses using facial expression analysis. Additionally, these results are inconsistent with those of Goda et al [19], who found that a 5-minute talk session with a socially assistive robot caused stress in people with dementia. In contrast to this study, the socially assistive robot’s interaction in the study by Goda et al [19] was mainly through verbal communication; thus, it was inferred that these stimuli were burdensome for people with dementia, who tend to have a decline in verbal communication skills. The positive expressions shown in this study are considered to have been observed as responses to sensory stimuli and not verbal stimuli.

Regarding the relationship between the type of sensory stimulus and emotional responses, the expression intensity values for “happy,” “sad,” and “disgusted” significantly increased with increasing sensory stimuli. Particularly, happy emotions were revealed to be elicited most strongly in persons with dementia when different varieties of sensory stimuli were presented. With respect to the values for “sad” and “disgusted,” we consider it natural that participants became somewhat careful or timid toward unknown experiences when interacting closely with robots. However, these emotional elements in automated analysis should be interpreted with caution, as they can occasionally include other negative emotions, such as fear [44], especially when accompanied by facial movements around the lips or jaws [31]. Nevertheless, the values for these negative emotions remain small compared to the value for “happy,” showing that positive emotions were dominant when visual, auditory, and tactile sensory stimuli were offered.

Notably, this increase in positive emotional responses may include changes over time, because the sensory stimuli were added over time in this study. Given the procedures in this study, the results could have been influenced by the novelty effect [20], which is derived from curiosity toward a new experience. However, the intensity of each emotional element did not change linearly when sensory stimuli were added over time. Moreover, the addition of an auditory stimulus did not significantly increase the expression intensity value, whereas the addition of a tactile stimulus did. These findings suggest the importance of adding tactile stimuli to visual and auditory stimuli. This is plausible considering that tactile information connects through several pathways to the insular cortex, which evokes emotional responses [45,46]. The finding that tactile stimuli evoked positive feelings is supported by previous studies that showed that haptic or tangible input was effective in helping people with dementia understand and adapt to their surroundings [47,48]. Regarding auditory stimuli, the results of the Questionnaire on Hearing did not indicate that the participants had very good hearing, suggesting that the effects of auditory stimuli on emotion elicitation may have been relatively small. Since hearing loss is associated with the risk of developing dementia [49], and a high percentage of people with dementia actually have hearing loss [50,51], this issue may also be of great clinical importance.

Furthermore, it is noteworthy that a significant increase in expression intensity values for “happy” with increased sensory stimuli was observed for doll-type robots and animal-type robots, but not for humanoid-type robots. One of the distinctive characteristics of the doll-type and animal robots used in this study was that they were covered by soft, fur-like materials. The importance of soft materials is commonly discussed in the field of soft robotics for medical use or human assistance [52,53]. Softness is considered effective not only in terms of safety for the human body but also in terms of the imitation of reality or the creation of familiarity [54] and emotional processing [55]. However, the emotional effects of various tactile sensations in people with dementia have not yet been studied; consequently, given the findings of this study, the effectiveness of soft tactile stimuli in dementia care may be worth exploring in future research.

Limitations

This study has a few limitations. First, it included a small number of participants and a single experimental group. Changes in facial expressions were reliably detected by using the participants’ resting states as controls. However, another study design, such as a randomized controlled trial, is required to confirm these effects more clearly. Second, the generalizability of our findings may be limited, as most of the participants in this study were female. Previous studies report that there are gender differences in emotional responses to some types of sounds [56], emotion expression [57], and emotion regulation [58], although gender and facial expression have been reported to have no significant correlation [40]. Further research with male participants will be needed to reveal possible gender differences in responses toward social robots. Third, since there is no prior literature that has identified a minimum detectable change or a minimal clinically important difference for expression intensity, the clinical significance of the changes in expression intensity values demonstrated in this study needs to be explored further. Finally, this study only investigated the immediate responses to socially assistive robots, with patients allowed to interact with each robot for only 1.5 minutes in total. However, in real clinical settings, people with dementia might express more diverse patterns of responses, using these robots as they would like. Moreover, any enthusiasm resulting from the novelty effect may diminish over time. Thus, further investigation is required to reveal the long-term emotional effects of socially assistive robots on people with dementia, including variability in positive responses over several hours or days of use and the effects of these robots on their neuropsychiatric symptoms.

Conclusions

This study quantitatively examined the emotional reactions of people with dementia to socially assistive robots. The expression intensity values, especially the values for “happy,” significantly increased with multiple sensory stimuli, including visual, auditory, and tactile stimuli. Therefore, this study shows that socially assistive robots may be more effective in arousing positive emotions when multiple sensory stimuli are involved. Further studies, including randomized controlled trials, are required to further explore the effectiveness of and the optimal methods for using socially assistive robots in dementia care.

Acknowledgments

EO, AO, KK, KM, and SH conceptualized and designed the study. EO collected and analyzed data and drafted the manuscript. MK participated in data collection, data interpretation, and manuscript editing. AO, KK, YO, and SU participated in data interpretation and manuscript editing. IK participated in data interpretation and critical revisions of the manuscript. All authors have read and approved the final manuscript. This study was supported by the Japan Health Research Promotion Bureau Research Fund for Young Investigators (JH2021-Y-11). We sincerely thank the staff of Wakyokai Nagomi-no-Sato and Jinshikai Ruminasu Obu (nursing homes for older people) and the Wellness Valley Promotion Office (Obu City) for their cooperation. We also thank Naho Hashimoto, Ai Sugiyama, Michiko Chiso, and Ayumi Ogura for their technical support.

Conflicts of Interest

None declared.

Abstract

Background: Artificial intelligence (AI) such as ChatGPT by OpenAI holds great promise to improve the quality of life of patients with dementia and their caregivers by providing high-quality responses to their questions about typical dementia behaviors. So far, however, evidence on the quality of such ChatGPT responses is limited. A few recent publications have investigated the quality of ChatGPT responses in other health conditions. Our study is the first to assess ChatGPT using real-world questions asked by dementia caregivers themselves.

Objectives: This pilot study examines the potential of ChatGPT-3.5 to provide high-quality information that may enhance dementia care and patient-caregiver education.

Methods: Our interprofessional team used a formal rating scale (scoring range: 0-5; the higher the score, the better the quality) to evaluate ChatGPT responses to real-world questions posed by dementia caregivers. We selected 60 posts by dementia caregivers from Reddit, a popular social media platform. These posts were verified by 3 interdisciplinary dementia clinicians as representing dementia caregivers' desire for information in the areas of memory loss and confusion, aggression, and driving. Word count for posts in the memory loss and confusion category ranged from 71 to 531 (mean 218; median 188), aggression posts ranged from 58 to 602 words (mean 254; median 200), and driving posts ranged from 93 to 550 words (mean 272; median 276).

Results: ChatGPT's response quality scores ranged from 3 to 5. Of the 60 responses, 26 (43%) received 5 points, 21 (35%) received 4 points, and 13 (22%) received 3 points, suggesting high quality. ChatGPT obtained consistently high scores in synthesizing information to provide follow-up recommendations (n=58, 96%), with the lowest scores in the area of comprehensiveness (n=38, 63%).

Conclusions: ChatGPT provided high-quality responses to complex questions posted by dementia caregivers, but it did have limitations. ChatGPT was unable to anticipate future problems that a human professional might recognize and address in a clinical encounter. At other times, ChatGPT recommended a strategy that the caregiver had already explicitly tried. This pilot study indicates the potential of AI to provide high-quality information to enhance dementia care and patient-caregiver education in tandem with information provided by licensed health care professionals. Evaluating the quality of responses is necessary to ensure that caregivers can make informed decisions. ChatGPT has the potential to transform health care practice by shaping how caregivers receive health information.

Introduction

Older adults have responded to the COVID-19 pandemic by increasing their internet-enabled behaviors, which include expanding their medical care to the use of web-based platforms [1]. Indeed the internet has become the most common source of information among dementia caregivers [2], and with recent advances in artificial intelligence (AI), caregivers will increasingly use AI to obtain information about health [3,4]. ChatGPT by OpenAI [5], an innovative, dialogue-based large language model that responds to complex natural language inquiries, holds great promise to improve the quality of life of patients with dementia and their caregivers by providing high-quality responses to meet their needs for information [4]. On the other hand, several studies have highlighted the limitations of generative AI models in health care, citing the lack of trust and reliability as some of the primary challenges [6,7]. Although there have been studies on the quality of ChatGPT responses to common questions about heart disease [8], cirrhosis [9], and bariatric surgery [10], to our knowledge, no studies have examined the quality of ChatGPT responses to real-world questions posed by dementia caregivers. We have addressed this gap by examining the quality of ChatGPT-3.5 responses to complex questions posted by dementia caregivers on social media.

Methods

Overview

From January to May 2023, a total of 60 social media posts representing dementia caregivers' needs for information in 3 areas (memory loss and confusion, aggression, and driving; 20 posts per area) were selected from Reddit, a popular social media platform. These topics were chosen because they are common clinical themes that are often complex and difficult to navigate with potential safety implications. Four seed posts were used in each area to discover the additional 16 posts. Posts were excluded if the poster's main question did not fall into the 3 aforementioned areas as verified by dementia clinicians or if the poster declared they were "venting" and/or no specific question was asked. Posts that were unclear on whether the person had a dementia diagnosis were excluded to avoid assessing posts that were not clearly dementia related. Word count for posts in the memory loss and confusion category ranged from 71 to 531 (mean 218; median 188), aggression posts ranged from 58 to 602 (mean 254; median 200), and driving posts ranged from 93 to 550 (mean 272; median 276). Of the 60 posts, the caregiver described the person with dementia as their parent (n=34, 56%), grandparent (n=22, 36%), uncle (n=2, 3%), or spouse (n=1, 1.6%). One post did not report relationship. The gender of the person with dementia was described as female in 57% (n=34) of posts and as male in 42% (n=25) of posts. One post did not report gender.

Three clinicians, each having more than 15 years of experience with patients with dementia and their caregivers, but from diverse disciplines (pharmacy, neuropsychology, and social work), assessed ChatGPT responses to the 60 posts using an adapted rating scale based on Hurtz et al's [11] levels of cognitive complexity pertaining to clinical decision-making (Table 1). Responses received 1 point for each of the following characteristics: *factuality*, *interpretation*, *application*, *synthesis*, and *comprehensiveness*, with a scoring range of 0-5 for each response, where higher scores indicate higher quality. Table S1 in Multimedia Appendix 1 presents examples of posts for each topic area, ChatGPT responses, and clinician ratings for each response category.

Table . Description of rating scale categories used to measure the quality of ChatGPT responses.

Characteristic	Description
Factuality	Response did not contain inaccurate or false information.
Interpretation	Response adequately interpreted the poster's main need, correctly disregarded nonpriority details, and did not recommend strategies that the poster had already tried.
Application	Response suggested tangible actions (eg, educational information, a change the caregiver could make, and communication strategies such as validation and redirection).
Synthesis	Response contained follow-up recommendations as needed (referrals to help beyond the caregiver-patient dyad, such as support groups, health care professionals, or other community resources).
Comprehensiveness	Response had strong depth, breadth; response was thorough and complete.

Although the results reported in this paper were based on raters' consensus scores, we acknowledge the potential benefits of expanding on ChatGPT responses that originally received different scores. Initially, 1 rater gave a point for comprehensiveness when the majority of suggestions they would provide clinically were conveyed in ChatGPT's response, but another rater did not give the point if they felt it was missing anything at all. It was agreed upon during consensus that if the majority of recommendations were provided, ChatGPT responses would receive full credit for *comprehensiveness*.

Ethical Considerations

This study was approved by the institutional review boards of The University of Texas at Austin (STUDY00003358) and the University of Pittsburgh (STUDY20020007).

Results

ChatGPT responses in the memory loss and confusion category ranged from 89 to 276 words (mean 170; median 165), 91 to 372 words in the aggression category (mean 221; median 234), and 65 to 359 words in the driving category (mean 175; median 130). At least 2 clinicians agreed on the ratings for all ChatGPT responses, with any disagreements resolved by discussion. ChatGPT scores ranged from 3 to 5. Overall, of the 60 responses, 26 (43%) received 5 points, 21 (35%) received 4 points, and 13 (21.7%) received 3 points (Table 2), suggesting high quality. There were no responses that scored a 0, 1, or 2; there were no fabricated responses; and no responses were considered harmful to posters. ChatGPT received the lowest ratings in *comprehensiveness*, followed by *interpretation*, and the highest ratings in *synthesis*, with only 2 out of 60 posts failing to receive the point (Table 3).

Table . Rating scale results by topic.

Score	Memory loss and confusion (n=20), n (%)	Aggression (n=20), n (%)	Driving (n=20), n (%)	Total (N=60), n (%)
3	6 (30)	3 (15)	4 (20)	13 (22)
4	7 (35)	6 (30)	8 (40)	21 (35)
5	7 (35)	11 (55)	8 (40)	26 (43)

Table . Number of ChatGPT points for each topic.

Characteristic	Memory loss and confusion (n=20), n (%)	Aggression (n=20), n (%)	Driving (n=20), n (%)	Total (N=60), n (%)
Factuality	17 (85)	19 (95)	20 (100)	56 (93)
Interpretation	17 (85)	17 (85)	13 (65)	47 (78)
Application	20 (100)	17 (85)	17 (85)	54 (90)
Synthesis	18 (90)	20 (100)	20 (100)	58 (96)
Comprehensiveness	9 (45)	15 (75)	14 (70)	38 (63)

Discussion

Principal Findings

In this study, ChatGPT responses to complex, real-world questions posted by dementia caregivers were assessed by dementia clinicians using a clinical decision-making rating scale. ChatGPT was found to produce high-quality responses, suggesting the potential of online chatbots to be a useful source of health information for dementia caregivers. The majority of responses contained factual information (n=56, 93%), with 78% (n=47) of responses correctly interpreting the poster's main need. The majority (n=54, 90%) of ChatGPT responses contained tangible actions the caregiver could apply to their situation. In only 2 instances, follow-up referrals were not suggested when reviewers felt recommendations were needed.

ChatGPT also had limitations, primarily in the areas of *interpretation* and *comprehensiveness*. In 22% (n=13) of posts, ChatGPT recommended strategies that posters had already explicitly tried, or missed subtleties that affected the accuracy of recommendations, such as failing to recognize that a person placed in a "home" meant a nursing home facility and not a traditional home. In another instance, ChatGPT recommended considering short-term hospitalization, but the poster already disclosed the person with dementia was currently hospitalized. In 37% (n=22) of posts, ChatGPT's response did not include information that dementia clinicians felt was important or was unable to anticipate future problems that a human clinician might choose to address in response to the same post. For example, if ChatGPT recommended a driving test, it did not suggest what to do if the patient in question refused to take the driving test. The data suggest that ChatGPT has strengths in providing objectively correct information (*factuality*, *application*, and *synthesis*) but is less successful in contextualizing the information it provides (*interpretation* and *comprehensiveness*).

Limitations

Study limitations included potential sample bias and small sample size. Very few posters in this study identified as a spousal caregiver (n=1, 1.6%) even though national studies report that 60% of dementia caregivers are a spouse or partner [12]. In selecting social media posts for inclusion, we included only those in which it was clear that the individual had a diagnosis of dementia. Historically, racial and ethnic minority groups are less likely to seek or receive a dementia diagnosis; thus, our sample may have been skewed for race and ethnicity. Posts were from one specific platform, which risked including caregivers with a certain level of technology access and literacy. This study did not evaluate differences in ChatGPT responses at multiple time points, so no conclusions can be made regarding reproducibility. Raters were aware that responses were generated by ChatGPT, which could have influenced stricter grading. Although our 5-point scale graded specific aspects of ChatGPT responses, it might have had a ceiling effect.

Conclusions

This study contributes to the currently small but rapidly growing literature on AI's potential to assist patient-caregiver education by providing high-quality information. Our study illustrates that ChatGPT-3.5 can provide high-quality responses to most questions in the areas of memory loss and confusion, aggression, and driving. Future research should examine family caregivers' receptiveness to using ChatGPT, as well as the usefulness of the responses from the perspective of family caregivers. Validated rating scales to assess the quality of ChatGPT responses are still in progress; the field would benefit from a reliable, validated method to evaluate the quality of AI responses to health care questions. We encourage future studies to expand on our findings and investigate how ChatGPT might be used in tandem with information provided by licensed health care professionals.

Abstract

Background: Reminiscence, a therapy that uses stimulating materials such as old photos and videos to stimulate long-term memory, can improve the emotional well-being and life satisfaction of older adults, including those who are cognitively intact. However, providing personalized reminiscence therapy can be challenging for caregivers and family members.

Objective: This study aimed to achieve three objectives: (1) design and develop the GoodTimes app, an interactive multimodal photo album that uses artificial intelligence (AI) to engage users in personalized conversations and storytelling about their pictures, encompassing family, friends, and special moments; (2) examine the app's functionalities in various scenarios using use-case studies and assess the app's usability and user experience through the user study; and (3) investigate the app's potential as a supplementary tool for reminiscence therapy among cognitively intact older adults, aiming to enhance their psychological well-being by facilitating the recollection of past experiences.

Methods: We used state-of-the-art AI technologies, including image recognition, natural language processing, knowledge graph, logic, and machine learning, to develop GoodTimes. First, we constructed a comprehensive knowledge graph that models the information required for effective communication, including photos, people, locations, time, and stories related to the photos. Next, we developed a voice assistant that interacts with users by leveraging the knowledge graph and machine learning techniques. Then, we created various use cases to examine the functions of the system in different scenarios. Finally, to evaluate GoodTimes' usability, we conducted a study with older adults (N=13; age range 58-84, mean 65.8 years). The study period started from January to March 2023.

Results: The use-case tests demonstrated the performance of GoodTimes in handling a variety of scenarios, highlighting its versatility and adaptability. For the user study, the feedback from our participants was highly positive, with 92% (12/13) reporting a positive experience conversing with GoodTimes. All participants mentioned that the app invoked pleasant memories and aided in recollecting loved ones, resulting in a sense of happiness for the majority (11/13, 85%). Additionally, a significant majority found GoodTimes to be helpful (11/13, 85%) and user-friendly (12/13, 92%). Most participants (9/13, 69%) expressed a desire to use the app frequently, although some (4/13, 31%) indicated a need for technical support to navigate the system effectively.

Conclusions: Our AI-based interactive photo album, GoodTimes, was able to engage users in browsing their photos and conversing about them. Preliminary evidence supports GoodTimes’ usability and benefits cognitively intact older adults. Future work is needed to explore its potential positive effects among older adults with cognitive impairment.

aging; knowledge graph; machine learning; reminiscence; voice assistant

Introduction

As the proportion of older individuals rapidly grows, an increasing number of older individuals are becoming concerned about their physical and mental well-being [1]. Steptoe et al [2] found that a decline in health is associated with a negative psychological state. In addition, aging is closely associated with various psychosocial stress factors, such as loneliness, personal losses, and lower socioeconomic status [3]. These factors may increase the risk of developing mental health disorders. In recent years, increasing evidence suggests that psychological well-being could be a potential asset for healthy aging [4].

Reminiscence therapy stands as a profound approach, rooted in a deep understanding of cognitive and emotional processes, designed to elevate the psychological well-being of older adults. This therapy transcends the mere recall of life histories, encompassing both oral and written narratives, in a multisensory journey that engages sight, sound, taste, touch, and smell [5-7]. It extends beyond a mere collection of activities, encompassing the contemplation of photographs, immersion in music, and the sharing of narratives about pivotal life events [5-8]. The underlying success of reminiscence therapy lies in its capacity to stimulate long-term memory, playing a pivotal role in fostering overall well-being, an attribute particularly invaluable for those grappling with short-term memory challenges [9]. As individuals review and discuss evocative materials, including vintage videos, cherished photographs, or sentimental household artifacts, they embark on a path to not only retrieve memories but also enhance their self-esteem, nurture interpersonal skills, and enrich their psychosocial well-being [4,10]. This is rooted in the therapy’s ability to harness the profound impact of these sensory stimuli. Significantly, the American Psychological Association recognizes the therapeutic potential of reminiscence therapy, attesting to its ability to ameliorate mental health conditions, elevate mood, and mitigate agitation, especially among individuals coping with Alzheimer disease or dementia [5].

Research by Tam et al [4] indicates that reminiscence intervention not only produces positive effects among older adults with dementia but also benefits cognitively intact older adults. For instance, it reduces the depressive symptoms of cognitively intact older adults, significantly improves their life satisfaction, and promotes their self-esteem, psychological well-being, and happiness.

Reminiscence interventions, whether administered within health care facilities such as hospitals, assisted living communities, or nursing homes, or within the familial cocoon of private homes, are bolstered by the skillful orchestration of trained professionals and caregivers [5,7,11]. In health care settings, psychologists, social workers, and specialists in geriatric care often take the helm in conducting these interventions, drawing upon a wealth of materials that hold personal significance for older adults. The tailored application of these materials, including photos, videos, and cherished objects, becomes a key facet in rekindling memory and reminiscence. These interventions can be adjusted to individual or group settings, finely attuned to the unique needs and preferences of older adults [5,11,12]. In private residences, reminiscence interventions are executed with dedication by family members, caregivers, or volunteers [5]. They use similar materials as those found within health care facilities, including familial photographs and cherished keepsakes, as a conduit to memory stimulation and the initiation of reminiscing. Nevertheless, conducting these interventions at home can be challenging due to a shortage of human resources [11]. Caregivers and family members, juggling numerous responsibilities, may find their time and resources stretched thin, underscoring the need for innovative approaches, such as the one proposed in this study, to bridge this gap.

To overcome the challenges of limited resources and specialized training in performing reminiscence interventions, flexible and effective computer-based interventions are highly beneficial [13-15]. We designed, developed, and tested GoodTimes, a personalized interactive multimodal photo album mobile app for cognitively intact older adults. It can be used on smartphones and tablets, providing older adults with on-the-go access to their photos as well as those provided by family members. This intelligent digital photo album allows users to browse and query photos in various orders, including chronological order, by location, by event, or by specific family members. To enhance the reminiscing experience, a voice assistant (VA) interacts with the user, providing information about the picture, such as the family members in the picture, the special moment, and the location. The VA also asks questions, answers user questions, and responds to user comments, creating a setting where special memories can be remembered and enjoyed. To ensure the user’s comfort and avoid any distress, the VA will not mention anything about depression or other challenges that older adults may be facing. Older adults can use the app independently, but it is also beneficial for families, caregivers, and assisted living staff to share the mobile app with the older adult they care for. Overall, GoodTimes is a convenient and effective tool that can be used anytime, anywhere, with or without caregiver support, for cognitively intact older adults. This user study indicates that after using this app, users reported engaging in enjoyable conversations with the app.

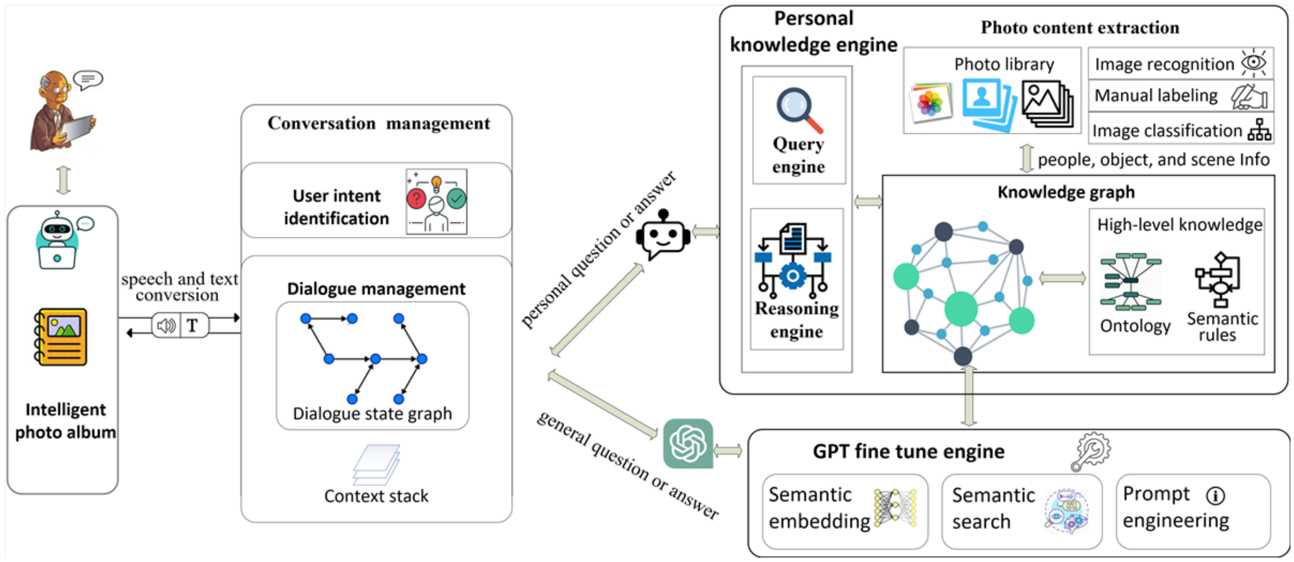
Overview

GoodTimes is built on artificial intelligence (AI) technologies, including image recognition, natural language processing, knowledge graph, logic, and machine learning, to provide an interactive and personalized experience for older adults. The system architecture is illustrated in Figure 1. The app can be accessed through smartphones and tablets, and users can interact with it using their voice or fingers. The VA, which uses automatic speech recognition and natural language understanding technologies, converts the user's voice into a text request. The conversation management module then processes the user's request through 2 steps: user intent identification and dialogue management (DM). First, the user intent identification matches the user's text request with predefined intents and dialogue states to create an input frame. Then, the DM module executes the dialogue policy based on the dialogue state graph and updates the dialogue state.

Figure 1. System Architecture.



There are 2 types of communication requests: personal requests, which involve questions and answers related to the user's personal information, and general requests, which do not necessarily involve personal information. Examples of personal questions include "Who is in the photo?" and "What is the story behind this photo?" General requests include knowledge not necessarily related to the user's personal information, for example, a commonplace or a piece of widely known artwork. For instance, the AI may provide an answer about art collections in the Louvre Museum in Paris.

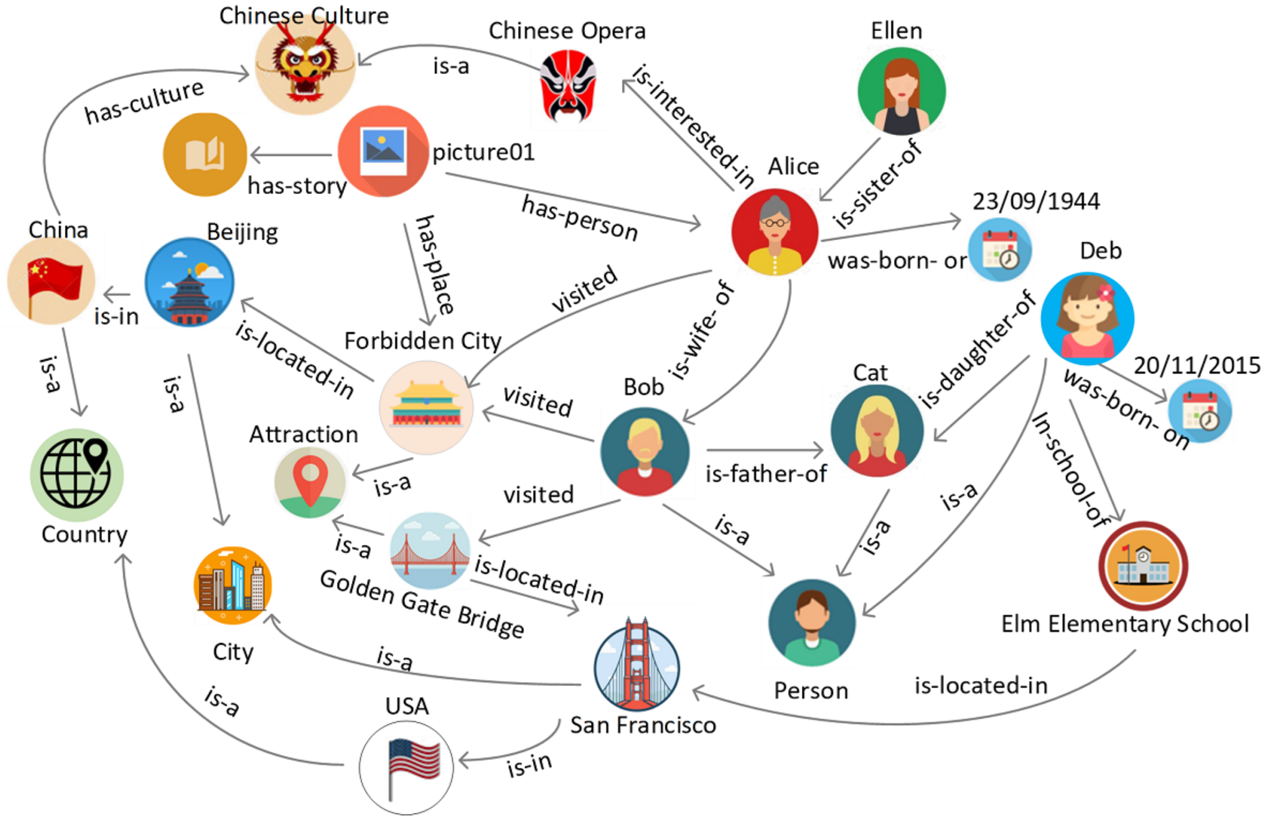
To handle general requests, we fine-tuned a Generative Pre-Trained Transformer (GPT; OpenAI) [16], a powerful neural language model. For personal requests, we have designed our own personal knowledge engine to provide tailored responses. Backend services of our personal knowledge engine are requested based on the user's intent, and these services are supported by a semantics-based query engine and reasoning engine. These engines work over a knowledge graph, which is the brain of the system. The knowledge graph contains facts, relationships, and rules about photos, people, places, time, and stories. The search and reasoning engines link the dialogue with a specific photo, user profile, and context to enable personalized services. Finally, the DM module generates responses using the speech act and content selected based on the input frame.

The system maintains a library of photos that can be uploaded by the older adult user's family members and caregivers. Metadata of a photo, such as people, animals, location, time, and special events, are also saved in the knowledge. Family members get involved in uploading, sharing, and explaining the photos, promoting collaboration, and having fun. Involving family members in the photo album can improve their relationship, help family members learn more about older adults, and facilitate reminiscence interventions for older adults, with or without caregiver support.

Constructing an Open Personal Knowledge Graph

The "brain" of the system is a comprehensive knowledge graph [17] that contains knowledge about the user and the photos. All the knowledge is represented as a graph in which data is modeled as nodes (vertices) and links (edges) between them. Nodes in our knowledge graph are normally a person, place, location, or thing, and links are how they are connected or related. Figure 2 shows an example knowledge graph about an older adult, Bob. In this graph, Bob, Alice, Cat, Person, Attraction, and Golden Gate Bridge are nodes. They are connected by many different relationships. For example, Alice is Bob's wife, and Bob is the father of Cat. Alice, Bob, and Cat are persons. Bob visited the Golden Gate Bridge, which is an attraction. This example graph shows many things and relationships about Bob. It is used by the system to explain the story of the picture, including the people inside the picture, their relationships, where they visited, etc.

Figure 2. An example of a personal knowledge graph of user Bob.



Graphs are used to model knowledge because they can encode real-world knowledge as “things” (not “strings”) and their interrelationships. This enables the system to communicate with users by analyzing what the words in a sentence actually mean rather than simply analyzing strings of characters. In addition, structuring knowledge in the form of graphs allows knowledge to evolve over time. New “things,” relationships, and external knowledge can be easily added or linked to the existing graph. In our system, we extend the core knowledge graph with external knowledge graphs, such as Wikidata [18,19], to extend our knowledge. Furthermore, reasoning and navigation can be performed over knowledge graphs.

Knowledge Graph Construction

First, we built a high-level ontology working as the schema of the knowledge graphs. Then, we create a knowledge graph by instantiating the ontology with detailed instances retrieved from uploaded photos (with metadata) and user surveys and external knowledge graphs, such as Wikidata. Using ontology would allow logical inference for retrieving implicit knowledge rather than only allowing queries requesting explicit knowledge. We proposed a “Who-What-When-Where” model as the foundation of this album ontology. “Who” represents the person in or not in the photo but related. “What” points to the story related to a photo. “When” specifies the time when the photo was taken, which can be a date, a social occasion, or a historical monument. “Where” describes the place where the photo is taken. Figure 3 shows a major part of the ontology. This ontology is instantiated with instances through photo metadata extraction, tagging extraction, image recognition, and social media extraction.

The ontology serves as schema-level knowledge used to instantiate instances or individuals, thereby creating a comprehensive knowledge graph. Instance information is collected through various means, such as automatically extracting metadata from photos or through manual input or voice-based question and answer. Through these processes, a detailed knowledge graph like the one shown in Figure 2 can be generated.

Semantic Rule Definition

In order to facilitate logical inference and gain new insights from the knowledge graph, we have established a set of rules and used logical reasoning over the ontology. We provide a few examples of these rules below, noting that some are specified within the ontology itself, while others are created separately using Semantic Web Rule Language [20-22]. For clarity, we present all rules using the same first-order logic [22] format.

Relatives:

If x is the husband of y, then y is the wife of x, and vice versa:

$$\forall x,y\ Husband(x,y) \Leftrightarrow Wife(y,x)$$

If x is the mother or father of y, then x is also the parent of y, and vice versa:

$$\forall x,y\ (Mother(x,y) \vee Father(x,y)) \Leftrightarrow Parent(x,y)$$

If z is the parent of both x and y, and x is not the same as y, then x and y are siblings:

$$\forall x,y,z\ (Parent(z,x) \wedge Parent(z,y) \wedge x \neq y) \Rightarrow Sibling(x,y)$$

If x is the parent of y, and y is the parent of z, then x is the grandparent of z:

$$\forall x,y,z\ (Parent(x,y) \wedge Parent(y,z)) \Rightarrow Grandparent(x,z)$$

Social Relations:

…

Time:

$$\forall x,y,z\ Time(x) \wedge Time(y) \wedge Time(z) \wedge Before(x,y) \wedge Before(y,z) \Rightarrow Before(x,z)$$

$$\forall x,y\ Time(x) \wedge Time(y) \wedge Before(x,y) \Rightarrow After(y,x)$$

…

Location:

…

Photo co-occurrence Relations:

//Person p visited location l at time t, and took a photo ph

$$\forall p,l,t,ph\ (Person(p) \wedge Location(l) \wedge Time(t) \wedge Photo(ph) \wedge PersonInPhoto(p, ph) \wedge PhotoTakenAtLocation(ph, l) \wedge PhotoTakenTime(ph, t)) \Rightarrow Visited(p, l, t, ph)$$

//Person p1 and p2 visited location l at time t together

$$\forall p1,p2,l,t,ph\ \ Person(p1) \wedge Person(p2) \wedge Visited(p1,l,t,ph) \wedge Visited(p2,l,t,ph) \Rightarrow VisitedTogether(p1,p2,l,t)$$

Dialogue Management

The photo album's VA is a machine learning-based system that enables users to engage with it through natural conversation. The VA is capable of understanding user intents from free text, answering questions, and asking questions for a specific purpose. To promote reminiscence intervention, GoodTimes guides users in recalling their memories by asking them photo-related questions and responding based on their answers. The VA facilitates personalized questions during the dialogue flow and can route natural conversations with users. A photo album with a VA can help older adults feel more connected to their past and present, providing them with a sense of familiarity and comfort, which is especially important for older adult users. Our dialogue flow management includes the following key points to facilitate engaging interactive conversation: VA-driven conversation, intent recognition, context management, personalization, and empathy incorporation.

VA-Driven Conversation

In our app, the VA initiates and guides the conversation. The conversation between the VA and the user begins with a friendly greeting or prompt, followed by a series of questions that revolve around the "Who-What-When-Where" themes but are not limited to them. These questions are designed to elicit specific information about the photos from the user and jog their memory. We use techniques including contextual prompts, confirmation prompts, and error handling to let the VA control the dialogue flow.

The VA provides prompts or suggestions to the user based on the current context of the conversation. For example, if the user talks about a specific photo, the VA can suggest related topics or questions to keep the conversation flowing smoothly. The VA uses confirmation prompts to confirm the user's intent or response to a question. This is useful when the VA needs to verify information before moving on to the next question or action. When the user provides incorrect or invalid input, the VA will provide appropriate responses, including rephrasing a question or prompt, asking for clarification, or providing an explanation of what the VA is looking for. By using these techniques, the VA can guide the conversation in a way that ensures the user provides the necessary information while keeping the conversation under control.

Intent Recognition

There are 2 ways to identify the user's intent. One is to fine-tune a GPT to let it specify the intent or use our designed intent identification model (IIM). In our implementation, we used our own IIM as the main method, as GPT is more expensive. In our IIM, the VA uses the natural language processing algorithm, part of speech tagging [23], to break down a sentence or phrase into its constituent parts, such as nouns, verbs, and adjectives. Then, it uses named entity recognition [24] to extract important information such as the user's intent, entities (relevant keywords or phrases), and context from these components. We use machine learning algorithms (eg, our previous proposed algorithm [25]) to analyze the user's input and match it with the most relevant intent. To train the model, we provide sample user inputs and assign them to specific intents. The VA then uses these examples to learn patterns in the data and improve its ability to recognize user intent over time.

Context Management

The VA also keeps track of the conversation's context, including previous statements made by the user and the VA's responses. This helps to ensure that the VA's responses are relevant to the current conversation. Context management in the VA of the interactive photo album is critical to providing a seamless and personalized user experience. VA uses a context stack to manage the context of the conversation. For example, suppose the user is looking at a photo of a trip to Paris taken in front of the Louvre Museum. In that case, the VA can use this information to provide related suggestions or ask follow-up questions, such as "Did you see Leonardo da Vinci's Mona Lisa in Louvre?" These questions are generated by prompting GPT using our knowledge graph and previous conversation history as context. The VA also needs to be able to handle changes in context, such as if the user switches to talking about a different topic. In such cases, the VA must recognize the change in context and adjust its responses accordingly. Overall, effective context management is crucial to creating a personalized and engaging experience for users interacting with the VA in the interactive photo album.

Personalization

The VA personalizes the conversation by considering multiple factors, including the user's preferences, personal profile such as name, age preferences, and conversation history. The very basic form of personalization is addressing the user by name to make the conversation more personal and engaging. In addition, the VA will use knowledge in the knowledge graph to address people or things in the photo. For example, the VA will use the information stored in the knowledge graph to refer to people or things depicted in the photos. For instance, if the user's mother is shown in the photo, the VA may address her as "your mother, Susan," as her name is known from the knowledge graph. Similarly, if the user's pet dog is in the photo, the VA may refer to the dog by its name, "Buddy." Additionally, suppose the knowledge graph indicates that the user has a close relationship with a particular person. In that case, the VA can refer to them with a personal term, such as "your dear friend, John." This personalization can enhance the user's experience and create a more natural and engaging conversation. Also, the VA uses the conversation history to tailor the conversation. For example, if the user has previously shown a preference for a particular type of photo or event, the VA can use this information to recommend similar photos or events.

Empathy Incorporation

The VA incorporates empathy into dialogue to create a more natural and engaging conversation. This involves understanding and responding to the user's emotional state, using appropriate tone and language, and showing concern for the user's needs and feelings. Older adults and people with Alzheimer disease may have difficulty understanding complex sentences or abstract concepts [26]. Our VA uses simple, clear language to make sure they understand what the VA is saying. The VA always tries to be patient and understanding when asking older adults about photos. The VA gives positive feedback when the user answers questions correctly or remembers important information. If they provide incorrect answers, the VA will gently correct them and provide additional context or information. It is also important to repeat questions if they are not answered correctly, as older adults may need more time to process and remember information. Asking related questions, such as about memories of a trip shown in the photo or the hobbies of a person in the photo, can also be helpful in stimulating memories and encouraging conversation. Overall, we try to create a comfortable and positive environment for older adults to share their memories and stories.

Conversation Using Knowledge Graph

The knowledge graph is the source of information for conversing with users and is stored in Neo4j [27-29], a graph database that the VA uses to ask and answer questions about photos. Cypher [27-29], Neo4j's query language, is used by the VA to navigate the graph and generate questions and responses. Natural language queries and answers from users are converted into Cypher queries. For example, if a user asks, "Who is in this photo?" the VA can convert this into a Cypher query that retrieves all people in the photo. To generate photo-related questions, Cypher first locates a specific photo node based on certain criteria. Relevant properties are then extracted from this node to generate a question, with the property value serving as the standard answer. Cypher can also query for a relationship linked to this node, creating a directional triple consisting of the photo node, a relationship, and another node. The knowledge graph uses directional triples (node-relationship-node) to express semantic data as subject-predicate-object. For more complex questions with multiple bindings, Cypher enables searching for nearby nodes and relationships by limiting the number of hops and specific relationships.

To keep the conversation engaging, the VA can ask follow-up questions related to the previous topic. For instance, if the previous query was about Mary, the VA might ask, "Do you remember Mary's hobby?" by using the previous query result (ie, Mary) as the subject or object of a new triple. The new question is generated based on this triple, with the other node or relationship serving as the question and the remaining element in the triple as the standard answer. In addition, GPT [30,31] is used to generate related questions and content, which will be discussed further later on.

GPT as a Complement

GPT is the state-of-the-art large language model used for various natural language processing tasks, including "question answering." One of the main advantages of GPT is its large amount of pretrained knowledge, which enables it to understand and generate natural language text with high accuracy. However, the cost of using GPT could be prohibitive for some applications, including our system. Despite this limitation, we still benefited from GPT's capabilities by using it to provide complementary functions. For example, we used GPT to help identify user intent if our IIM was not confident about its result. Moreover, GPT was used to enhance the conversational experience by generating follow-up questions and responses. For instance, if a user asks a question about a particular topic, GPT can generate related questions or statements that may help the user explore the topic further.

To ensure that the responses generated by GPT are relevant and accurate, we provided appropriate context for the conversation. One way to achieve this is by leveraging our local knowledge graph and conversation history as a source of relevant information. By converting the knowledge graph database into a triple format (subject, predicate, and object), we could index the triple file using semantic embeddings, which represent text data in a continuous vector space. This allows for efficient comparison and retrieval of similar text items while preserving semantic relationships between words and phrases. To generate embeddings, we used the pre-trained embedding model "Bidirectional Encoder Representations from Transformers" [32], resulting in a single vector embedding. These embeddings were then used in semantic search, enabling efficient and cost-effective searching. When a user query was received, we converted it into semantic embeddings and matched them with the embeddings of the knowledge graph using cosine similarity. This helped us identify the most relevant or related information sources in our knowledge graph that are related to the user's query. Once we had identified the most similar embeddings in our local knowledge base, we used them as context or query input for the GPT model. This context provides GPT with relevant information from our local knowledge base, allowing it to generate relevant responses. In summary, while GPT may not be used extensively in our system due to its cost, it can still provide valuable complementary functions that enhance the user experience and help us better understand the user's intent.

Prototype System

We have implemented GoodTimes as an Android-based app using a mobile app development framework called Flutter [33]. The app includes a VA that uses Google's Dialogflow [34] to understand natural language. When the VA identifies what the user wants, it uses Google Cloud Functions to interact with a backend server built with Spring Boot [35]. This server connects to a Neo4j database that stores information in the form of a knowledge graph. We used *LangChain* (Harrison Chase) [36], a Python package, to integrate OpenAI's GPT language models with the knowledge graph. Specifically, we used the GPT-3.5 Turbo model and defined the GPT language model using the LLMPredictor class and the input prompt format using the

PromptHelper class. The user has the option to interact with the app using either voice commands or touch input.

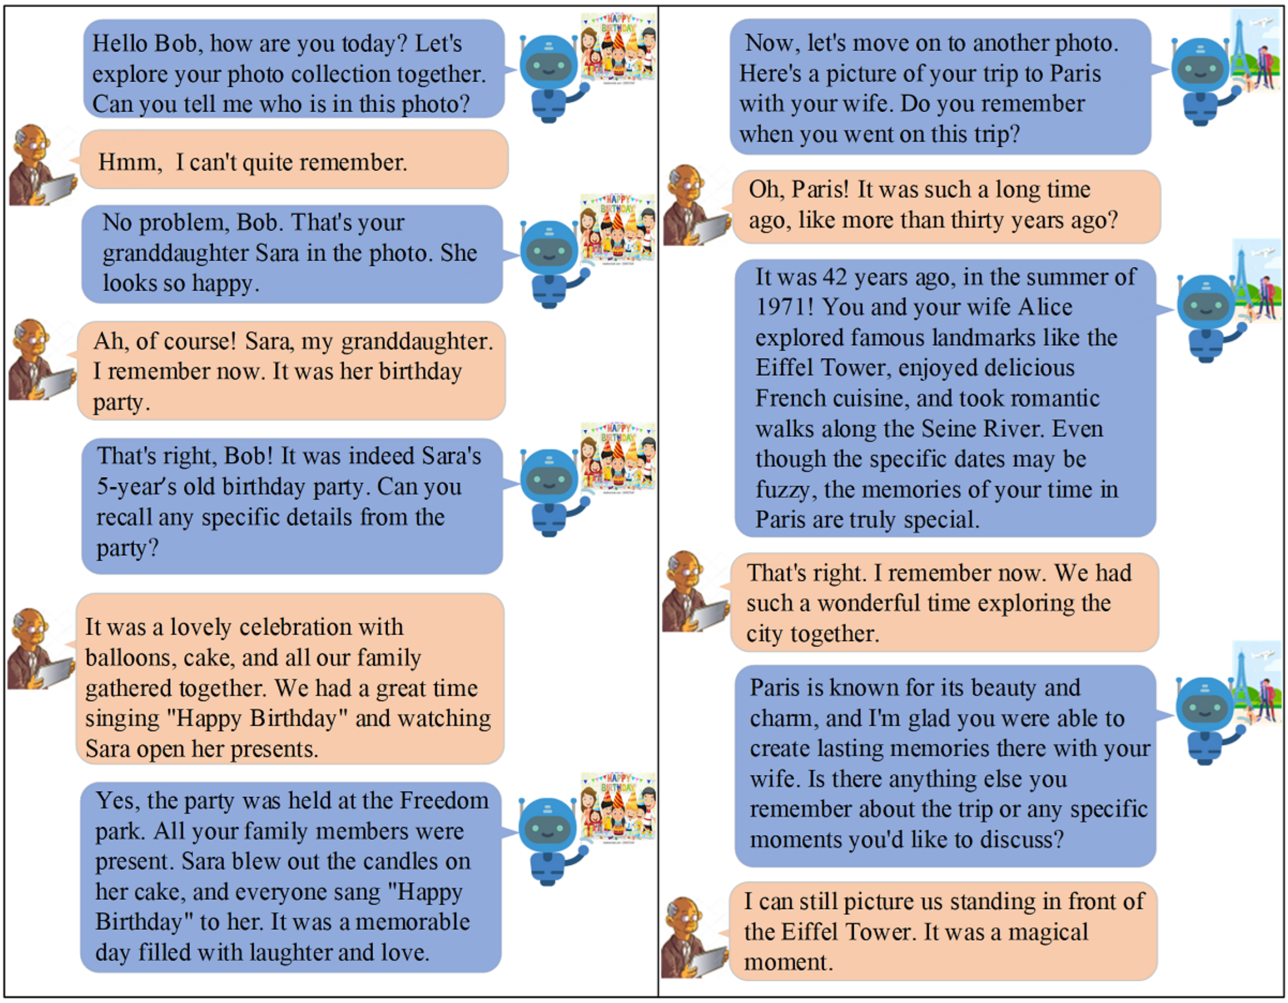
Use-Case Study

We conducted a use-case study to evaluate the functionality of our interactive photo album app before deploying it to real users. This involved identifying and analyzing specific scenarios in which the app could be used, such as browsing photos, sharing them with friends and family, and asking questions related or unrelated to the photo. By examining how the app was used in these scenarios, we were able to identify areas for improvement to make it more user-friendly. The creation of fictional users for the use cases involved careful consideration of relevant characteristics and demographics aligned with this study's objectives. Factors taken into account included age, gender, cultural background, language proficiency, cognitive and physical abilities, technological familiarity, and more. This iterative process allowed for refinement based on the specific goals and requirements of our research or design project.

Let us consider a fictional character, Bob, who is 79 years old and has memory challenges that affect his ability to remember things. As part of our use case, we presented Bob with a collection of photos encompassing significant moments such as his granddaughter Sara's birthday party, his memorable trip to Paris with his wife, and heartwarming memories with his beloved pet dog, Lucy.

Figure 4 exemplifies the interaction between Bob and the VA, showcasing their communication regarding photos in the album. This particular example demonstrates the VA's capability to engage with Bob and help him remember significant moments. In the conversation, Bob and the VA discuss a photo from Sara's birthday party. Initially, Bob is unsure of the people in the photo. The VA kindly reminds him that it is Sara in the picture, which prompts Bob's memory. The VA provides additional information about the event, refreshing Bob's memory and filling in the gaps. The VA also helps Bob recall his trip to Paris. This interaction highlights the VA's ability to serve as a helpful reminder and facilitator of memory recall. By engaging in conversations and providing contextual information, the VA helps Bob reminisce about important occasions and people in his life. This feature demonstrates the valuable role the VA plays in aiding individuals with memory challenges by providing gentle reminders and support.

Figure 4. An example case of communication between the voice assistant (VA) and a user.



Hello Bob, how are you today? Let's explore your photo collection together. Can you tell me who is in this photo?

Hmm, I can't quite remember.

No problem, Bob. That's your granddaughter Sara in the photo. She looks so happy.

Ah, of course! Sara, my granddaughter. I remember now. It was her birthday party.

That's right, Bob! It was indeed Sara's 5-year's old birthday party. Can you recall any specific details from the party?

It was a lovely celebration with balloons, cake, and all our family gathered together. We had a great time singing "Happy Birthday" and watching Sara open her presents.

Yes, the party was held at the Freedom park. All your family members were present. Sara blew out the candles on her cake, and everyone sang "Happy Birthday" to her. It was a memorable day filled with laughter and love.

Now, let's move on to another photo. Here's a picture of your trip to Paris with your wife. Do you remember when you went on this trip?

Oh, Paris! It was such a long time ago, like more than thirty years ago?

It was 42 years ago, in the summer of 1971! You and your wife Alice explored famous landmarks like the Eiffel Tower, enjoyed delicious French cuisine, and took romantic walks along the Seine River. Even though the specific dates may be fuzzy, the memories of your time in Paris are truly special.

That's right. I remember now. We had such a wonderful time exploring the city together.

Paris is known for its beauty and charm, and I'm glad you were able to create lasting memories there with your wife. Is there anything else you remember about the trip or any specific moments you'd like to discuss?

I can still picture us standing in front of the Eiffel Tower. It was a magical moment.

In addition to the previously mentioned use cases, we conducted evaluations on 12 additional scenarios for our app. The diverse range of use cases demonstrated the app's potential as a valuable tool for helping older adults cherish their memories and enhance their overall well-being.

User Study

We conducted a user study to evaluate the usability and features of the GoodTimes app. Participants were recruited through convenience sampling using various digital communication channels, such as phone calls, social media, and email. To accommodate participants' preferences, the study sessions were conducted in person at locations including their homes, local coffee shops, or parks. These sessions were conducted individually, allowing for personalized interaction and feedback.

At the beginning of each session, participants were provided with an overview of the study objectives and the app's key features. Written consent was obtained from each participant, following the approved study protocol by the institutional review board of North Dakota State University. A video demonstration was presented, and participants were given approximately 30 minutes of hands-on practice with the app. A researcher was present to address any questions during the session. Following the interaction, participants completed a set of questionnaires to provide feedback on their experience, which took approximately 15 minutes to complete. This approach enabled us to gather comprehensive insights into the app's usability and user experience.

The questionnaire consists of 2 main parts. The first part focused on participants' experiences with the app's features, including their interactions with the intelligent agent and their emotional responses to the digital photo gallery. They rated their experiences with 5 statements on a Likert scale ranging from "strongly agree" to "strongly disagree." The survey included questions developed by the research team based on previous research and expert opinions.

The second part focused on the overall usability of the app, and open-ended questions were used to identify areas for improvement. In this part, we used a subset of the System Usability Scale (SUS) to assess the app's usability. The SUS is a widely recognized and validated instrument for evaluating the usability of interactive systems. We selected 5 relevant SUS questions out of a total of 10 and included them in our survey.

In our evaluation of the app's usability and user experience, we used statistical analyses to objectively understand participant feedback. Specifically, we used a 1-sample 2-tailed *t* test, a parametric test used to determine if the sample mean significantly differs from a known or hypothesized population mean. Given that our data was interval in nature and derived from Likert-scale responses, the 1-sample *t* test was particularly apt. The hypothesized population mean in our context was the neutral point on our scale, allowing us to discern whether participants' responses significantly leaned toward agreement or disagreement.

Results

Participants

The user study included a total of 15 participants, with 13 of them completing the survey. Out of the 12 studies conducted, 11 were in-person sessions, while 1 was conducted on the web through Zoom (Zoom Video Communications) as per the participant's preference. The participant demographics are summarized in Table 1. Among the participants, 8 fell in the age range of 55-64 years, 2 were in the age range of 65-74 years, and 3 were in the age range of 75-84 years. In terms of gender distribution, there were 8 male participants and 5 female participants. Regarding education, 3 participants held a PhD degree, 4 participants had a master's degree, 3 participants had a bachelor's degree, 1 participant had a college degree, and 2 participants had completed high school.

Table 1. Demographic information of the participants.

Variable	Participants, n (%)
Age (years)	
55-64	8 (62)
65-74	2 (15)
75-84	3 (23)
≥85	0 (0)
Gender	
Man	8 (62)
Woman	5 (38)
Highest educational degree	
PhD	3 (23)
Master's	4 (31)
Bachelor's	3 (23)
College degree	1 (8)
High school	2 (15)
Less than high school	0 (0)

Evaluation Outcomes

In order to evaluate the GoodTimes app, we conducted a user study with 13 older adult participants to collect feedback on their experiences with the app and its usability. Table 2 encapsulates participants' feedback on their conversational experiences with the VA. The outcomes revealed an overwhelmingly positive response to their interaction experience with the VA. A significant majority of participants (12 out of 13) endorsed the efficacy and relevance of the VA in their conversations. Specifically, 8 participants were in strong agreement that the VA disseminated pertinent information, while the remaining 5 concurred with this sentiment. Furthermore, a compelling majority (11 out of 13) expressed strong affirmation regarding the VA's accuracy in sharing memory-related information. In terms of the VA's language clarity and appropriateness, 12 participants were either in strong agreement or in agreement, indicating near-universal approval.

The *P* value, a measure of statistical significance, provides robust statistical validation of these findings. For instance, the statement "The VA provided relevant information" had a *P* value of <.001, suggesting that the observed results are extremely unlikely to have occurred by chance alone. Similarly, the almost identical *P* values for "The VA provided correct information" and "The VA's language is appropriate and easy to understand" (both *P*<.001) underscore the authenticity and significance of these findings. A *P* value below the typical threshold of .05 indicates a significant difference from the expected neutral response. This provides strong evidence that participants genuinely felt the statements were accurate descriptors of their experiences.

Table 3 depicts a profound capacity to foster positive emotions and reminisce among the study participants. It was noteworthy that every participant either agreed or strongly agreed that the app invoked cherished memories. Moreover, a substantial majority signaled their agreement or strong agreement with the app's efficacy in reviving memories of dear ones, such as friends and family. Impressively, a significant 11 out of 13 participants articulated that the app augmented their happiness.

In Table 3, *P* values offer compelling evidence of these perceptions. For the statement "Brings a lot of Good Memories," a *P* value of <.001 indicates an exceptionally significant result, suggesting the overwhelmingly positive feedback was not a mere coincidence. The sentiment "accelerates thinking about friends and family" also received a *P* value of <.001, reinforcing the strong affirmation of the app's ability to stir memories of loved ones. Furthermore, the feedback "Makes me happy" also manifested a *P* value of <.001, emphasizing that a significant number of participants derived joy from the app's use. These *P* values, being well below the conventional .05 threshold, bolster the claim of the app's potent capability to enhance emotional health through memory stimulation.

During the usability assessment phase of our survey, we gauged the app's interface using standardized usability prompts. Table 4 depicts an overview of the results on app usability. The results elucidated a prevailing sentiment of approval among respondents concerning the app's usability. Notably, a significant desire was expressed to engage with the system regularly, as indicated by a *P* value of .005, which suggests this sentiment was not merely by chance. Additionally, the system's helpfulness and its design simplicity garnered significant endorsement, as evidenced by the compellingly low *P* values of <.001, respectively. This denotes a genuine appreciation for the system's functionality and design among users.

Table 2. Participants' feedback on their conversational experience with the voice assistant (VA).

Statement	Strongly agree, n	Agree, n	Neutral, n	Disagree, n	Strongly disagree, n	Mean (SD)	2-tailed *t* (*df*)	*P* value
Conversation was pleasant	8	3	1	1	0	4.3846 (0.9608)	5.1959 (12)	<.001
Conversation was fluent and natural	4	7	1	1	0	4.0769 (0.8623)	4.5029 (12)	<.001
The VA provided relevant information	8	5	0	0	0	4.6154 (0.5064)	11.5016 (12)	<.001
The VA provided correct information	11	2	0	0	0	4.8462 (0.3755)	17.7272 (12)	<.001
The VA's language is appropriate and easy to understand	11	2	0	0	0	4.8462 (0.3755)	17.7272 (12)	<.001

Table 3. Participants' feedback on their emotional response to app usage.

Statement	Strongly agree, n	Agree, n	Neutral, n	Disagree, n	Strongly disagree, n	Mean (SD)	2-tailed *t* (*df*)	*P* value
Brings a lot of Good Memories	10	3	0	0	0	4.7690 (0.4385)	14.5455 (12)	<.001
Accelerates thinking about friends and family	10	2	1	0	0	4.6920 (0.6304)	9.6773 (12)	<.001
Makes me happy	5	6	1	1	0	4.1538 (0.8987)	4.6290 (12)	<.001

Table 4. Overview of results on the app's usability.

Statement	Strongly agree, n	Agree, n	Neutral, n	Disagree, n	Strongly disagree, n	Mean (SD)	2-tailed *t* (*df*)	*P* value
I would like to use this system frequently	0	9	3	1	0	3.6154 (0.6504)	3.4115 (12)	.005
I think the system is very helpful	4	7	1	1	0	4.0769 (0.8623)	4.5029 (12)	<.001
I think the system design is very simple and easy to use	4	8	1	0	0	4.2308 (0.5991)	7.4073 (12)	<.001
I feel very confident about using the system	4	4	3	2	0	3.7692 (1.0919)	2.5400 (12)	.03
I think that I would need the support of a technical person to be able to use this system	1	3	2	6	1	2.7692 (1.1658)	0.7138 (12)	.49

Another commendable finding was the respondents' confidence in using the app without external technical assistance. This was statistically supported by a *P* value of .03, reflecting a valid level of user self-assurance. However, the topic of needing technical support to operate the system did receive varied responses. Interestingly, the statement "I think that I would need the support of a technical person to be able to use this system" had a *P* value of .49, indicating that this sentiment was not statistically significant and could likely be attributed to random variability.

Discussion

Principal Results

We designed, developed, and tested an interactive photo album app called GoodTimes that uses AI technology to engage in conversations with users and tell stories about pictures, including family, friends, and special moments. The app was developed using state-of-the-art AI technologies, including image recognition, natural language processing, knowledge graph, logic, and machine learning. We constructed a comprehensive knowledge graph that models the information required for effective communication, including photos, people, locations, time, and stories related to the photos. We then developed a VA that interacts with users by leveraging the knowledge graph and machine learning techniques.

In order to evaluate the GoodTimes app, we conducted a use-case study to verify its various functions in different real-life scenarios. Additionally, we conducted a user study with 13 older adult participants to collect feedback on their experiences with the app and its usability. We found that the feedback from our participants was highly positive, with 92% (12/13) reporting a positive experience conversing with GoodTimes. All participants mentioned that the app invoked pleasant memories and aided in recollecting loved ones, resulting in a sense of happiness for the majority (11/13, 85%). Additionally, a significant majority found GoodTimes to be helpful (11/13, 85%) and user-friendly (12/13, 92%). Most participants (9/13, 69%) expressed a desire to use the app frequently, although some (4/13, 31%) indicated a need for technical support to navigate the system effectively.

Limitations

Our research has some limitations that we aim to address in future work. First, we plan to increase family members' active involvement in the process of using the app by making it easy and enjoyable for them to upload pictures and record their voices. Additionally, the findings may not be generalizable to both cognitively impaired and cognitively intact older adults due to the small convenience sample used in this study.

To better understand the potential of our app as a supplementary tool for reminiscence therapy, we plan to deploy the app to their homes or assisted living environments, allowing them to use it for an extended period of time. By doing so, we can observe the app's impact over time and gain valuable insights into how it can provide emotional and mental stimulation to improve their quality of life.

Comparison With Previous Work

Previous research has shown that reminiscence therapy, which involves the use of photos and videos to stimulate long-term memory, can improve the emotional well-being of older adults [5,37]. However, providing personalized reminiscence therapy can be challenging for caregivers and family members.

Various studies have investigated technology as a means of supporting reminiscence therapy for older adults. For instance, Chen et al [38] developed an app that used a lifelogging device to capture photos and videos and presented them in a timeline format, resulting in improved quality of life and cognitive function for participants. However, this approach is limited to recent events and can be inconvenient for users to wear many devices. Additionally, the mashup process requires significant caregiver involvement.

Another study by Tsao et al [39] developed an augmented reality app that allows users to interact with virtual versions of their memories. The app was found to increase participants' sense of control and satisfaction with their lives. The study by Schoneveld [40] developed an AR photo album prototype to facilitate communication between a person with dementia and their caregiver, family member, or friend, aiming to evoke more details and elements of memory and contribute to additional discussion material. The prototype has shown positive results in low- and high-fidelity prototype testing with experts and proxy testers. Another study [41] created digital reminiscence and music therapies using prompts such as photos, videos, and music. The study focused on the rural population, which has reduced access to dementia care services.

Compared with these studies, our GoodTimes app uses AI technology to engage in conversations with users and tell stories about pictures, including friends, family members, and special moments. This personalized approach aims to provide a more engaging and emotionally supportive experience for older adults, requiring minimum efforts from caregivers. This study's results showed that the app was well-received by participants, who found it helpful, easy to use, and enjoyable. In conclusion, while previous research has shown the benefits of reminiscence therapy for older adults, our GoodTimes app adds a new dimension to the field by using AI technology to provide a personalized and engaging reminiscence therapy experience.

Conclusions

In conclusion, this study demonstrated the potential of the GoodTimes app to provide personalized reminiscence therapy to older adults, improving their emotional well-being. The use-case study and user study results showed that the app was well-received by participants and provided a helpful, easy-to-use, and enjoyable experience. Although this study has some limitations, such as the need for a larger sample size and a longer evaluation period, we plan to address these limitations in future work. Our GoodTimes app adds a new dimension to the field of reminiscence therapy by using AI technology to provide a personalized and engaging experience. Overall, we believe that the GoodTimes app has the potential to positively impact the lives of older adults and their families.

Acknowledgments

The authors would like to thank all the interviewees for their contributions to the study. This work was supported by the National Science Foundation (NSF) with award number 2218046.

Abstract

Background: With the aging global population and the rising burden of Alzheimer disease and related dementias (ADRDs), there is a growing focus on identifying mild cognitive impairment (MCI) to enable timely interventions that could potentially slow down the onset of clinical dementia. The production of speech by an individual is a cognitively complex task that engages various cognitive domains. The ease of audio data collection highlights the potential cost-effectiveness and noninvasive nature of using human speech as a tool for cognitive assessment.

Objective: This study aimed to construct a machine learning pipeline that incorporates speaker diarization, feature extraction, feature selection, and classification to identify a set of acoustic features derived from voice recordings that exhibit strong MCI detection capability.

Methods: The study included 100 MCI cases and 100 cognitively normal controls matched for age, sex, and education from the Framingham Heart Study. Participants' spoken responses on neuropsychological tests were recorded, and the recorded audio was processed to identify segments of each participant's voice from recordings that included voices of both testers and participants. A comprehensive set of 6385 acoustic features was then extracted from these voice segments using OpenSMILE and Praat software. Subsequently, a random forest model was constructed to classify cognitive status using the features that exhibited significant differences between the MCI and cognitively normal groups. The MCI detection performance of various audio lengths was further examined.

Results: An optimal subset of 29 features was identified that resulted in an area under the receiver operating characteristic curve of 0.87, with a 95% CI of 0.81-0.94. The most important acoustic feature for MCI classification was the number of filled pauses (importance score=0.09, *P*=3.10E–08). There was no substantial difference in the performance of the model trained on the acoustic features derived from different lengths of voice recordings.

Conclusions: This study showcases the potential of monitoring changes to nonsemantic and acoustic features of speech as a way of early ADRD detection and motivates future opportunities for using human speech as a measure of brain health.

KEYWORDS

early detection; Alzheimer disease and related dementias; mild cognitive impairment; digital voice; machine learning; smartphone; mobile phone

Introduction

Alzheimer disease and related dementias (ADRDs) constitute a significant public health issue, impacting an estimated 6.2 million individuals in the United States, with projections indicating the number of cases to grow to 12.7 million and 150 million globally by 2050 [1,2]. Emerging evidence suggests that the functional, psychological, pathological, and physiological alterations associated with ADRD may manifest many years prior to the clinical onset of cognitive dysfunction [3-6]. This increasing awareness has sparked interest in early detection and monitoring of ADRD, with the goal of implementing timely preventive and therapeutic strategies to slow the progression of the disease. As effective as they are in identifying individuals at high risk of ADRD, conventional diagnostic methods, such as cerebrospinal fluid biomarkers and neuroimaging, face accessibility limitations primarily due to their high costs [7] and high subject burden. This limits their applicability to other groups, particularly populations in lower-resourced settings, in effectively monitoring the dynamic progression of the disease. Therefore, there is an urgent need for an effective detection method that has a much broader and more inclusive reach for the early detection of ADRD.

Producing speech is a cognitively complex task that engages various cognitive domains [8], and the ease of audio data collection underscores the potential cost-effectiveness and noninvasiveness that using human speech-based features may offer to facilitate early identification of cognitive impairment, including mild cognitive impairment (MCI). Studies have indicated that language deficits may manifest in the prodromal stages of cognitive impairment, often years before the clinical diagnosis of dementia [9,10]. Speech, however, is far richer in characterizing cognition than just language. Audio recordings can yield a variety of attributes, encompassing both acoustic and linguistic features. Acoustic features, given their language independence, have the potential for broader global applicability. Previous studies from the Framingham Heart Study (FHS) demonstrated significant associations between acoustic features extracted from voice recordings and 2 primary clinical indices of neurodegeneration: neuropsychological (NP) test performance [11] and brain volumes [12]. Moreover, acoustic-based models can be readily deployed on devices such as hand-held recorders, smartphones, tablets, and other internet-connected mobile devices, enabling widespread usage. These characteristics enable voice as a potential digital biomarker for early cognitive impairment monitoring and detection of MCI.

While the use of speech recordings as a novel measure of cognition is still in the early stages of validation, most of the previous studies have relied on a limited set of acoustic features [13-16], potentially constraining the enhancement of early detection capabilities for ADRD. For instance, some studies have concentrated on Mel-frequency cepstral coefficients [13,15], while others have explored a narrow range of temporal and spectral features (such as duration of utterance, number and length of pauses, and F0) [14,16]. There has been a notable absence of exploration into diverse categories of features, including energy, spectral, cepstral, and voicing-related features. Although deep learning has been used to investigate these features, its complexity often compromises interpretability. Therefore, there is a need for research to use more interpretable methods for exploring a richer set of acoustic features for the detection of MCI. Furthermore, the question of whether extensive voice recordings are necessary to achieve better cognitive assessment performance has not been thoroughly investigated. These issues have significant implications for the widespread, real-world application of speech as a digital data modality for cognitive assessment.

Therefore, the aims of this study were to explore the utility of acoustic features derived from human speech for the identification of MCI and to assess the impact of the duration of voice recordings on the predictive performance of MCI identification.

Methods

Study Population

Initiated in 1948, FHS is a community-based, longitudinal cohort study. This study initially included 605 FHS participants with at least one audio recording who were aged 60 years or older at the time of the NP exam visit where the recordings were collected. Then, a case-control data set was created consisting of 100 MCI cases and 100 cognitively normal (CN) controls and matched on age, sex, and education to control for potential confounders and ensure the reliability of the study results. MCI cases were identified through a clinical review conducted by a panel including at least one neurologist and one neuropsychologist based on criteria from the *DSM-IV* (*Diagnostic and Statistical Manual of Mental Disorders* [Fourth Edition]) and the National Institute of Neurological Disorders and Stroke–Alzheimer Disease and Related Disorders [17]. The details of the cognitive status determination can be found in previous studies [15]. The participants were stratified into 6 age groups, with each group spanning a 5-year interval from 60 to 89 years (eg, 60-64, 65-69, 70-74, 75-79, 80-84, and 85-89 years). Additionally, there was a separate category for individuals aged 90 years and older. Study participants were also stratified into 4 education groups: high school nongraduates, high school graduates, individuals with some college education, and college graduates. Subsequently, controls were selected from the data set who matched the cases based on age, sex, and education. The earliest collected voice recording from each participant was included in this analysis.

Ethical Considerations

The procedures and protocols of the FHS were approved by the institutional review board of the Boston University Medical Campus (FHS is H-32132), and written informed consent was obtained from all participants.

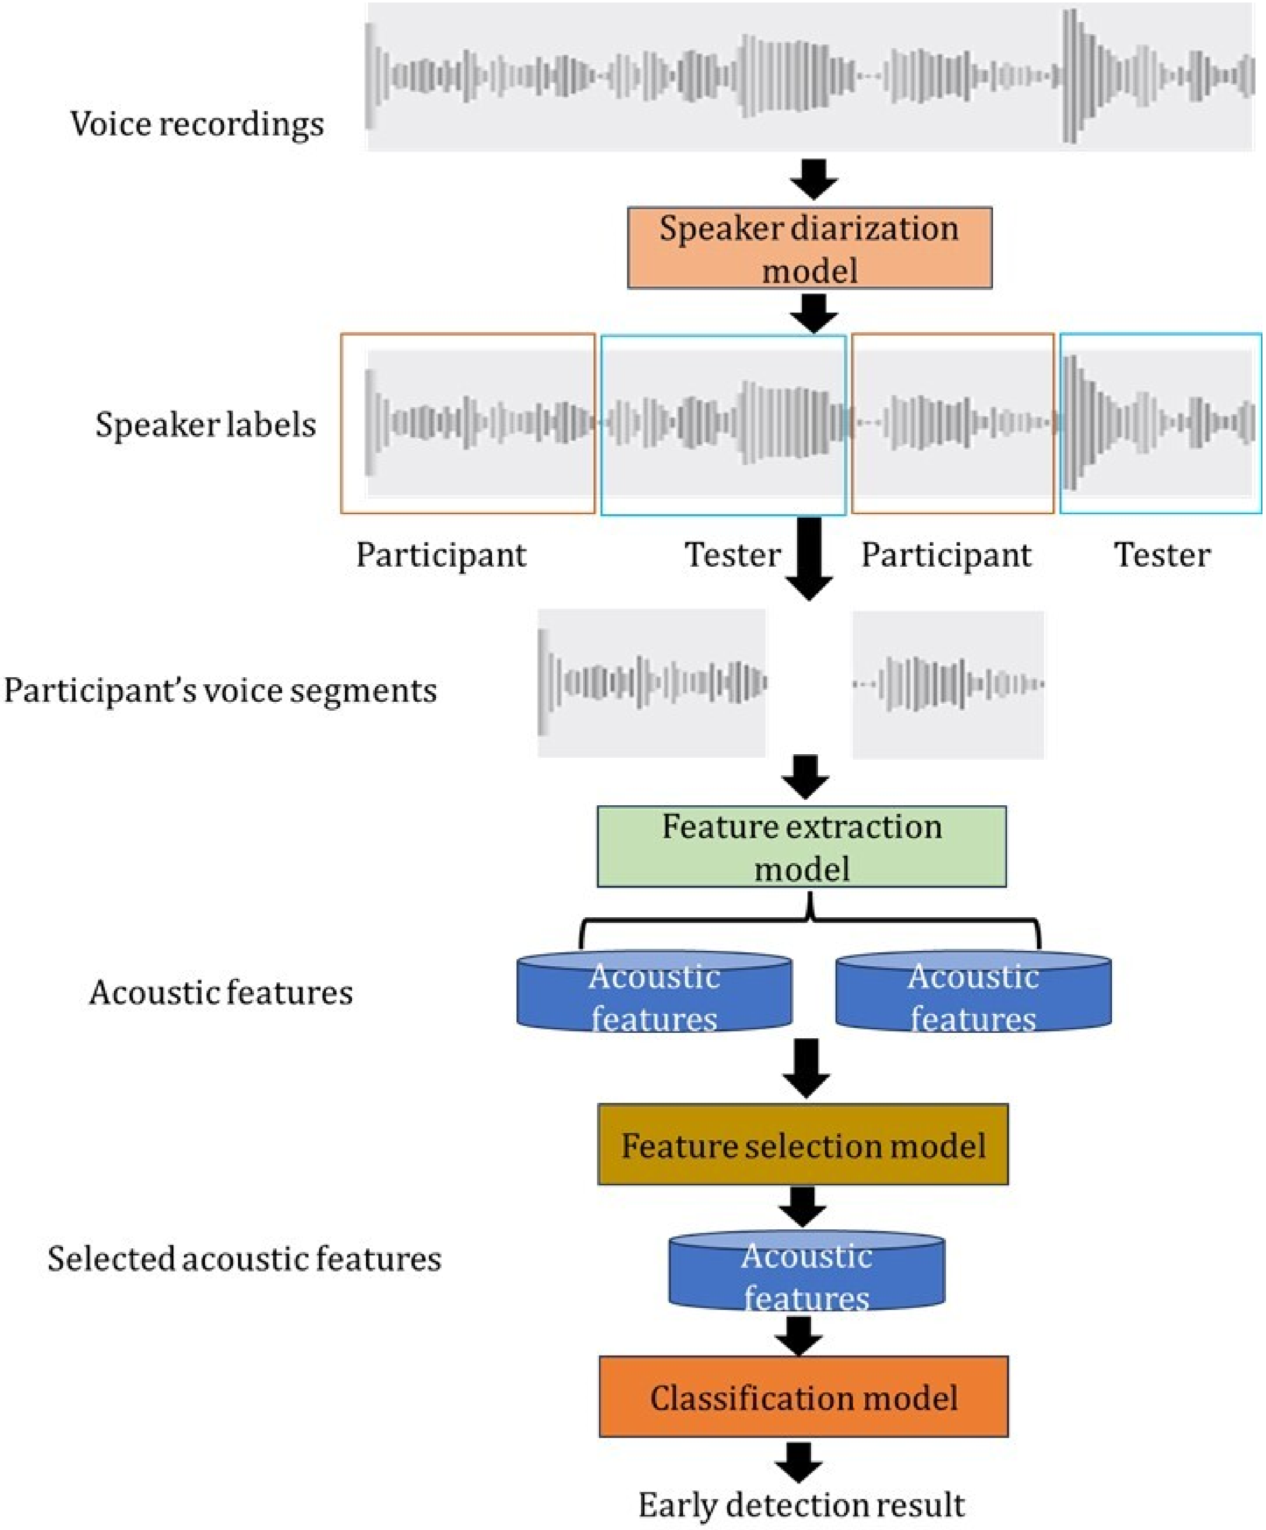
Voice Recordings

FHS has been monitoring cognitive status since 1976, which includes comprehensive NP testing [18]. Since 2005, FHS has digitally recorded all responses to NP test questions that required a voice response, which encompasses the spoken interactions between the tester and the participant. These recordings have been stored in the .wav format and downsampled to 16 kHz. This study included digital voice recordings between September 2005 and March 2020.

Machine Learning Pipeline

This study developed a machine learning pipeline that incorporated speaker diarization, feature extraction, feature selection, and classification to identify a set of acoustic features that exhibited strong MCI detection capability (Figure 1).

Figure 1. The machine learning pipeline for MCI detection from voice recordings.



Speaker Diarization

To accurately analyze the speech of the participants, it is crucial to distinguish between the participant and the tester and to determine “who spoke when” [19]. This process is known as speaker diarization, which involves segmenting the voice recordings based on the speaker's identity. In this study, the open-source speaker diarization package, pyannote, was used to automatically segment each recording into hypothesized utterances from the tester and the participant [20,21]. Since the NP administration testing process in FHS is standardized, the segmented dominant speaker, based on the duration of the voice recording, was labeled as the participant's speech in this study. These participant segments were combined for subsequent analysis.

Feature Extraction

To extract relevant information from the voice recordings, OpenSMILE software (version 2.1.3; audEERING) [22] and Praat software (University of Amsterdam) [23] were used, which facilitated the extraction of a comprehensive set of 6376 features [24] and 9 features, respectively. The OpenSMILE feature set used in this study consisted of 65 low-level descriptors (LLDs). These descriptors included energy, spectral, cepstral, and voicing-related features. Each recording was divided into segments of 20 milliseconds using a sliding window approach with a shifting size of 10 milliseconds [25,26]. The LLDs were extracted from each segment. By allowing for overlaps between successive windows, we were able to facilitate the conservation of information continuity and enable a more precise capture of the signal's dynamics [25,26]. First-order delta regression coefficients were calculated for all LLDs. A comprehensive set of functionals, such as mean, maximum, minimum, SD of segment length, and linear regression slope, were applied to extract statistical characteristics from the LLDs and deltas over the full recordings [27-29]. This process provided a concise representation of the acoustic features across the entire recording. As a result of this summarization process, each recording was represented by a set of 6376 features from OpenSMILE, capturing essential information about the acoustic properties of the audio data. The details of the feature generation process can be found in a prior study [30]. The Praat script was used to generate 9 features on syllable nuclei and fill pauses in the voice recordings [31].

Feature Selection

First, *z* scores were computed for each feature, and those with an absolute *z* score greater than 2 were removed as they were considered as outliers. Then, *t* tests (2-tailed) were used to determine whether there was a significant difference in each feature between the MCI and CN groups. Features that exhibited a significant difference below a *P* value threshold of .002 were then selected to be included in the model.

Classification Model

A random forest model was built using a final set of 29 selected features, and the performance of the model was evaluated using 10-fold cross-validation. To evaluate the MCI detection performance of the model, the area under the receiver operating characteristic curve (AUC), along with the 95% CI, for the random forest algorithm was obtained. The importance of each feature was computed using an impurity-based approach [32].

Comparison of Performance Across Different Audio Recording Lengths

To investigate the impact of the length of the audio recordings on the MCI classification performance, the first 5, 10, 15, and 30 minutes of the whole recording for each participant were extracted. Subsequently, the same processing steps were applied to each extracted audio segment, including speaker diarization, feature extraction, and the construction of the MCI classification model.

Results

Cohort Descriptive

The study sample included 200 participants, of whom 100 were diagnosed with MCI and the other 100 were classified as CN. In the overall sample, the average age was 74 (SD 6) years, and 46% (92/200) were female, with the sex distribution (females versus males) equal in both MCI and CN groups. Education in the overall sample was distributed as follows: 18 participants (18/200, 9%) did not graduate from high school, 54 participants (54/200, 27%) were high school graduates, 66 participants (66/200, 33%) had completed some college, and 62 participants (62/200, 31%) held at least a college degree.

Feature Selection and Detection Performance

Table 1 presents the 29 acoustic features significantly associated with cognitive status, selected using a *P* value threshold of .002. The table also displays the importance scores of these features for the classification of MCI, with higher values indicating greater importance. The most important acoustic feature for MCI classification was the number of filled pauses, with an importance score of 0.09. The optimal model was achieved when including these 29 acoustic features that were based on using a *z* score cutoff of 2 and a *P* value threshold of .002 (AUC 0.87, 95% CI 0.81-0.94; Figure 2).

Table 1. The optimal acoustic feature set for mild cognitive impairment detection.

Feature	Description	Importance[a]	*P* value[b]
nrFP	Number of filled pauses	0.09	<.001

audSpec_Rfilt_sma_de[5]_upleveltime90	Percentage of time over 90% of the range of variation of the deltas of the RASTA-style filtered auditory spectrum, band 5	0.03	.002
audSpec_Rfilt_sma_de[7]_upleveltime75	Percentage of time over 75% of the range of variation of the deltas of the RASTA-style filtered auditory spectrum, band 7	0.03	.002
audSpec_Rfilt_sma_de[15]_lpc0	Linear prediction coefficient zero of the delta of the RASTA-style filtered auditory spectrum, band 15	0.03	.002
audSpec_Rfilt_sma_de[15]_lpc1	Linear prediction coefficient one of the deltas of the RASTA-style filtered auditory spectrum, band 15	0.03	<.001
audSpec_Rfilt_sma_de[15]_lpc2	Linear prediction coefficient 2 of the delta of the RASTA-style filtered auditory spectrum, band 15	0.03	<.001
audSpec_Rfilt_sma[18]_qregc1	Quadratic regression coefficient 1 of the RASTA-style filtered auditory spectrum, band 19	0.03	<.001
audSpec_Rfilt_sma[18]_qregc2	Quadratic regression coefficient 2 of the RASTA-style filtered auditory spectrum, band 19	0.03	<.001
audSpec_Rfilt_sma_de[15]_lpc3	Linear prediction coefficient 3 of the delta of the RASTA-style filtered auditory spectrum, band 15	0.02	<.001

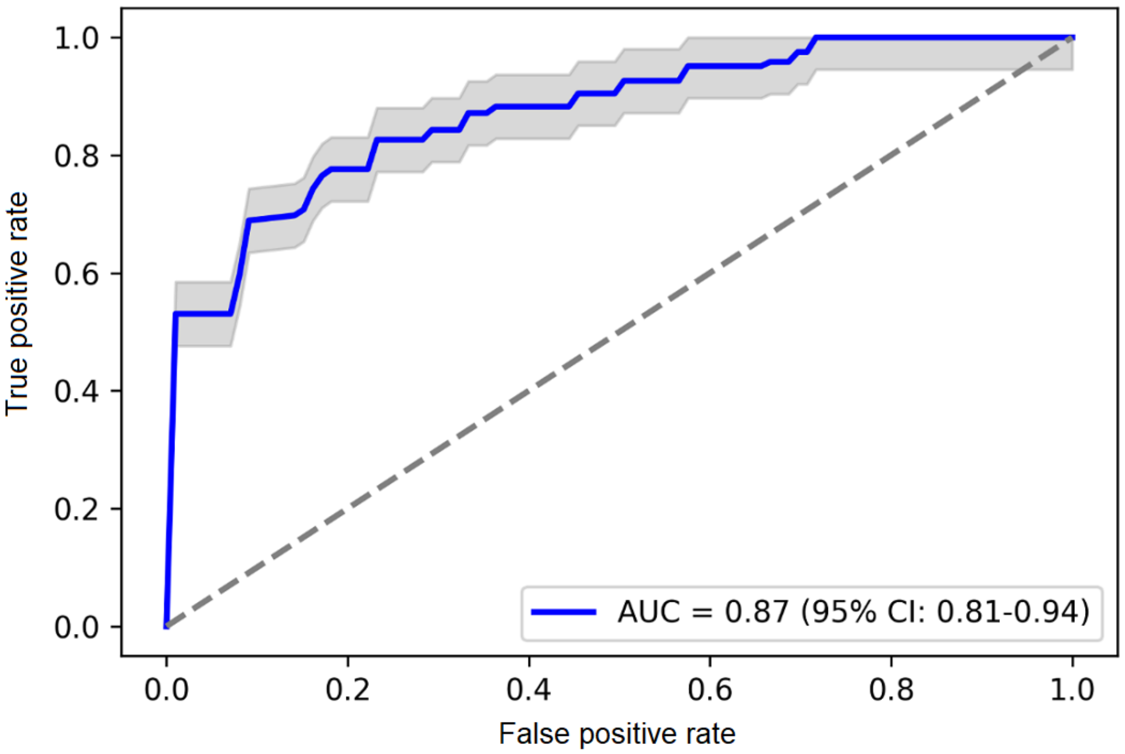
Feature	Description	Importance[a]	*P* value[b]
audspec_lengthL1norm_sma_peakRangeAbs	Absolute peak range of the sum of the auditory spectrum	0.02	.002
pcm_fftMag_spectralRollOff25.0_sma_pctlrange0-1	Outlier robust signal range “max-min” represented by the range of the 1% and the 99% percentile from the magnitude of the spectral roll-off point 25%	0.01	<.001
mfcc_sma_de[4]_peakMeanRel	Relative peak mean of the delta of the fourth MFCC	0.01	<.001
pcm_fftMag_spectralRollOff75.0_sma_quartile1	First quartile of magnitude of the spectral roll-off point 75%	0.00	<.001
pcm_fftMag_spectralRollOff75.0_sma_quartile3	Third quartile of magnitude of the spectral roll-off point 75%	0.00	<.001

[a] Importance was the impurity-based importance score of each acoustic feature that was computed as the mean of accumulation of the impurity decrease within each tree of the random forest.

[b] The *P* value was calculated using a *t* test (2-tailed) for each acoustic feature. Only the acoustic features with a *P* value less than .002 were included in the model.

[c] MFCC: Mel-frequency cepstral coefficient.

Figure 2. Receiver operating characteristic (ROC) curve of the random forest model for MCI classification. The mean ROC is depicted by the blue line, while the shaded gray area surrounding the curve represents confidence intervals, offering insights into the associated uncertainty of the curve.



Comparison of Performance Across Different Audio Recording Lengths

In addition to the optimal model based on whole recordings (1+ hour), we further examined the MCI detection performance of various audio recording lengths. In the case of 5-minute audio segments, we identified 21 acoustic features that exhibited significant associations with cognitive status (eg, $P<.002$). The random forest model constructed using these 21 features achieved an AUC of 0.79 (95% CI 0.73-0.86). Similarly, for the 10-minute audio segments, we identified 25 significant acoustic features and achieved an AUC of 0.81 (95% CI 0.75-0.87). When using 15-minute audio segments, 17 acoustic features were found to be significantly associated with cognitive status, leading to an AUC of 0.80 (95% CI 0.75-0.86) from the random forest model. Lastly, in the case of 30-minute audio segments, 17 acoustic features were significantly associated with cognitive status, and the random forest model achieved an AUC of 0.82 (95% CI 0.76-0.89). The accuracy, sensitivity, and specificity of these models were presented in Multimedia Appendix 1. These metrics were computed based on the means and SDs obtained using 10-fold cross-validation.

Discussion

Principal Findings

This study developed a machine learning pipeline to optimize the detection capability of acoustic features for MCI. We identified 29 acoustic features from 200 FHS participants' voice recordings collected at their NP exams, which yielded an AUC of 87% in classifying those with normal cognition versus MCI. Our findings highlight the significant potential of acoustic-based features of human speech as an easily collectible and accurate data modality for early ADRD detection.

Detecting ADRD early in the disease course and implementing timely interventions to slow its progression continue to be the primary strategies for addressing this condition. The method developed in this study using acoustic features for MCI monitoring aligns well with this goal. Specifically, despite recent FDA approvals for aducanumab and lecanemab as disease-modifying treatments for ADRD, concerns have emerged about the inclusivity of the trial population and the equitable distribution of benefits to all potential beneficiaries [33]. The acoustic feature-based machine learning approach in this study addresses the limited early detection capability of traditional NP tests for asymptomatic individuals, as well as the challenges associated with the cost and time-consuming nature of cerebrospinal fluid and blood-based biomarkers [34]. Speech data collection presents a noninvasive and accessible approach for cognitive health monitoring. This motivates potential future applications where passive voice collection tools, like hearing aids, could be used to gather such data. The use of nonsemantic, acoustic features of speech offers practical advantages from the perspective of data privacy and security. Unlike linguistic features, which may raise concerns around individual privacy and confidentiality, acoustic features can be derived without the need for direct access to sensitive personal information. The analysis based on acoustic features reduces privacy concerns and ensures that confidential data remain protected or unidentifiable during the cognitive monitoring process.

Studies examining discourse patterns in participants with ADRD have consistently observed difficulties in word retrieval, less efficient speech, and a notable increase in both the frequency and duration of pauses when their speech is compared to that of healthy adults [35,36]. Notably, in this study, among the features considered crucial for model performance, those related to filled pauses, such as the number of filled pauses and the total time of filled pauses, played a significant role. Filled pauses, such as "um" or "er," are nonlexical vocalizations. In individuals with dementia, pauses in speech are frequently longer and more frequent, which may indicate challenges with semantic and lexical decision-making, cognitive load, and familiarity with topics [36,37]. This study further highlights that pausing in the speech of individuals with dementia is often considered a dysfluency, serving as a behavioral hallmark that may signify difficulties in social interactions [38]. Our findings are also consistent with previous studies that have examined acoustic-based speech markers in older adults and found good predictive accuracy in identifying those with MCI as compared to being CN [39,40]. Other studies have also found temporal parameters, including prosodic rate and spectrum features, such as Mel-frequency cepstral coefficients, to predict those with MCI or early ADRD [41,42]. These findings offer a research target for further understanding speech issues and mechanisms related to cognitive health. By integrating acoustic analysis into routine clinical assessments, we can potentially enhance current diagnostic tools. This integration provides clinicians with additional quantitative data to support their diagnostic decisions and monitoring of disease progression. Furthermore, the acoustic features identified in this study hold promise for their potential application in large-scale screening programs aimed at identifying individuals at risk of developing MCI. Such screening tools, leveraging these features, could offer a cost-effective and scalable approach, enabling a broader population reach and early intervention strategies. Thus, these findings not only contribute to our scientific understanding but also have practical implications for improving early detection of cognitive impairment.

A unique contribution of our study that has not been well-examined in previous studies is the impact of the speech recording duration on the model performance. Although the full recording yielded the highest AUC (87%), we did not observe substantial differences in model performance based on varying voice recording lengths (eg, 5, 10, 15, and 30 minutes). This finding holds important implications for future studies that involve collecting voice recordings from participants, suggesting that achieving good predictive performance may not require collecting lengthy audio data. It underscores the potential to minimize participant burden and time spent collecting data, while preserving the data's analytical quality. Other strengths of this study include using a community-based sample within a controlled environment for the voice recordings taken during the NP exams. Furthermore, this study uses highly interpretable methods throughout, from feature selection to predictive model construction, achieving good MCI prediction capability. This sets a benchmark for future research attempting more complex analytical approaches. In the future, we can compare complex machine learning methods to fully investigate how to balance the relationship between interpretability and predictive performance.

Important limitations, however, include the inability to account for or investigate the impact of other conditions or risk factors, such as depression [43], that may influence speech patterns within the analysis. Due to the lack of available data on depression at the time of voice recording data collection in FHS, we did not investigate the relationship between depression, cognition, and acoustic features in this study. Future research will be essential to delve into this relationship using more comprehensive cohort data sets. Additionally, our sample consisted mostly of individuals who were White or of European descent, which could potentially limit the generalizability of our findings to other demographic groups. We also recognize that cognition and MCI are not static entities and that individuals with MCI can be considered to be CN at a later point in time [44]. Therefore, it may be possible that some participants were misclassified in terms of their cognitive status in our sample. For example, we acknowledge that the use of the National Institute of Aging–Alzheimer Association (NIA-AA) criteria

[45] offers advantages over the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association and *DSM-IV* criteria, which were used in this study, to ascertain individuals with MCI since it can provide a more comprehensive and inclusive approach, incorporating multiple pathological features. Additionally, the NIA-AA criteria use objective biomarkers and imaging techniques, enhancing diagnostic accuracy and reproducibility. The voice data used in this study were collected in quiet environments, which to some extent limits the widespread applicability of the study results in different environments, such as in-home settings.

To address these limitations, we plan to expand our research in several ways. First, we aim to include more diverse populations in future studies to assess whether the same acoustic features or different ones yield similar results in distinguishing MCI from normal cognition across various demographic groups. Future research should consider using cohorts with biomarker evidence of neurocognitive disorders for further validation of the findings. Additionally, we will explore the inclusion of other medical conditions or factors that may impact model performance, broadening our understanding of how speech patterns can be indicative of cognitive health. Specifically, we recognize that emotions may confound the relationship between speech patterns and cognition. Exploring the detection capability of MCI using voice collected in more real-life environments is another direction for future research. Finally, as we continue to advance in the development of speech-based screening and diagnostic tools, it is crucial to proactively address privacy and data security concerns. While our focus in this paper is primarily on the technical aspects of acoustic feature analysis for cognitive assessment, we recognize the importance of considering the broader societal implications of deploying such technologies in open source or free-market contexts. Safeguards must be implemented to ensure that individuals' privacy rights are respected and that their data are used responsibly and ethically.

Conclusions

This study demonstrated the potential for accurate identification of MCI using nonsemantic, acoustic speech features. Our research benefits from a well-defined sample and comprehensive speech data collected during NP exams, which have been rigorously analyzed.

Acknowledgments

We acknowledge FHS participants for their dedication. This study would not be possible without them. We also thank the researchers at FHS for their efforts over the years in the examination of participants. This work was supported by the Framingham Heart Study of the National Heart Lung and Blood Institute of the National Institutes of Health and Boston University School of Medicine. Funding for this work was provided in whole or in part with federal funds from the National Heart, Lung and Blood Institute, Department of Health and Human Services (contract 75N92019D00031, N01-HC-25195, and HHSN269201500001I), as well as grants from the National Institute on Aging (R01-AG016496, R01-AG008122, R01-AG049810, RF1AG054156, R01-AG062109, and U19AG068753). Funding for the analysis of this study was provided by the National Institute on Aging (grant R41-AG080977), which supported BB (main PI), AL, HL, PHH (subaward PI), HD, and CK.

Data Availability

The data sets generated during and/or analyzed during this study are available in the Framingham Heart Study [46].

Conflicts of Interest

Abstract

Background: About one-third of older adults aged 65 years and older often have mild cognitive impairment or dementia. Acoustic and psycho-linguistic features derived from conversation may be of great diagnostic value because speech involves verbal memory and cognitive and neuromuscular processes. The relative decline in these processes, however, may not be linear and remains understudied.

Objective: This study aims to establish associations between cognitive abilities and various attributes of speech and natural language production. To date, the majority of research has been cross-sectional, relying mostly on data from structured interactions and restricted to textual versus acoustic analyses.

Methods: In a sample of 71 older (mean age 83.3, SD 7.0 years) community-dwelling adults who completed qualitative interviews and cognitive testing, we investigated the performance of both acoustic and psycholinguistic features associated with cognitive deficits contemporaneously and at a 1-2 years follow up (mean follow-up time 512.3, SD 84.5 days).

Results: Combined acoustic and psycholinguistic features achieved high performance (F_1-scores 0.73-0.86) and sensitivity (up to 0.90) in estimating cognitive deficits across multiple domains. Performance remained high when acoustic and psycholinguistic features were used to predict follow-up cognitive performance. The psycholinguistic features that were most successful at classifying high cognitive impairment reflected vocabulary richness, the quantity of speech produced, and the fragmentation of speech, whereas the analogous top-ranked acoustic features reflected breathing and nonverbal vocalizations such as giggles or laughter.

Conclusions: These results suggest that both acoustic and psycholinguistic features extracted from qualitative interviews may be reliable markers of cognitive deficits in late life.

Introduction

It is estimated that approximately one-third of adults aged 65 years and older in the United States have mild cognitive impairment (MCI) or dementia [1]. Given the high prevalence of MCI and dementia, better methods are needed for earlier identification. Biomarkers associated with future cognitive decline can be evident decades before the deficits are clinically detected [2]. By the time cognitive changes are evident to the patient or their families, functional difficulties may be more advanced, and potential interventions to reduce decline may be less effective.

Language abilities remain largely preserved in typical aging, despite gradual declines in other cognitive functions such as processing speed. The decline in language abilities may serve as a key indicator of atypical or pathological aging such as MCI and dementia [3-5]. Prior studies have reported speech and language declines across disease progression from early MCI to moderate-stage Alzheimer disease [6-8]. Mueller et al [8] found that subtle declines in speech fluency and semantic content are apparent even prior to the onset of clinically diagnosed MCI. Therefore, developing techniques to identify early changes in language functioning may enhance the detection of subtle cognitive decline associated with pathological cognitive aging.

Natural language processing (NLP) has emerged as a promising approach for identifying early signs of pathological cognitive decline [9]. NLP includes a variety of techniques to capture and quantify linguistic or semantic aspects of speech (eg, syntactic complexity, idea density, and semantic content) and is often combined with machine learning (ML) to automate classification based on latent patterns in data. Asgari et al [10] used linguistic features derived from audio recordings of unstructured conversations with 41 older adults and were able to differentiate cognitively intact individuals from participants with MCI with 84% classification accuracy. Studies using intermittent audio recordings of older adults without cognitive impairment in real-world settings over 4 days found that several linguistic features were associated with performance on standardized measures of working memory [11,12]. In a longitudinal analysis of data from the Framingham Heart Study, linguistic variables derived from written responses to a picture description task (the cookie theft task), improved the predictive accuracy of conversion from cognitively normal to Alzheimer disease over nonlinguistic markers [13]. Though transcripts have been the current standard of understanding language, audio features remain underresearched in psychiatry. Another possibility is that audio feature files are difficult to share due to privacy controls, and therefore, are more difficult to access. Acoustic features of speech (eg, volume) have been evaluated to a lesser extent than linguistic features [14-16]. To date, few studies evaluated the relative predictive performance of acoustic versus psycholinguistic-derived features, and none, to our knowledge, have evaluated performance in predicting future cognitive deficits.

This study aimed to explore and identify acoustic and psycholinguistic features associated with cognitive abilities on neuropsychological measures, both contemporaneously and at follow-up assessments, among older adults recruited from an independent living facility. Our work is unique from prior research in several ways. First, we use both acoustic and psycholinguistic features from speech derived from a semistructured interview rather than using standardized tasks. Second, all participants underwent a research-based neuropsychological assessment comprising multiple cognitive domains (eg, global cognitive ability as measured by a screening instrument, verbal memory, and phonemic and semantic fluency). Third, we collected follow-up neuropsychological data to evaluate the stability of prediction. Finally, we used ML techniques to develop predictive algorithms to identify acoustic and psycholinguistic features associated with cognitive impairment and change, using sociodemographic features alone as a comparison. We hypothesized that both acoustic and psycholinguistic features derived from the recordings of semistructured interviews would predict baseline and follow-up cognitive deficits, exceeding the predictive accuracy of sociodemographic characteristics (eg, age). We explored the contribution of individual features to these predictions and the relative performance of acoustic and psycholinguistic feature-based models across cognitive domains.

Methods

Participants and Procedures

This is a secondary analysis of interview transcripts from a sample that was previously described [17,18]. The original study goals were to examine predictors of cognitive and functional decline in a community-dwelling sample of older adults; thus, the lower age limit was set at 65 years in order to be representative of older adult populations that are at risk for cognitive decline. There was no upper age limit for inclusion in this study [17]. Participants were recruited from the independent living sector of a continuing care senior housing community in San Diego County. Enrollment criteria were (1) English-speaking individuals aged 65 years or older, (2) ability to complete study assessments and engage in a qualitative interview, and (3) no known diagnosis of dementia or any other disabling illness. For the study, we excluded individuals with medical or neurological conditions that would impede their ability to complete the assessments. However, we did not exclude those with major depressive disorders, as our sample primarily consists of healthy older adults living independently. This study protocol was approved by the Human Research Protections Program of the University of California, San Diego, and written informed consent was obtained from all study participants.

In-person interviews by a trained professional were conducted between April 2018 and January 2020. The interviewer and other staff were trained to administer neuropsychological tests according to standardized procedures by a licensed neuropsychologist (EWT), who was continuously available to answer scoring questions for the duration of the study. A comprehensive battery of neuropsychological assessments was planned, but the follow-up neuropsychological assessments were modified due to the COVID-19 pandemic. The neuropsychological tests included in these analyses were limited to those that were suitable for remote assessment (via telephone or videoconference). Of the 71 individuals who had completed interviews and assessments at baseline, 55 individuals had follow-up assessments (46 assessments were recorded at ~12 months, 6 assessments at ~18 months, and 3 assessments at ~24 months) with a mean follow-up interval of 1.4 years (512.3, SD 84.5 days). Of those, 37 assessments had all included measures available. Participants who did not complete a follow-up assessment had either moved out of the facility, moved to a higher level of care (eg, a nursing facility), declined further participation, or died.

Sociodemographic and Clinical Neuropsychological Measures

Overview

The sociodemographic data collected included age, sex, marital status, and racial or ethnic background (Tables 1 and 2). Trained staff also administered a neuropsychological battery [19] to assess different cognitive domains. Information on the psychometric properties of the battery constituents can be found in Section S1 in Multimedia Appendix 1.

The Montreal Cognitive Assessment

The Montreal Cognitive Assessment (MoCA) [20] is a brief cognitive screening test to identify and stage dementia and includes items measuring attention, working memory, orientation, and short-term memory.

Hopkins Verbal Learning Test-Revised

The Hopkins Verbal Learning Test-Revised (HVLT) [21,22] is a list-learning and memory test that includes total recall (ie, total recalled words over 3 learning trials), a delayed recall trial, and a recognition trial.

Delis-Kaplan Executive Function System Verbal Fluency

This subtest [23] includes tests of verbal processing speed requiring the participant to name as many animals as possible in 1 minute and to name as many words starting with the letters F, A, and S in 1 minute.

Deficits Scores

For HVLT and Verbal Fluency tests, normative data from respective test manuals were used to convert raw scores to age-corrected T-scores. Each of the T-scores was converted into binary deficit scores. Deficits were defined as scores <23 on the MoCA or T-scores <40 on the remaining tests (reflecting >1 SD below the mean).

Overall Deficit

A composite binary variable was constructed by combining the MoCA, HVLT, and Verbal Fluency tests (0=no deficit, 1=deficit on any test).

Acoustic Features

This study used a standardized procedure for qualitative interview processing as outlined by previous research [24,25]. Acoustic files (digital speech standard) were obtained following testing and converted to .wav format using NCH Switch Audio Converter (NCH Software). The audio files included the interviewer’s speech; however, we note that although multiple staff members were involved in administering the battery of neuropsychological assessments, the interviews were conducted by the same person and included a common set of questions, see Section S2 in Multimedia Appendix 1 for details. To reduce the number of parameters, we used the feature set “eGeMAPSv02,” which is based upon the Geneva minimalistic acoustic parameter set for voice research and affective computing, which identifies a basic set of acoustic features commonly used in clinical speech analysis [26]. A total of 88 Geneva minimalistic acoustic parameter set acoustic features are identified in the Python openSMILE library, which has been previously validated for this purpose [27-29]. These features were then extracted from the entirety of the interview using openSMILE audio processing software (audEERING GmbH). Notable among these were features of spectral slope (alphaRatioUV, slope UV 500-1500 HZ) and balance or shape or flux (Mel-frequency cepstral coefficient). F0 in the context of acoustic features generally refers to the fundamental frequency or the lowest resonating frequency produced by the vocal tract, while F1, F2, and F3 refer to higher resonating frequencies seen as successive peaks in the frequency spectrum. These are also referred to as formants. More details on the acoustic features can be found in Section S3 in Multimedia Appendix 1.

Psycholinguistic Features

Linguistic features were extracted from the transcripts for each sample, drawing from established methodologies such as those detailed in Yamada et al [30] and other relevant literature [31]. In addition, we also explored the use of other higher-level psycholinguistic elements to assess language attributes, like readability, coherence, and references to forgetfulness and recollection. The interviews were transcribed using third-party services and were subsequently reviewed and verified manually.

In total, 86 distinct features were extracted to represent various linguistic traits: text statistics that denote parts of speech, vocabulary richness, grammatical complexity gauged by the nesting of phrases (Yngve depth) [32], verbal overlap between sentences (measured through cosine similarity [33,34]), sentiment analysis, readability metrics [35], and other features based on sentence embeddings generated by advanced language models such as the Bidirectional Encoder Representations from Transformers (BERT) [36]. Detailed interpretations of these features can be found in Table S1 in Multimedia Appendix 1.

Data Analysis

After incorporating sociodemographic variables, like age, gender, education, race (categorized as White, Black, or Other), and ethnicity (distinguished as Hispanic or non-Hispanic), the total feature set for classification encompassed 178 distinct features.

Predicting baseline and future cognitive deficits often uses traditional regression techniques such as linear regression analysis or mixed linear modeling. However, due to observed limitations in model fit with our data set, a classification approach was deemed more appropriate. Target variables were dichotomized using cutoffs based on literature recommendations. This adaptation not only improved model accuracy but also aligned with clinical standards, specifically diagnostic cutoffs like scores below 23 on the MoCA [37] or T-scores 1 SD below the mean [38].

Owing to the limited understanding of the audio feature space in the context of psychiatry and the sparse body of work on psycho-linguistic features, 6 diverse ML models were separately explored to determine their performance. This was done in part to characterize the problem space: a high-performing support vector machine model or k-nearest neighbor might suggest distinct regions or clusters in the feature space, which could be pursued for future investigation. The models were retrained for the follow-up assignments, in order to identify potential lead-lag effects. To address the risk of overfitting, the feature space was reduced to the top 10 using the Gini impurity index [39,40] and the performance results (ie, F_1-score, sensitivity, and specificity) were reported using leave-one-out cross-validation.

The following ML algorithms were used in the investigation: k-nearest neighbor, support vector machine, random forest, neural network, and naïve Bayes classifiers. Importantly, gender was considered alongside acoustic features in the ML analysis due to its potential impact on various acoustic properties, including pitch, which could represent a confounding variable. The hyperparameters applied across these models are exhaustively detailed in Table S2 in Multimedia Appendix 1.

The relative contribution of the features across domains was assessed by calculating the correlation between sociodemographic, acoustic, and psycholinguistic features with both raw scores and dichotomized deficits on neuropsychological subscales. Subsequently, the maximum correlation value for each feature with either the raw scores or deficit scores was determined, and the features were prioritized based on these values. The principal 25 features were then depicted in a heat map to facilitate the examination of their interrelationships. In addition, biclustering techniques [41] were used to delve deeper into the feature interdependencies. The emergent correlation matrix was visualized through a heat map, providing a comprehensive synopsis of the variable associations.

Ethical Considerations

The study procedures and data analyses were reviewed and approved by the University of California San Diego Human Research Protections Program (Institutional Review Board #170466). The participants provided written informed consent to participate in this study. All data were anonymized, by use of a manual review of each transcript to remove any proper names, addresses, or potentially identifying information. All participants whose data are presented here provided additional consent to the use of information extracted from audio recordings for research purposes. Participants were compensated US $75 for participation in the study, which included the clinical and neurocognitive tests and qualitative interviews detailed in this manuscript.

Results

Sample Characteristics

The sample's age ranged from 67 to 98 years at the initial visit, with a mean age of 83.3 (SD 7.0) years (Table 1). Most participants were single (n=45, 63%), White (n=65, 91%), and female (n=47, 66%), and had a high level of education (mean 15.9, SD 2.3 years). Cognitive functioning varied among participants, as indicated by MoCA scores ranging from 13 to 29. Depression scores were low (mean 9-item Patient Health Questionnaire score of 3.2, SD 3.8), rendering the sample inadequate for investigating the intersection of cognitive impairment with depression. The average time to the follow-up visit was 1.4 years (mean 512.3, SD 84.5 days) postbaseline (refer to Table 2). Attrition was primarily due to a lack of interest (n=27, 21%), transfer to more intensive care (n=11, 9%), participant deaths (n=11, 9%), and medical issues (n=3, 2%). A minority (n=3, 2%) reportedly withdrew due to cognitive decline. The reasons for the decrease in participation were not further analyzed.

Classification Performance Using Acoustic and Psycholinguistic Features

The initial assessment focused on the effectiveness of various feature groups in distinguishing individuals with cognitive impairment from those without at baseline. To this end, F_1-scores were used due to their balanced consideration of precision and recall, which is critical in the context of an uneven class distribution. Table 3 shows F_1 performance scores, sensitivity, and specificity for various feature groups. Assuming a threshold of 0.75 for F_1-scores (see Section S4, Multimedia Appendix 1 for the choice), acoustic and psycholinguistic features were acceptable and generally higher than F_1-scores of sociodemographic features. Given the limited performance, sociodemographic features (gender, age, race, years of education) were best at predicting HVLT total recall (or learning) deficits compared to other deficits. Acoustic features were the best predictors of animal naming and overall deficits, and the psycholinguistic features performed best for HVLT total recall. The performance for MoCA and HVLT retention was comparable for both acoustic (F_1 of 0.76 and 0.71, respectively) and psycholinguistic feature (F_1 of 0.78 and 0.70, respectively) sets. Acoustic features performed better than psycholinguistic features in HVLT delayed recall (F_1 of 0.72 vs 0.67), animal naming (F_1 of 0.80 vs 0.70), and letter fluency (F_1 of 0.78 vs 0.73), while psycholinguistic features performed better than acoustic in HVLT total recall (learning; F_1 of 0.82 vs 0.77). As expected, the combined set (acoustic, linguistic, and sociodemographic features) performed the best among all individual feature sets. Gender did not play a factor among the top 10 features for any target in the baseline or the follow-up visit.

Using baseline features to determine cognitive status at subsequent follow-up visits (Table 4), it was observed that the predictive capacity of these features remained consistent across tests (for instance, an F_1-score of 0.87 was noted for MoCA using all features). This observation was in line with the initial analysis, where psycholinguistic features outperformed acoustic features, which in turn were more predictive than sociodemographic variables. There was also an improvement in the performance of sociodemographic features (F_1-scores; Table 4) and sensitivity (of >0.5 in most cases, Table 4), but they continued to underperform compared with the acoustic and psycholinguistic features. MoCA (F_1=0.87, sensitivity=0.85, specificity=0.88) and letter fluency (F_1=0.91, sensitivity=1.00, specificity=0.87) were the best predicted cognitive tests for a year in the future. Among the ML models used, the naïve Bayes classifier generally performed better than other models for most classification targets (Table S3, Multimedia Appendix 1). In addition, we performed a 10-fold cross-validation; the results aligned closely with leave-one-out cross-validation for best-performing models and are reported in Table S4 in Multimedia Appendix 1.

Ranking and Proportion of Acoustic and Psycholinguistic Features and Demographics

Overall, acoustic features performed best in classifying animal fluency, letter fluency, and HVLT total recall (learning), while psycholinguistic features performed best in classifying MoCA and HVLT retention (Table 5). The prominence of acoustic features in deficit prediction prompted us to establish age correlates of acoustic features (Table S5, Multimedia Appendix 1). Few sociodemographic features were present in the top 10 features. Among acoustic features, the most predictive included ones corresponding to nonverbal vocalizations of energy and its distribution across frequencies (formants) in absolute ranges of 500-1500 Hz (slopeUV), as well as in terms of individual physiology (Mel-frequency cepstral coefficient), and jitter. Variation in loudness was also an important acoustic feature in identifying cognitive deficits. Among the psycholinguistic features, the amount of speech produced (number of transcribed characters and words, number of utterances) along with vocabulary richness (vocabulary type token ratio, interview readability), proportion of nouns (noun to verb ratio, verb frequency, pronoun, and particle frequency), repetition (cosine similarity), and sentiment were important correlates of cognitive deficits.

Table 5. Contribution profile of deficits based on top contributing features at the baseline visit. MoCA[a] scores are dominated by psycholinguistic predictors. HVLT[b] total and delayed recall, animal naming, and FAS[c] are all predominantly determined by acoustic features. Sociodemographic features play a minor role in HVLT total recall and the overall deficit.

Cognitive assessment target	Acoustic (%)	Psycholinguistic (%)	Sociodemographic (%)
MOCA	10	90	0
HVLT total recall	80	10	10
HVLT delayed recall	70	30	0
HVLT retention	40	60	0
Animals	70	30	0
FAS	70	30	0
Overall deficit	20	70	10

Clustering and Heat Map of Features and Targets

The raw scores of HVLT and MoCA tasks were clustered in a subtree, while all deficits were in a separate subtree. The clustering suggested that animal naming deficits very closely resembled the derived overall deficit.

Our analysis indicated that the set of top contributing features across all targets was clustered into 4 subtrees. The cluster labeled A (Figure 1) was comprised of psycholinguistic features representing vocabulary richness and other metrics of vocabulary use including type token ratio, noun-verb ratio, interview readability, and sentiment. These features correlated positively with task scores and negatively with deficits. The cluster labeled B in Figure 1 predominantly contains psycholinguistic features representing increased speech production. Included in this cluster were features corresponding to particle, verb, and pronoun use, increased utterances, transcribed characters, and words. The cluster labeled C also predominantly includes psycholinguistic properties features and contains features that represent speech fragmentation. This includes features that punctuate language (interjections) and repetition (cosine similarity), and also present were acoustic features representing variation in loudness (slopeUV500-1500, loudness) or the control of glottis closure. These features correlated positively with deficits and negatively with raw cognitive scores. In contrast to clusters A, B, and C, the cluster labeled D was comprised of almost all acoustic features representing spectral balance and tilt.

Figure 1. Heat map and results of biclustering of top 25 features by correlation. Along the x-axis, the acoustic features are in green, psycholinguistic features in pink, and sociodemographic are in black. Along the y-axis, the task scores are in brown and the deficits in blue. Four clusters of features are evident, (A) and (B) being predominantly psycholinguistic and (D) predominantly acoustic. (A) Lexical richness and positive sentiment: the group of features reflect vocabulary richness (interview readability, vocabulary type token ratio, noun to verb ratio) and sentiment that relates positively with the cognition scores and negatively with deficits. (B) Reversal of concreteness and greater speech production: comprises mostly of psycholinguistic features that suggest replacement of nouns by descriptive phrases (pronoun frequency, particle frequency, verb frequency, number of utterances, number of transcribed characters and words, yngve depth) but one acoustic feature is also included (mean alpha ratio UV simple moving average). These features correlate positively with some deficits and negatively with others and show a certain homogeneity, the cluster associates with increased language output. (C) Speech fragmentation: the cluster seems to encode speech fragmentation through interjection (interjection frequency), repetition (cosine similarity) and loudness variation (norm of loudness standard deviation), and audio features for spectral balance in absolute frequency terms (mean slope UV 500-1500 Hz and F1 bandwidth) correlating negatively with cognition scores and positively with the deficits. (D) Nonverbal vocalizations: acoustic features representing spectral balance or shape or dynamics in individual vocal tract and glottis physiology (mean and SD of mel-frequency cepstral coefficients, jitter) and age, that corelates negatively with the cognition scores but positively with deficits and can encode nonverbal emotions. HVLT: Hopkins Verbal Learning Test-Revised; MoCA: Montreal Cognitive Assessment.

Discussion

Principal Findings

A manual review of the cognitive measures of participants along the timeline revealed abrupt changes that were not always monotonic (strictly decreasing) as might be expected. In fact, MoCA has been shown to significantly improve in the second administration [42]. These effects combined with the noise in the testing, as well as the within-subject fluctuations, make regression over short intervals difficult. Furthermore, individuals transferred to higher care facilities, who may have shown greater declines, were not included in this analysis. The research and medical team agreed that modeling individual decline over 1.4 years might not be feasible. Posing it as a classification problem by dichotomization, however, allowed us to model age-related changes at a very broad level with a modest degree of success.

This work is among the first to evaluate both acoustic and psycholinguistic features in a longitudinal study of cognitive performance in an older adult sample. We found that both acoustic and psycholinguistic features provided a reasonably strong classification of overall cognitive impairment, verbal memory, and verbal fluency tasks at both baseline and follow-up assessments. While using psycholinguistic features and sociodemographic features alone, the classification of cognitive impairment was similar to previous approaches [13]. Combining the acoustic and psycholinguistic features, however, enhanced the classification performance. We found that baseline acoustic and psycholinguistic features predicted future performance on the same cognitive tasks at a mean follow-up of 1.4 years. Comparing the relative accuracy of acoustic versus psycholinguistic features, there was a slight disadvantage of acoustic features compared to psycholinguistic features using the F_1-score metric in the follow-up. Features clustered by type and varied across cognitive tasks, suggesting that different features may be useful for detecting different aspects of cognitive impairment. Since the actual performance scores (F_1-scores) were in the 0.7-0.8 range, separation boundaries were expected to be fuzzy. Overall, our findings add to the growing body of literature indicating that linguistic and acoustic analysis of speech samples may aid in the detection of cognitive deficits in aging.

Our findings are consistent with prior research that has investigated psycholinguistic markers of cognitive aging. A change, generally a reduction, in noun production, has long been identified as an early indicator of cognitive decline by several studies [43-45]. Nouns and verbs are the most common categories in the English language, and their use often declines in early dementia [46]. Word-finding difficulties foreshadow progressive aphasias and other degenerative dementias [47,48]. In our heat map–based analysis of the baseline data, we found that lexical richness related negatively to deficits and positively to cognitive performance. The reduced access to nouns due to a decline in semantic networks may initially result in longer phrases that describe the nouns, thus resulting in increased language production in social settings [49,50]. This may also be related to as "reversal of concreteness effect" [51-53]. This phenomenon is reflected in the features that represent an increase in the frequency of pronouns, particles, and verbs (eg, the inability to recall the word "fork" could result in saying "that thing you eat with," such that a noun is replaced by several other parts of speech) and increase in utterances, words and characters, and even coverbal gestures [54]. Grammatically, this would cause an increase in the depth of the parse tree, the Yngve depth [32], as a single word gets replaced by a phrase. Written grammatical complexity, however, decreases over longer timeframes, as suggested by a study spanning the lifetime of a novelist with Alzheimer disease [55]. Notably, we did not predict decline per se but rather future cognitive ability. Eyigoz et al [13] demonstrated the predictive value of linguistic features over a 7-year period in reference to conversion to Alzheimer disease. It is possible that our mean follow-up period of 1.4 years was too short to result in a significant number of individuals becoming impaired.

Our study adds to the comparatively smaller body of literature on acoustic features in cognitive aging. Exploring these features is important given that not all are detectable with the human ear, despite some evidence that they may covary with age and cognitive ability. Acoustic features relating to the Mel-frequency cepstral coefficient may have embedded within them artifacts of age-related decline [56,57] leading to the poorer representation of nonverbal vocalizations, possibly through the expression of emotions through glottis control, for example, laughter or giggle [58]. Some top predicting acoustic features were also associated with variation in loudness [59] or the glottis closing slowly or insufficiently due to aging [60]. Such nonverbal vocalizations are not correlated with grammar [61,62], so they are undetected by NLP extraction tools. Some, such as laughter or giggle, are produced in glottal or subglottal structures spontaneously and are in the annotation category, while others such as breathing, correlate with pauses in prosodic hierarchy [63]. Aging is also reflected in jitter [64] due to vocal fold atrophy [65]. Overall, it was notable that our best models combined acoustic and psycholinguistic features, and that our heat map suggested that different cognitive domains were predicted by unique feature sets that clustered with acoustic features or psycholinguistic. As such, future research should evaluate the dynamics of within-person change in acoustic and linguistic features as they may predict changes in cognitive performance in a range of cognitive tasks over time.

It is possible that the decline manifests itself in fits and bursts due to the noise in the measurement of cognitive tasks and within-individual fluctuations: the changes are small over the interval of 1.4 years compared to the overall value. Furthermore, individuals who were transferred to a higher level of care may have a greater decline but could not be included in this analysis. Hence, our data does not allow for the prediction of various cognitive scores on an individual basis. However, if the scores are dichotomized and aggregated, the predictions about the cognitive status change can achieve performance that is suitable for screening purposes. Future studies with larger samples and longer periods of follow-up would allow for finer-grained prediction of cognitive decline in specific domains.

One study [66] has documented extensively the performances of a variety of BERT-based transformers on this task. We found that most of these models under-performed our combined models, and only one approached a comparable performance ($\mathrm{BERT}_{\mathrm{Large}}$-LR; F_1-scores of 87%). This, in our opinion, can be attributed to our rich feature set that included acoustic features that potentially convey important information about the physical health of the participants. The use of large language models (such as ChatGPT) was avoided due to two concerns: (1) the models are criticized for opaqueness to feature interpretation, which was our focus, and (2) patient privacy concerns. At the time of our research, the available generative large language models did not meet our specific needs in terms of local deployment capabilities and data sensitivity [67] (ie, ChatGPT and Claude could not be run locally). We are excited to note that with the introduction of open-source models, such as Llama 3, which offers robust performance while being feasible for local deployment, we plan to bridge this gap.

Limitations

There are some limitations in this study. The sample was relatively homogenous, with high socioeconomic status, primarily White, and highly educated, relative to the broader older adult population. The acoustic recordings were roughly 1.5-2 hours in length, and thus the minimum length of speech data needed for these analyses is unknown. The current interview length may not be practical for clinical deployment. These analyses include acoustic features extracted from the entire interview; the fraction of the interviewer's speech was small and there were fixed questions. Although the same interviewer conducted the interview with the same set of prompts, it is reasonable to expect that some bias was introduced in the acoustic features of the interviewee resulting in some loss of performance of ML models. Other limitations include that drop out was significant and longitudinal prediction may be affected by this; as well, there was a variable follow-up duration. We also had planned a broader neuropsychological battery with nonverbal domains, but the transfer to a remote assessment paradigm due to the COVID-19 pandemic prevented this. In addition to impacting the shift to remote assessments, the COVID-19 pandemic may have impacted aspects of daily life that may influence cognitive ability (eg, access to physical activity), therefore, the findings should be interpreted in this light.

Finally, while we did perform leave-one-out cross-validation, we lacked an independent sample with which to validate these features or establish confidence intervals. Model fits were evaluated based solely on F_1-score comparisons. Constrained by the mentioned limitations, the study should be considered exploratory.

Conclusions

Despite these limitations, our study raised questions that warrant future investigation. We were unable to ascertain if the features most indicative of cognitive impairments are also predictive of those likely to experience decline in the near future. Furthermore, the mapping between the acoustic features and cognitive domains remains unclear. The value of adding acoustic and psycholinguistic features to assessments and the duration of speech needed to discriminate cognitive impairments could be contrasted to the relative importance beyond that associated with cognitive screening data. Although our semistructured interview was broad, it would be useful to understand both the impact of the nature of the prompts and topics covered, as well as the minimum duration of speech sample required, to achieve the desired accuracy in predicting cognitive deficits. The generalizability of acoustic and psycholinguistic features, especially beyond English-speaking and primarily well-educated White groups, requires confirmation across different languages and racial or ethnic backgrounds. Overall, our results suggest a potential role for acoustic and psycholinguistic data in cognitive assessment; the next step is to determine the timing and connection to brain changes that occur with pathological aging processes such as in dementia.

Acknowledgments

Some of the linguistic features in this paper were previously described and developed [30,31] by Kaoru Shinkawa and Yasunori Yamada. EWT gratefully acknowledges the support of a VA Rehabilitation Research and Development Research Career Scientist Award. This work is supported by IBM Research through the AI Horizons Network.

Data Availability

The datasets generated during or analyzed during this study are not publicly available due to privacy concerns, including Health Insurance Portability and Accountability Act regulations, but the code for generating custom features of machine learning model parameters is available from the corresponding author upon reasonable request.

Authors' Contributions

VDB designed and implemented the artificial intelligence-based (natural language processing and machine learning) approaches, performed data analysis, interpreted results, prepared the first draft of the manuscript, incorporated feedback, and edited and contributed to drafts of the manuscript. JMR proposed the research questions, helped with data analysis and interpretation, provided feedback, edited, and contributed to drafts of the manuscript. EWT proposed the research questions, helped with data analysis and interpretation, provided feedback, edited, and contributed to drafts of the manuscript. EEL oversaw the study, proposed the research questions, helped with data analysis and interpretation, provided feedback, edited, and contributed to drafts of the manuscript. RPF wrote sections of the first draft, helped with data analysis and interpretation, provided feedback, edited, and contributed to drafts of the manuscript. EB oversaw the study, proposed the research questions, implemented the natural language processing–based approaches, helped with data analysis and interpretation, provided feedback, edited, and contributed to drafts of the manuscript. CAD oversaw the study, proposed the research questions, helped with data analysis and interpretation, provided feedback, edited, and contributed to drafts of the manuscript. All authors contributed to the manuscript revision and read and approved the submitted version.

Abstract

Background: The severity of Alzheimer disease and related dementias (ADRD) is rarely documented in structured data fields in electronic health records (EHRs). Although this information is important for clinical monitoring and decision-making, it is often undocumented or "hidden" in unstructured text fields and not readily available for clinicians to act upon.

Objective: We aimed to assess the feasibility and potential bias in using keywords and rule-based matching for obtaining information about the severity of ADRD from EHR data.

Methods: We used EHR data from a large academic health care system that included patients with a primary discharge diagnosis of ADRD based on *ICD-9* (*International Classification of Diseases, Ninth Revision*) and *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) codes between 2014 and 2019. We first assessed the presence of ADRD severity information and then the severity of ADRD in the EHR. Clinicians' notes were used to determine the severity of ADRD based on two criteria: (1) scores from the Mini Mental State Examination and Montreal Cognitive Assessment and (2) explicit terms for ADRD severity (eg, "mild dementia" and "advanced Alzheimer disease"). We compiled a list of common ADRD symptoms, cognitive test names, and disease severity terms, refining it iteratively based on previous literature and clinical expertise. Subsequently, we used rule-based matching in Python using standard open-source data analysis libraries to identify the context in which specific words or phrases were mentioned. We estimated the prevalence of documented ADRD severity and assessed the performance of our rule-based algorithm.

Results: We included 9115 eligible patients with over 65,000 notes from the providers. Overall, 22.93% (2090/9115) of patients were documented with mild ADRD, 20.87% (1902/9115) were documented with moderate or severe ADRD, and 56.20% (5123/9115) did not have any documentation of the severity of their ADRD. For the task of determining the presence of any ADRD severity information, our algorithm achieved an accuracy of >95%, specificity of >95%, sensitivity of >90%, and an F_1-score of >83%. For the specific task of identifying the actual severity of ADRD, the algorithm performed well with an accuracy of >91%, specificity of >80%, sensitivity of >88%, and F_1-score of >92%. Comparing patients with mild ADRD to those with more advanced ADRD, the latter group tended to contain older, more likely female, and Black patients, and having received their diagnoses in primary care or in-hospital settings. Relative to patients with undocumented ADRD severity, those with documented ADRD severity had a similar distribution in terms of sex, race, and rural or urban residence.

Conclusions: Our study demonstrates the feasibility of using a rule-based matching algorithm to identify ADRD severity from unstructured EHR report data. However, it is essential to acknowledge potential biases arising from differences in documentation practices across various health care systems.

Introduction

More than 6 million Americans aged 65 years and older are currently living with Alzheimer disease and related dementias (ADRD), constituting about 11% of the total American population aged 65 years and older [1]. This number is projected to double by 2060, reaching 13.8 million individuals affected by ADRD [1]. Despite the absence of a cure, timely identification of ADRD can significantly improve the quality of life of patients and better prepare their families with essential support resources [2]. Early identification of ADRD will also allow health care professionals and policy makers to develop adequate care programs for both patients and their families. Furthermore, the recent US Food and Drug Administration approval for ADRD treatment, lecanemab-irmb, has demonstrated promising advancements in the pharmacological management of the disease [3]. However, it is important to note that most of these treatments are only targeted at patients with mild cognitive impairment or early-stage dementia. Therefore, identifying ADRD at an early stage of the disease has become even more critical.

Early identification of ADRD poses significant challenges [4,5]. Even among patients with diagnosed ADRD, determining disease severity remains complex from a clinical perspective. Information regarding the presence and severity of ADRD is often limited to structured fields of electronic health records (EHRs) and is more likely to be stored within unstructured EHR sections, such as clinical reports. Moreover, wide variability exists in documentation practices and data structures across different health care systems, specialties, and even among clinicians within the same clinic [6]. Over the past decade, there has been a substantial increase in leveraging information contained in the EHR to improve diagnostic precision [7]. In this context, natural language processing (NLP) has emerged as a promising approach to extract relevant information from EHR data, bridging the gap between structured and unstructured clinical information.

In recent years, EHR data and NLP have been used in various ways to improve ADRD care, such as identifying corelated symptoms [8] and common description of cognitive impairment used by clinicians [9], establishing consensus on cognitive test scores [10], phenotyping of cognitive status [11], and predicting the onset of cognitive decline [12]. However, while structured EHR data have traditionally been used in previous research, they fall short of adequately documenting the severity of ADRD [13]. To address this gap, the unstructured component of EHR becomes critical for capturing essential symptoms and severity indicators related to ADRD [11]. The extent to which unstructured EHR data can be used to determine the severity of ADRD remains largely unknown.

In this study, we assess the feasibility and potential bias of a rule-based matching algorithm for extracting information on ADRD severity in patients with a primary discharge diagnosis of ADRD. Specifically, we develop an algorithm that acquires cognitive test scores and identifies distinct mentions of the presence and severity of ADRD from the primary discharge diagnosis. As each health care system may encode clinical information in the EHR differently, we propose a general framework that health care systems can adopt to tailor their needs and reduce irrelevant “noise” in the EHR—any unwanted irrelevant information.

Methods

Data Sources and Study Population

This is a retrospective cohort study that used data from Duke University Health System. Due to the sensitive nature of the data, qualified researchers trained in human subject confidentiality protocols may send requests to access the data that support the findings of this study to the corresponding author.

EHR data were extracted using Duke Enterprise Data Unified Content Explorer, a data extraction system based on Epic (Maestro Care) that identifies patient cohorts and provides access to clinical data stored in the organizational data warehouse [14]. According to previous research, we identified patients with ADRD as those who had at least one clinical encounter at Duke University Health System with at least one principal discharge diagnosis of ADRD based on *ICD-9* (*International Classification of Diseases, Ninth Revision*) or *ICD-10* (*International Statistical Classification of Diseases,Tenth Revision*) codes [9,15,16]. The list of *ICD-9/10* codes was based on an established algorithm from previous literature [10,17]. A total of 9115 patients aged 40 years or older, diagnosed with ADRD between January 1, 2014, and December 31, 2019, were included, totaling 65,576 patient records.

Data Management

As most of the content present in a patient record is not directly related to the severity of ADRD, we used a keyword list that contains common ADRD terminologies to flag patient records and sections of the record that include words directly related to ADRD. The initial list was generated based on previous work [9] and was further modified to include synonyms and additional keywords corresponding to *ICD-9/10* codes related to ADRD. An expert panel of clinicians provided input on the list through an iterative process. The final list (Table S1 in Multimedia Appendix 1) included 38 unique ADRD keywords, consisting of terminologies used by clinicians at Duke University Health System to document ADRD-related information in patient records. This step helped us extract the context in which these words and phrases were mentioned to reduce noise (ie, text not related to the severity of ADRD).

NLP Algorithms

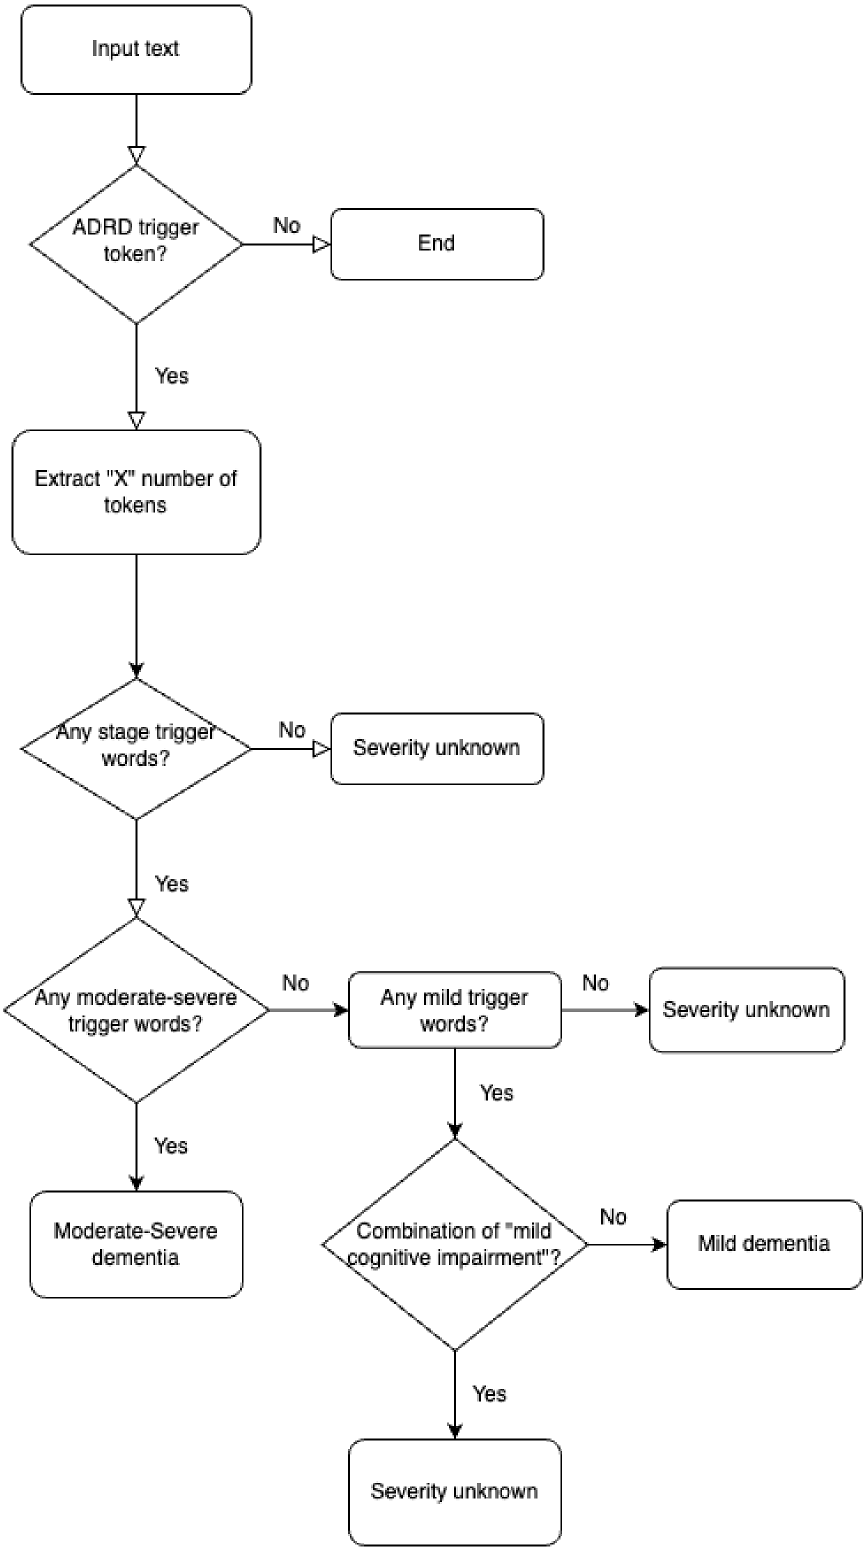
Unstructured EHR data, characterized by its absence of standardized writing patterns, often manifests inconsistencies in both quality and content. This includes the presence of spelling errors, typographical inaccuracies, formatting inconsistencies, uncommon abbreviations, and other customary challenges inherent in note-taking practices [18]. In response to these challenges, progress in NLP capabilities has helped to filter out important and relevant information from EHR data automatically. This can be done through a rule- or learning-based approach. Previous research has suggested that learning-based methods struggle with interpretability [19] and require a considerable amount of labeled text data, which can hinder scalability. Therefore, in our study, we used a rule-based approach, allowing us to interpret our results clearly and quantify the scope of our algorithm.

Specifically, our algorithm worked by sequentially narrowing down the target tokens (parts of the sentence) to extract information pertaining to ADRD textual mentions (ie, ADRD Text) and cognitive scores (ie, ADRD Cognitive Score). Then the algorithm determined the severity of ADRD based on either the direct mention of keywords pertaining to ADRD severity, or cognitive test scores. We categorized the severity of ADRD into three categories that include (1) mild, (2) moderate-to-severe (ie, advanced stage of ADRD), and (3) no severity indicated. Keywords corresponding to each severity stage are included in Table S2 in Multimedia Appendix 1. In the absence of any direct mention of the severity keywords in patient records, the severity of ADRD was defined based on cognitive test scores (Table S3 in Multimedia Appendix 1). Separate lists of keywords for the severity and cognitive scores were generated to aid the NLP algorithm. For patients whose records contained multiple severity levels from the same source (eg, all from cognitive scores), the more severe ADRD was assigned to the patient. As patients are likely to progress from mild to more advanced dementia over time, the more severe disease information was more likely to be the most updated information. In cases where there were discrepancies between the severity indicated by the explicit keywords and the cognitive scores, we defined the severity of ADRD based on the keywords, as providers may characterize the severity of the condition of the patients comprehensively based on additional assessments besides cognitive tests.

ADRD Text

We used the Python package spaCy’s pattern-matching function to identify occurrences of words listed in the ADRD keyword list (ie, trigger words). Once a word was identified, we assigned it a positional value of 0. We then extracted 5 tokens before and after the identified word (–5,5), creating a variable with 11 tokens, including the trigger word. The decision to extract this specific number of tokens was based on language constraints and observations from chart reviews, which revealed that most keywords related to the severity of ADRD appeared near the trigger words (eg, “mild dementia”). Next, we performed another pattern search using the severity keywords listed in Table S2 in Multimedia Appendix 1, but this time only on the previously extracted 11 tokens. If a match was confirmed, we extracted the keyword defining the severity of ADRD. The extracted keyword was then assigned a severity category based on the Montreal Cognitive Assessment (MoCA) and Mini Mental State Examination (MMSE) score ranges as outlined in Table S3 in Multimedia Appendix 1. The flowchart for this method is illustrated in Figure 1.

Figure 1. Flowchart to determine the severity of Alzheimer disease and related dementias based on Alzheimer disease and related dementias trigger words. ADRD: Alzheimer disease and related dementias.



ADRD Cognitive Score

Based on previous literature and input from clinicians, we focused on the cognitive scores from MMSE and MoCA to define the severity of ADRD [16,20]. These 2 cognitive tests were widely used in clinical practice with established cutoffs to determine the severity of cognitive impairment [16,20]. Through chart review and consultation with clinicians, we observed the following patterns for reporting the scores in patient records. For MMSE, the scores were reported either as variations of “AB/30” or “AB”. For MoCA, the scores were reported as variations of “AB/30,” “AB,” or a special case, “score AB,” where A $\in$ (0,3), B $\in$ (0,9). Some exemplars are present in Table 1. For each patient record, a pattern-matching search was performed to identify occurrences of MoCA and MMSE trigger words. Once a keyword was identified, it was assigned a positional value of 0, and 10 tokens before and after the word were extracted together (–10,10) into a variable. We then used regular expression (Regex) to extract only the numerical score value from the variables with extracted tokens.

The above method was used for all the cases mentioned above, with MoCA scores including a special case, due to a slight deviation in terms of extracted tokens, belonging to (0,50) as seen in Figure 2.

Table 1. Examples of potential causes of misclassification and representative phrases.

Category and cause of error	Sample sentence	Explanation
ADRD[a] text		
Incorrect textual representation	• Patient demonstrates decreased function secondary to deceased activity tolerance; cognitive deficits; medical status limitations • [‘contrast. \r\n\r\n indication: dementia \r\n\r\n findings: \r\n no’, ‘ -- -- -- -- -- -- ’]	• Token delimiter missing
Lack of contextual relationship between texts	• Lost 2 points for recalling only 1 out of 3 words after 3 minutes. Her neuropsychological testing concluded that she had evidence of a “mild cognitive disorder, nos.” • Mini-cognitive total scoring 1-2 recall and normal cdt: negative for cognitive impairment • Vascular dementia with a superimposed severe delirium	• Presence of “mild” and “cognitive” words in close vicinity • Failure to identify negative context. • Presence of “dementia” and “severe” in close vicinity.
ADRD cognitive score		
Particular pattern of reporting MoCA[b] score	• MoCA XX/XX/20XX trails 1 cube 1 clock 2 naming 3 digit span 1 letter a 1 serial 7s 3 sentence repetition 2 fluency 1 abstraction 2 orientation 6 memory 0 education level 0 total score 23	• Consistent pattern has been addressed in the algorithm.
Complex score reporting format	• Montreal Cognitive Assessment by on 8/22 (scored 19/30, normal is 26-30/30)	• Multiple scores in AB/30 format.
Human error	• MMSE[c] 36/50	• Out of bounds for MMSE score and spelled wrong.

Sampling, Testing, and Analysis

The rule-based algorithm was fine-tuned on a set of 200 patient records. To test the performance of the algorithm, we generated 2 additional sample files with 200 records each. The index of the first record was chosen using a random number generator to avoid bias. The annotation and validation were done at the level of each patient visit record. A certified clinician reviewed each EHR and determined the severity of ADRD. This manual annotation method served as our gold standard. All discrepancies were reviewed manually by both the data scientist and the clinician and were discussed on a case-by-case basis for resolution. Table 1 was also reviewed by 2 additional team members: 1 data scientist and 1 clinical scientist. We assessed the model performance by comparing the results generated from the algorithm against the gold standard based on the following parameters: F_1-score (ie, the predictive power of the algorithm), accuracy (ie, correct classification), sensitivity, and specificity. In addition, we compared patient characteristics between patients with and without documented dementia severity using Mann - Whitney U and Pearson chi - square tests for continuous and categorical variables, respectively. Among patients with documented severity of dementia, we further compared patient characteristics between those with mild ADRD and those with moderate-to-severe ADRD.

Ethical Considerations

This study was approved by the DUHS Institutional Review Board (Pro00104990).

Results

A total of 9115 eligible patients were included in the study with over 65,000 records. The median age of the patient population was 78 (IQR 70-84) years. Approximately 60% (5547/9115) of the patients were female, 22.9% (2087/9115) were non-Hispanic Black, and about half were diagnosed by an ADRD specialist (neurologists, neuropsychiatrists, geriatricians, etc). On average, each record contained 931.15 words.

Among all included patients, less than half (3992/9115, 43.8%) had documented information on the stage of their dementia in the EHR. Specifically, about 35% (3190/9115) of the records (3172/9115, 34.8%) included explicit terms that indicated dementia severity, whereas about one-third of the notes (n=2977, 32.7%) included scores from cognitive tests that indicated the severity of patients' dementia. We found no differences between patients with and without their dementia severity documented with regard to sex (*P*=.45) and race (*P*=.31). However, patients who were older at the time of diagnosis (*P*=.01) and those who were diagnosed at an ADRD specialty clinic or an in-hospital setting (*P*<.001) were more likely to have the severity of their dementia documented in the EHR.

Among those with documented dementia severity, less than 25% (n=920, 23.0%) were determined only based on cognitive scores. In our data, approximately half of these patients (n=1902, 47.7%) were documented to have moderate-to-severe ADRD. Compared with patients with mild ADRD, patients with moderate-to-severe ADRD were more likely to be older.

Table 1 shows potential causes of misclassification and representative phrases from the data sets used. Common causes of these challenges include (1) incorrect textual representation, (2) lack of contextual relationship between texts, (3) either particular or complex patterns of documenting cognitive scores, and (4) human data entry error.

Table 2 presents the performance of our algorithm across 3 sets of data. Overall, the algorithm can identify the presence of information on ADRD severity with high levels of accuracy (F_1-score=0.94, accuracy=0.97, sensitivity=0.94, and specificity=0.98) for training data (set 1). The overall accuracy across the 4 matrices in the 2 testing data sets (sets 2 and 3) was greater than 0.91, except for the F_1-score for set 3. To evaluate the performance of identifying the severity of ADRD, we defined a binary metric with "moderate-to-severe" diagnosis being positive and "mild" being negative. The ability of the algorithm to identify ADRD severity is comparable, if not better than identifying the presence of ADRD severity (F_1-score=0.94, accuracy=0.96, sensitivity=0.88, and specificity=1.0) for training data (set 1). The algorithm had accuracy greater than 0.91 with sensitivity of 1.00 in 2 testing data. The specificity for the 2 testing sets was greater than 0.80.

Table 2. Evaluation of ADRD[a] stage labeling algorithm for patient stage identification and severity of the diagnosis from unstructured EHR data.

Category	Set 1		Set 2		Set 3

[e] TN: True negative.

Discussion

Principal Findings

In this study, we developed and successfully implemented a rule-based algorithm to identify the severity of ADRD from unstructured EHR data. We detailed the steps to be taken for extracting the relevant information from EHR data and highlighted the challenges associated with it due to heterogeneity in textual representation. We find a lack of access to specialty facilities may impede timely diagnosis and the possibility of treatment at early stages of ADRD progression. As the severity of dementia is critical for health care providers to prescribe appropriate treatment and link resources to patients and their caregivers, our 2-pronged approach to search for relevant information presents a parsimonious yet effective way to make the disease severity information readily available across disciplines and care settings.

Similar to previous research [21-24], we developed the algorithm using a rule-based approach. Starting with an initial list of keywords or phrases based on previous work and contextual clinical knowledge, the list is refined iteratively to identify the target information. This step is followed by sampling the reports from the data set and dividing them into training and testing sets for gold-standard comparison and evaluation. Previous research applied a rule-based approach to identify caregiver availability [21], a record of mild cognitive impairment or Alzheimer disease [22], documentation of cognitive tests [23], and social determinants of health for patients with ADRD [24]. Unlike previous work, where either the rule definition step specific to the medical system [21], included *ICD* (*International Classification of Diseases*) codes [22], or had additional biomarker and cognitive tests information [23]. In comparison, our method shows robustness by using common occurring keywords and points toward the need for defining a minimum number of umbrella rules that have the potential to be generalizable for the entire data set and have better performance. Our developed algorithm is independent of the health care systems and provides clinicians with the flexibility to either use it without any modification or adapt it to their needs. A recent systematic review paper has suggested that rule-based NLP algorithms had similar performance compared with those using more sophisticated methods when the information is scarce in the EHR [25]. In our case, information on the severity of ADRD was presented using a few words, in less than half of the data. To evaluate the performance of our algorithm, we divided the tests into two categories that are (1) identifying the "presence of information on ADRD severity" and (2) "severity of ADRD." We found our algorithm to be highly accurate in extracting documented information on ADRD severity from the EHR. The performance on sensitivity and specificity also indicates that our algorithm was able to correctly extract stage information where present and reduce false positive results. Taken together, these results support the clinical use of our simplified and generalizable approach to identify the severity of ADRD. Furthermore, compared with previous work, our algorithm showed an improved average F_1-score in identifying the ADRD severity of the condition of the patient [26]. The better performance of our algorithm compared with previous work could be attributed to the use of unstructured EHR data instead of structured EHR and defining clear umbrella rules by identifying recurring patterns in our data set for ADRD severity categorization.

The performance of our algorithm is slightly diminished in identifying the severity of dementia from the records. Upon inspection of the wrongly labeled cases, it can be attributed to (1) the test scores not reflecting the correct severity compared with the clinician's evaluation, (2) lack of contextual understanding of the sentence, and (3) noise in EHR note (irrelevant information), also noted in previous work [21]. A majority of the abovementioned issues were mitigated by defining subrules [27]. However, any further inclusion would have come at the cost of reduced performance and the need for increased clinician oversight, which limits its generalizability.

Although the rule-based algorithm worked considerably well in most of the cases, it is limited by the patterns and rules defined by the developer. For cases where the token default token delimiter, in our case "space," is changed or missing, the algorithm fails to extract information. One approach to solve this could be to have an alternative copy of the algorithm that includes other common delimiters (eg, ";" "," ":") to identify word tokens. In our evaluation, we only found a few outliers not following the default way of describing texts with "space" as the delimiter. The urge to include all the stray cases would lead to the hard coding of the algorithm and give rise to new challenges with considerable false positive results, making it difficult to comb through. With the development of large language models (LLMs), 1 potential solution might be to use LLM to shape the EHR data in the same format, such as converting all patient records to have equal spacing, removing random commas, etc, without changing textual content and then follow a rule-based approach as presented in this study. Our design philosophy has been to keep the algorithm general while including common patterns. One possible criticism of our study could be dichotomizing the severity of ADRD. The rationale for dichotomizing the severity of ADRD into mild versus moderate-to-severe dementia is related to clinical decision-making. Given that there are several types of ADRD, such as Alzheimer disease, vascular dementia, and Lewy body dementia, to name a few, the differential treatment and care plans are limited as a considerable number of patients have mixed dementia, and the gold standard for a definitive differential diagnosis is still based on autopsy studies. Therefore, for this study, we only focused on a dichotomized version of the severity of ADRD. Future studies should further investigate a more comprehensive classification of ADRD severity and possibly include other tests for diagnosis of ADRD outside MoCA and MMSE.

Overall, we demonstrate the ability of our rule-based algorithm to identify the severity of ADRD, where present, in the EHR and narrow it down to the location of occurrence in the EHR. This not only allows us to comb through valuable unstructured data with ease, but the sequential nature of the algorithm provides us with contextual data that has a high probability of containing information about the severity of dementia. The extracted data can be used in future work to train a machine learning (ML) model with rich and high-quality data. We expect to enhance our method to further identify and predict the progression of ADRD over time. As the performance of an ML model depends on the quality of the data set, following a segmented approach of using a rule-based algorithm for extracting relevant paragraphs from the EHR can be used first to enrich the data set and reduce noise (ie, nonrelevant information from the EHR) followed by model training on the data. Previous research has found that combining structured and unstructured data might be a viable approach to classify patients. With structured data containing useful demographic information and unstructured data containing contextual, patient, and clinical notes, the path forward could be to leverage the qualities of both kinds of data [28] for the use of EHR.

Previous studies that used traditional ML models, such as logistic regression and support vector machine, often include only the structured EHR data due to the limited requirement for data management [6,12,13]. In recent years, increasing numbers of studies have applied deep learning approaches to classify patients for a given condition [6,29,30]. One of the strengths of the deep learning approach is its ability to incorporate relationships between words and a large amount of data in the analysis, which fits the need for using both structured and unstructured data together. Despite its strength, a common criticism against the implementation of deep learning approaches in clinical settings is the lack of interpretability [19]. The use of an interpretable rule-based approach has enabled us to highlight potential biases and pitfalls to be considered when using black-box deep learning models. One potential solution is to use rule-based pattern matching to highlight the trigger words and related neighborhood of words for added context and classify or label the patient record using deep learning techniques [31,32]. With the improvements in LLMs and their enhanced contextual and semantic understanding of texts, our rule-based method can be coupled with a pretrained LLM in pre- or postprocessing of the extracted texts [33]. Care must be taken while using LLMs due to the generative nature of text predictions in avoiding alteration of textual information and being limited to standardizing textual information. The proposed approach needs to be thoroughly evaluated through data privacy and model uncertainty lens before adoption.

We also found that the percentage of patients with missing information on the severity of ADRD is very high. Given the added significance of such information in recent times due to newly approved treatment, it is critical in current clinical practice to improve documentation of the severity of dementia to promote high-quality care. In addition, despite the missing information, our relatively simple algorithm approach has been successful in making previously inaccessible and hard-to-find information readily available to clinicians for a large number of patients. These patients would have otherwise not had this information available to their care team without our very practical approach.

Our study has a few limitations due to the algorithm of our choice and design decisions. First, as mentioned earlier, the rules have to be manually defined and fine-tuned based on a training set. This process, although simple in complexity, can be challenging as EHR can be very different based on health care systems. As the rules are manually defined, it has room for human error. On the other hand, this approach gives the researchers the flexibility to adapt the algorithm structure easily to their health care systems and needs to be fine-tuned. Second, rule-based algorithm matching studies are limited by a lack of contextual understanding between text groups and fail to recognize connotations in sentences. For example, the presence of a negative test result may confuse the algorithm pattern identification process unless explicitly included in the algorithm definition. Third, our approach has been able to only include rules for patterns that are common throughout the data set, such as for the ADRD Cognitive Score function, we include every score defined in the format of AB/30, AB, and a special type of definition as mentioned before. Therefore, we might have missed out on some of the cases straying away from the common patterns. For our instance, attempts to include every unique case led to the results being very irrelevant as it started capturing a lot of unimportant information and the algorithm became very rigid. Fourth, the study determines dementia severity based on cognitive test scores and trigger words for ADRD and does not include medical prescriptions being used by the patient which can be a future direction to make our approach holistic.

Finally, even though we have attempted to keep our method generalizable, the data were extracted from 1 health care system, and the developed rules may not directly apply to data from other health care systems. We have described in detail the steps taken in designing the algorithm with the aim of serving as a baseline approach for research in identifying ADRD severity from unstructured EHR data. The algorithm does the job well for the criteria chosen, and the choice of criteria to include can be a decision of the study designer.

Conclusion

Rule-based algorithms can provide an interpretable approach to process unstructured EHR data. This study demonstrates the value of unstructured EHR data in providing critical information about ADRD severity from patient records. Pattern-matching rule-based algorithms can be tuned and adapted to health care systems and study-specific needs. The proposed algorithm can serve as a baseline or initial point to shift through pages of EHR reports to identify the most relevant sections or regions. However, it is important to clearly identify the assumptions made, and their limitations while defining the rules. Differences in documentation may also introduce bias in the algorithm as it is fine-tuned. Overall, rule-based algorithms are powerful in handling unstructured EHR data while being transparent and interpretable.

Abstract

Background: To diagnose Alzheimer disease (AD), individuals are classified according to the severity of their cognitive impairment. There are currently no specific causes or conditions for this disease.

Objective: The purpose of this systematic review and meta-analysis was to assess AD prevalence across different stages using machine learning (ML) approaches comprehensively.

Methods: The selection of papers was conducted in 3 phases, as per PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) 2020 guidelines: identification, screening, and final inclusion. The final analysis included 24 papers that met the criteria. The selection of ML approaches for AD diagnosis was rigorously based on their relevance to the investigation. The prevalence of patients with AD at 2, 3, 4, and 6 stages was illustrated through the use of forest plots.

Results: The prevalence rate for both cognitively normal (CN) and AD across 6 studies was 49.28% (95% CI 46.12%-52.45%; *P*=.32). The prevalence estimate for the 3 stages of cognitive impairment (CN, mild cognitive impairment, and AD) is 29.75% (95% CI 25.11%-34.84%, *P*<.001). Among 5 studies with 14,839 participants, the analysis of 4 stages (nondemented, moderately demented, mildly demented, and AD) found an overall prevalence of 13.13% (95% CI 3.75%-36.66%; *P*<.001). In addition, 4 studies involving 3819 participants estimated the prevalence of 6 stages (CN, significant memory concern, early mild cognitive impairment, mild cognitive impairment, late mild cognitive impairment, and AD), yielding a prevalence of 23.75% (95% CI 12.22%-41.12%; *P*<.001).

Conclusions: The significant heterogeneity observed across studies reveals that demographic and setting characteristics are responsible for the impact on AD prevalence estimates. This study shows how ML approaches can be used to describe AD prevalence across different stages, which provides valuable insights for future research.

Introduction

The progression of Alzheimer disease (AD) affects memory, thinking, and behavioral functions over time [1]. Not only the individuals affected by the condition but also their families and caregivers, who have to cope with it daily. AD has become a major health concern worldwide because of the aging population in the last 3 decades [2,3]. The majority of cases of AD occur among older individuals, and increasing evidence suggests that a combination of genetic, lifestyle, and environmental factors is behind it [3,4]. The progression of the disease causes a slow deterioration of memory and cognitive abilities.

AD is represented by different stages of progression such as cognitively normal (CN) [5], significant memory concern (SMC) [6], early mild cognitive impairment (EMCI) [7], mild cognitive impairment (MCI) [8], and late mild cognitive impairment (LMCI) [7,8]. Biomarkers could help detect individuals at risk of AD before symptoms occur. Cerebrospinal fluid (CSF) testing is considered the most reliable marker of progression of AD. Brain neuroimaging like computerized tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET), blood tests, and genetic testing are attracting increasing attention as important markers of this pathology [1,9,10]. CSF biomarkers such as β-amyloid 42 and tau and phosphor tau are key indicators of AD [11]. An MRI or CT scan can reveal structural changes associated with AD, while a PET scan can reveal amyloid plaques and tau tangles in the brain [12]. The early diagnosis of AD can be aided by the identification of novel biomarkers, the identification of hidden data patterns, and the generation of hypotheses [13-16]. Machine learning (ML)–based predictive models can help us detect early signs of AD, improve diagnostic accuracy, and enable timely interventions [16,17].

ML applications in medicine have received significant attention for their potential in disease detection and diagnosis [18]. ML models have been proposed in existing literature to improve diagnostic accuracy for early detection of AD [19-21]. It is said that ML algorithms aid in forecasting outcomes for patients with AD, diagnosing illnesses, and tailoring treatments [15]. ML models have been reported to be able to predict patient readmissions, which allows health care providers to allocate resources more efficiently and improve patient outcomes [15,22]. In addition, deep learning (DL) algorithms can examine medical images, like CT scans or MRIs, to aid in identifying abnormalities [23-25]. The application of DL techniques to conventional MRI could reduce patient burden, risk, and cost when extracting biomarker information [26,27].

DL-based neural networks contribute significantly to AD detection [28,29]. Hierarchical representations can be learned by neural networks and achieve promising results in AD, especially when applied to neuroimaging data [30,31]. Their role includes assisting in the discovery of new AD biomarkers and analyzing large datasets to identify patterns and correlations that are indicative of AD progression [32]. Convolutional neural networks (CNNs) are used in the analysis of AD image data in the form of MRI [33], PET [34], and CT scans [35]. CNNs can automatically extract relevant features from complex imaging data and learn hierarchical representations of subtle AD patterns.

Advanced techniques like Gradient-Weighted Class Activation Mapping after CNN model training highlight important regions of the input MRI brain image [36,37]. The brain areas in these regions are responsible for influencing the model's AD prediction. These techniques bridge the gap between accuracy and interpretability in AD detection. Moreover, recurrent neural networks are capable of analyzing temporal data, such as longitudinal studies examining cognitive decline over time [38]. Predicting cognitive decline trajectories and future outcomes is possible through the capture of sequential dependencies in data [38,39]. Multimodal data integration can enhance the accuracy of AD detection models, resulting in a more comprehensive view of the patient's condition [40].

The role of ML models in the early diagnosis of AD has not been determined through extensive review of ML algorithms and meta-analysis. The accuracy and efficiency of AD diagnosis can be enhanced by using advanced algorithms and models as well as careful feature selection and extraction. However, the level of reliability of these techniques is a significant factor. The objective of this study is to address the knowledge gap by conducting a systematic review and meta-analysis of ML applications for AD detection, which aim to establish their role in improving diagnostic accuracy and patient outcomes. The main contribution of this study is (1) assessing the role of image feature selection methods in achieving competitive accuracy in AD classification modeling, (2) examining the ML methods that can be used to detect AD with the help of magnetic resonance image modeling, and (3) identifying the best ML classifier based on accuracy metrics.

Methods

This study was conducted by identifying, selecting, and analyzing relevant studies, which included a literature search, screening document inclusion criteria, and tools for risk bias assessment.

Search Strategy

A systematic search was carried out using libraries such as PubMed (MEDLINE), Scopus, and Web of Science. The search followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) 2020 guidelines to maintain transparency, authenticity, and completeness of details of reporting [41]. The PRISMA checklist of this paper can be found in Multimedia Appendix 1. This search was carried out over the last 15 years and was centered on published studies specific to early-stage AD detection and classification (between January 2010 and March 2024). Limiting our review to the last 15 years of publication allowed us to focus on papers reflective of current trends in research.

The search strategy used the following keywords: "Alzheimer's disease," "machine learning," "early detection," "diagnostic accuracy," "diagnosis," "predictive models," "biomarkers," "deep learning," "diagnostic accuracy," "feature selection," "AD biomarkers," and "ML models." The search strategy was ("machine learning" OR "artificial intelligence" OR "classification") AND "Alzheimer's disease" AND "MRI" AND "diagnosis" AND "classification."

Inclusion and Exclusion Criteria

Full-text papers in the English language were considered. We have included in this study only published papers in peer-reviewed journals. The majority of the papers analyzed were centered on MRI data combined with ML models in AD diagnosis. Selected studies included patients diagnosed with early-stage AD and healthy controls. The papers published with a title or abstract containing at least 1 abovementioned keyword were considered for inclusion.

Papers written in a language other than English were excluded. We excluded studies that were not specifically conducted in the context of AD diagnosis using MRI and were not primarily focused on ML models. Papers published before 2010 were not considered. Studies in which ML in MRI was not explicitly linked to clinical diagnosis, medical training, or initiatives to improve AD diagnosis were excluded. This review excluded studies using PET and CT scans because the primary focus was on ML in MRI, which is specifically linked to clinical diagnosis, medical training, and initiatives to enhance AD diagnosis. The selection process excluded review papers, conference proceedings, and gray literature reports.

Paper Screening

Multiple stages were involved in the paper selection process. The results of the systematic search were documented in a spreadsheet using the above strategy. The selected papers were equally distributed among the authors, and each paper was screened by examining titles and abstracts to identify potentially relevant publications. The selected papers were then reviewed comprehensively according to predefined inclusion and exclusion criteria in the subsequent phase. To facilitate synthesis, relevant information was extracted and organized in a tabular format, covering study design, datasets, performance metrics, model validation, and feature selection. As a result, a summary of each study’s main findings to discern trends, patterns, and common themes was done.

Quality and Publication Bias

The Newcastle-Ottawa Scale [42] was used to assess the study quality based on different factors such as selection, comparability, and outcome, providing a structured approach to gauge the risk of bias. In terms of quality, scores ranged from very poor (0-3) to moderate (4-6) to excellent (7-9). The papers meeting the score (Newcastle-Ottawa Scale≥7) were only considered for final review. Two authors (GB and NC) independently assessed the quality, and any discrepancies were resolved through discussion or consultation with a third author (FA).

Statistical Analysis

The statistical tests Egger regression [43] and Begg rank correlation [44] were used to address the potential bias of publications. To assess the strength of our findings against potential biases or variations in study characteristics, sensitivity analyses were performed. Lower methodological quality or different study designs were excluded. To identify the effect size measures and quantify the strength or magnitude of the relationship between variables or the magnitude of differences between AD groups, we applied the “PLOGIT” function to the logit transformation of the proportion [45]. The logit transformation is commonly used when dealing with proportions or probabilities, especially when they are bounded between 0 and 1. An inverse variance method has been applied that specifies the method for pooling effect sizes. There were 2 types of models considered in the meta-analysis: fixed effects and random effects. Using the fixed effects model when we observed a low level of heterogeneity, the test is not statistically significant.

The random effects model (REM) was considered for the heterogeneity test with statistical significance [46]. By calculating T^2, the amount of heterogeneity between the true effect sizes of different studies was quantified. An estimation method using a restricted maximum likelihood estimator that maximizes the likelihood function while accounting for other parameters of the model was used [47]. I^2 and Cochran Q statistic tests were conducted to assess the heterogeneity among the effect sizes of individual studies [48,49]. The measures of heterogeneity (T^2 and I^2) indicate the variability in AD prevalence estimates across the studies [50].

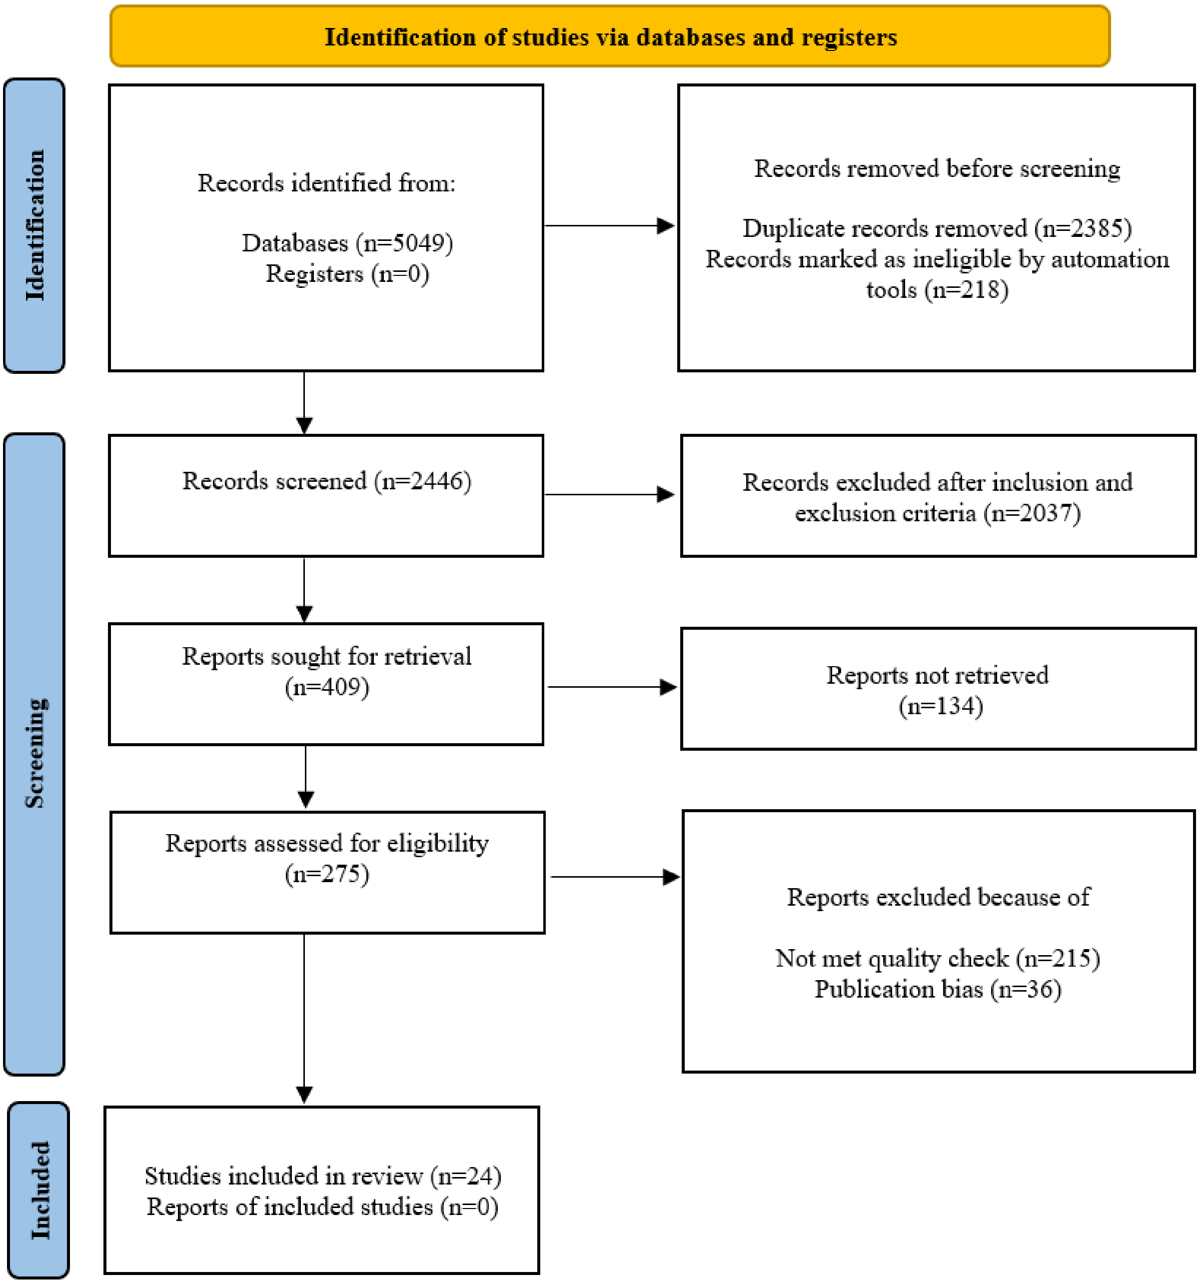
The prevalence of patients with AD across different subgroups within the overall population was also investigated. Subgroup analysis enables the identification of factors that can influence prevalence estimates and provide insight into the sources of heterogeneity [51]. A subgroup-specific meta-analysis model was used to calculate the pooled prevalence estimates for each subgroup, followed by a comparison of the prevalence estimates across subgroups to assess whether there were any significant differences. Data were subgrouped into 4 category-based AD classifications namely, 2-group classification, 3-group classification, 4-group classification, and 6-group classification. The 2-group classification involved individuals either without dementia (nondemented, ND) or with dementia (demented, AD). The 3-group classification includes CN, MCI, and AD. The 4-group classification comprises ND, mildly demented (MD), moderately demented (MoD), and AD. Meanwhile, the 6-group classification involves CN, SMC, EMCI, MCI, LMCI, and AD. Each subgroup data was recorded separately into a Microsoft Excel spreadsheet, which was further supplied as input to R software (version 4.3.3; R Foundation for Statistical Computing). For prevalence and summary meta-analysis, we used the “meta prop” functions available in the *meta* package.

Results

Search Outcomes

During the identification phase, 5049 records were obtained from 3 major scientific databases using the given search strategy. Following the removal of duplicates (n=2355) and the assessment of ineligibility using tools (n=218), 2446 records were included in the screening stage. The inclusion and exclusion criteria determined that 2037 records were ineligible. We further screened 409 records, with 134 being excluded due to lack of full-text availability. In total, 251 records from the remaining 275 were excluded due to low-quality scores and publication bias. A total of 24 papers were included in the final analysis. Details on the procedures for selecting papers are summarized in Figure 1.

Figure 1. Paper screening procedure flowchart.



Data Sources

The data collected for this study were collected from various geographical locations and may have included memory clinics and neurology departments, suggesting a focus on cognitive impairment and related conditions. Table 1 displays the distribution of AD imaging sample data along with data sources.

Table 1. Participants' data collected from different sources.

Data source	AD[a], n/N (%)	Reference

[a] AD: Alzheimer disease.

[b] ADNI: Alzheimer's Disease Neuroimaging Initiative.

[c] AIBL: Australian Imaging Biomarkers and Lifestyle Flagship Study of Ageing.

[d] OASIS: Open Access Series of Imaging Studies.

[e] NACC: National Alzheimer's Coordinating Center.

The analyzed studies collected image data from various sources such as Alzheimer's Disease Neuroimaging Initiative (ADNI) [76], Open Access Series of Imaging Studies (OASIS) [77], Australian Imaging Biomarkers and Lifestyle Flagship Study of Ageing [78], and public domains like Kaggle [79]. ADNI datasets were used more often for image collection [52,54,56-59,61,64-68,72-75,80]. The purpose of ADNI is to develop biomarkers for early detection and AD tracks through a multicenter study involving clinical imaging, genetics, and biochemistry. The studies that use ADNI datasets aim to detect AD at its prime stage. One study jointly applied 2 image datasets from ADNI and Australian Imaging Biomarkers and Lifestyle Flagship Study of Ageing [54].

OASIS brains aim to make it possible for anyone to access neuroimaging datasets of the brain through an initiative known as Open Access to Neuroimaging Datasets. Through this project, researchers can access and use a variety of brain imaging data for free. This resource assists neuroscience researchers in advancing their research by providing a comprehensive collection of brain imaging datasets. Cross-sectional OASIS 1 data were used by researchers for hypothesis-driven analysis, neuroanatomical atlases, and segmentation algorithms [69]. In another study, OASIS-3 was integrated with longitudinal neuroimaging, clinical, cognitive, and biomarker data [55]. The use of public datasets or participation in Kaggle competitions related to AD research helps as a platform for data science competitions and datasets [70]. Three studies collected data from 3 hospitals in China [53,63,71]. The findings indicate that a diverse dataset from multiple sources, such as clinical settings and publicly available datasets, could provide a comprehensive basis for AD research and analysis.

Study Characteristics

AD Stages

Table 2 presents a summary of various studies, which includes authors, publication year, AD stages, preprocessing techniques, classifiers, validation methods, and the best-performing model. Four studies have examined the progression of AD over 6 stages to gain a better understanding of how diseases develop and change [52,54,68,73]. Seven studies examined 4 groups of AD stages analyzing neurobiological mechanisms behind cognitive decline or exploring nonpharmacological treatments [55,58-60,64,66,70]. Similarly, 7 works associated with 3-stage classification studies involved patients with CN, MCI, and AD [56,57,62,65,67,71,74]. These studies were mainly focused on the early detection of dementia with subtle differences in biomarkers and cognitive performance. Moreover, the ML models used in the study predicted AD progress in estimating the transition from MCI to dementia. Finally, 6 studies associated a binary or 2-stage classification of AD with ML models to identify biomarkers that predict treatment response or disease progression [53,61,63,69,72,75]. This enables more effective targeted therapies and biomarker-driven clinical trials to be developed.

Table 2. Machine learning models and their characteristics.

	Author	Year	AD[a] stages	Image preprocessing methods	ML[b] models incorporated	Validation	Diagnosis accuracy (%)	Best model
1	Alorf and Khan [52]	2022	6	Normalization and smoothing	GLMICA[c]	K-fold (10)	84.03	BC-GCN[d]

[a] AD: Alzheimer disease.

[b] ML: machine learning.

[c] GLMICA: generalized linear model incorporating covariates analysis.

[d] BC-GCN: brain connectivity–based graph convolutional network.

[e] ROI: region of interest.

[f] SVM: support vector machine.

[g] DKI: diffusion kurtosis imaging.

[h] LME: linear mixed-effects model.

[i] SVC: support vector classifier.

[j] DenseNet: dense convolutional network.

[k] ResNet: residual network.

[l] VGG: Visual Geometry Group.

[m] CNN: convolutional neural network.

[n] DL: deep learning.

[o] SMOTE: Synthetic Minority Oversampling Technique.

[p] LSTM: long short-term memory.

[q] XGB: extreme gradient boosting.

[r] KNN: k-nearest neighbor.

[s] DT: decision tree.

[t] NB: Naïve Bayes.

[u] MLP: multilayer perceptron.

[v] GNB: Gaussian Naive Bayes.

[w] LR: logistic regression.

[x] MRMR: minimum redundancy maximum relevance.

[y] SFC: sparse functional connectivity.

[z] ANN: artificial neural network.

[aa] VGG Net: Visual Geometry Group network.

Feature Engineering Techniques

Feature engineering plays an important contribution in brain image analysis [81]. Various feature techniques were discussed to tackle challenges in AD classification, such as class imbalance, feature extraction, robustness, and generalization. ConvNet or CNN was designed for processing grid-like data, such as images, using convolutional layers to learn spatial hierarchies of features automatically [62]. Visual Geometry Group (VGG16) uses 3×3 convolution filters to construct a 16-layer CNN architecture and is known for its simplicity and high performance in image classification tasks [60]. Models like multilayer perceptron, Dense Net, Efficient Net, and residual network in AD classification lie in their ability to effectively handle deep neural networks for feature extraction and classification, which is crucial in analyzing complex brain magnetic resonance images for AD detection. Support vector machine (SVM) is a supervised learning algorithm used for AD classification, and it constructs hyperplanes in a high-dimensional space to separate different classes. In contrast, diffusion kurtosis imaging (DKI) is an MRI procedure that captures non-Gaussian diffusion, giving insight into tissue microstructure and facilitating better brain mapping. These techniques range from basic normalization [55,58,70], outlier detection [69], interpolation [59], and transfer learning [75] to more advanced methods such as data augmentation [61,70,73], feature extraction using DL models like VGG16 [60], deep feature extraction [72], ConvNet [62], and statistical modeling for region of interest extraction [54]. Another paper extracted features related to corpus callosum atrophy for AD diagnosis [67]. A single study investigated texture analysis in brain images using the Gabor and gray-level co-occurrence matrix [52]. For feature selection and analysis of functional connectivity patterns, another investigation used the minimum redundancy maximum relevance algorithm alongside the sparse functional connectivity method [55]. Unified hyperparameter tuning was applied to optimize model parameters across algorithms and settings [58].

Classifiers

Supervised models like SVM were used by several studies for classification tasks due to their effectiveness in handling high-dimensional magnetic resonance image data and nonlinear relationships [53,54,58,64,67-69,71,75]. The generalized linear model incorporating covariates analysis was used by Alorf and Khan [52] to assess a model's performance and generalization ability by ensuring that all data points are used during both training and validation, reducing overfitting risk and allowing more reliable model performance estimates. The authors demonstrated that MRI data can be fine-tuned to capture subtle differences in brain morphology associated with AD by using pretrained models [55].

Similarly, to learn discriminative patterns, other models like logistic regression (LR), decision tree, Gaussian Naive Bayes, and k-nearest neighbor (KNN) largely contribute to the MRI-based AD classification. The combination of these multimodal classifiers was adopted among 6 works to leverage AD early diagnosis [63,64,66,68-70]. Alternatively, CNN-based DL models have the capability of autonomous learning and represent complex patterns in magnetic resonance images. In this review were identified 2 studies that used dense convolutional network (DenseNet) [55,62] and Inception [55,73]. In total, 4 studies applied residual network [55,61,73,75], 5 studies used VGG [55,58,60,73,75], and 1 study the EfficientNet [55]. The multimodeling approaches (comparison of 16 and 20 classifiers) of CNN models were incorporated in 2 works [56,57]. Long short-term memory, another DL framework largely used in the context of MRI classification, can be used to analyze sequential data, such as time-series MRI scans, to detect temporal changes in brain structures characteristic of AD progression [58]. One study used a different approach, the multimodal neural networks for analyzing data from multiple sources or modalities [74]. Ensemble learning techniques like extreme gradient boosting (XGB), gradient boosting, and Ada boosting combine weak learners to create a more powerful classification. MRI data in 4 studies were successfully handled by the XGB classifier, which captured nonlinear relationships between features and predicted AD status accurately [61,68-70].

Validation Techniques

K-fold cross-validation is a common method used by most studies, where the dataset is divided into K subsets, and the model is trained and tested for K times. Testing was conducted on each subset, while the remaining ones served as training. This method can be used to assess model performance and generalization across different subsets of data. The K-fold has been used in most studies with varying values of K including 3 [74], 5 [61,72,75], 10 [52,53,55-60,62-64,69,71,72], 15 [54], and 100 [67], indicating that the total partitioning of data varies depending on the level of validation. It is important to take into account the differences between different methods of validation. A recent study used a holdout technique and external validation, dividing the dataset into training and testing sets and performing an additional test on completely new, from-scratch datasets [65]. A unique approach to data analysis that uses multifractal geometries has been introduced by Elgammal et al [66] and is likely to involve characterizing complex patterns in data using fractal-based techniques. The findings above show that many validation methods need to be considered. Therefore, adaptable methodologies are necessary when it comes to datasets and objectives. On the other hand, there are a few mentions of specific evaluation metrics [68]. The use of K-fold cross-validation remains common, but the inclusion of alternative methods such as holdout and multifractal geometry suggests a willingness to explore new approaches to evaluating model performance and ensuring the robustness of ML and data analysis tasks.

Prevalence-Based Participant Pooling

There was no evidence of publication bias with Eggers (P=.49) or Begg (P=.38) tests. Figures 2-5 present the forest plot with the prevalences of participants with AD for 2, 3, 4, and 6 AD stage subgroups, respectively. Six studies with 1562 participants were identified among disease diagnoses with 2 stages including CN and AD [53,61,63,69,72,75]. The overall pooled prevalence of the REM reported 49.28% (95% CI 46.12%-52.45%; I^2=15%; P=.32). Studies do not differ significantly in their estimates of prevalence, and the test of heterogeneity does not reveal substantial differences between them. Seven studies were identified with a total sample of 17,588 patients with AD with 3-stage AD classification including CN, MCI, and AD [56,57,62,65,67,71,73]. The overall prevalence of AD diagnosis is estimated at 29.75% (95% CI 25.11%-34.84%; I^2=97%; P<.001). Each study provides an estimate of the AD prevalence among their respective populations with 95% CI. For example, Hazarika et al [56] found AD prevalence at 33.33% (95% CI 27%-40.15%). This indicates that if we were to combine the results of all the studies, this would be the estimated AD prevalence. I^2=97% indicates that a large proportion of the total variation in prevalence estimates is due to true differences between study populations rather than random error. The significant P value (<.01) for the test of heterogeneity indicates that there is substantial variability in AD diagnostic prevalence estimates among the studies.

Figure 2. A forest plot AD diagnosis prevalence (%) among 2-stage classification using random effects model [53,61,63,69,72,75]. AD: Alzheimer disease.

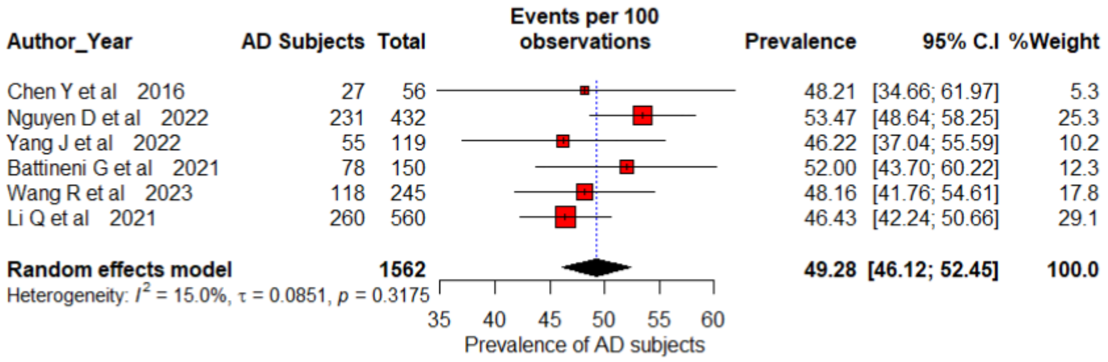

Figure 3. A forest plot AD diagnosis prevalence (%) among 3-stage classification using random effects model [56,57,62,65,67,71,74]. AD: Alzheimer disease.

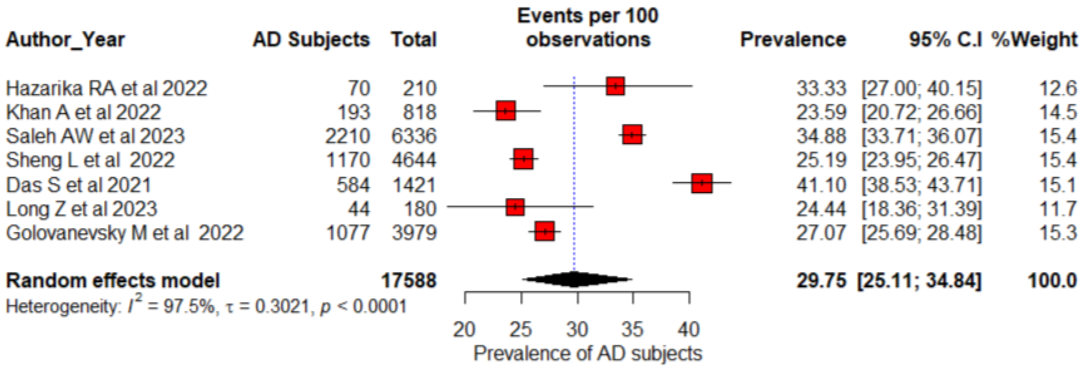

Figure 4. A forest plot AD diagnosis prevalence (%) among 4-stage classification using random effects model [55,59,64,66,70]. AD: Alzheimer disease.

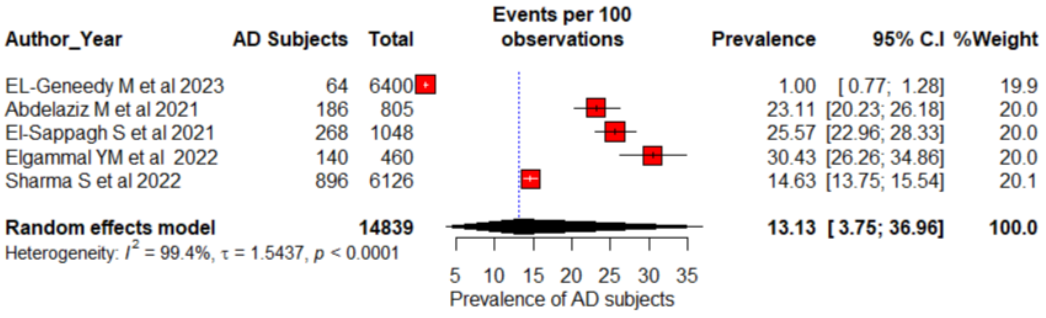

Figure 5. A forest plot AD diagnosis prevalence (%) among 6-stage classification using random effects model [52,54,68,73]. AD: Alzheimer disease.

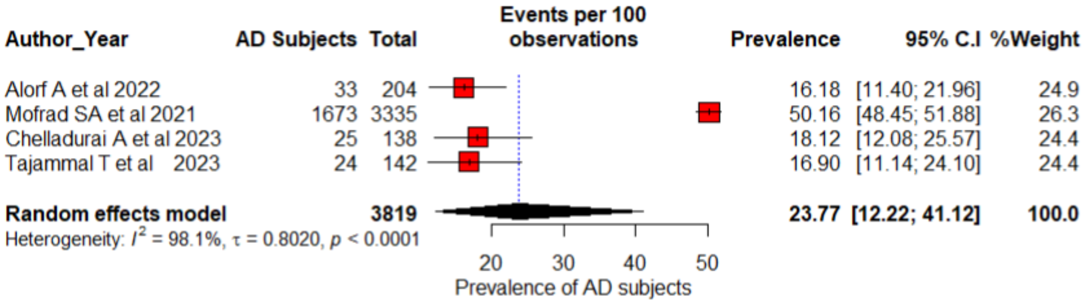

Five studies with 14,839 participants were included for the meta-analysis of 4-stage AD classifications as ND, MoD, MD, and overt AD [55,59,64,66,70]. This systematic review included 7 studies, but we excluded 2 studies [58,60] because they used the same dataset with 6400 ADNI participants. Overall prevalence estimation with REMs is 13.13% (95% CI 3.75%-36.96%; I^2=99%; P<.001). There is significant heterogeneity in the studies based on the high I^2 and significant P value and a considerable variation in the prevalence of AD across these studies, according to these estimates. Different research studies have found prevalence estimates ranging from 1% [55] to 30.43% [66]. The CIs indicate the degree of uncertainty in these estimates. As a result of the high degree of heterogeneity observed in the study, the true prevalence of AD may vary significantly between populations and settings. Four studies with 3819 were considered for the calculation of the overall prevalence of AD diagnosis of 6 stages such as CN, SMC, EMCI, MCI, LMCI, and AD [52,54,68,73]. The estimated prevalence for each study is ranging from 16.18% [52] to 50.16% [54]. The overall estimate of prevalence from the REM stands at 23.77% (95% CI 12.22%-41.12%; I^2=0.8020; P<.001). One study has a substantially greater estimated proportion of AD prevalence diagnosis than the other studies [54]. Compared to others, it reported the highest prevalence of 50.16% (95% CI 48.45%-51.88%) but does not differ weights (26.3%) significantly from other studies.

Meta-analysis through forest plots provides a comprehensive way of understanding meta-analysis results. It can be argued, however, that forest plots can only display CIs by assuming a fixed significant threshold (P<.05). It causes a replication crisis when hypothesis tests are conducted using P values. Based on P value functions, drapery plots were proposed to resolve this problem [82]. Using a drapery plot, an average effect and a confidence curve can be identified. The x-axis shows the effect size metric, and the y-axis shows the assumed P value. Multimedia Appendix 2 presents the drapery plots. There is a red curve showing the overall REM, which shows the P values for various effect sizes. Compared to the CI of pooled effects, the shaded area represents the prediction range. The prediction range is noticeably wider than the CI for the pooled effect. It indicates that the overall pooled effect does not fully capture the variability or uncertainty across different effect sizes.

Discussion

Principal Findings

In this work, we conducted a systematic review and meta-analysis based on the prevalence of patients with AD among different disease progression stages. For the systematic review, 24 studies were selected, among 22 selected for the meta-analysis. Due to their association with the same dataset of ADNI and similar sample size of patients with AD, these 2 studies avoid bias in the analysis [58,60]. The studies included in this review have explored the ML applications for AD diagnosis and intended to provide an understanding of AD progression, potentially with a focus on biomarker identification.

Different preprocessing techniques used to extract relevant features including cortical thickness [83], hippocampal volume [84], and brain activity patterns [85] from magnetic resonance images associated with AD were examined. According to the research objectives and AD stages being investigated, each study applied specific image preprocessing techniques. The progression of AD has been evaluated across multiple stages in our work. An accuracy range of 69%-75% is achieved with linear mixed-effects models that account for region of interest features with interparticipant variability of hierarchical structures [54]. Using image normalization, 1 study classified AD stages with different labeling with 84.03% accuracy by ensuring consistency in intensity and spatial properties [52,86]. Combining DL models with imaging techniques like MRI and PET has shown that structural and functional changes in the brain associated with AD can be detected [87,88]. Water molecules' diffusion properties in brain tissue can be measured using diffusivity and kurtosis mapping. The results provided insight into microstructural changes for a maximum accuracy of 96.23% [53]. By conducting magnetic resonance image normalization, the authors proposed an MRI-based DL technique for 99.68% accurate AD detection [55]. Magnetic resonance images were investigated for pixel intensity distributions to detect AD abnormalities [56].

These techniques encompass diverse methodologies ranging from normalization and smoothing to advanced mapping and feature extraction methods [89-91]. Several approaches have demonstrated high accuracy in identifying AD features, including image normalization, histogram-based approaches, and diffusion mapping [92-95]. Techniques like recursive feature elimination and outlier detection showcase promising results, emphasizing the importance of feature selection and data quality assessment in enhancing classification performance [57,63]. A similar study analyzed and segmented different tissue types within MRI scans using unified segmentation. A magnetic resonance image of the brain was segmented simultaneously into different tissue types with 85.12% accuracy [65,96]. KNN-trained data can be used to classify AD with 99.4% accuracy using the generalization method [66]. Moreover, the use of advanced DL architectures such as VGG16 [60] and ConvNet [62] for feature extraction underscores the significance of leveraging sophisticated computational tools in AD research. Augmentation methods, interpolation, and transfer learning also emerge as valuable strategies for improving classification accuracy and robustness [73-75].

By integrating statistical and ML algorithms with preprocessing techniques, AD diagnosis research further enhances its interdisciplinary nature. The CNN-long short-term memory model had an accuracy of 99.92%, followed by the multimodal AD diagnosis framework model with a precision of 96.88%. The accuracy of a customized CNN model was 99.68%, SVM with DKI was 96.23%, XGB was 96.20%, and multilayer perceptron was 99.44%. In addition, DenseNet121, CNN, DenseNet201, random forest, and gradient boosting achieved accuracy levels between 90% and 97%. While some models demonstrated higher accuracy, such as 3D CNN and SVM, others demonstrated lower accuracy, 85.12% and 80.36%, respectively.

Many ML modeling techniques have been explored, including SVM, LR, and DenseNet. Ensemble methods like gradient boosting and Ada boosting have highlighted the importance of aggregating multiple models to improve predictive accuracy and robustness, especially when dealing with complex neurological disorders like AD [69,97]. The identification of specific best-performing models further underscores the importance of optimization of methods and model selection to improve diagnostic accuracy. The use of SVM along with DKI or DenseNet201 in different studies illustrates the researchers' tailored approach to leveraging each algorithm's and feature representation's strengths [98-100]. AD diagnosis is a nuanced process, where the choice of ML model can have a significant impact on model reliability and efficacy.

Data from magnetic resonance images have been analyzed using various ML models and validation techniques. To ensure robustness and generalization, the common technique used is K-fold cross-validation. Additionally, some authors have applied specific DL models along with traditional ML techniques, reflecting the diversity of approaches for modeling and validation [72,73]. Different mechanisms and approaches are used in each of these models to detect AD using magnetic resonance images. We have observed that SVM classifiers are largely used for 2-stage classification such as CN and AD [53,54,67,71]. Similarly, LR classifiers were used in other studies to assess MRI-based AD status interpretation and predictive factors for disease risk assessment. Based on learned discriminative patterns from magnetic resonance images, these models, as well as others mentioned, produce accurate AD detection predictions. Additionally, KNN can be used to identify magnetic resonance images with feature vectors similar to those associated with AD helping to detect patterns.

The meta-analysis shows that there is a great deal of variation between studies when it comes to estimating AD prevalence. The reason for this is probably because the study involved a wide range of diagnostic criteria and populations, not just prevalence rates. The prevalence estimates are diverse due to some studies focusing on specific AD stages while others cover a wider spectrum. The significant P values and I^2 statistics show that the diagnosis of AD is highly heterogeneous and requires a nuanced understanding of its epidemiology. The challenges associated with synthesizing prevalence data from disparate sources are revealed by this analysis. The prevalence of AD is subject to complex and variable research, which leads to wider CIs in some studies. Even after trying to use REMs to account for this heterogeneity, significant variation persists, suggesting that variables like demographics, study design, and diagnostic methodology may play a significant role. The provision of more reliable estimates requires the adoption of standardized protocols and collaboration in future research efforts, which stresses the importance of rigorous methodology and careful interpretation of results.

Comparison With Existing Reviews

There have been a few systematic reviews and meta-analyses about the importance of ML models in AD diagnosis. Table 3 summarizes the comparison between our work and the reviews that have already been published. In our analysis, we concentrated on using ML for AD diagnosis, while other studies were focused on using it for dementia forecasting [101]. In a similar study [102], the authors explored the effectiveness of both ML and DL models in AD diagnosis. In this study, the authors did not examine multistage AD cases but only the binary classification of AD. A single study [103] conducted a meta-analysis based on Wilcoxon signed rank tests and discussed multiple imaging modalities, including MRI, PET, and CSF. Despite this, there is a lack of discussion about feature selection techniques and their potential impact on ML accuracy. A prevalence-based meta-analysis on MRI-centered AD discussions is presented in our study along with an in-depth description of subcategories of AD. Our study stands out because it covers all aspects of ML in AD diagnosis, including imaging modalities and stages of AD. We reviewed and analyzed various imaging modalities, talked about feature selection methods, and delved deeper into AD subcategories in our research.

Table 3. Comparison of this review with existing systematic reviews.

Study	Systematic review	Meta-analysis	Imaging modalities	Feature selection	Alzheimer disease stages

Future Directions and Study Limitations

Data from open-access libraries such as ADNI, Kaggle, and others were used in studies, as evidenced by the analysis of datasets. Prospective validation studies should be carried out in the future to assess the accuracy of ML models for AD diagnosis across diverse populations and clinical settings. The incorporation of multimodal data, including imaging, genetics, and clinical information, into ML models can improve their accuracy and robustness in diagnosing AD and distinguishing it from other brain disorders [89]. To enhance their clinical utility and acceptability, ML models must be interpretable and explainable. It may be possible to use these models to predict the onset and AD progression based on longitudinal studies that track individuals over time [14,101]. Future research must incorporate ML models into diagnostic workflows and assess their influence on patient outcomes and health care delivery.

Despite its comprehensiveness, this study is characterized by some shortcomings. The availability and quality of data are essential for the effectiveness of ML approaches. The outcome of the meta-analysis may have been influenced by the limitations in access to complete datasets with different levels of quality. The potential for publication bias, in which studies with positive findings are more likely to be published, may lead to an overestimation of the effectiveness of ML approaches for diagnosing AD. The included studies may have experienced heterogeneity due to variations in study designs, patient populations, imaging modalities, and ML algorithms, making it difficult to draw definitive conclusions. Despite our best efforts to conduct a thorough review, some relevant studies may have been mistakenly excluded, potentially creating gaps in the analysis. The generalizability of ML models for AD diagnosis may be limited by their development and validation on specific datasets.

Conclusions

A summary comparison of current literature on ML approaches in AD diagnosis, along with a systematic review and meta-analysis, helps to understand the prevalence of disease at different stages. Our analysis of 24 relevant papers shows a significant difference in AD prevalence estimates, as individuals progress from CN to MCI and ultimately to overt AD. We observed a pooled prevalence of 49.28% during the CN to AD transition. This was followed by 29.75% for CN, MCI, and AD, 13.13% for CN, MoD, MD, and AD, and 23.75% for CN, SMC, EMCI, MCI, LMCI, and AD. Our analysis reveals the importance of adjusting diagnostic and management strategies to minimize the impact of demographic and setting characteristics on AD prevalence estimates. Due to the heterogeneity observed across studies, it is necessary to consider various factors to accurately estimate the prevalence of AD. Our study is different from other studies by comparing it to existing systematic reviews and meta-analyses, which provide an original contribution to the topic under evaluation. Unlike previous studies that have focused on imaging modalities and AD stages, our study has comprehensively analyzed ML in AD diagnosis. Multiple imaging modalities were reviewed and analyzed, feature selection techniques were discussed, and AD subcategories were explored, focusing particularly on MRIs. Although none of the biomarkers currently available can provide a precise diagnosis of AD, using ML approaches to identify prevalence patterns across disease stages will lead to progress in AD diagnosis.

Abbreviations

AD: Alzheimer disease
ADNI: Alzheimer’s Disease Neuroimaging Initiative
CN: cognitively normal
CNN: convolutional neural network
CSF: cerebrospinal fluid
CT: computerized tomography
DenseNet: dense convolutional network
DKI: diffusion kurtosis imaging
DL: deep learning
EMCI: early mild cognitive impairment
KNN: k-nearest neighbor
LMCI: late mild cognitive impairment
LR: logistic regression
MCI: mild cognitive impairment
MD: mildly demented
ML: machine learning
MoD: moderately demented
MRI: magnetic resonance imaging
ND: nondemented
OASIS: Open Access Series of Imaging Studies
PET: positron emission tomography
PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analysis
REM: random effects model
SMC: significant memory concern
SVM: support vector machine
VGG: Visual Geometry Group
XGB: extreme gradient boosting

Edited by J Wang; submitted 10.04.24; peer-reviewed by U Snekhalatha, Z Wu; comments to author 24.05.24; revised version received 12.06.24; accepted 25.09.24; published 23.12.24.
