JMIR Aging

Journal Impact Factor (JIF) (2023): 5.0
Volume 7 (2024) ISSN 2561-7605 Editor in Chief: Yun Jiang, PhD, MS, RN, FAMIA; Jinjiao Wang, PhD, RN, MPhil

Contents

Original Papers

Assessment of Wearable Device Adherence for Monitoring Physical Activity in Older Adults: Pilot Cohort Study (e60209)
Huitong Ding, Kristi Ho, Edward Searls, Spencer Low, Zexu Li, Salman Rahman, Sanskruti Madan, Akwaugo Igwe, Zachary Popp, Alexa Burk, Huanmei Wu, Ying Ding, Phillip Hwang, Ileana Anda-Duran, Vijaya Kolachalama, Katherine Gifford, Ludy Shih, Rhoda Au, Honghuang Lin. . . 1 1

Quantifying the Enhancement of Sarcopenic Skeletal Muscle Preservation Through a Hybrid Exercise Program: Randomized Controlled Trial (e58175)
Hongzhi Guo, Jianwei Cao, Shichun He, Meiqi Wei, Deyu Meng, Ichen Yu, Ziyi Wang, Xinyi Chang, Guang Yang, Ziheng Wang. 23

Digital Peer-Supported App Intervention to Promote Physical Activity Among Community-Dwelling Older Adults: Nonrandomized Controlled Trial (e56184)
Kento Tabira, Yuko Oguma, Shota Yoshihara, Megumi Shibuya, Manabu Nakamura, Natsue Doihara, Akihiro Hirata, Tomoki Manabe. 54

Exploring the Feasibility of Digital Voice Assistants for Delivery of a Home-Based Exercise Intervention in Older Adults With Obesity and Type 2 Diabetes Mellitus: Randomized Controlled Trial (e53064)
Costas Glavas, David Scott, Surbhi Sood, Elena George, Robin Daly, Eugene Gvozdenko, Barbora de Courten, Paul Jansons. 69

Development of a 12-Week Unsupervised Online Tai Chi Program for People With Hip and Knee Osteoarthritis: Mixed Methods Study (e55322)
Shiyi Zhu, Kim Bennell, Rana Hinman, Jenny Harrison, Alexander Kimp, Rachel Nelligan. 82

Designing Telemedicine for Older Adults With Multimorbidity: Content Analysis Study (e52031)
Nida Buawangpong, Kanokporn Pinyopornpanish, Suphawita Pliannuom, Nopakoon Nantsupawat, Nutchar Wiwatkunupakarn, Chaisiri Angkurawaranon, Wichuda Jiraporncharoen. 95

Internet-Based Social Activities and Cognitive Functioning 2 Years Later Among Middle-Aged and Older Adults: Prospective Cohort Study (e63907)
Sangha Jeon, Susan Charles. 108

Examining the Effect of Contactless Intergenerational Befriending Intervention on Social Isolation Among Older Adults and Students' Attitude Toward Companionship: Content Analysis (e47908)
Keya Sen, Nida Laheji, Zo Ramamonjiarivelo, Cecil Renick, Randall Osborne, Brad Beauvais. 121

Determinants of Implementing an Information and Communication Technology Tool for Social Interaction Among Older People: Qualitative Content Analysis of Social Services Personnel Perspectives (e43999)
Johanna Fritz, Petra von Heideken Wågert, Annelie Gusdal, Rose-Marie Johansson-Pajala, Caroline Eklund. 132

Perceptions Toward Telemedicine of Health Care Staff in Nursing Homes in Northern Germany: Cross-Sectional Study (e47072)
Pia Traulsen, Lisa Kitschke, Jost Steinhäuser. 146

Factors That Influence Successful Adoption of Real-Time Location Systems for Use in a Dementia Care Setting: Mixed Methods Study (e45978)
Lynn Haslam-Larmer, Alisa Grigorovich, Leia Shum, Andria Bianchi, Kristine Newman, Andrea Iaboni, Josephine McMurray. 155

Using the TrueLoo Smart Device to Record Toileting Sessions in Older Adults: Retrospective Validation and Acceptance Study (e50856)
Jordan Glenn, Parmoon Sarmadi, Paul Cristman, Gabrielle Kim, Ting-Hsuan Lin, Vikram Kashyap. 169

Efficacy of COMPAs, an App Designed to Support Communication Between Persons Living With Dementia in Long-Term Care Settings and Their Caregivers: Mixed Methods Implementation Study (e47565)
Ana Ansaldo, Michèle Masson-Trottier, Barbara Delacourt, Jade Dubuc, Catherine Dubé. 180

Factors Influencing Drug Prescribing for Patients With Hospitalization History in Circulatory Disease–Patient Severity, Composite Adherence, and Physician-Patient Relationship: Retrospective Cohort Study (e59234)
Tomoyuki Takura, Hiroyoshi Yokoi, Asao Honda. 203

Medication Self-Management for Home Care Users Receiving Multidose Drug Dispensing: Qualitative Interview Study (e57651)
Anette Josendal, Trine Bergmo. 221

Functional Monitoring of Patients With Knee Osteoarthritis Based on Multidimensional Wearable Plantar Pressure Features: Cross-Sectional Study (e58261)
Junan Xie, Shilin Li, Zhen Song, Lin Shu, Qing Zeng, Guozhi Huang, Yihuan Lin. 230

Development and Usability of an Advance Care Planning Website (My Voice) to Empower Patients With Heart Failure and Their Caregivers: Mixed Methods Study (e60117)
Chetna Malhotra, Alethea Yee, Chandrika Ramakrishnan, Sanam Kaurani, Ivy Chua, Joshua Lakin, David Sim, Iswaree Balakrishnan, Vera Ling, Huang Weiliang, Lee Ling, Kathryn Pollak. 249

Determinants of Successful Implementation of Assistive Technologies for Dementia: Exploratory Survey (e53640)
Henriëtte Van der Roest, Hannah Christie, Manuel Franco-Martin, Rose-Marie Dröes, Marjolein de Vugt, Franka Meiland. 266

How Time, Living Situation, and Stress Related to Technology Influence User Acceptance and Usability of a Socialization Service for Older Adults and Their Formal and Informal Caregivers: Six-Month Pilot Study (e54736)
Jasmine Pani, Letizia Lorusso, Lara Toccafondi, Grazia D'Onofrio, Filomena Ciccone, Sergio Russo, Francesco Giuliani, Daniele Sancarlo, Novella Calamida, Gianna Vignani, Tarmo Pihl, Erika Rovini, Filippo Cavallo, Laura Fiorini. 279

Digital Storytelling Intervention for Enhancing the Social Participation of People With Mild Cognitive Impairment: Co-Design and Usability Study (e54138)
Di Zhu, Abdullah Al Mahmud, Wei Liu. 329

Experiences of Older Adults, Physiotherapists, and Aged Care Staff in the TOP UP Telephysiotherapy Program: Interview Study of the TOP UP Interventions (e53010)
Rik Dawson, Heidi Gilchrist, Marina Pinheiro, Karn Nelson, Nina Bowes, Cathie Sherrington, Abby Haynes. 349

Acceptance of a Digital Assistant (Anne4Care) for Older Adult Immigrants Living With Dementia: Qualitative Descriptive Study (e50219)

Marloes Bults, Catharina van Leersum, Theodorus Olthuis, Egbert Siebrand, Zohrah Malik, Lili Liu, Antonio Miguel-Cruz, Jan Jukema, Marjolein den Ouden. 365

Technology Usability for People Living With Dementia: Concept Analysis (e51987)

Shao-Yun Chien, Oleg Zaslavsky, Clara Berridge. 376

A Voice-Activated Device Exercise and Social Engagement Program for Older Adult–Care Partner Dyads: Pilot Clinical Trial and Focus Group Study Evaluating the Feasibility, Use, and Estimated Functional Impact of EngAGE (e56502)

Megan Huisingh-Scheetz, Roscoe Nicholson III, Saira Shervani, Chelsea Smith, Margaret Danilovich, Laura Finch, Yadira Montoya, Louise Hawkley. 392

Decoding the Influence of eHealth on Autonomy, Competence, and Relatedness in Older Adults: Qualitative Analysis of Self-Determination Through the Motivational Technology Model (e56923)

Lynne Cotter, Dhavan Shah, Kaitlyn Brown, Marie-Louise Mares, Gina Landucci, Sydney Saunders, Darcie Johnston, Klaren Pe-Romashko, David Gustafson, Adam Maus, Kasey Thompson, David Gustafson. 405

Exploring How Older Adults Experience semAPP, a 360° Media–Based Tool for Memory Assessment: Qualitative Study (e56796)

Francesca Bruni, Valentina Mancuso, Jonathan Panigada, Marco Stramba-Badiale, Pietro Cipresso, Elisa Pedroli. 422

The Prevalence of Missing Incidents and Their Antecedents Among Older Adult MedicAlert Subscribers: Retrospective Descriptive Study (e58205)

Antonio Miguel-Cruz, Hector Perez, Yoojin Choi, Emily Rutledge, Christine Daum, Lili Liu. 458

Toward Safe and Confident Silver Drivers: Interview Study Investigating Older Adults' Driving Practices (e57402)

Sunyoung Kim, Phaneendra Sivangula. 474

Development of a Dementia Case Management Information System App: Mixed Methods Study (e56549)

Huei-Ling Huang, Yi-Ping Chao, Chun-Yu Kuo, Ya-Li Sung, Yea-Ing Shyu, Wen-Chuin Hsu. 487

Social Robots and Sensors for Enhanced Aging at Home: Mixed Methods Study With a Focus on Mobility and Socioeconomic Factors (e63092)

Roberto Vagnetti, Nicola Camp, Matthew Story, Khaoula Ait-Belaid, Suvobrata Mitra, Sally Fowler Davis, Helen Meese, Massimiliano Zecca, Alessandro Di Nuovo, Daniele Magistro. 501

Improving How Caregivers of People Living With Dementia Are Identified in the Electronic Health Record: Qualitative Study and Exploratory Chart Review (e59584)

Ariel Green, Cynthia Boyd, Rosalphie Rosado, Andrea Daddato, Kathy Gleason, Tobie Taylor McPhail, Marcela Blinka, Nancy Schoenborn, Jennifer Wolff, Elizabeth Bayliss, Rebecca Boxer. 561

An Evidence-Based IT Program With Chatbot to Support Caregiving and Clinical Care for People With Dementia: The CareHeroes Development and Usability Pilot (e57308)

Nicole Ruggiano, Ellen Brown, Peter Clarke, Vagelis Hristidis, Lisa Roberts, Carmen Framil Suarez, Sai Allala, Shannon Hurley, Chrystine Kopcsik, Jane Daquin, Hamilton Chevez, Raymond Chang-Lau, Marc Agronin, David Geldmacher. 571

Internet-Based Supportive Interventions for Family Caregivers of People With Dementia: Randomized Controlled Trial (e50847)

Yanhong Xie, Shanshan Shen, Caixia Liu, Hong Hong, Huilan Guan, Jingmei Zhang, Wanqi Yu. 584

mHealth Apps for Dementia Caregivers: Systematic Examination of Mobile Apps (e58517)

Ning Zou, Bo Xie, Daqing He, Robin Hilsabeck, Alyssa Aguirre. 596

Refining Cultural Adaptations of a Behavioral Intervention for Latino Caregivers of People Living With Dementia: Qualitative Interview Study in Washington State (e53671)

Celeste Garcia, Miriana Duran, Magaly Ramirez. 608

Expectation, Attitude, and Barriers to Receiving Telehomecare Among Caregivers of Homebound or Bedridden Older Adults: Qualitative Study (e48132)

Pansiree Onseng, Wichuda Jiraporncharoen, Sasiwimon Moonkayaow, Pimchai Veerasirikul, Nutchar Wiwatkunupakarn, Chaisiri Angkurawaranon, Kanokporn Pinyopornpanish. 621

A Web-Based Intervention Based on Acceptance and Commitment Therapy for Family Caregivers of People With Dementia: Mixed Methods Feasibility Study (e53489)

Golnaz. Atefi, Rosalia van Knippenberg, Sara Bartels, Andrés Losada-Baltar, María Márquez-González, Frans Verhey, Marjolein de Vugt. . .
6 3 2

The Olera.care Digital Caregiving Assistance Platform for Dementia Caregivers: Preliminary Evaluation Study (e55132)

Qiping Fan, Minh-Nguyet Hoang, Logan DuBose, Marcia Ory, Jeswin Vennatt, Diana Salha, Shinduk Lee, Tokunbo Falohun. 651

Digital Adoption by an Organization Supporting Informal Caregivers During COVID-19 Pandemic Showing Impact on Service Use, Organizational Performance, and Carers' Well-Being: Retrospective Population-Based Database Study With Embedded User Survey (e46414)

Ala Szczepura, Amir Khan, Deidre Wild, Sara Nelson, Sonja Woodhouse, Mark Collinson. 685

Sentiment Dynamics Among Informal Caregivers in Web-Based Alzheimer Communities: Systematic Analysis of Emotional Support and Interaction Patterns (e60050)

Congning Ni, Qingyuan Song, Qingxia Chen, Lijun Song, Patricia Commiskey, Lauren Stratton, Bradley Malin, Zhijun Yin. 701

The Implementation Outcomes and Population Impact of a Statewide IT Deployment for Family Caregivers: Mixed Methods Study (e63355)

Orly Tonkikh, Heather Young, Janice Bell, Jessica Famula, Robin Whitney, Jennifer Mongoven, Kathleen Kelly. 714

The CareVirtue Digital Journal for Family and Friend Caregivers of People Living With Alzheimer Disease and Related Dementias: Exploratory Topic Modeling and User Engagement Study (e67992)

Andrew Pickett, Danny Valdez, Lillian White, Priya Loganathar, Anna Linden, Justin Boutilier, Clover Caldwell, Christian Elliott, Matthew Zuraw, Nicole Werner. 731

Evaluating the Prognostic and Clinical Validity of the Fall Risk Score Derived From an AI-Based mHealth App for Fall Prevention: Retrospective Real-World Data Analysis (e55681)

Sónia Alves, Steffen Temme, Seyedamirhosein Motamedi, Marie Kura, Sebastian Weber, Johannes Zeichen, Wolfgang Pommer, André Baumgart. 747

Sleep Duration and Functional Disability Among Chinese Older Adults: Cross-Sectional Study (e53548)

Minjing Luo, Yue Dong, Bingbing Fan, Xinyue Zhang, Hao Liu, Changhao Liang, Hongguo Rong, Yutong Fei. 763

Factors Influencing Malnutrition Among Older Adult Residents in the Western Region of Saudi Arabia: Sex Differential Study (e55572)

Mai Ghabashi, Firas Azzeh. 777

Interrelationships Among Individual Factors, Family Factors, and Quality of Life in Older Chinese Adults: Cross-Sectional Study Using Structural Equation Modeling (e59818)

Yuting Wu, Cong Gong, Lifang Pi, Meixin Zheng, Weifang Liu, Yamei Wang. 789

Exploring the Perspectives of Older Adults Living With HIV on Virtual Care: Qualitative Study (e65730)
Kristina Kokorelias, Dean Valentine, Erica Dove, Paige Brown, Stuart McKinlay, Christine Sheppard, Hardeep Singh, Andrew Eaton, Laura Jamieson, Marina Wasilewski, Alice Zhabokritsky, Ashley Flanagan, Reham Abdelhalim, Rahel Zewude, Rabea Parpia, Sharon Walmsley, Luxey Sirisegaram. 821

Understanding Older Adults' Experiences With a Digital Health Platform in General Practice: Qualitative Interview Study (e59168)
Hanna Knotnerus, Hà Ngo, Otto Maarsingh, Vincent van Vugt. 832

Sociodigital Determinants of eHealth Literacy and Related Impact on Health Outcomes and eHealth Use in Korean Older Adults: Community-Based Cross-Sectional Survey (e56061)
Myat Kyaw, Myo Aung, Yuka Koyanagi, Saiyud Moolphate, Thin Aung, Hok Ma, Hocheol Lee, Hae-Kweun Nam, Eun Nam, Motoyuki Yuasa. . .
8 4 3

Adoption and Use of Telemedicine and Digital Health Services Among Older Adults in Light of the COVID-19 Pandemic: Repeated Cross-Sectional Analysis (e52317)
Motti Haimi, Ruslan Sergienko. 890

Experiences of a Community-Based Digital Intervention Among Older People Living in a Low-Income Neighborhood: Qualitative Study (e52292)
Si Lu, Sungwon Yoon, Wan Yee, Nerice Heng Wen Ngiam, Kennedy Ng, Lian Low. 911

Digital Literacy Training for Low-Income Older Adults Through Undergraduate Community-Engaged Learning: Single-Group Pretest-Posttest Study (e51675)
Lisa Miller, Rachel Callegari, Theresa Abah, Helen Fann. 924

Long-Term Adoption of Televisits in Nursing Homes During the COVID-19 Crisis and Following Up Into the Postpandemic Setting: Mixed Methods Study (e55471)
Tobias Martin, Sarah Veldeman, Heidrun Großmann, Paul Fuchs-Frohnhofen, Michael Czaplik, Andreas Follmann. 939

Exploring the Sociodemographic and Health-Related Determinants of Telehealth Use Among a Cohort of Older Australians During the COVID-19 Pandemic: Repeated Cross-Sectional Study (e58594)
Shanna Fealy, Suzanne McLaren, Claire Seaman, Melissa Nott, Donovan Jones, Pauletta Irwin, Patricia Logan, Rachel Rossiter, Simon McDonald. 959

Requirement Analysis of Different Variants of a Measurement and Training Station for Older Adults at Risk of Malnutrition and Reduced Mobility: Focus Group Study (e58714)
Lisa Happe, Marie Sgraja, Vincent Quinten, Mareike Förster, Rebecca Diekmann. 978

Internet Use and Higher-Level Functional Capacity Decline Suppression in Japanese Older Adults With Low Education: JAGES 2016-2019 Longitudinal Study (e53384)
Atsuko Tajika, Atsushi Nakagomi, Yasuhiro Miyaguni, Chie Koga, Katsunori Kondo, Toshiyuki Ojima. 990

Examining Whether Patient Portal and Video Visit Use Differs by Race and Ethnicity Among Older Adults in a US Integrated Health Care Delivery System: Cross-Sectional Electronic Health Record and Survey-Based Study (e63814)
Nancy Gordon, Chelsea Yin, Joan Lo. 1004

Nurses' and Nursing Assistants' Experiences With Teleconsultation in Small Rural Long-Term Care Facilities: Semistructured Interview Pilot Study (e65111)
Veronique Nabelsi, Marie Leclerc, Véronique Plouffe. 1020

Tailored Self-Management App to Support Older Adults With Cancer and Multimorbidity: Development and Usability Testing (e53163)
Sang-Wha Sien, Francis Kobekyaa, Martine Puts, Leanne Currie, Margaret Tompson, Penelope Hedges, Joanna McGrenere, Caroline Mariano, Kristen Haase. 1035

Remote Evidence-Based Programs for Health Promotion to Support Older Adults During the COVID-19 Pandemic and Beyond: Mixed Methods Outcome Evaluation (e52069)
Lesley Steinman, Kelly Chadwick, Erica Chavez Santos, Sruthi Sravanam, Selisha Johnson, Elspeth Rensema, Caitlin Mayotte, Paige Denison, Kate Lorig. 1051

Self-Explainable Graph Neural Network for Alzheimer Disease and Related Dementias Risk Prediction: Algorithm Development and Validation Study (e54748)
Xinyue Hu, Zenan Sun, Yi Nian, Yichen Wang, Yifang Dang, Fang Li, Jingna Feng, Evan Yu, Cui Tao. 1072

Exploring Older Adults' Perceptions of Using Digital Health Platforms for Self-Managing Musculoskeletal Health Conditions: Focus Group Study (e55693)
Sophie Clohessy, Christian Kempton, Kate Ryan, Peter Grinbergs, Mark Elliott. 1084

Perspectives and Experiences on eHealth Solutions for Coping With Chronic Pain: Qualitative Study Among Older People Living With Chronic Pain (e57196)
Annalisa De Lucia, Valeria Donisi, Ilenia Pasini, Enrico Polati, Lidia Del Piccolo, Vittorio Schweiger, Cinzia Perlini. 1098

Exploring the Linkages Among Chronic Illness, Substance Use, and COVID-19 Infection in Adults Aged 50 Years and Older: Retrospective Cross-Sectional Analysis of National Representative Data (e63024)
Suebsarn Ruksakulpiwat, Atsadaporn Niyomyart, Chontira Riangkam, Lalipat Phianhasin, Chitchanok Benjasirisan, Jon Adams. 1113

An eHealth Intervention to Improve Quality of Life, Socioemotional, and Health-Related Measures Among Older Adults With Multiple Chronic Conditions: Randomized Controlled Trial (e59588)
David Gustafson Sr, Marie-Louise Mares, Darcie Johnston, Olivia Vjorn, John Curtin, Gina Landucci, Klaren Pe-Romashko, David Gustafson Jr, Dhavan Shah. 1128

Age Variation Among US Adults’ Social Media Experiences and Beliefs About Who Is Responsible for Reducing Health-Related Falsehoods: Secondary Analysis of a National Survey (e56761)
Prathyusha Galinkala, Elise Atkinson, Celeste Campos-Castillo. 1149

The #SeePainMoreClearly Phase II Pain in Dementia Social Media Campaign: Implementation and Evaluation Study (e53025)
Louise Castillo, Vivian Tran, Mary Brachaniec, Christine Chambers, Kelly Chessie, Alec Couros, Andre LeRuyet, Charmayne LeRuyet, Lilian Thorpe, Jaime Williams, Sara Wheelwright, Thomas Hadjistavropoulos. 1182

Social Media Discourse Related to Caregiving for Older Adults Living With Alzheimer Disease and Related Dementias: Computational and Qualitative Study (e59294)
Andrew Pickett, Danny Valdez, Kelsey Sinclair, Wesley Kochell, Boone Fowler, Nicole Werner. 1201

Internet Use as a Moderator of the Relationship Between Personal Resources and Stress in Older Adults: Cross-Sectional Study (e52555)
Angélique Roquet, Paolo Martinelli, Charikleia Lampraki, Daniela Jopp. 1216

Barriers to and Facilitators of Older People’s Engagement With Web-Based Services: Qualitative Study of Adults Aged >75 Years (e46522)
Annemarie Money, Alex Hall, Danielle Harris, Charlotte Eost-Telling, Jane McDermott, Chris Todd. 1250

Online Cognitive Stimulation Therapy for Dementia in Brazil and India: Acceptability, Feasibility, and Lessons for Implementation (e55557)
Emily Fisher, Shreenila Venkatesan, Pedro Benevides, Elodie Bertrand, Paula Brum, Céline El Baou, Cleusa Ferri, Jane Fossey, Maria Jelen, Jerson Laks, Lisa Liu, Daniel Mograbi, Nirupama Natarajan, Renata Naylor, Despina Pantouli, Vaishnavi Ramanujam, Thara Rangaswamy, Raquel Santos de Carvalho, Charlotte Stoner, Sridhar Vaitheswaran, Aimee Spector. 1262

The Needs and Experiences of People With Early-Stage Dementia Using an Application for Cognitive and Physical Activation in Germany: Qualitative Study (e62689)

Melina Klein, Alexa von Bosse, Christophe Kunze. 1278

Baseline Smartphone App Survey Return in the Electronic Framingham Heart Study Offspring and Omni 1 Study: eCohort Study (e64636)

Jian Rong, Chathurangi Pathiravasan, Yuankai Zhang, Jamie Faro, Xuzhi Wang, Eric Schramm, Belinda Borrelli, Emelia Benjamin, Chunyu Liu, Joanne Murabito. 1285

Feasibility of Measuring Smartphone Accelerometry Data During a Weekly Instrumented Timed Up-and-Go Test After Emergency Department Discharge: Prospective Observational Cohort Study (e57601)

Brian Suffoletto, David Kim, Caitlin Toth, Waverly Mayer, Sean Glaister, Chris Cinkowski, Nick Ashenburg, Michelle Lin, Michael Losak. 1299

Performance Differences of a Touch-Based Serial Reaction Time Task in Healthy Older Participants and Older Participants With Cognitive Impairment on a Tablet: Experimental Study (e48265)

Christian Mychajliw, Heiko Holz, Nathalie Minuth, Kristina Dawidowsky, Gerhard Eschweiler, Florian Metzger, Franz Wortha. 1319

Smartwatch-Based Interventions for People With Dementia: User-Centered Design Approach (e50107)

Doreen Goerss, Stefanie Köhler, Eleonora Rong, Anna Temp, Ingo Kilimann, Gerald Bieber, Stefan Teipel. 1340

Examining Associations Between Smartphone Use and Clinical Severity in Frontotemporal Dementia: Proof-of-Concept Study (e52831)

Emily Paolillo, Kaitlin Casaletto, Annie Clark, Jack Taylor, Hilary Heuer, Amy Wise, Sreya Dhanam, Mark Sanderson-Cimino, Rowan Saloner, Joel Kramer, John Kornak, Walter Kremers, Leah Forsberg, Brian Appleby, Ece Bayram, Andrea Bozoki, Danielle Brushaber, R Darby, Gregory Day, Bradford Dickerson, Kimiko Domoto-Reilly, Fanny Elahi, Julie Fields, Nupur Ghoshal, Neill Graff-Radford, Matthew G H Hall, Lawrence Honig, Edward Huey, Maria Lapid, Irene Litvan, Ian Mackenzie, Joseph Masdeu, Mario Mendez, Carly Mester, Toji Miyagawa, Georges Naasan, Belen Pascual, Peter Pressman, Eliana Ramos, Katherine Rankin, Jessica Rexach, Julio Rojas, Lawren VandeVrede, Bonnie Wong, Zbigniew Wszolek, Bradley Boeve, Howard Rosen, Adam Boxer, Adam Staffaroni, ALLFTD Consortium. 1359

Optimizing Technology-Based Prompts for Supporting People Living With Dementia in Completing Activities of Daily Living at Home: Experimental Approach to Prompt Modality, Task Breakdown, and Attentional Support (e56055)

Madeleine Cannings, Ruth Brookman, Simon Parker, Leonard Hoon, Asuka Ono, Hiroaki Kawata, Hisashi Matsukawa, Celia Harris. 1376

Digital Storytelling for People With Cognitive Impairment Using Available Mobile Apps: Systematic Search in App Stores and Content Analysis (e64525)

Di Zhu, Abdullah Al Mahmud, Wei Liu, Dahua Wang. 1399

Comparison of the Burdens and Attitudes Between Standard and Web-Based Remote Programming for Deep Brain Stimulation in Parkinson Disease: Survey Study (e57503)

Xiaonan Wan, Zhengyu Lin, Chengcheng Duan, Zhitong Zeng, Chencheng Zhang, Dianyou Li. 1415

Predicting Adherence to Computer-Based Cognitive Training Programs Among Older Adults: Study of Domain Adaptation and Deep Learning (e53793)

Ankita Singh, Shayok Chakraborty, Zhe He, Yuanying Pang, Shenghao Zhang, Ronast Subedi, Mia Lustria, Neil Charness, Walter Boot. . . .
1 4 2 5

Developing a Life Story Intervention for Older Adults With Dementia or at Risk of Delirium Who Were Hospitalized: Multistage, Stakeholder-Engaged Co-Design Study (e59306)

Sarah Flessa, James Harrison, Roniela Turnigan, Megan Rathfon, Michael Chandler, Jay Newton-Small, Stephanie Rogers. 1477

Brief Video-Delivered Intervention to Reduce Anxiety and Improve Functioning in Older Veterans: Pilot Randomized Controlled Trial (e56959)

Christine Gould, Chalise Carlson, Julie Wetherell, Mary Goldstein, Lauren Anker, Sherry Beaudreau. 1500

Evaluating a Smart Textile Loneliness Monitoring System for Older People: Co-Design and Qualitative Focus Group Study (e57622)

Freya Probst, Jessica Rees, Zayna Aslam, Nikitia Mexia, Erika Molteni, Faith Matcham, Michela Antonelli, Anthea Tinker, Yu Shi, Sebastien Ourselin, Wei Liu. 1517

Development and Validation of an Explainable Machine Learning Model for Predicting Myocardial Injury After Noncardiac Surgery in Two Centers in China: Retrospective Study (e54872)

Chang Liu, Kai Zhang, Xiaodong Yang, Bingbing Meng, Jingsheng Lou, Yanhong Liu, Jiangbei Cao, Kexuan Liu, Weidong Mi, Hao Li. 1669

Expectations and Requirements of Surgical Staff for an AI-Supported Clinical Decision Support System for Older Patients: Qualitative Study (e57899)

Adriane Uihlein, Lisa Beissel, Anna Ajlani, Marcin Orzechowski, Christoph Leinert, Thomas Kocar, Carlos Pankratz, Konrad Schuetze, Florian Gebhard, Florian Steger, Marina Fotteler, Michael Denkinger. 1681

Social Media Programs for Outreach and Recruitment Supporting Aging and Alzheimer Disease and Related Dementias Research: Longitudinal Descriptive Study (e51520)

Anthony Teano, Ashley Scott, Cassandra Gipson, Marilyn Albert, Corinne Pettigrew. 1698

Automatic Spontaneous Speech Analysis for the Detection of Cognitive Functional Decline in Older Adults: Multilanguage Cross-Sectional Study (e50537)

Emilia Ambrosini, Chiara Giangregorio, Eugenio Lomurno, Sara Moccia, Marios Milis, Christos Loizou, Domenico Azzolino, Matteo Cesari, Manuel Cid Gala, Carmen Galán de Isla, Jonathan Gomez-Raja, Nunzio Borghese, Matteo Matteucci, Simona Ferrante. 1718

Using Existing Clinical Data to Measure Older Adult Inpatients' Frailty at Admission and Discharge: Hospital Patient Register Study (e54839)

Boris Wernli, Henk Verloo, Armin von Gunten, Filipa Pereira. 1735

Enhancing Frailty Assessments for Transcatheter Aortic Valve Replacement Patients Using Structured and Unstructured Data: Real-World Evidence Study (e58980)

Mamoun Mardini, Chen Bai, Anthony Bavry, Ahmed Zaghloul, R Anderson, Catherine Price, Mohammad Al-Ani. 1748

Determinants of Visual Impairment Among Chinese Middle-Aged and Older Adults: Risk Prediction Model Using Machine Learning Algorithms (e59810)

Lijun Mao, Zhen Yu, Luotao Lin, Manoj Sharma, Hualing Song, Hailei Zhao, Xianglong Xu. 1760

Developing Independent Living Support for Older Adults Using Internet of Things and AI-Based Systems: Co-Design Study (e54210)

Claire Timon, Emma Heffernan, Sophia Kilcullen, Louise Hopper, Hyowon Lee, Pamela Gallagher, Alan Smeaton, Kieran Moran, Pamela Hussey, Catriona Murphy. 1772

Promoting Personalized Reminiscence Among Cognitively Intact Older Adults Through an AI-Driven Interactive Multimodal Photo Album: Development and Usability Study (e49415)

Xin Wang, Juan Li, Tianyi Liang, Wordh Hasan, Kimia Zaman, Yang Du, Bo Xie, Cui Tao. 1800

Detection of Mild Cognitive Impairment From Non-Semantic, Acoustic Voice Features: The Framingham Heart Study (e55126)

Huitong Ding, Adrian Lister, Cody Karjadi, Rhoda Au, Honghuang Lin, Brian Bischoff, Phillip Hwang. 1814

Investigating Acoustic and Psycholinguistic Predictors of Cognitive Impairment in Older Adults: Modeling Study (e54655)

Varsha Badal, Jenna Reinen, Elizabeth Twamley, Ellen Lee, Robert Fellows, Erhan Bilal, Colin Depp. 1825

Extracting Critical Information from Unstructured Clinicians' Notes Data to Identify Dementia Severity Using a Rule-Based Approach: Feasibility Study (e57926)
Ravi Prakash, Matthew Dupre, Truls Østbye, Hanzhang Xu. 1842

Reviews

Characteristics and Range of Reviews About Technologies for Aging in Place: Scoping Review of Reviews (e50286)
Jenny Bergschöld, Mari Gunnes, Arne Eide, Eva Lassemo. 437

In-Home Positioning for Remote Home Health Monitoring in Older Adults: Systematic Review (e57320)
Andrew Chan, Joanne Cai, Linna Qian, Brendan Coutts, Steven Phan, Geoff Gregson, Michael Lipsett, Adriana Ríos Rincón. 520

Factors Affecting Clinician Readiness to Adopt Smart Home Technology for Remote Health Monitoring: Systematic Review (e64367)
Gordana Dermody, Daniel Wadsworth, Melissa Dunham, Courtney Glass, Roschelle Fritz. 536

The Use of Digital Technologies in the Promotion of Health Literacy and Empowerment of Informal Caregivers: Scoping Review (e54913)
Suzete Soares, Louíse Hoffmeister, Maria Fernandes, Adriana Henriques, Andreia Costa. 670

Markerless Motion Capture to Quantify Functional Performance in Neurodegeneration: Systematic Review (e52582)
Julian Jeyasingh-Jacob, Mark Crook-Rumsey, Harshvi Shah, Theresita Joseph, Subati Abulikemu, Sarah Daniels, David Sharp, Shlomi Haar.
1 4 6 0

The Implementation Success of Technology-Based Counseling in Dementia Care: Scoping Review (e51544)
Dorothee Bauernschmidt, Janina Wittmann, Julian Hirt, Gabriele Meyer, Anja Bieber. 1533

Patient and Public Involvement in Technology-Related Dementia Research: Scoping Review (e48292)
Pippa Kirby, Helen Lai, Sophie Horrocks, Matthew Harrison, Danielle Wilson, Sarah Daniels, Rafael Calvo, David Sharp, Caroline Alexander.
1 5 4 9

Strategies to Mitigate Age-Related Bias in Machine Learning: Scoping Review (e53564)
Charlene Chu, Simon Donato-Woodger, Shehroz Khan, Tianyu Shi, Kathleen Leslie, Samira Abbasgholizadeh-Rahimi, Rune Nyrup, Amanda Grenier. 1572

Adoption of Artificial Intelligence–Enabled Robots in Long-Term Care Homes by Health Care Providers: Scoping Review (e55257)
Karen Wong, Lillian Hung, Joey Wong, Juyoung Park, Hadil Alfares, Yong Zhao, Abdolhossein Mousavinejad, Albin Soni, Hui Zhao. 1586

Nursing Staff's Perspectives of Care Robots for Assisted Living Facilities: Systematic Literature Review (e58629)
Katie Trainum, Jiaying Liu, Elliott Hauser, Bo Xie. 1606

Exploring the Landscape of Standards and Guidelines in AgeTech Design and Development: Scoping Review and Thematic Analysis (e58196)
Shahabeddin Abhari, Josephine McMurray, Tanveer Randhawa, Gaya Bin Noon, Thokozani Hanjahanja-Phiri, Heather McNeil, Fiona Manning, Patricia Debergue, Jennifer Teague, Plinio Pelegrini Morita. 1618

Machine Learning Driven by Magnetic Resonance Imaging for the Classification of Alzheimer Disease Progression: Systematic Review and Meta-Analysis (e59370)
Gopi Battineni, Nalini Chintalapudi, Francesco Amenta. 1854

Viewpoint

The Best of Two Worlds to Promote Healthy Cognitive Aging: Definition and Classification Approach of Hybrid Physical Training Interventions (e56433)
Fabian Herold, Paula Theobald, Thomas Gronwald, Navin Kaushal, Liye Zou, Eling de Bruin, Louis Bherer, Notger Müller. 1649

Corrigenda and Addenda

Correction: Detecting Anomalies in Daily Activity Routines of Older Persons in Single Resident Smart Homes: Proof-of-Concept Study (e58394)

Abstract

Background: Physical activity has emerged as a modifiable behavioral factor to improve cognitive function. However, research on adherence to remote monitoring of physical activity in older adults is limited.

Objective: This study aimed to assess adherence to remote monitoring of physical activity in older adults within a pilot cohort from objective user data, providing insights for the scalability of such monitoring approaches in larger, more comprehensive future studies.

Methods: This study included 22 participants from the Boston University Alzheimer's Disease Research Center Clinical Core. These participants opted into wearing the Verisense watch as part of their everyday routine during 14-day intervals every 3 months. Eighteen continuous physical activity measures were assessed. Adherence was quantified daily and cumulatively across the follow-up period. The coefficient of variation was used as a key metric to assess data consistency across participants over multiple days. Day-to-day variability was estimated by calculating intraclass correlation coefficients using a 2-way random-effects model for the baseline, second, and third days.

Results: Adherence to the study on a daily basis outperformed cumulative adherence levels. The median proportion of adherence days (wearing time surpassed 90% of the day) stood at 92.1%, with an IQR spanning from 86.9% to 98.4%. However, at the cumulative level, 32% (7/22) of participants in this study exhibited lower adherence, with the device worn on fewer than 4 days within the requested initial 14-day period. Five physical activity measures have high variability for some participants. Consistent activity data for 4 physical activity measures might be attainable with just a 3-day period of device use.

Conclusions: This study revealed that while older adults generally showed high daily adherence to the wearable device, consistent usage across consecutive days proved difficult. These findings underline the effectiveness of wearables in monitoring physical activity in older populations and emphasize the ongoing necessity to simplify usage protocols and enhance user engagement to guarantee the collection of precise and comprehensive data.

physical activity; remote monitoring; wearable device; adherence; older adults

Introduction

The global demographic shift toward an aging population has become a pressing concern, with an increasing number of individuals being affected by cognitive disorders [1]. However, the limited number of effective treatments for cognitive diseases such as Alzheimer disease and other forms of dementia underscores the importance of early detection and monitoring of cognitive decline [2]. Early detection not only facilitates timely intervention but also allows for the management and possibly slowing of the progression of cognitive decline. Therefore, identifying modifiable risk factors plays a critical role in cognitive intervention strategies [3]. Among these, physical activity has emerged as a significant factor closely linked to health across many domains, including cardiovascular health [4] and cognitive functioning [5]. It has been recognized as one of the 12 modifiable risk factors for dementia [6]. A growing body of research indicates that regular physical activity can mitigate the risk of cognitive decline and improve brain function among older adults [7,8]. Moreover, meta-analyses have shown an association between increased physical activity and a reduced risk of dementia [9-11]. Such findings highlight the potential of evaluating and monitoring physical activity levels in older adults to improve detection and intervention of cognitive decline. By accurately capturing participants' physical activity, actionable insights can be provided to inform lifestyle recommendations. This approach supports cognitive well-being and may help delay the onset of cognitive diseases.

Traditional in-clinic assessments of physical activity, however, are limited by their episodic nature, failing to consistently track an individual's activity patterns over time. Additionally, these assessments are susceptible to modifications in gait when individuals are aware they are being observed, a phenomenon known as the Hawthorne effect [12,13]. In contrast, remote monitoring technologies offer a promising solution by enabling continuous and unobtrusive tracking of physical activity outside of clinical settings. This approach provides a more comprehensive picture of an individual's physical activity patterns. This information is crucial for developing personalized interventions that are tailored specifically to the activity habits and needs of each participant. By identifying periods of inactivity or suboptimal activity levels, interventions can be more precisely targeted, thereby facilitating the effective implementation of strategies that are likely to be more engaging and beneficial for the individual. Therefore, our team has developed a pilot study using a participant-driven digital brain health platform [14], which incorporates wearable devices to collect physical activity data from participants. This initiative aims to facilitate comprehensive digital phenotyping of cognitive functions in the future.

However, monitoring physical activity continuously among older adults presents unique challenges, particularly concerning adherence issues [15]. Older adults may face physical, cognitive, or technological barriers that affect their consistent use of activity tracking devices [16]. These complexities require tailored approaches to ensure effective and sustained engagement in physical activity monitoring within this demographic. While some studies have focused on daily [17] and long-term [18] adherence to wearable devices, more studies that assess adherence metrics both daily and cumulatively throughout an entire study protocol could offer additional understanding of how older adults engage with these technologies. Additionally, this approach would be beneficial in exploring the consistency of the data collected, offering deeper insights into how consistently participants engage with the wearables over extended periods.

Therefore, this study aims to evaluate the adherence of wearable devices in remote monitoring of physical activity among older adults within a pilot study of digital brain health platform from the Boston University Alzheimer's Disease Research Center (BU ADRC). Our objective is to evaluate older adults' adherence at both daily and cumulative levels and the consistency of physical activity tracking and to explore preliminary strategies for optimizing study protocols, such as adjusting required wear durations. Our detailed examination of adherence patterns and device-specific data reliability aims to offer a unique addition to the collective understanding of wearable technology apps in aging populations.

Methods

Study Population

Participants from the Clinical Core of the BU ADRC were included in this study. The BU ADRC is one of around 33 ADRCs funded by the National Institute on Aging, sharing its findings with the National Alzheimer's Coordinating Center to advance collaborative Alzheimer disease research. The BU ADRC is located in the urban area of Boston, focusing on the older adult population within this community. Detailed information about the ADRC has been documented in a prior study [19]. In 2021, the BU ADRC introduced a digital brain health platform incorporating various digital tools for data collection, such as wearable devices for monitoring physical activity [14]. The cognitive status of participants was determined through comprehensive consensus conferences involving multiple disciplines [20]. Additional information about these diagnostic procedures can be found in the previous study [21].

Verisense Device

Verisense, developed by Shimmer Research Ltd, is a wrist-worn inertial measurement unit designed for tracking physical activity. This device integrates a tri-axial accelerometer and gyroscope, weighing 29.6 grams with dimensions of 35 mm × 43 mm × 12 mm, making it suitable for continuous wear on the wrist. With an IP55 resistance rating, the Verisense device is designed to be water-resistant and has protection against environmental contaminants and factors, safeguarding its functionality. Additionally, the device boasts a battery life of up to 6 months without the need for recharging, enhancing its usability for long-term monitoring. The sampling rate of the accelerometer of the Verisense device is 25 Hz. More description of Verisense can be found in a prior study [22]. Eighteen physical activity features (Table S1 in Multimedia Appendix 1), extracted using the GGIR software [23], were divided into 2 primary categories. The first category encompasses durations of various physical activities. These physical activities are classified by intensity levels from inactive to vigorous. The second category includes features related to acceleration, such as total acceleration during the most active 5 hours.

Study Procedure

Participants were presented with available technologies from a digital brain health platform that spanned different test instrument options from smartphone apps to wearable devices with the level of use commitment for each defined [14]. Depending on participant preference, the presentation of technologies took place remotely over videoconference or in person. For in-person study visits, the Verisense device was configured and given to the participant during the visit. For remote visits, or quarterly check-ins following an in-person visit, the device was configured at the study site and then shipped to participants. Using a participant-centric study design, participants opted into the technologies of their choice. They were given a 2-week assessment period to use their selected technologies and assessment periods were scheduled at quarterly intervals. Participants who opted into Verisense were instructed to wear the tracker continuously over the 14-day period within a quarter. During the 14-day use period, there was no need to recharge the device, and thus could seamlessly integrate this monitoring tool into their routine activities for a comprehensive capture of physical activity data. Participants returned devices after the 14-day period. Every 3 months, the device was mailed back to them, and participants were given a reminder about using their technologies at the start of their 14-day assessment period, at the midpoint, and at the end. The physical activity data was retrieved from the Verisense cloud-based portal. The duration of this study was from September 2021 to February 2023. More information about the study procedures can be found in a previous publication [14].

Statistical Analyses

Adherence metrics were derived from objective user data and analyzed daily, as well as cumulatively, for the first quarter of the 14-day follow-up period. First, daily adherence was evaluated by calculating the proportion of days where the daily wear rate surpassed predetermined thresholds relative to the total number of wear days. The thresholds denote the proportion of the days when participants wore the device. Given that participants maintain a high daily wear rate, we established thresholds of 90%, 95%, and 100% to differentiate levels of compliance throughout the day. Then, cumulative adherence was determined by assessing the overall proportion of days the device was worn (at least 8 hours a day [24]) during the requested 14-day period.

To assess the consistency of physical activity data across all participants over the entire study duration, we computed the within-person coefficient of variation (CV). This statistical parameter, defined as the ratio of the standard deviation to the mean of physical activity metrics, offers a uniform measure of data variability [25]. A lower CV value indicates greater consistency in the physical activity measure captured by the wearable devices.

We conducted a preliminary investigation to determine the potential for acquiring reliable physical activity data from participants within a shortened wear period. Specifically, we assessed the stability of physical activity measures through just 3 days of device use to increase the number of participants in the study samples. To measure the consistency of the data collected during these 3 consecutive wear days, including baseline, second, and third days between persons, the intraclass correlation coefficient (ICC) complemented by a 95% CI was calculated by a 2-way random-effects model [26].

Ethical Considerations

The institutional review board of the Boston University Medical Campus approved the procedures and protocols of this study (H 405 - 42). All participants provided written informed consent.

Results

Cohort Description

Our study included 22 participants from the BU ADRC (mean age 75, SD 7 years; 9/22, 41% women; an average of 16 years of education; Table 1). During the study period, 1 participant was diagnosed with non-amnestic, single-domain mild cognitive impairment. The distribution of each physical activity measure across 3 days, including 25th percentile, median, and 75th percentile values, is provided in Table S1 in Multimedia Appendix 1.

Table . Baseline demographics of the study participants (N=22).

Variable		Values
Age (years), mean (SD)		75 (7)
Gender, n (%)		
	Women	9 (41)
	Men	13 (59)
Years of education, mean (SD)		16 (2)
Race, n (%)		
	White	20 (91)
	Black or African American	2 (9)
Current marital status, n (%)		
	Married	16 (73)
	Divorced	5 (23)
	Never married	1 (4)
Level of independence, n (%)		
	Able to live independently	22 (100)
Living situation, n (%)		
	Lives alone	3 (14)
	Lives with spouse or partner	18 (82)
	Lives with relative or friend	1 (4)

Study Adherence

Adherence to the study on a daily basis outperformed cumulative adherence levels. The median proportion of days where wear time surpassed 90% of total wear days stood at 92.1%, with an IQR spanning from 86.9% to 98.4%. As the threshold for daily wear duration increased, adherence notably declined. For days achieving 100% wear time, the median proportion dropped to 86.8%, with an IQR between 83.4% and 95.6% (Table 2).

Table 3 represents participant-level daily adherence to device usage at different compliance thresholds. It is evident that 5 participants maintain high adherence rates even as the thresholds increase, the overall daily adherence rates of 82% (18/22) participants tend to decrease as the threshold for daily wear time increases. At the 90% threshold, most of the participants show a high percentage of daily adherence, with many participants nearing or achieving full daily adherence. However, as the threshold increased to 95% and 100%, the number of days meeting the daily adherence criteria decreased. Table 4 represents participant-level cumulative adherence with the total number of worn days within the required initial 14-day period for each participant. There are varying levels of compliance across participants. Where 59% (13/22) of participants demonstrated high compliance, wearing the device for 10 or more days within the first quarter of the 14-day period, 32% (7/22) of participants exhibited notably lower compliance, with the device worn on fewer than 4 days. We also presented the daily adherence of participants to device usage during the initial 14-day period in Figure S1 in Multimedia Appendix 1.

Table . Summary of study adherence statistics at the population level.

Adherence level		Median (IQR)
Daily		
	Proportion of days with a daily wear rate above 90% of total wear days	92.1 (86.9-98.4)
	Proportion of days with a daily wear rate above 95% of total wear days	89.6 (83.4-95.6)
	Proportion of days with 100% daily wear rate of total wear days	86.8 (79.3-92.4)
Cumulatively		
	Proportion of wear days during the initial 14-day follow-up period	71.4 (21.4-78.6)

Table . Participant adherence to the wearable device usage at varying daily compliance thresholds.

Data Consistency

Figure 1 displays the CV for different physical activity measures across participants. The vertical axis represents individual participants, with each row corresponding to 1 participant and their respective variability in physical activity measures. As shown by the heatmap, 4 physical activity measures—total vigorous activity during the day, light activity that occurred in bouts of 10 minutes or greater, moderate to vigorous activity that occurred in bouts of 1‑10 minutes, and moderate to vigorous activity that occurred in bouts of 10 minutes or greater—showed high variability (CV>1) for some participants, as evidenced by the darker shades in the respective columns. Conversely, other measures such as total inactivity time during the day displayed lower variability across participants, suggesting more consistency in those activity types.

Given that 32% (7/22) of participants wore the device for less than 4 days out of the initial required 14-day wear period, we conducted a preliminary investigation to determine if reliable data for specific physical activity measures could be obtained with just 3 days of wear. As shown in Table 5, four physical activity measures—total moderate activity during the day, total moderate to vigorous activity during the day, light activity that occurred in bouts of 1‑10 minutes, and daytime inactivity that occurred in bouts of 30 minutes or greater—demonstrated a moderate consistency with ICC greater than 0.5 over 3 wear days.

Figure 1. Variability of physical activity measures across participants. The vertical axis represents individual participants, with each row corresponding to 1 participant and their respective variability in physical activity measures. The coefficient of variation values are color coded, with darker shades indicating higher variability and lighter shades indicating lower variability.

	Total moderate activity during the day	*0.55* (0.17 to 0.79)	.004	*0.61* (0.27 to 0.82)	<.001
	Total unbouted moderate activity during the day	0.49 (0.08 to 0.75)	.01	0.75 (0.48 to 0.89)	<.001
Vigorous (minutes), ICC (95% CI)					
	Total vigorous activity during the day	0.37 (−0.69 to 0.68)	.047	0.17 (−0.24 to 0.53)	.21
	Total unbouted vigorous activity during the day	0.84 (0.66 to 0.93)	<.001	−0.00 (−0.43 to 0.42)	.51
Moderate to vigorous (minutes), ICC (95% CI)					
	Total moderate to vigorous activity during the day	*0.55* (0.16 to 0.78)	.004	*0.60* (0.27 to 0.81)	<.001
	Moderate to vigorous activity that occurred in bouts of 10 minutes or greater	0.64 (0.30 to 0.83)	<.001	0.26 (−0.15 to 0.60)	.11
	Moderate to vigorous activity that occurred in bouts of 1 - 10 minutes	0.51 (0.11 to 0.76)	.008	0.46 (0.08 to 0.73)	.009
Acceleration, mg[c] (95% CI)					

Physical activity measure		Baseline to day 2		Days 2 to 3	
		Values	*P* value	Values	*P* value
	Total acceleration in the least active 5 hours	0.66 (0.34 to 0.84)	<.001	0.20 (−0.23 to 0.56)	.18
	Total acceleration in the most active 5 hours	0.49 (0.08 to 0.75)	.01	0.32 (−0.06 to 0.64)	.047

[a] ICC: intraclass correlation coefficient.

[b] Italic values represent ICC greater than 0.5 over 3 wear days.

[c] mg: milligee.

Discussion

Principal Findings

This study evaluated the adherence and consistency of remote monitoring physical activity among older adults. While adhering to a continuous 14-day device wear protocol posed challenges, the daily adherence levels were high, with many participants diligently following the usage guidelines. Furthermore, this study identified ICC values above 0.5 for certain physical activity measures, indicative of moderate reliability. While these results may not meet the highest standards for data stability, they demonstrate the feasibility of obtaining moderately reliable data with just 3 days of device wear. This insight supports the potential for shorter monitoring durations in future studies, which could reduce participant burden while still capturing consistent data.

Physical activity represents a modifiable behavioral factor with an association with enhanced outcomes across various health fields [27-29]. Yet, the deployment of physical activity interventions in clinical settings is not as prevalent as it could be [30]. Moreover, while participants may be encouraged or advised to increase their physical activity, healthcare professionals frequently face challenges in providing long-term follow-up [31]. This is particularly true for monitoring adherence to activity recommendations as outlined by the US Preventive Services Task Force [32]. Wearable technology presents an accessible approach to narrowing the divide between research and practical application in using physical activity as a preventive health strategy [33]. Especially, wrist-worn devices for monitoring physical activity are increasingly embraced by older adults [34]. The perspectives of older adults on activity trackers and their practical applications have been thoroughly documented, revealing generally high acceptability rates among this demographic [16]. However, whether older adults can strictly adhere to study protocols involving wearable devices still requires further investigation. In this study, participants are required to return the device after completing a 14-day wear period. This process assists in recalibrating the device and checking its functionality. Additionally, research indicated that the usage rates of wrist-worn devices decline over time after they are distributed to participants [35]. Therefore, returning the device acts as a reminder for participants, encouraging continued adherence to the usage protocol. While other reminder methods are available, this study opts for device return as the chosen strategy.

This study examined the adherence at both daily and cumulative levels. Overall, study adherence daily outperformed cumulative adherence levels. The median proportion of days where wear time surpassed 90% of total wear days stood at 92.1%, indicating that a substantial proportion of participants comply well with the device wear requirements at the daily level. However, ensuring near-perfect or perfect daily adherence remains a challenge, as seen in the decrease in adherence days at the strictest threshold of 100%. However, at the cumulative level, 32% (7/22) of participants in this study exhibited notably lower adherence, with the device worn on fewer than 4 days within the requested initial 14-day period. While 5 participants adhered to the protocol of recording their activity every 3 months, discrepancies were observed, with 5 participants having intervals of device use exceeding the 3-month interval. This variability signals that while some participants readily integrate the wearable devices into their daily routines, others face barriers that hinder consistent use. These barriers emphasize the necessity for adaptable and personalized approaches in encouraging sustained device usage. We also explored the implication of marital status, level of independence, and living situation on the study adherence. Three participants lived alone, two of which demonstrated relatively good adherence. We did not observe distinct patterns in adherence among participants with different marital statuses. Acknowledging and addressing these individual needs are pivotal in ensuring the efficacy of wearable technology as a tool for health monitoring in research settings.

Given that 32% (7/22) of participants wore the device for less than 4 days out of the requested 14-day wear period, we conducted a preliminary investigation to determine if some physical activity measures with moderate reliability (ICC bigger than 0.5) [36] could be obtained with just 3 days of wear. This investigation revealed that specific physical activity measures demonstrating moderate reliability, with ICC values greater than 0.5, can be reliably captured within this shorter timeframe. However, the overall reliability of these measures is not as strong as desired, suggesting that extended wear durations may still be necessary to ensure comprehensive data reliability across a broader range of physical activities. While this exploratory study suggests that shorter wear durations might reduce participant burden and enhance data collection efficiency for specific activities, it also highlights the need for careful result interpretation. Future research should prioritize enhancing the reliability of these measures before considering reduced monitoring durations to ensure that the data collected remains both robust and reliable. Our study employed the Verisense watch, a wearable technology that captures a comprehensive array of physical activity measures, offering a valuable data resource for further research into cognitive impairment. This pilot study not only assesses the adherence of older adults to a long-lasting, waterproof wearable device but also evaluates the consistency of detailed physical activity measures. As part of our ongoing digital brain health platform, we aim to integrate these physical activity insights with other modalities such as sleep and digital cognitive assessments to enhance our understanding of cognitive health. With an anticipated increase in sample size, we plan to provide a more complete digital phenotyping of cognition that leverages the combined strengths of various data types.

We recognized a few limitations in our study. First, the relatively small sample size makes this study serving primarily to offer preliminary insights at a pilot study level. Second, there is a potential for selection bias to influence the findings of this study. Specifically, within the digital brain health platform, participants are given the freedom to choose from various technologies according to their comfort and commitment levels. This choice means that participants who are more comfortable using the Verisense device might be more likely to participate in this study. Further research is also necessary to investigate the reasons behind the instances when the devices were taken off by participants. Third, investigating the impact of different wear time thresholds for defining worn days could be a valuable direction for future research, particularly in assessing device compliance and changes in physical activity measures. Fourth, the consistent inactivity observed in certain participants underscores the necessity for in-depth investigations into the potential health implications or obstacles preventing adherence, as well as the causes of activity variability. Future research should collect more comprehensive lifestyle and social determinant data to explain it.

Conclusion

In summary, this study revealed that while older adults generally showed high daily adherence to the wearable device, consistent usage across consecutive days proved difficult. The varied adherence rates highlight the importance of tailored strategies to improve commitment to the study. Additionally, our initial analysis suggests that stable data for specific activities can be achieved with as little as 3 days of device wear, opening the door to potentially shorter required wear times in subsequent studies. These findings underline the effectiveness of wearables in monitoring physical activity in older populations and emphasize the ongoing necessity to refine usage protocols and enhance user engagement to guarantee the collection of precise and comprehensive data.

Acknowledgments

The authors acknowledge the participants of the BU ADRC for their commitment, without which this study could not have been conducted. This work was supported by a National Heart, Lung, and Blood Institute contract (N01-HC-25195) and by grants from the National Institute on Aging (R01AG008122, R01AG062109, R01AG049810, U19AG068753, R01AG054156, R01AG083735, 2P30AG013846, P30AG073107, R01AG080670, and U01AG068221), the National Institute of Neurological Disorders and Stroke (NS017950), the Alzheimer's Association (AARG-NTF-20-643020), and the American Heart Association (20SFRN35360180). Abstract

Background: Sarcopenia is characterized by the loss of skeletal muscle mass and muscle function with increasing age. The skeletal muscle mass of older people who endure sarcopenia may be improved via the practice of strength training and tai chi. However, it remains unclear if the hybridization of strength exercise training and traditional Chinese exercise will have a better effect.

Objective: We designed a strength training and tai chi exercise hybrid program to improve sarcopenia in older people. Moreover, explainable artificial intelligence was used to predict postintervention sarcopenic status and quantify the feature contribution.

Methods: To assess the influence of sarcopenia in the older people group, 93 participated as experimental participants in a 24-week randomized controlled trial and were randomized into 3 intervention groups, namely the tai chi exercise and strength training hybrid group (TCSG; n=33), the strength training group (STG; n=30), and the control group (n=30). Abdominal computed tomography was used to evaluate the skeletal muscle mass at the third lumbar (L3) vertebra. Analysis of demographic characteristics of participants at baseline used 1-way ANOVA and χ^2 tests, and repeated-measures ANOVA was used to analyze experimental data. In addition, 10 machine-learning classification models were used to calculate if these participants could reverse the degree of sarcopenia after the intervention.

Results: A significant interaction effect was found in skeletal muscle density at the L3 vertebra, skeletal muscle area at the L3 vertebra (L3 SMA), grip strength, muscle fat infiltration, and relative skeletal muscle mass index (all P values were <.05). Grip strength, relative skeletal muscle mass index, and L3 SMA were significantly improved after the intervention for participants in the TCSG and STG (all P values were <.05). After post hoc tests, we found that participants in the TCSG experienced a better effect on L3 SMA than those in the STG and participants in the control group. The LightGBM classification model had the greatest performance in accuracy (88.4%), recall score (74%), and F_1-score (76.1%).

Conclusions: The skeletal muscle area of older adults with sarcopenia may be improved by a hybrid exercise program composed of strength training and tai chi. In addition, we identified that the LightGBM classification model had the best performance to predict the reversion of sarcopenia.

Introduction

With the rapid development of medicine and technology, people are increasingly empowered to face life-threatening diseases, which has led to a prolonged human lifespan. However, this has also resulted in a higher prevalence of age-related illnesses. Further, 1 significant issue is the gradual decline in skeletal muscle function, particularly sarcopenia, which is the loss of strength, power, and muscle mass due to aging [1]. Sarcopenia is characterized by decreased muscle strength and impaired regeneration, with individuals potentially losing up to half of their skeletal muscle mass by the age of 80 years [2,3]. This decline is driven by interactions between systemic signaling and intrinsic muscle tissue mechanisms, leading to decreased protein synthesis and myofiber denervation. Additionally, the reduced regenerative potential of aging muscle cannot effectively regulate cell quality [4-6]. These pathological changes in the important part can seriously impact the quality of life and the ability to perform daily activities in older people [7-11]. Sarcopenia is also an objective indicator of cancer cachexia [12] and is associated with suboptimal surgical postoperative outcomes [13], lower survival [12,14], and toxic counteraction [15-17]. Mortality rates nearly double when sarcopenia is combined with inflammation [18]. Therefore, addressing the serious health issues of older people with sarcopenia is imperative.

Many approaches have been proposed to address the muscle loss associated with sarcopenia, including managing chronic low-grade systemic inflammation [19], leveraging the anabolic effects of insulinlike growth factor 1 (IGF-1) signaling [20], and increasing the intake of protein and vitamin D [7]. Correspondingly, hormones, anabolic drugs, and nutritional interventions have been explored for therapeutic applications. It is well established that lean body mass is critical to health, yet the effectiveness of protein interventions in increasing lean body mass remains inconsistent [21,22]. Notably, there is no positive impact on lean body mass or testosterone-induced anabolic responses when protein intake exceeds the recommended intake (0.8 g/kg/day for adults) [23,24]. While treatments such as myostatin antagonists and androgens are being developed and have garnered optimism [25], many commonly prescribed medications have unwanted side effects [25]. Consequently, the Food and Drug Administration has been cautious in approving drugs to treat sarcopenia and has yet to approve any such drug, emphasizing the importance of drug safety. Therefore, the treatment of sarcopenia requires consideration of alternative approaches.

Fortunately, exercise therapy has shown positive effects on older adults with sarcopenia [5]. Specifically, strength exercise training (SET) is regarded as the most effective intervention due to its ability to improve the activation of IGF-1, the Akt/mTOR, and Akt/FOXO3 pathways [26,27]. Additionally, several studies have shown that traditional Chinese exercise also has positive effects on muscle health. Over the last 15 years, 12 traditional Chinese exercise–based studies have been conducted [28-39], with 2 focusing on tai chi [37,38]. Tai chi, which combines physical exercise and respiration, has been shown to decrease fat mass and improve lower limb muscle strength. For example, Yang-style 24-form tai chi over 10 months decreased fat mass [38], while 8-style tai chi significantly improved lower limb muscle strength compared to a control group (CG) [37]. A cross-sectional study on 139 Italian older adults also found that tai chi practitioners had lower body fat content and higher muscle content in the trunk [40]. Altogether, tai chi has demonstrated positive effects on older individuals with sarcopenia. However, it remains unclear whether combining tai chi with SET can further enhance muscle growth and potentially reverse sarcopenia.

In recent years, the increasing interest in applying artificial intelligence (AI) in health care has extended to this field [41,42-44]. Among these applications, a model produced by an explainable AI (XAI) system is particularly noteworthy. This automated diagnostic platform enhances system understandability and trustworthiness through its human-interpreted, high-level learning capabilities. Consequently, this study developed an offline XAI model to forecast whether sarcopenia can be reversed and to boost its clinical applicability.

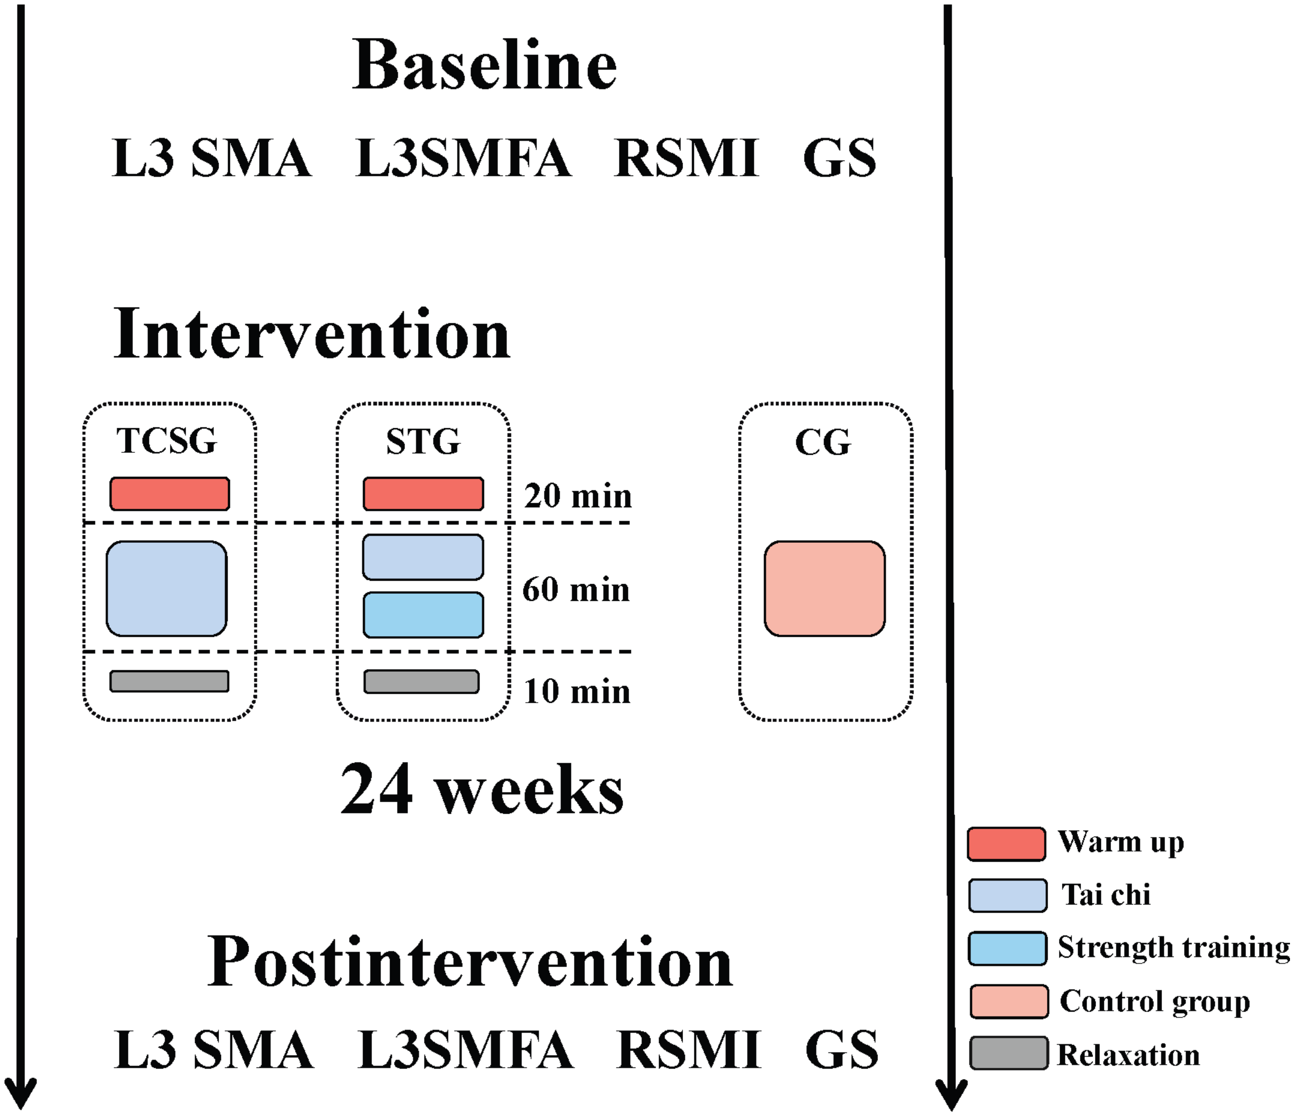
In summary, this study proposed a novel intervention method for older adults with sarcopenia, combining SET and tai chi. We discuss both the predictive and final effects on participants' sarcopenia state after 24 weeks of intervention. Based on initial physical ability, computed tomography (CT) scan findings, and 3 types of interventions, the effect was predicted using classic machine learning models. The final effect was quantified and visualized through CT scans. We hypothesized that the combined exercise intervention program of SET and tai chi will more effectively increase muscle mass and reverse sarcopenia than SET alone.

Methods

Research Experimental Program

This research was designed as a randomized controlled and double-blind trial with 3 different intervention groups: a tai chi exercise and strength training hybrid group (TCSG), a strength training group (STG), and a CG. This study was approved by the Ethics Committee of the Northeast Normal University (NC2019030702) and registered at ClinicalTrials.gov (NCT05694117). The random number table method was used to randomly assign participants to the 3 groups. CT provides precise estimates of muscle quality [45], and quantitative CT (QCT) can reveal the level of muscle edema and steatosis. It can also accurately analyze the form and structure of skeletal muscle by removing measurement errors caused by unstable CT readings [46]. Therefore, QCT scans were used to assess the area and density of skeletal muscle at the third lumbar (L3) in each group of participants at the imaging department of Baishan Central Hospital. The training was conducted 3 times a week for 90 minutes, for a total of 24 weeks of intervention from June 1, 2019, to December 30, 2019. The experimental protocol design is shown in Figure 1. During the experiment, each participant was requested to refrain from taking part in any other sort of physical exercise.

Figure 1. Experimental design flow chart. Participants were assigned to 1 of 3 intervention groups at random: the TCSG, the STG, or the CG. CG: control group; GS: grip strength; RSMI: relative skeletal muscle mass index; SMA: skeletal muscle area; SMFA: skeletal muscle intramuscular fat area; STG: strength training group; TCSG: tai chi exercise and strength training hybrid group.



Intervention

In total, 2 experimental groups and 1 CG were set for this trial. The intervention regimens included tai chi exercise hybrid strength training and strength training. The TCSG and the STG were the experimental groups. All participants in the experimental groups started with a 20-minute warm-up exercise and concluded with a 10-minute cool-down exercise. The following is a comprehensive outline of the intervention programs:

1. Tai chi exercise: The TCSG's tai chi training was structured into 2 cycles. The first cycle (weeks 1 - 12) focused on learning and consolidating basic tai chi movements, while the second cycle (weeks 13 - 24) aimed at improving and refining these movements. Each tai chi session lasted 30 minutes and included slow, flowing movements combined with deep breathing exercises to promote physical and mental relaxation.
2. Strength training: We designed a total of 5 strength training movements, 2 of which were for training the lower body muscles and 3 for training the upper body muscles. The movements to exercise the upper limb muscles were reverse grip curls, seated pull-downs, and bicep curls. The movements to train the muscle strength of the lower limbs were standing leg raises with an elastic band and supine leg lifts with an elastic band. Further, 1 training cycle lasted for 8 weeks, and the whole training had 3 cycles. In the first cycle, we trained with a light load but many repetitions (from 40% to 60% of 1 repetition maximum [RM] and 12 - 20 repetitions). A moderate-intensity load with a medium number of repetitions (60% - 80% of 1 RM and 5 - 12 repetitions) was used in the second cycle of training to further enhance the training load. To increase the participants' maximum muscular strength in the third cycle, we used a greater training load and fewer repetitions (70% - 85% of 1 RM and 5 - 8 repetitions). Participants in the STG performed 4 sets of each movement, while the TCSG completed 2 sets with a 2 to 3 minute rest between each set.
3. CG: Participants in the CG were provided with information on sarcopenia treatment and prevention, such as increasing protein intake and engaging in general physical activities.

Participants

We recruited volunteers from the Baishan Ciming Health Screening Center and the Health Screening Center of Baishan Central Hospital in Baishan, China, for this randomized controlled experiment. A form requesting informed permission was completed by each participant before the beginning of the trial. The screening process involved using the following inclusion and exclusion criteria to choose participants. Inclusion criteria: (1) patients between the ages of 60 - 75 years and (2) patients who meet the screening criteria for sarcopenia in Asia established by Asian Working Group for Sarcopenia (AWGS) 2016 [47]. Exclusion criteria: (1) participants taking medications that significantly impact musculoskeletal function, (2) participants enduring respiratory failure or other bodily problems, (3) participants with mental disorders or neurological disorders, and (4) patients who participate in other training programs on a regular basis. Prior research served as the basis for the calculation of the required sample size [48], which was at an α level of .01; we used 80% power and a 0.53 effect, and we assumed a 20% dropout rate. This resulted in a required sample size of 106 participants.

Assessment of Sarcopenia

The AWGS screening criteria [47] were used for each individual participant's evaluation. For a participant to be diagnosed with sarcopenia, they must satisfy each criterion listed below:

1. Grip strength: We used a Jamar Hydraulic Hand Dynamometer (SH5001, Saehan Corp, 2017) to measure participants' grip strength. Participants were instructed to maintain a natural standing posture during the duration of the test. They were also instructed to keep their wrists in a neutral position and their elbows completely extended [49]. The maximum value was retained after they were given 2 separate grip strength tests. The diagnostic boundary values for grip strength that met the screening criteria were <28 kg for males and <18 kg for females.
2. Physical performance: We assessed physical performance using the 6-meter gait speed recommended by AWGS 2016 [47]. Participants prepared behind the starting line, and when they heard the "start" command, they walked at normal speed toward the finish line, taking a few steps after walking across the finish line before stopping to avoid early deceleration [50]. Participants were considered to meet the criteria when their walking speed was less than 0.8 m/s.
3. Appendicular skeletal muscle mass (ASM): We used a multifrequency bioelectrical impedance analysis (Inbody S10 Biospace, Biospace Co Ltd) to measure the ASM. The screening criteria were satisfied by the men and women whose ASM was less than 7 kg/m^2 and less than 5.7 kg/m^2, respectively.

Assessment Methods for Skeletal Muscle and Fat

Overview

Further, 1 week prior to the beginning of the intervention and 1 week after it had concluded, we used a GE Revolution 256-row CT (General Electric Company, 2015) to measure the participants' abdomens. The scan was performed from the top of the diaphragm to the level of the umbilicus, and it was performed with the patient in a supine position with the hands raised flat over the head and the breath held at the end of a deep inspiration. The Gemstone Spectral Imaging scan used tube voltages ranging from 80 to 140 kVp (Peak kilovoltage), currents in the tubes that were intelligently regulated, a layer thickness of 5 millimeters, and a layer spacing of 5 millimeters. Immediately after the scanning process, the data and photos were saved in an automated manner in the workstation. The region of interest was manually defined at the L3 level using the X Section software on the GE ADW (version 4.7) workstation.

Measurement of Skeletal Muscle

Skeletal muscle density at the L3 vertebra (L3 SMD; Hounsfield units [HU]) and skeletal muscle area at the L3 vertebra (L3 SMA; cm^2) were measured using abdominal CT, with the HU range from −30 to 150 HU. This range provides the most realistic measurement of muscle and fat mass [51]. After a scan, an X Section software was used to manually outline the edges of the skeletal muscle tissue at this level, and the software automatically calculated the area of the corresponding tissue within the outlined area and the mean value of the CT.

Measurement Method for Skeletal Muscle Intramuscular Fat

Skeletal muscle intramuscular fat accumulates as the muscle mass decreases during the aging process [52]. At baseline and after the intervention, QCT was used to quantify the skeletal muscle intramuscular fat density at the L3 vertebra (L3 SMFD; HU), and the skeletal muscle intramuscular fat area at the L3 vertebra (L3 SMFA; cm^2). We used a range from −200 to 0 HU for the quantitatively measuring the fat threshold. After scanning, the X Section software was used again to manually outline the edges of the skeletal intermuscular fat at this level, and the software automatically calculated the area of corresponding tissue within the outlined area and the mean value of the CT.

Measurement Method for Relative Skeletal Muscle Mass Index

A relative skeletal muscle mass index (RSMI; kg/m^2) could be used to assess muscle growth [53]. The RSMI, which is represented as muscle mass per m^2 of the limbs, can be used to evaluate sarcopenia. Thus, RSMI was chosen as the main result indicator in the research and was evaluated using multifrequency bioelectrical impedance analysis.

Measurement Method for Muscle Fat Infiltration

According to research, muscle fat infiltration (MFI; %) will cause a reduction in muscle mass, producing muscular atrophy and leading to sarcopenia [54]. Therefore, we used the MFI as one of the observed indicators of the results as well. MFI was calculated by Equation 1:

(1)MFI=SMFA/(SMA+SMFA)\times 100

Measurement Method for Grip Strength

Grip strength is the most important criterion for diagnosing sarcopenia and a common indirect measure of total muscle strength [55]. Therefore, grip strength was selected as the primary observation and measured before and after the intervention. We used a Jamar Hydraulic Hand Dynamometer to measure grip strength of participants. Participants were instructed to maintain a natural standing posture during the duration of the test. They were also instructed to keep their wrists in a neutral position and their elbows completely extended [49]. The maximum value was retained after they were given 2 separate grip strength tests.

Data Analysis

In order to make the intervention runs as accurate as possible, we used a machine learning method to predict whether older people had sarcopenia after 24 weeks of intervention based on the participants' initial status before the intervention and the intervention protocol they received as features. The data used to train the model consisted of each participant's age, gender, and initial grip strength, RSMI, L3 SMA, and L3 SFMA as features and the presence or absence of sarcopenia after the intervention as a label. The performance of classification models was assessed per the F_1-score, precision, area under the curve (AUC), recall, and accuracy. These metrics were averaged across all validation or test sets during the repeated cross-validation process, with SD used to provide uncertainty estimates for these averages. Each model was trained 100 times individually using a 10-fold cross-validation. Hyperparameter tuning was performed using a grid search with cross-validation within each training fold to identify the optimal parameters for each model. For example, for the random forest (RF) model, we varied the number of trees (50 to 200), maximum depth (5 to 20), and minimum samples split (2 to 10). The best model was defined as the one with the highest average AUC across all folds. We also calculated the precision, recall, and F_1-score using a threshold of 0.5 for class predictions, ensuring consistency in performance evaluation. First, we trained 9 machine learning classification models using a k neighbors classifier [56], logistic regression (LR) [57], a gradient boosting classifier [58], linear discriminant analysis [59], an extra tree classifier [60], an RF classifier [61], a decision tree classifier [62], an XGBoost classifier [63], and a LightGBM classifier [64]. Then, the 3 best-performing models were selected for the stacking model in this dataset. The first layer consisted of the LightGBM, XGBoost, and RF classifiers. The second-level classifier, used to combine the outputs of these 3 models, was LR. In this research, a stacking technique was used in order to integrate numerous classifiers that were produced by various algorithms $L_1,...,L_n$ and applied to a singular dataset S. This dataset included instances of the type $S_i = (x_i, y_i)$, where x_i indicates the characteristic vectors and y_i indicates the classifications. In the beginning of this procedure, a group of base-level classifiers—C_1, C_2, and C_3, together with Ci = $L_n(S)$—were developed. Then, we had predictions for S_i, as per Equation 2:

(2)y^ik=Cki(xi)

The meta-level data were made up of several illustrations of the form ((y^i1,..., y^in), yi), in which features represent the output of the first-level classifier and categories are the appropriate labels for this sample.

The dataset was divided into 10 folds for cross-validation. Each model was trained on 9 folds and validated on the remaining fold, repeated 10 times for a total of 100 repetitions. For each fold, the model was trained and predictions were made on the validation fold. These predictions were saved. For each cross-validation run, the precision, recall, accuracy, and F_1-score were calculated. The means and SDs of these metrics over the 100 repetitions are reported in Table 1, providing an estimate of model performance and its variability. Predictions from all 100 cross-validation runs were aggregated to form a single prediction set. This aggregated prediction set was then used to generate the normalized confusion matrix presented in Figure 2, ensuring a comprehensive evaluation of the model's performance.

Table . Comparison of the performance of machine learning classification models. Performance metrics are reported as mean (SD), calculated over 100 repeats of 10-fold cross-validation.

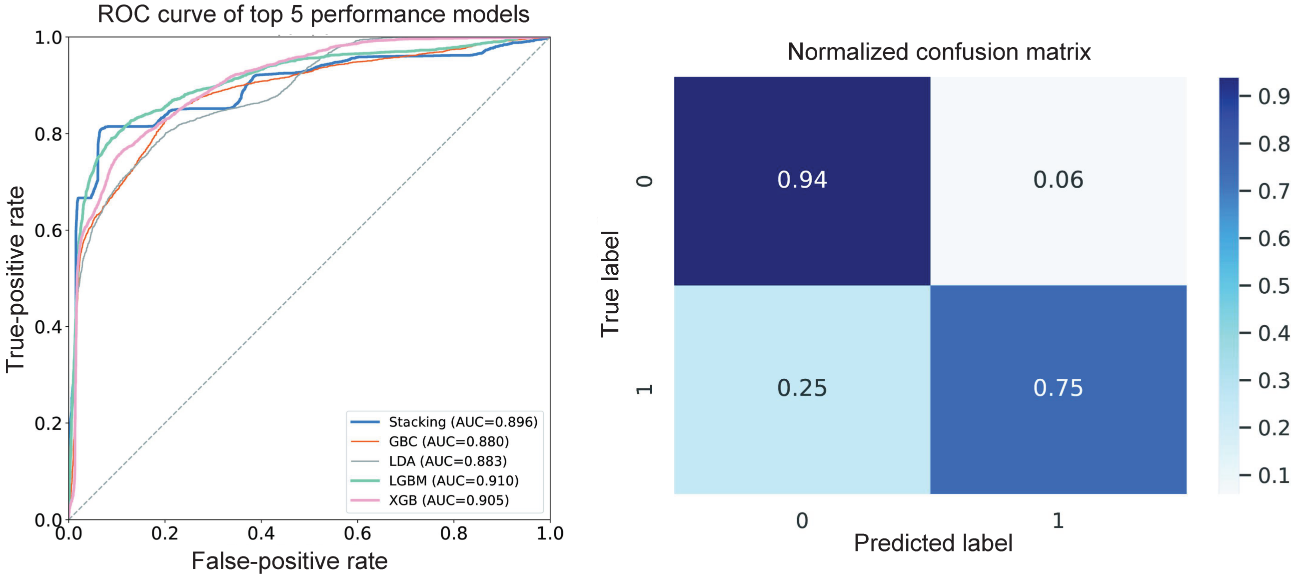
Models	Accuracy (%), mean (SD)	Precision (%), mean (SD)	Recall (%), mean (SD)	F_1-score (%), mean (SD)
KNN[a]	78.6 (1.9)	65.7 (5.9)	61.9 (5.2)	61.6 (4.2)
Decision tree	80.6 (2.5)	69.4 (6.7)	70.2 (5.7)	66.4 (5)
Logistic regression	82.8 (1.4)	75.9 (6.8)	60.6 (3.9)	63.6 (3.3)
Gradient boosting	83.5 (1.9)	76.5 (5.9)	67.1 (4.1)	67.9 (4.2)
LDA[b]	84.4 (1.6)	78 (4.9)	68 (3.4)	69.3 (3.7)
Extra tree	84.9 (1.8)	80.6 (7.1)	65.6 (4.8)	68.4 (4.9)
Random forest	85.5 (1.8)	81.7 (7.9)	60.3 (4.3)	65.7 (5.2)
XGBoost	85.8 (1.7)	81.4 (5.5)	68 (4)	71.2 (3.5)
Stacking	86.6 (2.6)	83.9 (5)[c]	67 (1.8)	71.3 (2.3)
LightGBM[c]	88.4 (2)[c]	83.9 (6.1)	74 (4.5)[c]	76.1 (5.1)[c]

[a] KNN: k neighbors classifier.

[b] LDA: linear discriminant analysis.

[c] The values indicate the best performance achieved by each model for the corresponding metric.

Figure 2. The results of the model’s performance to predict whether a participant is a patient with sarcopenia at second evaluation; the ROC curve of the top 5 models, and the confusion matrix of the LightGBM classifier model. (A) The top-5 performance models’ ROC curve; (B) normalized confusion matrix. AUC: area under the curve; GBC: gradient boosting classifier; LDA: linear discriminant analysis; LGBM: LightGBM classifier; ROC: receiver operating characteristic; XGB: XGBoost classifier.



(A) (B)

Moreover, the receiver operating characteristic curves for the top 5 models are shown in . The horizontal axis depicts false-positive rate, while the vertical axis depicts true-positive rate. A greater AUC indicates superior performance. The LightGBM classifier model had the highest AUC (0.910). The normalized confusion matrix offers a more perceptible view of the accuracy of each category’s predictions made by the model, while the prediction result confusion matrix clearly displays all model predictions, with the real labels in the horizontal direction and the outcomes predicted by the model in the vertical direction. It is clear from that the model showed great performance in predicting whether or not participants reversed sarcopenia after the intervention (94% and 75%, respectively).

In addition, we calculated SHAP (Shapley additive explanations) values, because it could assign an important value to each feature that represents the effect on the model prediction of including that feature [65]. Any machine learning model’s output can be interpreted using SHAP, a game-theoretic approach. The SHAP value quantifies the contribution of each feature to the model’s predictions, represented by Equation 3:

$$(3)\varphi j=\sum SF\subseteq F\ \{j\}|SF|!(|F|-|SF|-1)!|F|![fSF\cup\{j\}(xSF\cup\{j\})-fSF(xSF)]$$

in which S_F stands for all of the potential subsets that do not contain characteristic j, x stands for the values of the input characteristics, $|S_F|$ stands for the dimension of S_F, and j stands for a specific characteristic. To calculate this effect, 2 models, fSF∪j and fSF, were trained, conditioned on the presence or absence of feature j throughout the training process. This allows the contribution of each feature to be calculated. We used the SHAP TreeExplainer algorithm to identify important features that could accurately predict whether participants could reverse muscle loss after the intervention.

Statistical Analysis

All data analysis, statistical analysis, and visualization procedures for this study were completed using Python (version 3.7.1; Python Software Foundation) and SPSS (version 25.0; IBM Corp) software. Before performing ANOVA, data distribution was assessed using the Shapiro-Wilk test to check for normality, and Levene test was used to check for homoscedasticity. Nonnormally distributed data were log-transformed. Further, 1-way ANOVA and χ^2 tests were responsible for assessing baseline differences in demographic data among groups. Repeated-measures ANOVA was used to examine the impact of the 3 different intervention programs on the participants. Simple effects were used for the factors that had further interaction effects. The Bonferroni post hoc test was used to further investigate group differences when ANOVA indicated statistical significance. The Bonferroni post hoc test was chosen for its control of the family-wise error rate, making it suitable for pairwise comparisons. A *P* value of <.05 was used as the threshold for statistical significance

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee of Northeast Normal University (approval NC2019030702). A written informed consent form was obtained from each participant. Measures were implemented to safeguard participants’ privacy during data analysis.

Results

Overview

A total of 164 individuals were recruited (Figure 3); however, only 106 (48 females and 58 males) were found to meet the inclusion and exclusion criteria. Finally, 93 (50 females and 43 males) participants finished the research. Dropping out of the training (n=8) and being unable to continue due to illness (n=5) were the reasons for not finishing the program. The demographic characteristics of the participants at baseline are summarized in Table 2.

Figure 3. CONSORT flow diagram. CG: control group; CONSORT: Consolidated Standards of Reporting Trials; STG: strength training group; TCSG: tai chi exercise and strength training hybrid group.

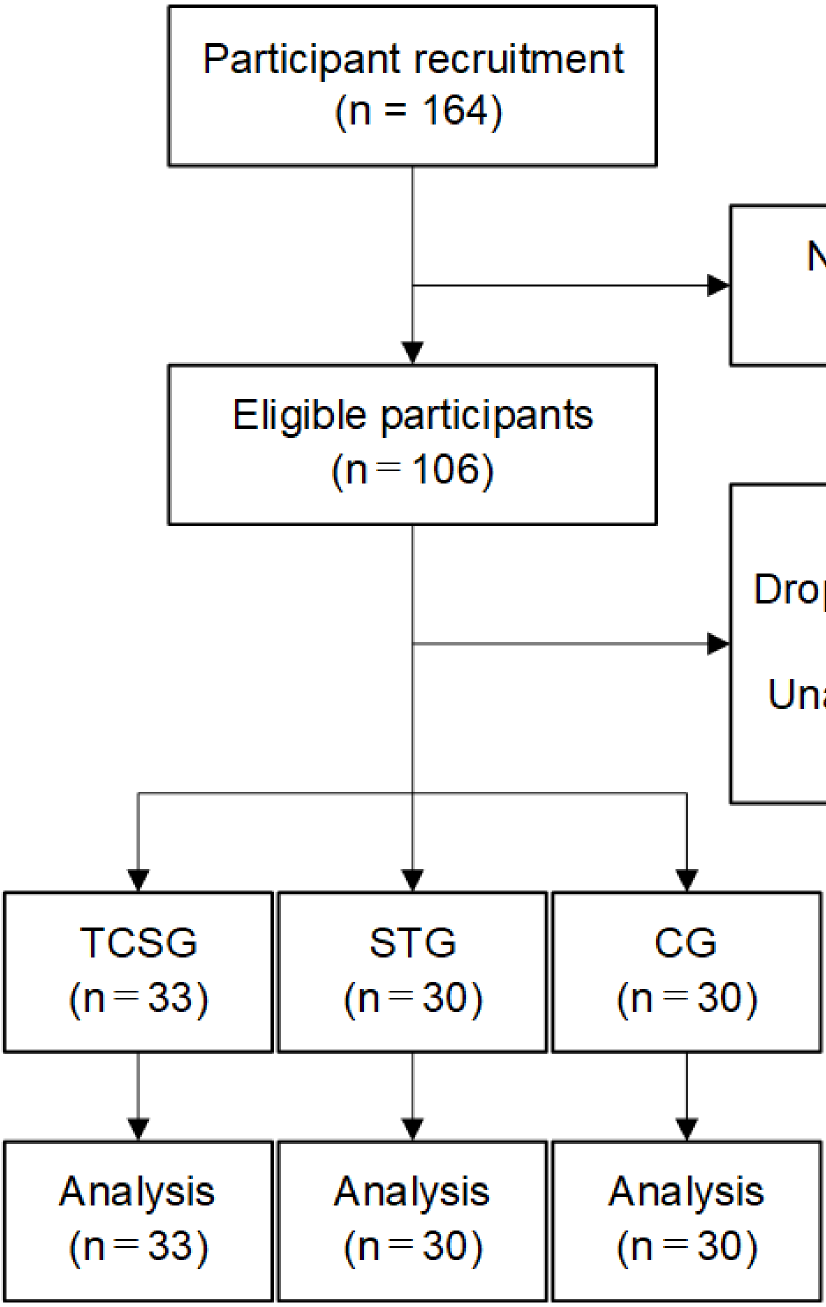


Table . Demographic features of the participants at baseline.

Items	TCSG[a] (n=33)	STG[b] (n=30)	CG[c] (n=30)	*P* value
Gender, n	male: 14; female: 19	male: 13; female: 17	male: 16; female: 14	.64
Age (years), mean (SD)	66.94 (4.42)	66.87 (3.84)	65.42 (3.97)	.34
BMI (kg/m^2), mean (SD)	23.23 (2.06)	22.8 (3.18)	21.93 (2.86)	.79

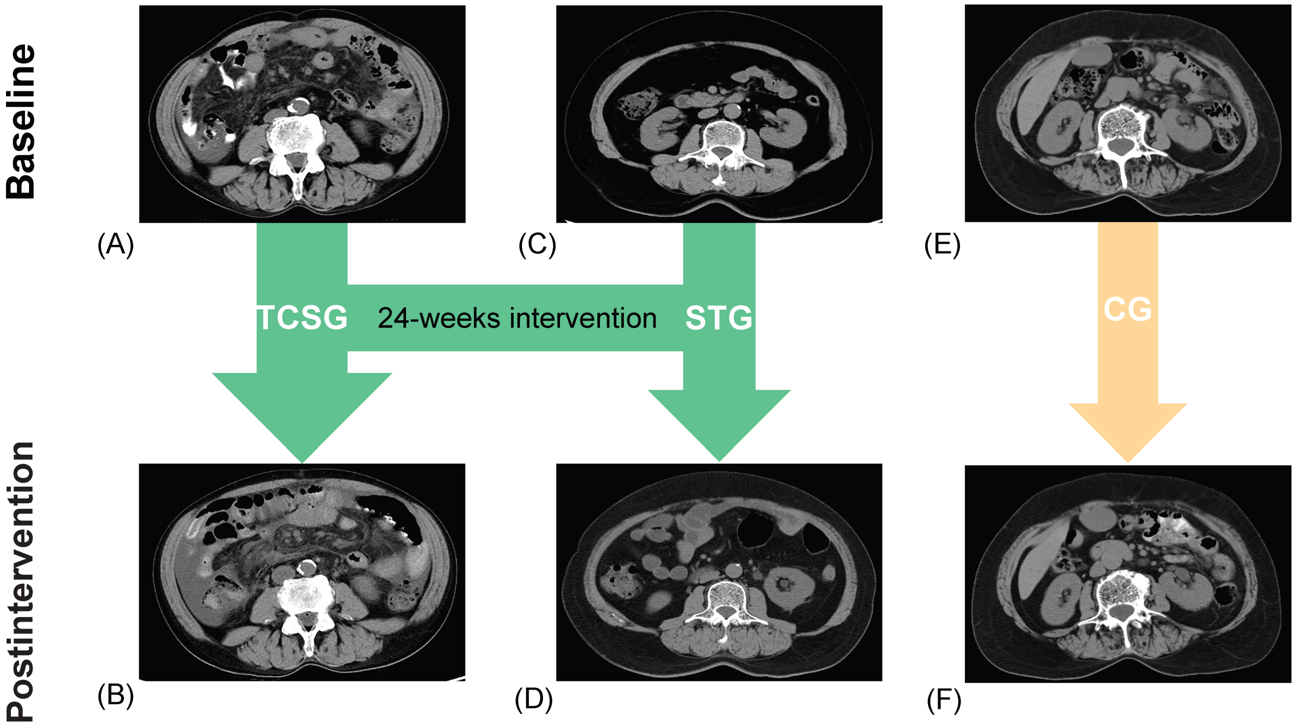
[a] TCSG: tai chi exercise and strength training hybrid group.

[b] STG: strength training group.

[c] CG: control group.

Further, a week after the experiment finished, we reassessed participants for sarcopenia. In the TCSG, we observed the reversal of sarcopenia in 15 (45.5%) participants, and in the STG, we observed the reversal of sarcopenia in 12 (40%) participants, for a total of 27 (29%) with reversal of sarcopenia. Expectedly, sarcopenia was not reversed in the CG participants. Furthermore, Figure 4 shows the QCT measurements of representative participants in each group before and after the intervention.

Figure 4. Shows the results of QCT scans of representative participants in each group before and after receiving the intervention. (A) Preintervention TCSG, (B) postintervention TCSG, (C) preintervention STG, (D) postintervention STG, (E) preintervention CG, and (F) postintervention CG. CG: control group; QCT: quantitative computed tomography; STG: strength training group; TCSG: tai chi exercise and strength training hybrid group.



Statistical Analysis Results

Figure 5 depicts the main results, and Table 3 presents results of repeated-measures ANOVA for each observation indicator. All variables did not differ between groups at baseline. It was found that grip strength (*P*=.008), RSMI (*P*=.002), L3 SMD (*P*<.001), L3 SMA (*P*=.005), and MFI (*P*=.008) had a statistically significant interaction effect. A significant improvement in grip strength, RSMI, L3 SMA, and L3 SMD was seen in the TCSG and STG at 24 weeks. There was a significant difference in postintervention L3 SMA in the TCSG compared to the STG and CG, as determined by a post hoc test. However, we did not find any significant interactions among L3 SMFA and L3 SMFD.

Figure 5. Violin plots of main results before and after the intervention for each group of participants. (A) RSMI; (B) L3 SMFA, (C) L3 SMA; and(D) grip strength. Violin plots show the distribution of the data, with the width of the plot indicating the density of data points at each value. Thex-axis represents the intervention groups (TCSG, STG, and CG), and the y-axis represents the measured outcomes (RSMI, L3 SMFA, L3 SMA, gripstrength). The green area represents the distribution of pretest values, and the orange area represents the distribution of posttest values. Individualpretest samples are marked by orange dots, and posttest samples are marked by red dots. CG: control group; RSMI: relative skeletal muscle massindex; SMA: skeletal muscle area; SMFA: skeletal muscle intramuscular fat area; STG: strength training group; TCSG: tai chi exercise and strengthtraining hybrid group.

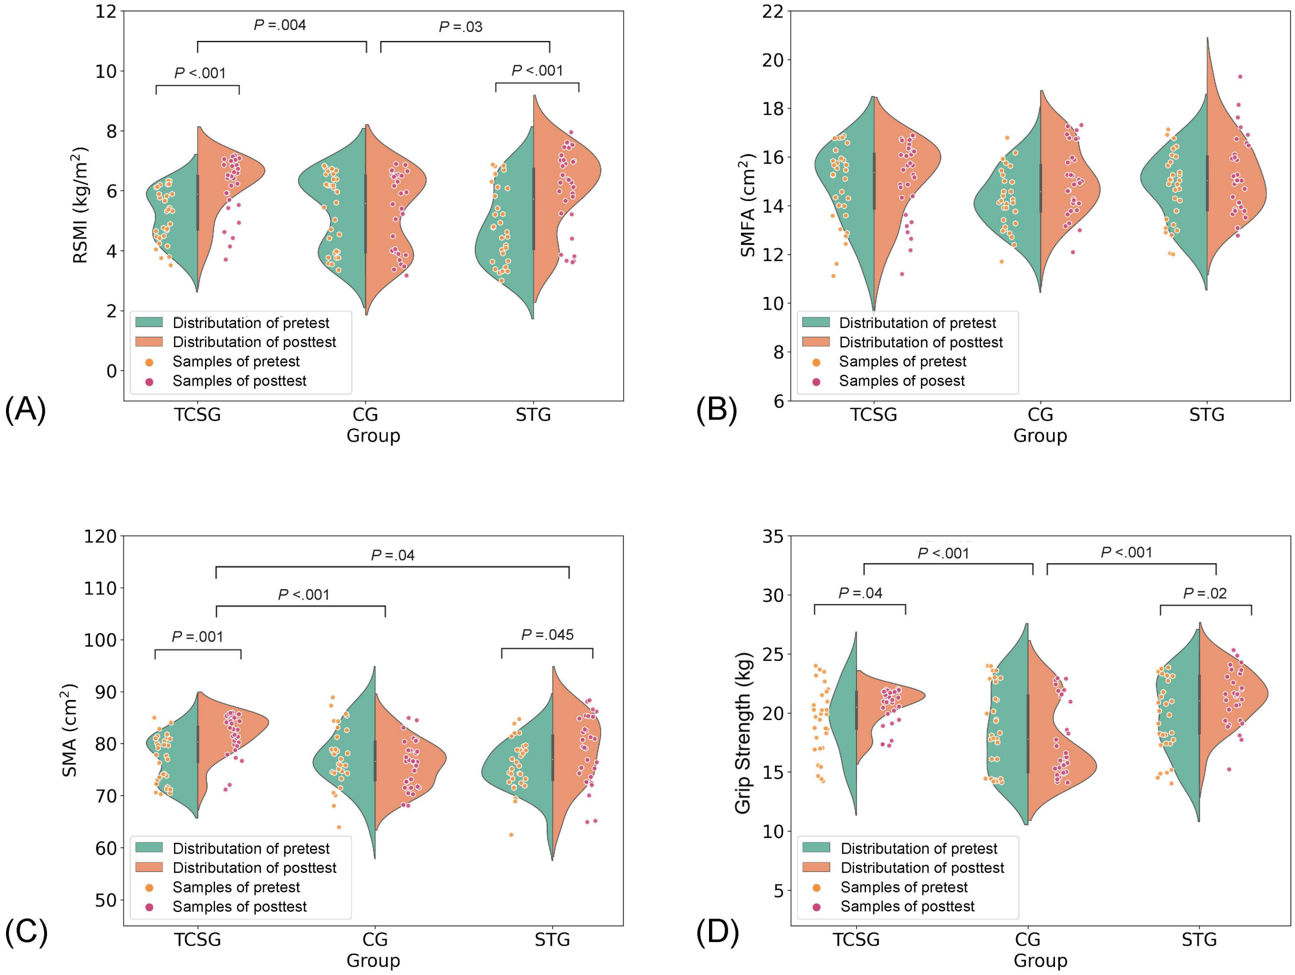


Table . Comparison of intervention effects between groups. Repeated-measures ANOVA analysis.

Parameters	TCSG[a] (n=33)		STG[b] (n=30)		CG[c] (n=30)		Group × time[d]

Results of Machine Learning Model Classification

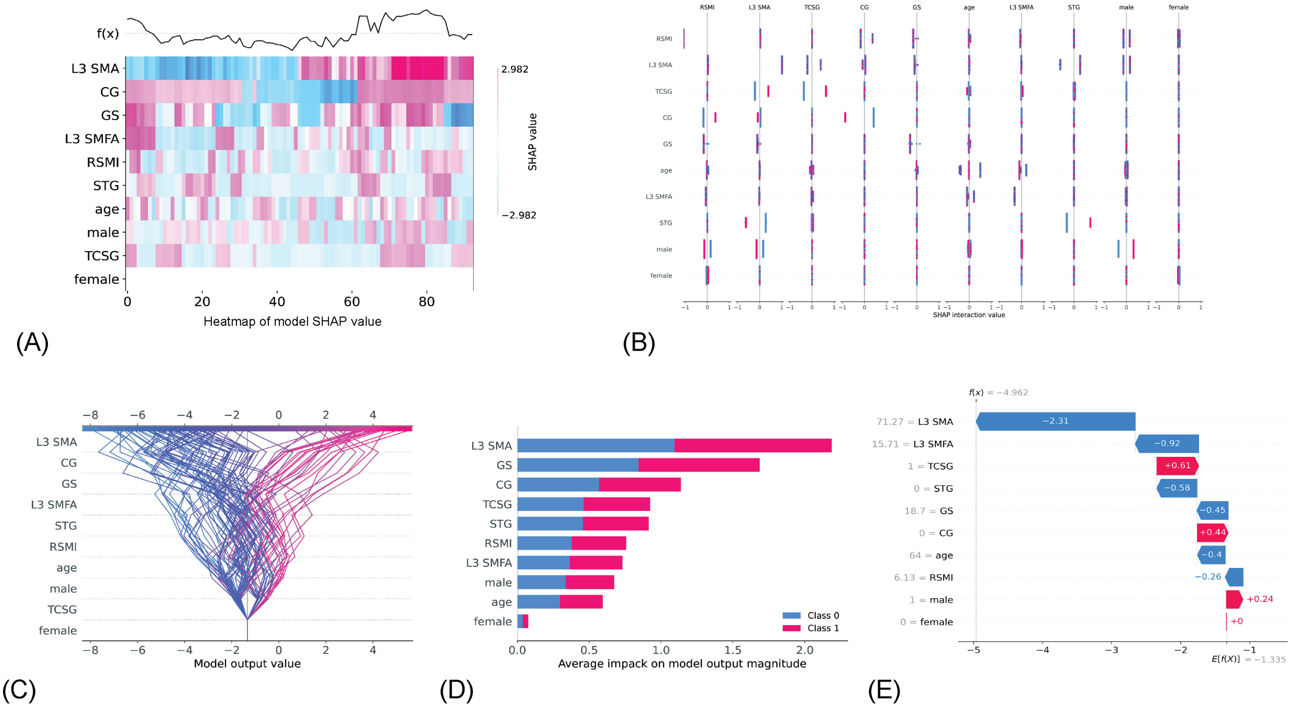
The average performance evaluation of the machine learning model after 100 rounds of training is shown in Table 1. We found that the LightGBM classification model exhibited the best performance in terms of average accuracy (88.4%, SD 2%), average recall (74%, SD 4.5%), and average F_1-score (76.1%, SD 5.3%). In addition, our stacking model with the first layer consisting of LightGBM classification model, XGBoost classification model, and RF classification model, and the second layer consisting of LR exhibited the best average precision (83.9%, SD 5%).

Moreover, the receiver operating characteristic curves for the top 5 models are shown in Figure 2A. The horizontal axis depicts false-positive rate, while the vertical axis depicts true-positive rate. A greater AUC indicates superior performance. The LightGBM classifier model had the highest AUC (0.910). The normalized confusion matrix offers a more perceptible view of the accuracy of each category's predictions made by the model, while the prediction result confusion matrix clearly displays all model predictions. This was with the real labels in the horizontal direction and the outcomes predicted by the model in the vertical direction. It is clear from Figure 2B that the model showed great performance in predicting whether or not participants reversed sarcopenia after the intervention.

Results of Feature Contribution

The SHAP values of features for contribution are presented in Figure 6. We used SHAP values specifically derived from the LightGBM model, as it demonstrated the best performance among all models. The feature's shape value indicates the degree to which the feature contributes to the overall model. The greatest contributions were shown in grip strength and L3 SMA across all variables. It is clear from Figure 6B that the characteristics may have an effect on one another. This implies that by evaluating all possible combinations of features, the optimal combination of features that would increase the performance of the model can be identified.

Figure 6. The SHAP values for each feature are shown in this plot. The various characteristics are shown along the y-axis. (A) Heat map plot: shows the SHAP values for each feature; the x-axis denotes the sample sequence; red denotes positive impacts and blue represents negative impacts; the degree of contribution is determined by the color shade. *f*(*x*) denotes the output of before activation function. (B) Interaction values plot: illustrates the connection that exists between the various features. (C) Decision plot: the influential features in deriving the model's output are shown. The features are listed on the y-axis in order of decreasing influence, while the x-axis reflects the model's output value. A line depicts the prediction for each observation. Each line crosses the x-axis at the predicted value for the relevant observation at the top of the figure. The SHAP values of each parameter are added to the base value of the model from the bottom to the top of the plot, illustrating how each feature affects the final prediction. Features moving rightward positively influence the model, while those moving leftward have a negative effect. (D) Bar plot: displays the average absolute SHAP values for each characteristic, with the x-axis indicating that L3 SMA has the greatest contribution of all the features. (E) Waterfall plot: illustrates the degree to which each feature in a single sample has an effect on the model. The x-axis indicates the SHAP value, with the expected value of the model output shown at the bottom. Each row illustrates how the contribution of each feature shifts the value from the expected model output to the prediction. This graph shows that the TR (intervention type) feature has the highest positive influence on model prediction performance, while the L3 SMA feature has the largest negative effect. CG: control group; GS: grip strength; RSMI: relative skeletal muscle mass index; SHAP: Shapley additive explanations; SMA: skeletal muscle area; SMFA: skeletal muscle intramuscular fat area; STG: strength training group; TCSG: tai chi exercise and strength training hybrid group; TR: intervention type.



Discussion

Principal Findings

This study suggests a novel hybrid training strategy for older individuals with sarcopenia that combines SET and tai chi. In addition, AI was used to foresee if the intervention in older adults will reverse their sarcopenia. The results of this study showed that at the end of the 24-week intervention, participants in both the TCSG and STG improved their grip strength, RSMI, and L3 SMA, albeit to varying degrees. In terms of L3 SMA, the TCSG outperformed the others and exhibited the most substantial improvement. The strongest results in reversion of sarcopenia, however, were seen with the hybrid exercise program combining the TCSG and STG. As well as this, we were among the first to use XAI to predict sarcopenia in a Chinese sample of older people with an average accuracy rate of 88.4% (SD 2%).

We revealed that older people with sarcopenia in the STG and TCSG showed improvements in hand grip strength, RSMI, L3 SMA, and L3 SMD after 24 weeks of intervention. In comparison to both the STG and CG, the L3 SMA of the patients in the TCSG significantly improved. In accordance with the present results, previous studies have demonstrated that SET intervention has the ability to reverse sarcopenia and improve physical health [66]. This result may be explained by the fact that the contraction of strength training's mechanical stress has a variety of positive consequences that increase intracellular protein accumulation net-positively, leading to the remodeling of the extracellular matrix and the growth of muscle fibers [67]. Specifically, SET stimulates PGC-1α expression in a working muscle, which could induce IGF-1 and suppress myostatin, leading to significant skeletal muscle growth [68], and IGF-1 expression increased, which might prevent atrophy and encourage hypertrophy; this might be a contributing factor to the amelioration of skeletal muscle area. Meanwhile, mechanical loading encourages the expression of growth hormone, as the growth hormone/IGF-1 axis and enhanced IGF-1 gene expression are thought to be the primary mechanisms by which growth hormone regulates postnatal bone development.

Perhaps the most important finding is that in terms of L3 SMA and RSMI, the TCSG considerably outperformed the STG after 24 weeks. These findings corroborate those of prior research suggesting that hybrid exercise may have a more potent effect on muscles [39,69-71]. Chinese traditional exercise, an assortment of low-intensity cardio mind-body exercises such as tai chi, Yijin Jing, Baduanjin, etc, has been used in China for centuries to both prevent and treat illness. As an aerobic training with low intensity, tai chi is commonly regarded as that it can improve physical condition, including improving endurance ability, increasing insulin sensitivity, and modulating fat metabolism. This impact is principally linked to the skeletal muscle's markedly increased mitochondrial volume and density. PGC-1α/FNDC5/UCP1 signaling pathway activation and PGC-1α overexpression are the 2 factors responsible for this increase [72]. This effect increases the amount and activity of mitochondrial enzymes while also increasing the rate of fat burning in muscles both at rest and during low-intensity exercise [73-76]. Another possible explanation for this is that the theoretical principles of traditional Chinese medicine are helpful in maintaining a calm and composed state of mind. They also help the body's innate self-regulatory or self-repair mechanisms to trigger and help the body to release endogenous neurohormones in a balanced manner [77,78]. Thus, the hybrid exercise training protocol of SET and tai chi had better performance and greater advantages than other intervention strategies.

Further, 1 unexpected finding was the extent to which neither the hybrid program nor SET could prevent intramuscular fat buildup. It is commonly known that as people age, their intramuscular fat content gradually increases [79,80]. The L3 level of the skeletal muscle intramuscular fat area showed a growing tendency in all 3 groups following the exercise intervention, but no statistical significance was identified. The findings of this study do not support the previous research finding that strength training and aerobic activity might assist older persons in avoiding age-related intramuscular fat accumulation [81]. This finding may be attributable to differences in the intensity and frequency of aerobic activity between studies.

The discovery that a total of 29% (n=27) of the participants were able to reverse their sarcopenia is perhaps the most clinically important finding. This included 40% (n=12) of the STG and 45.5% (n=15) of the TCSG. Our study links recovery from geriatric disease with a mixed exercise intervention, and the findings of this study could provide a new option for the treatment of sarcopenia and broadly support other research efforts in similar areas linking geriatric disease recovery to hybrid exercise [69,71].

Several limitations need to be noted regarding this study. First, given that there has been a wealth of research performed on the benefits of tai chi on skeletal muscle, we did not set up a distinct tai chi intervention group. Second, despite its effectiveness in enhancing the skeletal muscle area and RSMI in geriatric individuals with sarcopenia, the hybrid exercise program has limitations in terms of skeletal muscle intramuscular fat area. Third, we believe individual factors, such as the severity of sarcopenia and the activity habits of older people with sarcopenia, may influence the reversibility of sarcopenia. This study's sample size offers valuable insights, yet further validation in larger cohorts is recommended in alignment with the sample size guidelines proposed [82] for clinical prediction models prior to clinical implementation. By using initial sarcopenia in older individuals, reversal of sarcopenia, and interventions as foundational data, a more comprehensive system with diverse features may be developed in the future to provide specialized medical assistance to this patient population.

Conclusions

According to the results of our research, a combination exercise program consisting of SET and tai chi is capable of increasing muscle mass and reversing sarcopenia in older people effectively. In addition, the LightGBM classifier model performed better in determining if sarcopenia in older people can be reversed.

Acknowledgments

The Fundamental Research Funds for the Central Universities (135222026) funded our research.

Authors' Contributions

Data curation was handled by ZW, SH, and DM. Formal analysis was performed by ZW. Funding acquisition was carried out by GY. SH and MW was responsible for this study's investigation. ZW and DM aided in this study's methodology. MW and GY were involved in handling this study's resources. Supervision was done by GY. Writing of the original draft was worked on by HG, IY, XC, and JC. Review and editing of the writing was by HG, IY, XC, MW, ZW, and GY.

Abstract

Background: Walking is important for maintaining physical and mental well-being in aged residential care (ARC). Walking behaviors are not well characterized in ARC due to inconsistencies in assessment methods and metrics as well as limited research regarding the impact of care environment, cognition, or physical function on these behaviors. It is recommended that walking behaviors in ARC are assessed using validated digital methods that can capture low volumes of walking activity.

Objective: This study aims to characterize and compare accelerometry-derived walking behaviors in ARC residents across different care levels, cognitive abilities, and physical capacities.

Methods: A total of 306 ARC residents were recruited from the Staying UpRight randomized controlled trial from 3 care levels: rest home (n=164), hospital (n=117), and dementia care (n=25). Participants' cognitive status was classified as mild (n=87), moderate (n=128), or severe impairment (n=61); physical function was classified as high-moderate (n=74) and low-very low (n=222) using the Montreal Cognitive Assessment and the Short Physical Performance Battery cutoff scores, respectively. To assess walking, participants wore an accelerometer (Axivity AX3; dimensions: 23×32.5×7.6 mm; weight: 11 g; sampling rate: 100 Hz; range: ±8 g; and memory: 512 MB) on their lower back for 7 days. Outcomes included volume (ie, daily time spent walking, steps, and bouts), pattern (ie, mean walking bout duration and alpha), and variability (of bout length) of walking. Analysis of covariance was used to assess differences in walking behaviors between groups categorized by level of care, cognition, or physical function while controlling for age and sex. Tukey honest significant difference tests for multiple comparisons were used to determine where significant differences occurred. The effect sizes of group differences were calculated using Hedges *g* (0.2-0.4: small, 0.5-0.7: medium, and 0.8: large).

Results: Dementia care residents showed greater volumes of walking ($P<.001$; Hedges g=1.0-2.0), with longer ($P<.001$; Hedges g=0.7-0.8), more variable (P=.008 vs hospital; $P<.001$ vs rest home; Hedges g=0.6-0.9) bouts compared to other care levels with a lower alpha score (vs hospital: $P<.001$; Hedges g=0.9, vs rest home: P=.004; Hedges g=0.8). Residents with severe cognitive impairment took longer ($P<.001$; Hedges g=0.5-0.6), more variable ($P<.001$; Hedges g=0.4-0.6) bouts, compared to those with mild and moderate cognitive impairment. Residents with low-very low physical function had lower walking volumes (total walk time and bouts per day: $P<.001$; steps per day: P=.005; Hedges g=0.4-0.5) and higher variability (P=.04; Hedges g=0.2) compared to those with high-moderate capacity.

Conclusions: ARC residents across different levels of care, cognition, and physical function demonstrate different walking behaviors. However, ARC residents often present with varying levels of both cognitive and physical abilities, reflecting their complex multimorbid nature, which should be considered in further work. This work has demonstrated the importance of considering a nuanced framework of digital outcomes relating to volume, pattern, and variability of walking behaviors among ARC residents.

KEYWORDS

residential aged care facility; cognitive dysfunction; mobility limitation; accelerometry; physical activity; aged residential care

Introduction

Physical mobility, such as walking, is a key predictor of health [1] and is considered a multifaceted experience that interconnects the physical, mental, social, and emotional needs of an individual with their sense of self [2,3]. Loss of physical mobility (eg, reduced volume of walking) is associated with increased safety risks (eg, falls), social withdrawal, and poorer well-being [4,5]. Supporting residents' physical mobility in aged residential care (ARC) can decelerate the progression of disabilities and dependency [6]. ARC refers to long-term full-time residential care, which provides multiple levels of care depending on an individual's needs. Other common terms for ARC include assisted living facilities, care homes, and nursing homes. It is recommended that all residents who can ambulate, regardless of cognitive abilities, should increase their activity levels to support their functional independence [7]. Continuous remote digital monitoring of mobility outcomes has been proposed as a method to objectively quantify changes in walking behaviors. This approach will inform the development of interventions aimed at better supporting mobility, which is a key factor in influencing well-being and function in the older population [2].

Accelerometers are the most common method to continuously assess walking behaviors in ARC residents [8], with outcomes relating to volume (eg, steps per day) and intensity (eg, moderate-vigorous physical activity) of walking activities most frequently reported. Based on the current literature, ARC residents primarily participate in low volumes of light-intensity walking and show little variation in their walking behaviors [8]. Based on prevailing gaps in the literature, current recommendations for the assessment of walking behaviors in ARC include the use of validated digital methods that can capture very low volumes of activity, using low cutoff thresholds (eg, any walking activity ≥3 steps), and derive standardized outcomes relating to volume (ie, the amount or duration of walking activity), pattern (ie, the distribution of walking activity across a time period), and variability (ie, changes in walking activities—either within-person or group activities—and over time) of walking behaviors [8,9].

Using this nuanced framework, we can consider how different attributes impact discrete walking behaviors. For example, we previously found that better physical function was associated with higher walking volumes in ARC residents in intermediate (ie, rest homes) and high-level (ie, hospitals) care, while surprisingly, moderate dementia, mild depression, and pain had no effect on walking volumes [10]. In contrast, people with mild cognitive impairment in the community show no differences in walking volumes compared to people who undergo normal aging, but they do demonstrate different patterns and greater variability in their walking behaviors [9]. By looking beyond the volume of walking activities to pattern and variability, we may garner information about people's routines and the time they spend indoors and outdoors (based on walking bout lengths) [8,9,11-14]; we can then examine the impact of cognitive and physical impairments on these behaviors [14]. This information can contribute toward the development of more holistic interventions to support mobility in ARC.

Notably, ARC residents are a complex multimorbid population with significant variation in cognitive and physical function, often reflected in the level of care provided. These heterogeneities are not reflected in the literature regarding walking behaviors, highlighting a clear gap [8,15,16]. For example, Mc Ardle et al's [8] review on the quantification of ambulatory activities in ARC reported that 26% of studies excluded people with cognitive impairment and only 17% explicitly characterized walking activities in people with cognitive impairment, despite a 65%-70% prevalence of cognitive impairment in ARC residents [17,18]. Additionally, no studies compared different levels of care. As such, Mc Ardle et al [8] recommended that we must characterize and compare the volumes, patterns, and variability of walking behaviors in ARC residents across different care levels, with different cognitive and physical abilities. By characterizing walking behaviors in a representative group of ambulatory ARC residents, we can gain a better understanding of physical mobility in ARC, which will inform future interventions and policies to promote walking activities and support mobility and function in ARC residents.

To address the highlighted gaps and recommendations, the primary aim of this study was to digitally characterize and compare walking behaviors across different levels of ARC using a validated and standardized framework, encompassing volume, pattern, and variability of walking. Secondary aims of this study were to characterize and compare walking behaviors in ARC residents according to their cognitive status and physical function.

Methods

Participants

Residents from 24 ARC facilities in New Zealand were recruited as part of the Staying UpRight randomized controlled trial (RCT), which evaluated an exercise intervention to reduce fall risk [19]. Only baseline data are included in this study. Participants were included if they were aged ≥65 years and mobile (ie, able to walk and transfer independently or with supervisory assistance). Participants were receiving one of the following levels of care: hospital-level care (24-hour care by, or under the supervision of, a nurse), rest home–level care (24-hour health-related care but not nursing care), or dementia-level care (rest-home level care in a secure environment to minimize the risks associated with dementia).

We excluded residents in psychogeriatric, respite, or palliative care; residents unable to undertake the assessment or the exercise intervention in the main RCT because they were acutely unwell (eg, gastroenteritis), or immobile (ie, unable to mobilize without 2-person assistance or bed bound) were also excluded.

Ethical Considerations

Participants who were able to give informed written consent did so before enrollment, and the facility clinical lead provided written consent for residents unable to provide their own informed consent because of cognitive impairment. The study was conducted according to the guidelines of the Declaration of Helsinki. Ethics approval was provided by the New Zealand Health and Disability Ethics Committee on October 31, 2018 (NZHDEC 18/NTB/151).

Clinical and Cognitive Outcomes

Demographic information for ARC residents included the following: age, sex, and years spent in the ARC facility. Physical function was measured using Short Physical Performance Battery (SPPB) [20] and the Timed Up and Go test [21]. Cognitive ability was assessed using the Montreal Cognitive Assessment (MoCA) [22].

Assessment of Walking Behaviors

ARC residents were asked to wear a small body-worn accelerometer (Axivity AX3; dimensions: 23×32.5×7.6 mm; weight: 11 g; sampling rate: 100 Hz; range: ±8 g; and memory: 512 MB) on the fifth lumber vertebra on the lower back. The accelerometer was affixed onto the skin using a double-sided hydrogel adhesive and a hypoallergenic plaster (Hypafix BSN Medical Limited). This particular protocol has been found to be feasible for multisite studies [23] in different aging cohorts [11,13,24]. Of particular note, algorithms used in this study for walking bout detection have been validated in ARC residents, with high accuracy for start and end time [25].

Participants were asked to wear the accelerometer continuously for 7 days, including in the shower and to bed. Once the assessment was complete, data were downloaded to a computer and processed via a validated analytical pipeline in MATLAB.

Data Processing and Walking Behavior Outcomes

Signals from the accelerometer were transformed to a horizontal-vertical co-ordinate system. Walking bouts were identified by filtering raw acceleration data using a second-order low-pass Butterworth two-pass digital filter, with a cutoff frequency of 17 Hz, and by applying selective thresholds on the vector magnitude and standard deviations of triaxial acceleration signals [11,23,26,27]. Once walking bouts were identified, for detecting steps, raw acceleration signals were filtered with low-pass, fourth-order Butterworth filter with cutoff frequency of 20 Hz. A Gaussian continuous wavelet transform of vertical acceleration was then applied to identify initial and final contacts, allowing the identification of steps. For each walking bout, total steps per bout and bout length were calculated. Sleep, lying, and sitting data were excluded based on the thresholds applied on the magnitude and standard of the accelerometry signal used to identify walking (eg, vertical acceleration, in a vertical position, needs to be −1 g and acceleration magnitude or standard needs to exceed these thresholds to be classified as walking). For sleep, the magnitude and standard of acceleration would be lower and the vertical acceleration would not be −1 g, so the position (orientation) excludes sleep, lying, or sitting.

A framework of walking behaviors was derived to remain consistent with previous literature [11,12,23,26], including volume, pattern, and variability of walking. Volume characteristics included total minutes spent walking as well as steps and bouts per day. Pattern characteristics included mean bout duration and alpha, which is derived by logarithmic transformation of bout density and length and is based on shape and power-law distribution [28,29]; alpha refers to the ratio of short to long walking bouts, which are scaled relative to an individual's shortest walking bout. A high alpha score indicates that an individual's total walking time is composed of proportionally shorter walking bouts compared to long walking bouts. Variability (S_2) refers to the variability of bout duration between walking bouts, estimating how much an individual's bout duration changes over the time period of data collection, and it was estimated using the maximum likelihood technique (previously described by Mc Ardle et al and Del Din [9,13]. The proportion of walking bouts taken in very short (<10 s), short (10-30 s), medium (30-60 s), and prolonged (>60 s) walks were calculated. These walking bout thresholds have been used commonly in other studies of a similar nature and provide contextual information regarding how walking takes place [13,30,31].

Considerations for Inclusion of Data

Given that most habitual walking takes place in <10-second bouts [13,32,33], we applied a minimum bout duration of 3 consecutive steps, and any period of rest that was ≥2.5 seconds was considered resting time [32]. Additionally, we included participants if they had ≥2 days of continuous walking activity data collected, as this is the minimum number of days required to reliably quantify our primary outcomes (ie, the volume of walking) across different care levels, based on Buckley et al [27].

Data Analysis

For demographic variables, chi-square tests and Fisher exact test were used to determine differences between groups for nominal variables, while one-way ANOVA was used to determine between-group differences for continuous variables; post hoc Tukey honest significant difference (HSD) tests determined where the differences lay.

Prior to statistical analysis relating to our primary and secondary aims, walking activity data were inspected visually using box plots, and outliers were identified. Separate analyses of covariance were used to assess differences in walking behaviors between groups categorized by level of care, cognition, or physical function while controlling for age and sex. Tukey HSD tests for multiple comparisons were used to determine where significant differences occurred. Sensitivity analysis was conducted by removing outliers more than 1.5 times above the third quartile or below the first quartile and by conducting the analysis of covariance and subsequent post hoc tests for each discrete grouping separately (eg, level of care, cognition, or physical function).

The effect size of group differences was calculated using the Hedges *g* formula to account for disparities between groups' sample sizes [34]. Effect sizes are interpreted as follows: 0.2-0.4:

small, 0.5-0.7: medium, and ≥0.8: large. Assumptions were evaluated (eg, normality of residuals) for all models, and statistical significance was defined as a $P<.05$.

Cognitive levels were assessed and categorized using MoCA cutoff scores, as follows: cognitively intact (MoCA ≥26), mild cognitive impairment (MoCA 18-25), moderate cognitive impairment (MoCA 10-17), and severe cognitive impairment (MoCA <10) [35]. Cognitively intact participants were excluded from the cognitive impairment severity analysis due to the small sample size but retained for illustrative purposes in Figures. Physical function levels were assessed and categorized using the SPPB cutoff scores, as follows: high-moderate function (SPPB 12-7) or low-very low function (SPPB <7) [36].

Results

Demographic Information

A total of 306 ARC residents were included in this analysis and were primarily grouped according to their level of care (Table 1). Figure 1 outlines reasons for exclusion and inclusion of participants for this secondary analysis from the Staying UpRight RCT. Hospital-level care residents had lower physical function compared to rest home–level care residents ($P=.01$) and took a longer time to complete the Timed Up and Go test compared to rest home–level ($P<.001$) and dementia-level ($P=.03$) residents. MoCA scores were significantly lower in dementia-level residents compared to rest home–level and hospital-level care residents ($P<.001$).

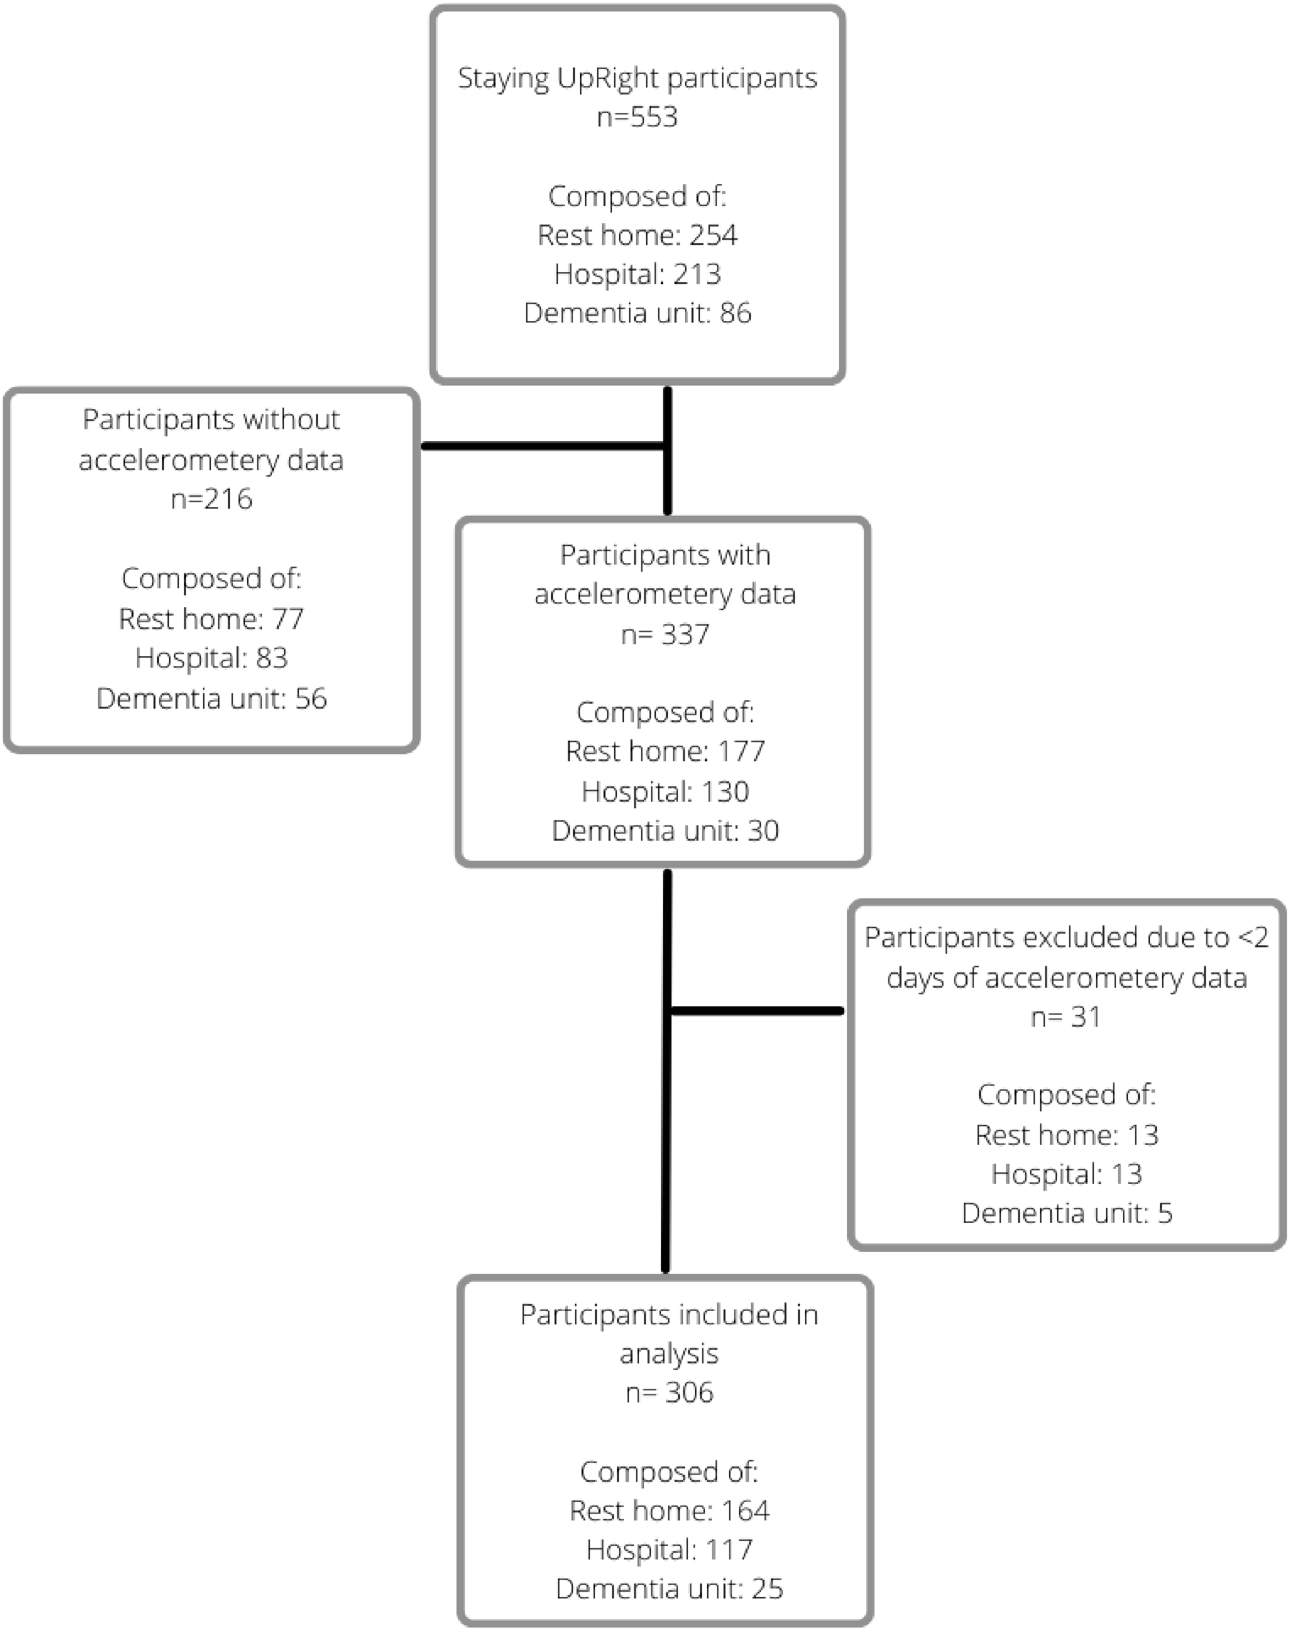
Figure 1. Flowchart for inclusion of participants in this analysis.



Walking Behaviors Across Care Levels

Dementia care residents demonstrated higher volumes of walking, with longer, more variable bout durations and lower alpha scores compared to residents in both rest homes and hospitals (moderate to large effect sizes). Residents in rest homes also showed higher volumes of walking compared to those in hospitals (small effect sizes). Table 2 provides further details; Multimedia Appendix 1 provides *P* values for post hoc tests and details regarding effect sizes. Notably, sensitivity analysis indicated that variability of walking bout length did not differ between groups following the removal of outliers (*P*=.16).

Table . Characterization of walking behaviors, categorized by level of care (N=306).

Characteristics		Hospital (n=117)	Rest home (n=164)	Dementia care (n=25)	Overall *P* value[a]
Walk time per day (min), mean (SD)		58 (37)[b,c]	74 (39)[b,d]	137 (59)[c,d]	<.001
Steps per day, mean (SD)		4138 (2766)[b,c]	5216 (2925)[b,d]	10,886 (5453)[c,d]	<.001
Bouts per day, mean (SD)		256 (165)[b,c]	321 (160)[b,d]	496 (238)[c,d]	<.001
Mean bout duration (s), mean (SD)		13.9 (3.6)[c]	14.1 (3.3)[d]	20.1 (20.4)[c,d]	<.001
Variability, mean (SD)		0.81 (0.11)[c]	0.80 (0.09)[d]	0.89 (0.18)[c,d]	.002
Alpha score, mean (SD)		1.68 (0.08)[c]	1.67 (0.07)[d]	1.61 (0.09)[c,d]	<.001
Distribution of walking bouts by discrete walking bout length (%), mean (SD)					
	<10-second bouts	65 (8)[c]	64 (8)[d]	56 (10)[c,d]	<.001
	10- to 30-second bouts	25.9 (5.5)[c]	27.6 (5.5)[d]	30.8 (5.8)[c,d]	<.001
	30- to 60-second bouts	5.81 (3.05)[c]	5.51 (2.42)[d]	8.64 (3.64)[c,d]	<.001
	>60-second bouts	3.20 (2.13)[c]	3.15 (2.06)[d]	4.82 (4.92)[c,d]	.01

[a] One-way ANOVA, controlling for age and sex.

[b] Hospital vs rest home.

[c] Hospital vs dementia care.

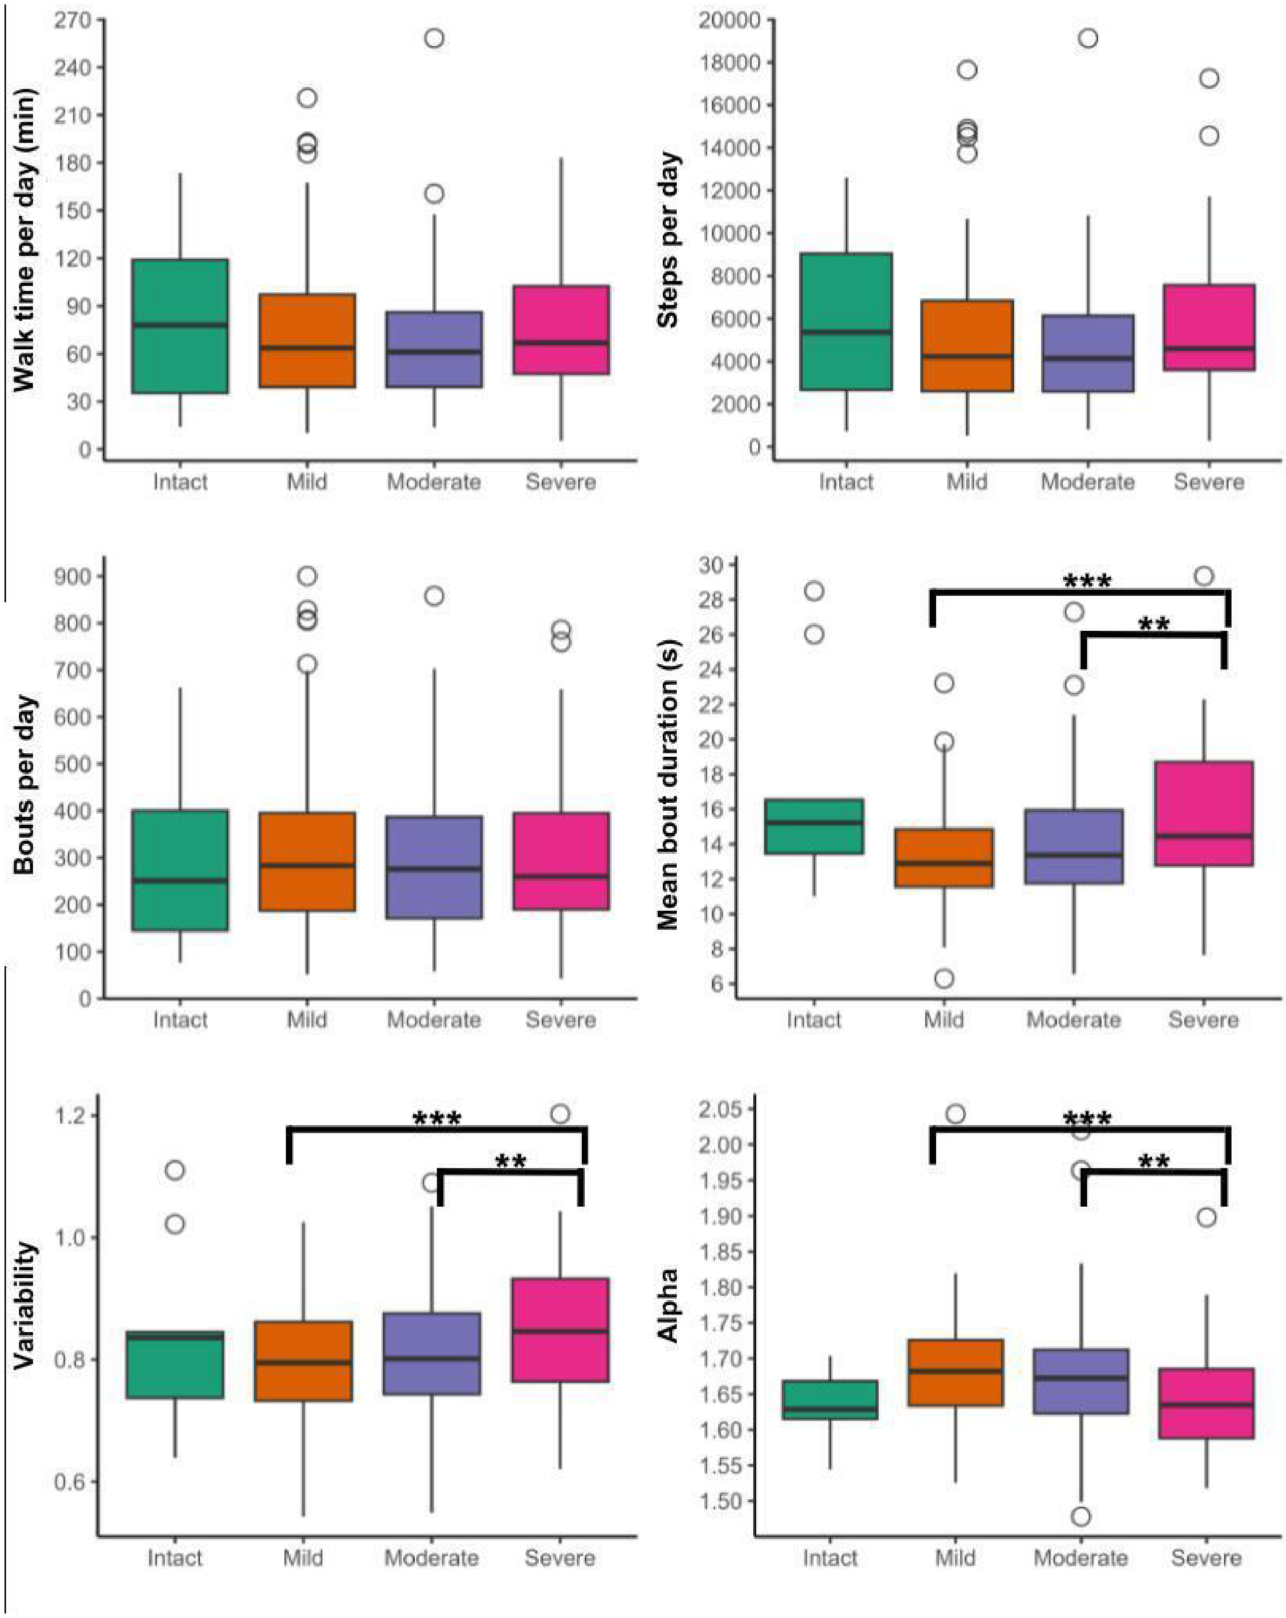
[d] Rest home vs dementia care.

Additionally, dementia care residents spent a significantly lower percentage of their walking bouts in very short bouts (eg, <10 s) and a greater percentage in short, medium, and prolonged walking bouts compared to residents in other care levels (moderate to large effect sizes; Table 2).

Walking Behaviors Across Cognitive Impairment Severities

There were no significant differences between cognitive groups for any volume characteristics (Figure 2 and Multimedia Appendix 2). People with severe cognitive impairment took longer, more variable walking bouts with a lower alpha score compared to those with mild (moderate to large effect sizes) and moderate cognitive impairment (small to moderate effect sizes). Figure 2 and Multimedia Appendix 2 provide further details.

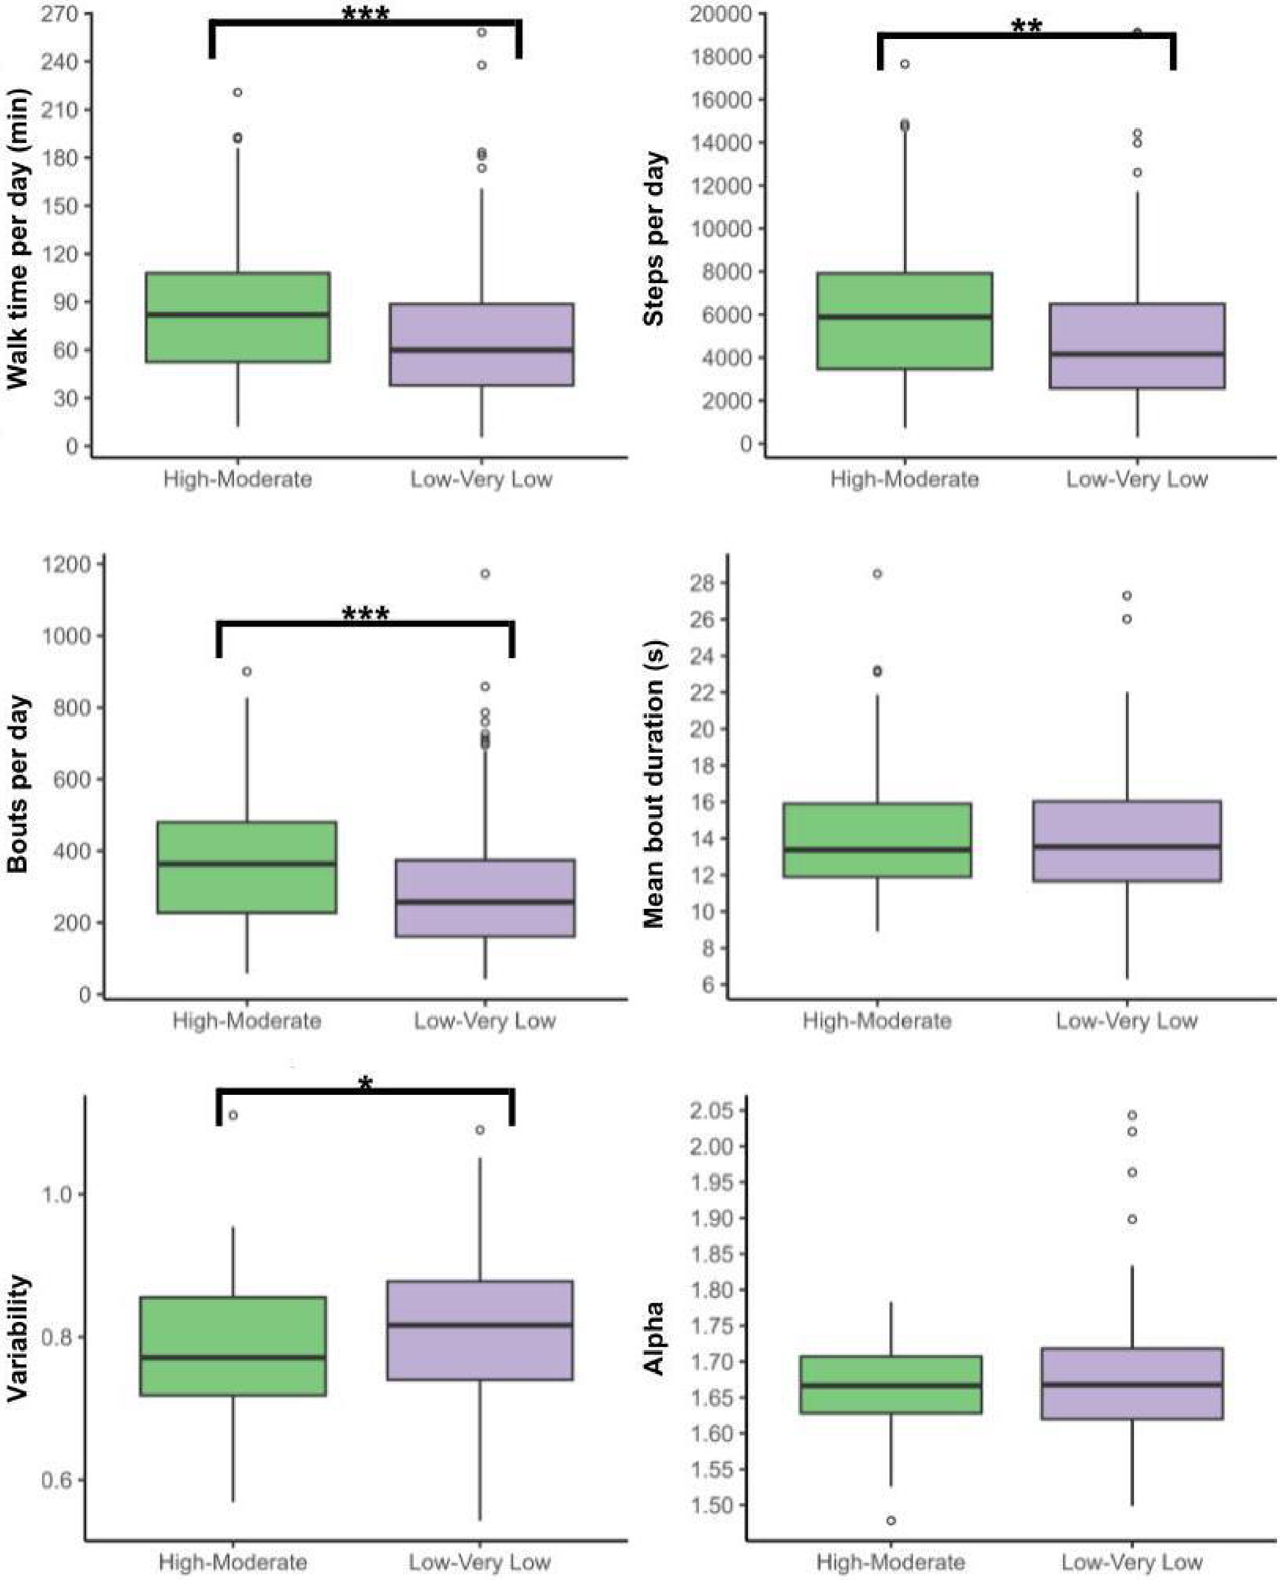
Figure 2. Volume, pattern, and variability of walking behaviors across cognitive groups. ***P≤.001; **P≤.01.



Walking Behaviors Across Physical Function Levels

ARC residents with high-moderate physical function spent more time walking and took more steps and bouts per day, with less variability for bout length, compared to those with low-very low physical function (Figure 3 and Multimedia Appendix 3 present further details).

Figure 3. Volume, pattern, and variability of walking behaviors across physical function groups. ***$P≤.001$; **$P≤.01$.



Discussion

Principal Findings

This is the first study to describe the volume, pattern, and variability of walking behaviors in ARC, captured by an accelerometer, with consideration of different care levels, cognitive abilities, and physical function, reflecting the typical population of residents. Key findings highlight that dementia care residents have significantly higher volumes of walking, take longer and more variable walking bouts on average, and spend proportionately more of their walking time in prolonged bouts of walking compared to rest home and hospital levels of care. Although the volume of walking is similar across different levels of cognitive impairment severity, people with more severe cognitive impairment show different patterns (eg, longer walking bouts) and greater variability compared to those who are less cognitively impaired. In contrast, people with lower physical function have significantly lower volumes of walking and higher variability of walking bout lengths but do not differ in terms of the pattern of this activity. ARC residents are a complex multimorbid population who often present with varying levels of both cognitive and physical abilities, and these nuances should be considered in further research aiming to improve mobility and reduce fall risk.

Walking Behaviors Across Different Care Environments

This is the first study to show that people living in a dementia unit participate in higher volumes of walking, with different patterns (ie, longer walking bouts) and greater variability compared to other ARC environments, with medium to large effect sizes. However, differences between groups for the variability of walking bout length disappeared following the removal of significant outliers, therefore, results should be interpreted with caution. As physical function scores are comparable between the dementia care and rest home residents (Table 1), the differences in walking behaviors may illustrate a behavioral component of dementia (eg, wandering—a dementia-related locomotor behavior involving frequent and repetitive movements, such as pacing). Objective remote monitoring of wandering behaviors using digital methods has previously been proposed to detect and monitor wandering behaviors [37,38]. We propose that variability of walking bout lengths should be considered in future research in this area, as it may reflect wandering behaviors[39]; clinical validation is required to investigate this hypothesis.

Contrary to our findings, baseline results from one previous RCT reported very low volumes of walking activity in dementia care units, showing <400 steps in one 24-hour period assessed via an activity armband [40]. However, these studies are difficult to compare due to differences in device location (ie, lower back compared to arm) and data collection periods. Moyle et al [40] noted that these activity armbands were unreliable and resulted in large amounts of missing data. Additionally, high volumes of walking activity reported here (eg, >4000 steps per day) are likely due to our low cutoff thresholds for defining walking activity, as most walking takes place in very short walking bouts in this population. The cutoff threshold applied to characterize walking behaviors can make significant differences in the volume of walking captured—with differences ranging from 2000 to 10,000 steps in previous literature [30]. This study has expanded beyond simple volume metrics and highlighted the importance of selecting validated and sensitive digital methods when assessing walking behaviors in this population [8].

Walking Behavior Across Cognitive Impairment Severity and Physical Capacities

This is the first study to demonstrate that people with severe cognitive impairment have similar volumes but significantly different patterns (ie, longer bouts) and greater variability of walking compared to less cognitively impaired groups, suggesting that although cognition does not influence the amount of activity, it may change the way this activity is carried out. This finding is supported by and extends our previous work, which excluded dementia care residents and highlighted that while worse physical function is associated with lower volumes of walking in ARC, cognitive impairment showed no effect on walking volume [10]. Perhaps this indicates that pattern and variability of walking behaviors are cognitively mediated outcomes and may be useful to monitor in ARC as a proxy for cognitive decline. For example, in line with our results from the dementia care unit, the literature indicates that people with severe dementia are more likely to wander [41] and we propose that this is reflected in the pattern and variability of walking. Longer walking bouts and higher variability of bout length are considered positive outcomes in cognitively healthy individuals, indicative of dynamic and varied routines [11], but perhaps higher variability in tandem with significant cognitive impairment is more reflective of repetitive lapping behaviors (ie, wandering). Clinical validation is required to address this speculation. Differences in pattern of walking behaviors have previously been reported between community-dwellers with mild cognitive impairment and normal aging [42], supporting the hypothesis that cognitive decline may influence these behaviors.

In contrast, people with worse physical function have significantly lower volumes of walking but show no differences in pattern or variability compared to those with better physical function. The association between higher walking volumes and better physical function confirms the findings of previous studies [43,44]. However, the cross-sectional design of this study precludes commentary on the direction of causality. Although from our results, we cannot determine if encouraging walking as part of a resident's daily activities can result in clinically meaningful improvements in function, previous research demonstrated that function-focused care (ie, increasing routine activities) leads to increased activity volumes and improved functional outcomes in ARC residents with moderate functional dependency [44] but not in dementia residents with severe functional dependency [45]. However, pattern and variability of walking are considered to reflect daily routines, and the effects of function-focused care may be more readily observed in these outcomes rather than in volume, especially in individuals with severe cognitive impairment. Additionally, marginal increases in the duration and variability of walking bouts may lead to significant improvements in function [28] and should be considered in very frail residents. These hypotheses could be considered in future intervention studies, with consideration for the multimorbid nature and varying levels of both cognitive and physical issues inherent in ARC residents.

Strengths and Limitations

Strengths of this study were the large sample, drawn from multiple facilities, distributed across 3 levels of care and encompassing a broad spectrum of cognitive and physical capacities. This is particularly notable, as there can be significant difficulties in collecting data using wearable technology from people with dementia in ARC facilities [29]. We used a technically appropriate digital method to collect low volumes of walking data¸ meeting the recommendations from Mc Ardle et al [8]. Additionally, we used a standardized framework to characterize walking behaviors, making our findings comparable to multiple other cohorts and enhancing our understanding of walking behaviors across the spectrum of care and cognition [11,12]. We addressed the reliability of our primary outcomes based on previous empirical evidence [27].

Our study has several limitations. Residents were only included if they could ambulate, and residents who could not complete the MoCA or SPPB were not included in our secondary analysis; therefore, we may have reduced representation of different levels of cognitive and physical capacities. Although this is only the second study to specifically characterize walking activity in a dementia care unit [8], it should be noted that our sample size for this group was low and likely to have limited statistical power; therefore, statistical analysis was exploratory and results should be considered with that in mind. This is a cross-sectional study; therefore, assessing changes in walking activity over time or establishing causality of influences on walking activity is not possible; in the future, a longitudinal study may offer valuable insights into predictors of walking behaviors in ARC. Although we adjusted for multiple corrections within statistical models (ie, Tukey HSD tests), we did not adjust for multiple comparisons for multiple outcomes, and there may be a risk of type I error. We also included participants with ≥2 days of walking activity data, as this is the number of days required to obtain reliable volume outcomes (ie, our primary outcome) in ARC [27]; however, our secondary outcomes of pattern and variability require 2-5 days of data to ensure reliability, pending on the discrete variable, and thus, results should be interpreted with caution. Although commonly assessed in ARC [8], we did not include outcomes relating to the intensity of walking activity, as this has been suggested to be inappropriate to characterize in this population, given that ARC residents primarily engage only in light-intensity activities [8]. Additionally, the ARC facilities included in this study reflect a New Zealand context, and findings may be different in other countries due to alternative organizational features and policies [46]. We recognize that apart from resident-related factors of physical function and cognition, walking activity may be influenced by the physical and organizational environment [46]—aspects that were not measured in our study. As previously noted, ARC residents may have varying levels of both cognitive and physical impairments, and the combined spectrum should be considered in future research. Finally, digital outcomes beyond those described in this analysis can provide important clinical information about ARC residents and should be considered in future research. For example, sleep disturbances can be measured using actigraphy. Sleep disturbances are common in people living in ARC and are associated with neuropsychiatric symptoms and prescription of psychotropic drugs, which can enhance fall risks and greater staff distress [47]. Although it is beyond the scope of this study, further research may consider using qualitative approaches to complement current findings and the wider literature [8], which would allow us to garner rich insights from ARC residents regarding which digital outcomes relate to their lived experiences and are meaningful to assess.

Conclusions

This is the first study to show the influence of care environment, cognitive status, and physical function on walking behaviors in ARC residents. Our results indicate that cognitive and physical abilities may discretely impact the volumes, pattern, and variability of walking. This work has addressed a significant gap in the literature and has generated new hypotheses regarding which digitally derived walking outcomes are meaningful to assess in ARC residents.

Acknowledgments

The study has been funded by a Health Research Council of New Zealand project grant (reference 18/414). The study funder plays no role in study design, data collection, or analyses.

RMA received funding from the National Institute for Health and Care Research (NIHR) for her fellowship (NIHR 301677). SDD and LR were supported by the Innovative Medicines Initiative 2 Joint Undertaking (IMI2 JU) project IDEA-FAST (grant agreement 853981). This joint undertaking (JU) receives support from the European Union's Horizon 2020 research and innovation program and the European Federation of Pharmaceutical Industries and Associations (EFPIA). SDD and LR were also supported by the Mobilise-D project, which has received funding from the Innovative Medicines Initiative 2 JU (grant agreement 820820). RMA, SDD, and LR were supported by the NIHR Newcastle Biomedical Research Centre (BRC) based at The Newcastle Upon Tyne Hospital National Health Service (NHS) Foundation Trust, Newcastle University, and the Cumbria, Northumberland and Tyne and Wear (CNTW) NHS Foundation Trust. SDD and LR were supported by the NIHR/Wellcome Trust Clinical Research Facility (CRF) infrastructure at Newcastle Upon Tyne Hospitals NHS Foundation Trust.

All opinions are those of the authors and not the funders.

The authors would like to acknowledge the care home residents who participated in this study and the study research assistants for their time in data collection and analysis.

Authors' Contributions

RMA, LT, LR, SDD, and NK contributed to the conceptualization and design of the study as well as data analysis and interpretation. RMA, LT, and SDD were in charge of data curation. RMA conducted data analysis and statistical work. AC provided support for statistical work. RMA and LT wrote the original draft. RMA, LT, LR, AC, SDD, and NK wrote the draft, reviewed, and edited it. All authors approved the final version of this manuscript. RMA and LT contributed equally to this manuscript; SDD and NK also contributed equally to this manuscript.

Conflicts of Interest

SDD reports consultancy activity with Hoffmann-La Roche Ltd. LR consults for MJ Fox Foundation for service on Endpoints Advisory Committee.

Abstract

Background: The use of mobile apps has promoted physical activity levels. Recently, with an increasing number of older adults accessing the internet, app-based interventions may be feasible in older populations. Peer support–based interventions have become a common method for promoting health-related behavior change. To our knowledge, the feasibility of using digital peer support apps (DPSAs) to increase physical activity among older adults and its impact on physical activity and physical function have not been investigated.

Objective: This study aims to assess the feasibility of using DPSAs in older adults and to assess changes in physical activity and physical function in DPSA users.

Methods: We conducted a nonrandomized controlled trial of older adults aged ≥65 years. We recruited participants for 2 distinct 12-week programs designed to increase physical activity. Participants could choose between an intervention group (app program and exercise instruction) or a control group (exercise instruction only). DPSA creates a group chat for up to 5 people with a common goal, and participants anonymously post to each other in the group. Once a day, participants posted a set of their step counts, photos, and comments on a group chat box. The intervention group used the DPSA after receiving 2 face-to-face lectures on its use. The participants were characterized using questionnaires, accelerometers, and physical function assessments. The feasibility of the DPSA was assessed using retention and adherence rates. Physical activity was assessed using accelerometers to measure the daily step count, light intensity physical activity, moderate to vigorous intensity physical activity (MVPA), and sedentary behavior. Physical function was assessed using grip strength and the 30-second chair-stand test.

Results: The participants in the intervention group were more frequent users of apps, were more familiar with information and communication technology, and had a higher baseline physical activity level. The retention and adherence rates for the DPSA intervention were 88% (36/41) and 87.7%, respectively, indicating good feasibility. Participants in the intervention group increased their step count by at least 1000 steps and their MVPA by at least 10 minutes using the DPSA. There was a significant difference in the interaction between groups and intervention time points in the daily step count and MVPA (step count, *P*=.04; duration of MVPA, *P*=.02). The DPSA increased physical activity, especially in older adults with low baseline physical activity levels.

Conclusions: The feasibility of DPSA was found to be good, with the intervention group showing increases in daily steps and MVPA. The effects of DPSA on step count, physical activity, and physical function in older adults with low baseline physical activity should be investigated using randomized controlled trials.

Introduction

Background

The health benefits of regular physical activity are familiar [1]. Physical activity reduces the risk of chronic diseases such as type 2 diabetes, cardiovascular disease, and hypertension [2-4]. In addition, physical activity improves the overall physical and mental functioning and controls morbidity and mortality rates [5,6]. However, globally, the level of physical activity has remained stable or declined, despite several efforts to promote physical activity [7,8]. In addition, social distancing during the COVID-19 pandemic has caused changes in lifestyle and social behavior [9]. The level of physical activity among older adults in Japan is reported to have declined due to the COVID-19 pandemic [10,11] and needs to be increased.

Recently, mobile apps have been used successfully to increase physical activity levels [12,13]. eHealth encompasses health care services and information delivered with the aid of information and communication technology (ICT), including computers, mobile phones, and satellite communications. Mobile health (mHealth) refers to the use of smart or portable devices for providing health services and information [14]. With an increase in the population of older adults using the internet, mHealth and eHealth approaches may be feasible [15,16]. A total of 3 out of 4 reviews concluded that mHealth or eHealth interventions are effective in the short term in promoting physical activity in adults aged ≥50 years [17]. Furthermore, eHealth interventions targeting physical activity have revealed that theory-based interventions are more effective than interventions that are not grounded in theory [18]. However, there has been limited focus on social cognitive theory–based interventions aimed at promoting physical activity among older adults through peer support.

Peer support–based interventions have become a common method for promoting health-related behavior change [19]. Webel et al [20] defined peer support as “a method of teaching or facilitating health promotion that makes use of people sharing specific health messages with members of their own community.” The effectiveness of peer support–based interventions for physical activity has a theoretical basis, often explained by social cognitive theory [21]. The social cognitive theory proposed by Bandura [22] stipulates that behavior is learned by observing and imitating others. This process is called observational learning or modeling and has been extensively studied in the context of motor skill development and education. Peer-mediated delivery of information regarding physical activity through apps could facilitate attention, retention, and motivation to work on that information, as per social cognitive theory. Liu and Lachman [23] conducted a 4-week randomized controlled trial based on social cognitive theory in which older adults aged ≥60 years used the WeChat and WeRun apps to increase their step counts by recording and exchanging them through SMS text messages. This social engagement through SMS text messages increased the step count. However, the step count was the only physical activity outcome measure, and the effect of the intervention on physical activity intensity, sedentary behavior (SB), and physical function was not assessed. Therefore, using an app based on social cognitive theory, we examined the effects of a digital peer-supported intervention on step counts, physical activity intensity, SB, and physical function among older adults aged ≥65 years.

Objective

This study used a digital peer-supported app (DPSA) to conduct a 12-week intervention study on older adults aged ≥65 years. The objectives of this study were threefold: (1) to understand the characteristics of older adults who choose to use the DPSA to increase their physical activity; (2) to evaluate the feasibility of using the DPSA to promote physical activity in older adults; and (3) to measure the effect of using the DPSA on users’ level of physical activity, SB, physical function, and self-efficacy for exercise.

Methods

Study Design

This nonrandomized pretest-posttest comparison trial of 2 groups was conducted in Fujisawa City, Kanagawa Prefecture, Japan. In April 2022, the city had an area of 69.57 km^2 and a population of 442,892, of whom 108,472 (24.49%) were aged ≥65 years. The study was conducted as an industry-government-academia collaboration between the local government, an app-making company, and a university.

Ethical Considerations

The study was approved by the Research Ethics Committee of Sports Medicine Research Center at Keio University (approval number 2022-07). Informed consent was obtained from all participants. The study protocol was registered with the University Hospital Medical Information Network (UMIN000050618).

Participants

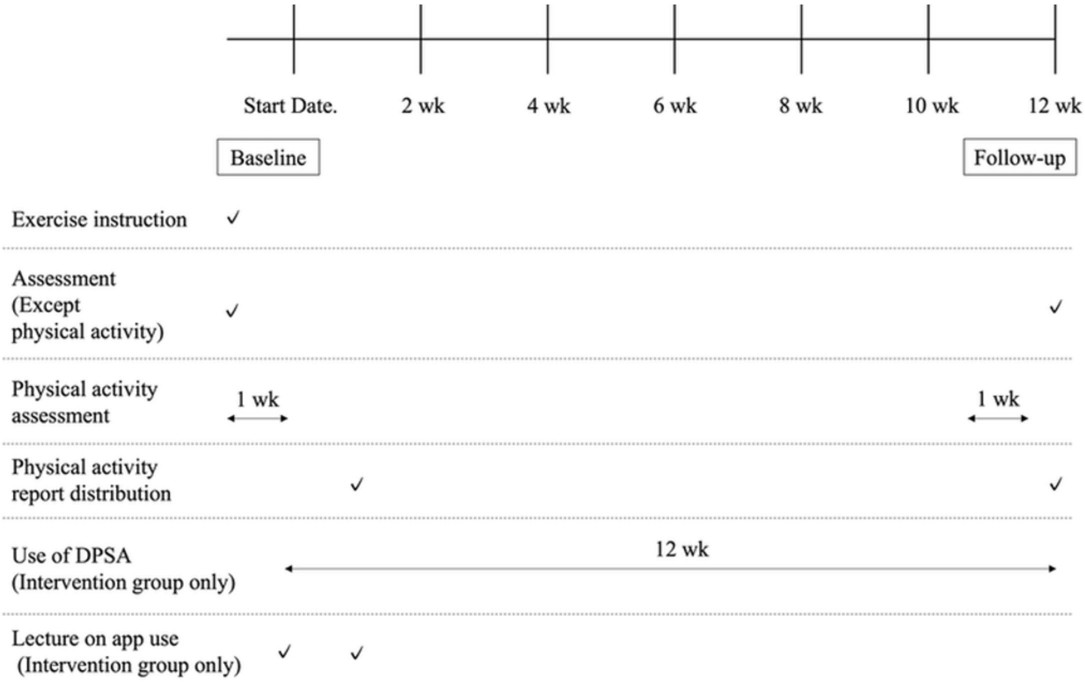
The study was conducted on Fujisawa City older adults aged ≥65 years. We recruited participants for 2 distinct 12-week programs designed to increase physical activity. Participants could choose between an intervention group (app program and exercise instruction) and a control group (exercise instruction only). Participants from different areas within the municipality were recruited through flyers, publicity, and calls to related organizations. The intervention was implemented in two phases: (1) from October 2022 to January 2023 and (2) from December 2022 to March 2023. Participants selected programs according to their preferences (the app program was for smartphone owners only). The eligibility criteria were older adults aged ≥65 years, who were able to walk independently and perform other activities of daily living and had not been advised to refrain from physical activity by a physician. Before participation, prospective participants were screened using a personal health status questionnaire based on the Physical Activity Readiness Questionnaire [24-26] to ascertain whether there were any potential problems with participation in the study. Because older adults are generally assumed to be less familiar with smartphones and apps than younger adults [27] and may not be able to completely use the DPSA, we provided 2 lectures about using the app; 1 lecture was conducted at the start of the DPSA use, and another was conducted 1 week later. Participants were instructed to download the app, and its use was explained during the first lecture. Each lecture lasted for 1 to 1.5 hours, and the participants were able to receive instructions directly from the instructor and ask questions.

Intervention

Program

The timeline of the study procedure is presented in Figure 1. Regardless of program selection, all participants participated in face-to-face exercise instruction, program introduction, and baseline assessment conducted by a physical therapist or a health fitness instructor. Exercise instructions focused on aerobic, stretching, muscle strengthening, and balance exercises based on the original “Fujisawa +10 exercise” program [28,29]. Exercise instruction was provided for 15 minutes for the intervention group and 30 minutes for the control group. Both intervention and control groups were instructed to increase their daily physical activity. Participants completed questionnaires and underwent physical activity and physical function assessments using a triaxial accelerometer at baseline (start date) and during follow-up (weeks 10-12). Individual physical activity reports were generated from the data obtained and fed back to the participants. The intervention group began using the app 1 week after the baseline outcome assessment was conducted. The timing of the evaluation of each measurement item is described in Multimedia Appendix 1.

Figure 1. Timeline of study procedures. DSPA: digital peer support app; wk: weeks.



DPSA Intervention

The study was conducted using Minchalle (A10 Lab Inc), a commercially available DPSA [30]. This app was developed in June 2015 and launched in November 2015. Figure 2 shows example screens from the app. The DPSA creates a group chat for up to 5 people with a common goal, and participants anonymously post messages to each other in the group. The common goal of the intervention group was to increase physical activity through walking and exercise. Once a day, participants posted a set of their step counts, photos, and comments on a group chat box. The main functions of the DPSA used in this study were to enable the participants to (1) post step counts, photos, and comments about the day; (2) post approvals from group members to each other’s postings; (3) set step count goals on a group basis; and (4) get feedback on the team’s total daily step count. Step counts were measured using a smartphone, with the DPSA reporting the number of steps taken on the day at the time of posting. Participants had the option to post comments or photos multiple times a day and engage with other members, although this was not mandatory. The app was available for participants to use free of charge.

Figure 2. Examples of app screens. (A) Select a group. (B) Post photos, step count, and comments on the group. Post a photo taken that day and comment on the day's events. (C) The contents of the posts are displayed in the group. The total number of steps for the group is displayed. (D) Response to posts by group members.

Measurements

Demographic Characteristics of Participants

In addition to general characteristics such as age and sex, the survey asked about smartphone ownership, the frequency of app use, exercise habits, the frequency of neighborhood interaction, participation in group exercise, history of falls in the past year, the effect of the COVID-19 pandemic on their level of physical activity, self-reported decrease in walking speed, the use of ICT, and self-efficacy for exercise.

Participant's body weight (kg) was measured using a digital scale, and height (m) was measured on a stadiometer after participants removed their shoes. BMI was then calculated as body weight divided by the square of height.

Exercise habits were defined as "those who exercise at least twice a week, for at least 30 minutes each time, for at least one year" [31].

The frequency of neighborhood interaction was assessed by asking how many times one interacts with people in the neighborhood within 1 week.

Group exercise participation was defined as those who participate in a group of three or more people who meet voluntarily to exercise.

Information about the use of ICT was collected using questions about "Gathering information and shopping on the internet," "Using social networking services (Facebook, LINE, Instagram, etc)," and "Do not use any information devices." The percentages for the intervention and control groups were compared with representative values from the Annual Report on the Ageing Society, published by the Japanese Cabinet Office, to determine the extent to which participants are using ICT compared with other older adults [32].

Outcome Measures of Participants

To assess physical activity, participants were asked to wear a triaxial accelerometer [33] (Active Style Pro HJA-750C Activity Meter, Omron Health Care) at waist level for 7 consecutive days before the intervention and 10 to 11 weeks after the intervention commenced. The accelerometer display was configured to prevent users from viewing the amount of physical activity for the day. Participants were instructed not to remove the device unless required for certain tasks, such as changing their clothes and bathing. At the end of the measurement, all the data collected were transferred from the accelerometer to a PC. Following the method suggested by Jefferis et al [34] for estimating physical activity, an individual needed to record at least 10 hours of activity per day for 3 days to be included in the subsequent analyses. The data were collected in 60-second epochs for data analysis and used to estimate the intensity of activity in metabolic equivalents (METs). The mean daily step count and time spent in SB (≤1.5 METs), light intensity physical activity (LPA; 1.6-2.9 METs), and moderate to vigorous intensity physical activity (MVPA: ≥3 METs) per day were used for outcome measurements of physical activity.

Physical function was assessed using grip strength and the 30-second chair-stand test (CS-30). Grip strength was measured using a digital dynamometer (Grip D, TKK 5401, Takei Scientific Instruments). Measurements were taken in the standing position, with the elbow joint in extension and the wrist joint in midextension. Both the left and right hands were measured once each, and the maximum value was used. For the CS-30 test [35], seated participants were instructed to stand up from the chair with their arms crossed at chest level as many times as possible in 30 seconds.

Self-efficacy for exercise was assessed using 4 questions pertaining to participants' self-confidence in exercising under each of the following conditions [36]: "Do you have the confidence to exercise regularly under the following conditions? physical fatigue, mental stress, lack of time, and bad weather."

In response to the question, participants were asked to select 1 of the 5 answers ranging from "No, I don't have any confidence at all (1 point)" to "Yes, I am quite confident (5 points)." The total score ranged from 4 to 20. Textbox 1 summarizes the measures related to the characteristics of the participants.

Textbox 1. Measurements related to participant characteristics.

Measurement methods and items

- Questionnaire
  - Age, sex, living alone, self-rated health, perceived household economic status, life satisfaction, employment status, smartphone ownership, frequency of app use, exercise habits, frequency of neighborhood interaction, participation in group exercise, history of falls in the past year, effect of the COVID-19 pandemic on decreased physical activity, self-reported decrease in walking speed, and self-efficacy for exercise
- Triaxial accelerometer
  - Steps, light intensity physical activity, moderate to vigorous intensity physical activity, and sedentary behavior
- Physical function assessment
  - BMI, grip strength, and 30-second chair-stand test

Feasibility of DPSA Intervention

The feasibility of DPSA intervention was assessed by retention and adherence rates during the 12-week program implementation. The DPSA could exclude a person from a group if they have not posted a set of their step counts, photos, and comments for 15 consecutive days. Dropouts were defined as those who were excluded from the group during the 12 weeks of DPSA intervention. The retention rate was calculated using a denominator of 41 participants including those who withdrew consent. The adherence rate of DPSA intervention was calculated by dividing the number of sets of their step counts, photos, and comments posted during the intervention period by the duration of the intervention. DPSA adherence rates were also calculated by group (9 groups: A-I). The number of all chat posts per person by group was calculated to assess group use. Negative physical effects that occurred during the intervention were ascertained by interviewing the participants during follow-up. We report on privacy breaches and technical problems with the app. Privacy breaches were identified by the municipality, and technical problems were identified by the app company. Continuity was evaluated using a questionnaire on factors that contributed to exercise continuation by the DPSA and the intention to continue using the DPSA after 12 weeks.

Changes in Physical Activity, SB, Physical Function, and Self-Efficacy for Exercise

Physical activity (step count, LPA, MVPA, and SB); physical function (grip strength and CS-30); and self-efficacy for exercise were assessed at 2 time points: baseline and follow-up. The follow-up data were measured in the same way as at baseline. For follow-up data, physical activity was measured between weeks 10 and 11 of the intervention. Physical function and self-efficacy for exercise were measured after 12 weeks of the intervention.

Statistical Analysis

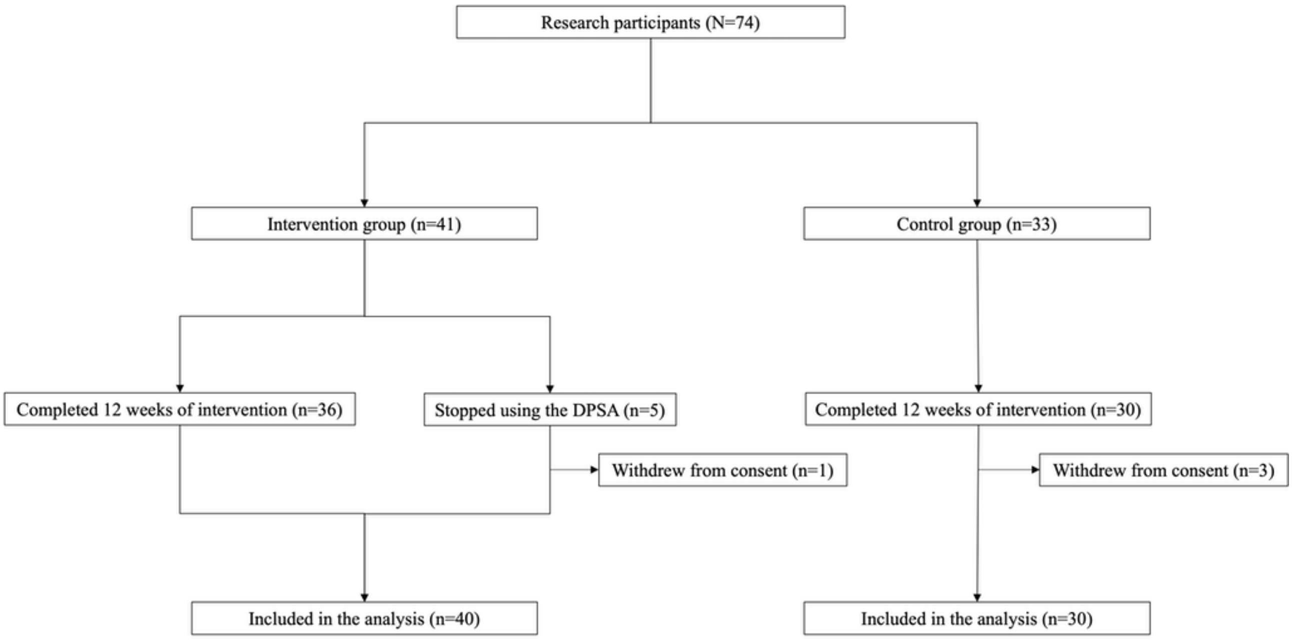
Comparisons of participant characteristics in each group were analyzed using the independent samples *t* test (2-tailed), chi-square test, and Mann-Whitney *U* test. The interaction between the group and time of intervention was analyzed using a linear mixed model with baseline and follow-up group differences adjusted for baseline age, sex, and frequency of app use (at baseline). Consent withdrawers were excluded, and older adults who dropped out of the intervention were included in the analysis in a modified intention-to-treat analysis. The daily step count, SB, LPA, MVPA, grip strength, CS-30, and self-efficacy for exercise were analyzed as dependent variables in separate models. The daily step counts were positively skewed; therefore, square root transformations were applied to improve normality. To increase the comprehensibility of the tables, raw descriptive data were reported, although analyses were conducted using the square root–transformed values. We defined high and low levels of physical activity based on step counts, using 7000 steps per day as the cutoff, as the recommended step goal for older adults is typically 7000 to 10,000 steps [37]. To examine the impact of physical activity at baseline on the intervention effect, a post hoc subgroup analysis was conducted on participants in the intervention group who had different levels of physical activity at baseline (≥7000 steps per day vs <7000 steps/day). The interaction between the physical activity level and intervention time point was analyzed in a linear mixed model adjusted for baseline age, sex, and frequency of app use. The data were analyzed using SPSS (version 29.0; IBM Corp). The statistical significance level was set at 5%.

Results

Participants

A total of 74 participants were initially enrolled in the study. However, 4 (5%) withdrew consent during the 12-week intervention period, with 1 (25%) withdrawal in the intervention group and 3 (75%) in the control group. The final analysis included 70 participants, 40 (57%) in the intervention group and 30 (43%) in the control group, in a modified intention-to-treat analysis, excluding those who withdrew consent (Figure 3). The intervention group comprised 9 groups of 4 to 5 participants each. A total of 5 (12%) out of 41 participants in the intervention group dropped out, including the 1 who withdrew consent.

Figure 3. Flow diagram of participants. DPSA: digital peer support app.



Participant Characteristics

The baseline participant characteristics are shown in Tables 1 and 2. The mean age of the participants (n=70) was 77.3 (SD 6.1) years, with 26 (37%) male participants included in the study. There were no differences in baseline demographic characteristics between the intervention and control groups. However, participants in the intervention group were more likely to use apps and exercise more frequently. “Gather information and shop on the internet” for the intervention group, the control group and representative percentage were 78%, 57%, and 23.7%, respectively. “Use social networking services” for the intervention group, the control group and representative percentage were 60%, 37%, and 13.1%, respectively. “Do not use any information devices” for the intervention group, the control group and representative percentage were 0%, 3%, and 17%, respectively. Compared to the representative percentage of Japanese older adults based on the Annual Report on the Ageing Society published by the Japan Cabinet Office [32], both groups used ICT, with the intervention group exhibiting greater ICT use compared to the control group.

Although the difference in the baseline daily step count between groups was not statistically significant, the step count was higher in the intervention group than in the control group, with a median difference of >1000 steps. There was a statistically significant difference in baseline LPA and MVPA between the 2 groups; the intervention group exhibited significantly higher MVPA levels, while the control group showed significantly higher LPA levels. Furthermore, grip strength was higher in the intervention group, likely owing to the greater proportion of male participants; however, the difference was not statistically significant.

Table 1. Demographic characteristics of the participants (n=70).

Characteristics	Total sample	Intervention group (n=40)	Control group (n=30)	*P* value
Age (years), mean (SD)	77.3 (6.1)	76.9 (6.1)	77.9 (6.1)	.49[a]

Feasibility: Retention Rate, Number of Posts, Negative Impact, Continuation Factors, and Willingness to Continue

A total of 5 (12%) out of the 41 participants in the intervention group dropped out, resulting in a DPSA continuation rate of 88% (36/41). Reasons for dropping out included “withdrew research consent,” “not a good fit for me,” and “unknown cause” (n=1, 20% each), as well as “poor health” (n=2, 40%). The average number of total posts per person was 2.76 (SD 1.99) per day. After excluding participants who dropped out, the adherence rate was 96%, and the average number of total posts per person was 3.02 (SD 1.93) per day (Table 3).

Table 3. Digital peer support app adherence rate and average number of total posts per day among participants in the intervention group.

Group	All participants (n=40)		Excluding participants who drop out (n=36)	
	n (adherence rate, %)	Total posts/person/day, mean (SD)	n (adherence rate, %)	Total posts/person/day, mean (SD)
All	40 (87.7)	2.76 (1.99)	36 (95.9)	3.02 (1.93)
A	4 (95.8)	1.55 (0.32)	4 (95.8)	1.55 (0.32)
B	5 (88.3)	1.83 (0.88)	5 (88.3)	1.83 (0.88)
C	5 (80.4)	2.62 (1.72)	4 (98.6)	3.24 (1.15)
D	5 (79.8)	1.12 (0.59)	4 (99.2)	1.38 (0.15)
E	5 (77.1)	1.19 (1.72)	4 (91.6)	1.22 (0.32)
F	4 (99.7)	6.25 (1.46)	4 (99.7)	6.25 (1.46)
G	4 (98.6)	3.36 (1.16)	4 (98.6)	3.36 (1.16)
H	4 (95.5)	4.20 (1.07)	4 (95.5)	4.20 (1.07)
I	4 (74.1)	3.83 (2.88)	3 (96.2)	4.88 (2.40)

A total of 3 minor negative physical effects were reported; 2 participants reported knee pain and 1 reported plantar pain. There were no breaches of privacy associated with the use of the app. A total of 14 inquiries were received about how to use the app. The average response took approximately 15.4 (10.7) minutes per case. The reported reasons for continuing to use the app were continuing fellowship (28/36, 78%), having a common goal (24/36, 67%), having fun (20/36, 56%), tracking their step counts (20/36, 56%), maintaining motivation (18/36, 50%), sense of improved mental health (17/36, 47%), sense of improved physical health (14/36, 39%), being on the internet (14/36, 39%) and Emotional painless (11/36, 31%). Figure 4 presents the intention to continue using the DPSA after the 12-week intervention. The responses were strongly agree (11/36, 31%), somewhat agree (12/36, 33%), undecided (11/36, 31%), somewhat disagree (1/36, 3%), and strongly disagree (1/36, 3%). More than half of the participants (23/36, 64%) indicated an intention to continue.

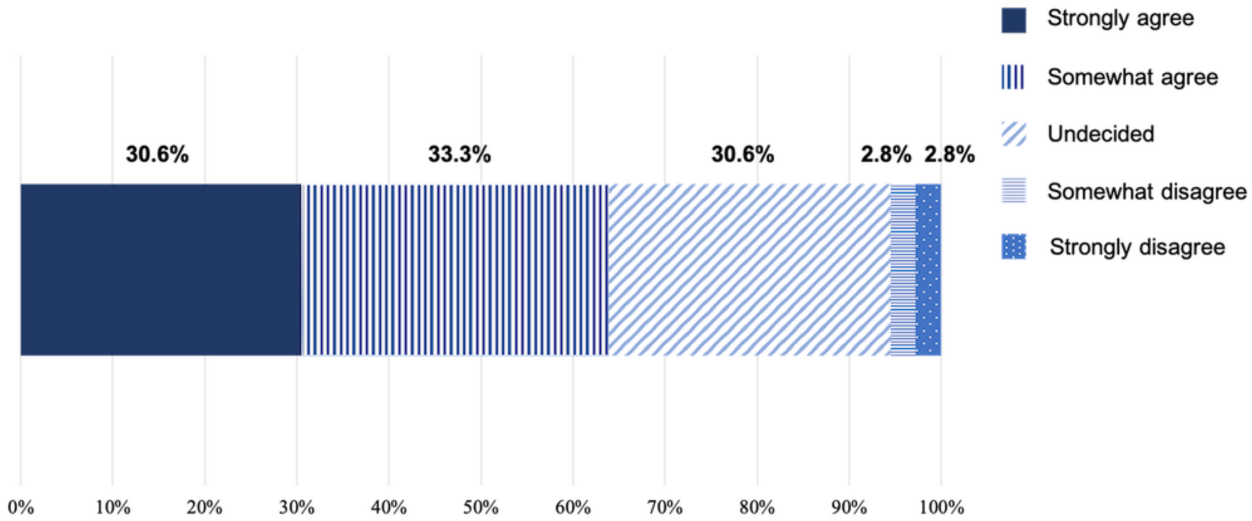

Figure 4. Intention to continue using the digital peer support app after the end of the study among participants in the intervention group.

Changes in Physical Activity, Physical Function, and Self-Efficacy for Exercise

The results of the linear mixed model analysis of physical activity, physical function, and self-efficacy for exercise are listed in Table 4. There was a significant difference in the interaction between groups and intervention time points in the daily step count and MVPA (daily step count: *P*=.04 and MVPA: *P*=.03) but not in LPA, SB, grip strength, CS-30, and self-efficacy for exercise.

A post hoc subgroup analysis was conducted by dividing the intervention group into high-level physical activity and low-level physical activity subgroups [37] based on their level of physical activity at baseline. The step count, LPA, MVPA, and SB were compared (Table 5). The analysis showed a significant difference in the interaction between the groups and the daily step count at baseline (*P*=.04).

Table 4. Intervention effects on physical activity, physical function, and self-efficacy for exercise before and after the intervention.

[d] MVPA: moderate to vigorous intensity physical activity.

[e] SB: sedentary behavior.

Discussion

Principal Findings

The study aimed to determine the characteristics of older adults who wanted to use the DPSA, which aimed to increase physical activity among older adults, and to confirm the feasibility of the DPSA and its impact on physical activity. Older adults who wanted to use the DPSA were more likely to be frequent users of the app and were more familiar with the use of ICT. Participants who reported an exercise habit tended to be more physically active at baseline. The retention rate was 88% (36/41) and the adherence rate was 87.7%, demonstrating the feasibility of older adults using the DPSA. The step count and MVPA increased significantly in the intervention group compared with those in the control group, demonstrating that the DPSA effectively increased physical activity. In DPSA users, participants with lower levels of baseline physical activity showed a more significant increase in their daily step count compared with those with higher levels of physical activity.

Comparison With Previous Studies

In this study, the retention and adherence rates were 88% (36/41) and 87.7%, respectively. These values are favorable compared to those reported in previous studies that have used digital technology to increase physical activity among older adults [38-42]. The findings from this study show that it is feasible for older adults to use DPSA to increase their level of physical activity. While differences were observed in adherence rates and the average number of total posts per day between groups, it is unclear what factors contribute to these differences. Only 3 negative physical effects were reported, but they were all minor and did not cause privacy breach issues. In contrast to our findings, Kullgren et al [43] showed that peer support using a 4-person web-based SMS text message board did not lead to an increase in physical activity among older adults. The authors attributed this lack of effectiveness to the failure to facilitate communication. In this study, the average number of comments per day in the intervention group was 2.76 overall and 3.01 excluding dropouts, indicating that many participants were actively using the DPSA. In addition, the fellowship was the factor with the highest percentage of intention to continue using DPSA. These may indicate that peer support based on social cognitive theory increased physical activity, as hypothesized. Self-efficacy is a key aspect of social cognitive theory [21]. However, in this study, although there was an increase in self-efficacy for exercise scores, the change was not significant. Possible reasons for the lack of a significant increase in self-efficacy for exercise in this study include the high baseline self-efficacy for exercise of the study population, the ceiling effect, and the short intervention period. In addition, the questionnaire used in this study may not reflect the impact of DPSA on self-efficacy. In this study, DPSA users showed a significant increase in their daily step count and MVPA duration despite the winter season. Participants with lower baseline physical activity levels showed a greater increase than those with higher levels of physical activity, suggesting that older adults with lower levels of physical activity may benefit more from using the DPSA than those with higher levels of physical activity. In the intervention group, the daily step count increased by >1000 steps on average. A systematic review of 17 prospective studies by Hall et al [44] has shown that each 1000-step increase in the daily step count decreases the risk of death and heart disease, with a 6% to 36% decrease in all-cause mortality risk and a 5% to 21% decrease in heart disease risk. Furthermore, it has been shown that an increase of 1000 steps per day decreases a woman's risk of diabetes by 6% and an increase of 2000 steps per day decreases the risk of diabetes by 12% [45]. In this study, the duration of MVPA increased by >10 minutes. Previous studies conducted in the United States [46] have shown that adding 10 minutes per day of MVPA could prevent 6.9% of deaths per year in the US adult population aged between 45 and 85 years. A greater increase in physical activity is predicted to have a greater protective effect. In Japan, the Ministry of Health, Labour and Welfare published the ActiveGuide, the Japanese official physical activity guidelines for health promotion, in March 2013 [47]. The key message of this guideline is "+10," indicating "add 10 minutes of MVPA per day." We increased physical activity in older adults through a 5-year community-wide intervention that incorporated this guideline [48]. According to a meta-analysis of 26 cohort studies by Miyachi et al [49], an increase of 10 minutes of MVPA per day can cause a 3.2% reduction of the average relative risk of noncommunicable diseases, dementia, joint-musculoskeletal impairment, and mortality. The 2010 National Health and Nutrition Survey [50] found that 60.8% of the respondents are willing to take part in an additional 10 minutes of physical activity per day. Therefore, the "+10" recommendation could be feasible and efficient for the Japanese population [49]. On the basis of previous findings and the results of this study, DPSA is a viable and effective tool for increasing physical activity.

Limitations

This study has a few limitations. First, sampling problems such as small sample size and low statistical power, as well as the influence of confounding factors such as academic background, digital literacy, and motivation, cannot be ruled out. Indeed, there was a difference between the 2 groups regarding the percentage of information about the use of ICT. The enrolment to the intervention and control groups was nonrandomized, and participation was voluntary. A previous study by Tudor-Locke et al [37] has shown that healthy older adults tend to walk between 2000 and 9000 steps per day, with a median of 5500 steps. The control group had about the same number of steps as the average older adult in Japan, whereas the intervention group took approximately 1000 more steps per day than the average older adult in Japan. Both groups were highly interested in exercise, which might have influenced the effectiveness of the DPSA intervention. Second, this study used a short-term intervention period of 12 weeks. Previous studies have found that mHealth physical activity interventions are more effective over short periods of time (<16 and <12 weeks) than over longer periods of time and that the effects may not be maintained for longer periods of time [51,52]. Furthermore, other reviews have shown that mHealth interventions may promote small to moderate increases in physical activity and that the effects are maintained over time but that the effect size decreases over time [53]. In this study, 6% (2/36) of the participants stated that they did not have intention to continue the intervention after 12 weeks and 31% (11/36) answered undecided, indicating that high retention and adherence rates can be achieved for short-term use of 12 weeks but that the long-term retention rate is unknown. Third, the generalizability is limited, as participation in the intervention group was limited to those who owned a smartphone. In addition, they were already familiar with the use of ICT. In this study, training sessions were provided on the use of the app, so that even those who were less familiar with the use of the app could participate, but participation was low.

Conclusions

In this study, a 12-week intervention was conducted with older adults aged ≥65 years, using DPSA to increase physical activity. Older adults who used DPSA to increase physical activity tended to be more familiar with ICT and more physically active at baseline compared to the general older adult population. The feasibility of DPSA was good, with increases in daily steps and MVPA in the intervention group. Peer support–based interventions using digital apps may be effective in promoting physical activity among older adults. Notably, participants with lower levels of baseline physical activity showed a more significant increase in their daily step count compared with those with higher levels of physical activity. To confirm the effect of DPSA on physical activity and physical function in older adults, a randomized controlled trial should be conducted.

Acknowledgments

This study was supported by a Doctoral Student Grant-in-Aid Program from the Ushioda Memorial Fund. The authors would like to thank the staff of the Elderly Support Division of the Fujisawa City Government (Shinichi Sakae, Mayumi Taguchi, Mari Sakata, and Shizuka Kobayashi) for recruiting participants and managing the project; Ken Takahashi of the Fujisawa City Health and Medical Foundation for his cooperation as a health fitness instructor; Oguma laboratory staff for their help in collecting the data; and Professor Wataru Yamamoto for his guidance and support throughout the data analysis process. The authors would also like to thank Editage for English language editing.

Authors' Contributions

KT, YO, SY, and MS were responsible for designing this study. All authors were responsible for data collection. KT and YO were responsible for analyzing and interpreting the data. All authors edited, reviewed, and approved the final manuscript.

Conflicts of Interest

SY and MS were employees of A10 Lab Inc at the time of research.

Abstract

Background: Current clinical guidelines for the management of type 2 diabetes mellitus (T2DM) in older adults recommend the use of antihyperglycemic medications, monitoring of blood glucose levels, regular exercise, and a healthy diet to improve glycemic control and reduce associated comorbidities. However, adherence to traditional exercise programs is poor (<35%). Common barriers to adherence include fear of hypoglycemia and the need for blood glucose level monitoring before exercise. Digital health strategies offer great promise for managing T2DM as they facilitate patient-practitioner communication, support self-management, and improve access to health care services for underserved populations. We have developed a novel web-based software program allowing practitioners to create tailored interventions and deliver them to patients via digital voice assistants (DVAs) in their own homes.

Objective: We aim to evaluate the feasibility of a 12-week, home-based, personalized lifestyle intervention delivered and monitored by DVAs for older adults with obesity and T2DM.

Methods: In total, 50 older adults with obesity aged 50-75 years with oral hypoglycemic agent–treated T2DM were randomized to the intervention (DVA, n=25) or a control group (n=25). Participants allocated to the DVA group were prescribed a home-based muscle strengthening exercise program (~20- to 30-min sessions) and healthy eating intervention, delivered via DVAs (Alexa Echo Show 8; Amazon) using newly developed software ("Buddy Link"; Great Australian Pty Ltd). Control group participants received generalized physical activity information via email. Outcomes were feasibility, DVA usability (System Usability Scale), and objectively assessed physical activity and sedentary time (wrist-worn accelerometers).

Results: In total, 45 (90%) out of 50 participants completed this study. Mean adherence to prescribed exercise was 85% (SD 43%) with no intervention-related adverse events. System usability was rated above average (70.4, SD 16.9 out of 100). Compared with controls, the DVA group significantly decreased sedentary time (mean difference –67, SD 23; 95% CI –113 to –21 min/d), which was represented by a medium to large effect size (*d*=–0.6).

Conclusions: A home-based lifestyle intervention delivered and monitored by health professionals using DVAs was feasible for reducing sedentary behavior and increasing moderate-intensity activity in older adults with obesity and T2DM.

older adults; type 2 diabetes mellitus; voice activation; digital health; exercise

Introduction

Background

Current clinical guidelines for type 2 diabetes mellitus (T2DM) recommend the use of antihyperglycemic medications, self-monitoring of blood glucose levels (BGLs), regular exercise, and a healthy diet to improve glycemic control and reduce vascular complications associated with this disease [1]. However, a recent meta-analysis of older adults with chronic conditions including T2DM reported that 12-month adherence to exercise programs supervised by health professionals was poor (<35%) [2]. Furthermore, a 12-week feasibility trial investigating adherence to home-based exercise in 76 adults with T2DM (mean age 56.6, SD 9.6 years) reported that only 38% of participants in the exercise group adhered to approximately 80% of their prescribed exercises [3].

Common barriers to adhering to clinical exercise guidelines for the management of T2DM include fear of hypoglycemia, demands of day-to-day management, and the need for monitoring of BGLs before exercise [4]. Monitoring of BGLs before exercise is recommended in clinical guidelines [4], but health care professionals (HCPs) have limited capacity to monitor patients when delivering group-based exercise programs [5]. Furthermore, most exercise programs are center-based, and lack of time, transportation, and cost requirements are additional barriers to participation in such programs for older adults with T2DM [6].

Emerging evidence suggests that the implementation of digital health strategies offers great promise for managing T2DM as they allow for improvements to patient-practitioner communication, support patient self-management, improve clinical decision-making, and increase health care services for underserved populations [7]. Various studies support the role of digital health technologies as safe, effective, and even cost-effective models for the management of T2DM in older adults [8-17], but the prescription and monitoring of individually tailored exercise programs remains an ongoing challenge for HCPs [18-22]. Currently, HCPs using traditional methods of communication such as telephone and videoconferencing have a limited capacity to monitor patient progress throughout home-based exercise programs, and this limitation is magnified the more participants they have [18]. Self-administered programs which may be delivered via web-based or mobile technologies may reduce the burden on HCPs through the automation of exercise monitoring, but many older patients have difficulty using these technologies [23-25].

The introduction of digital voice assistants (DVAs), which include embedded home speakers and display units capable of interpreting human speech and providing automated, personalized responses, allows older adults to communicate with these devices via natural conversation. This may overcome barriers related to technological accessibility thereby allowing for an engaging and effective self-management experience.

We have developed a novel web-based software program ("Buddy Link") that allows HCPs to create individually tailored exercise programs and deliver these to patients via DVAs in their own homes. In a recent feasibility trial including 15 older adults living alone, we observed 100% participant retention and 115% (SD 57%) mean adherence (participants completed 15% more than their prescribed exercise sessions) to a 12-week exercise program with no adverse events and above-average system usability (score of 75 out of 100) [26]. A novel feature of this system is the capacity for DVAs to obtain self-reported health information (eg, BGL values) via patient voice responses, interpret these responses using artificial intelligence, and then direct patients to exercise or take action as appropriate using predefined algorithms consistent with clinical guidelines. As such, the use of DVAs may offer an effective approach to delivering personalized and safe remote exercise prescriptions for older adults with T2DM.

Aims and Hypotheses

The primary aim of this 12-week feasibility randomized controlled trial (RCT) of a DVA-delivered exercise program for older adults with obesity and T2DM was to assess retention rate, adherence, incidence of (and types) of adverse events, and perceived system usability to the DVA intervention. The secondary aims were to compare between-group changes in health-related quality of life using the EQ-5D-5L, diabetes self-care management using the Diabetes Self-Management Questionnaire (DSMQ), physical activity, and sedentary behavior.

Methods

Study Design

This was a 12-week feasibility RCT in which adults with obesity aged 50-75 years treated with oral hypoglycemic agent–controlled T2DM were randomized (1:1), stratified by gender, to an individually prescribed, DVA-delivered, home-based exercise and healthy eating nutrition program developed by an accredited exercise physiologist (AEP) and Accredited Practicing Dietician, or general physical activity and healthy eating information delivered via email (control group). Group randomization was computer generated (using Microsoft Excel) by an independent person not directly involved in this study. All assessments were conducted via web-based questionnaires at baseline and 12 weeks.

Participants and Recruitment

In total, 50 older men and women with obesity and T2DM were recruited via email invitation from a database of previous research participants who provided consent to be recontacted for future trials. We recruited 50 participants (25 per arm) in this trial as this is consistent with current sample size guidelines for feasibility studies [27]. Sample sizes of 25 participants per arm are also recommended for pilot studies as they are capable of detecting small effect sizes (0.2) with 90% power and 2-sided significance at 5% [28].

Interested participants were initially directed to complete a web-based form to register their interest. To be eligible, participants were required to be aged 50-75 years, treated with oral hypoglycemic agent for T2DM, have a self-reported BMI>30, English-speaking, residing anywhere in Australia, sedentary (≥9 h/d self-reported sitting), able to walk across a room unaided, and have access to a smart mobile phone capable of making and receiving phone calls on an Australian network and home Wi-Fi network. Participants were deemed ineligible if they had difficulty communicating with study personnel or a DVA device due to speech or hearing problems, were unwilling to be randomized, planned to be away from the DVA device for ≥4 weeks during the 12-week intervention period, had severe knee or hip osteoarthritis (awaiting a joint replacement) that would interfere with the ability to complete the exercises, had a recent fracture (past 3 months) limiting exercise, had renal disease requiring dialysis, had any disorder of such severity that life expectancy was less than 12 months, or any cognitive or physical impairment or disability that in the opinion of this study's investigators would result in the participant having difficulty interacting with DVAs or performing unsupervised exercise safely. Participants were also required to answer "no" to all 6 questions on the Exercise & Sports Science Australia pre-exercise screening tool to ensure safety for exercising unsupervised at home.

Intervention

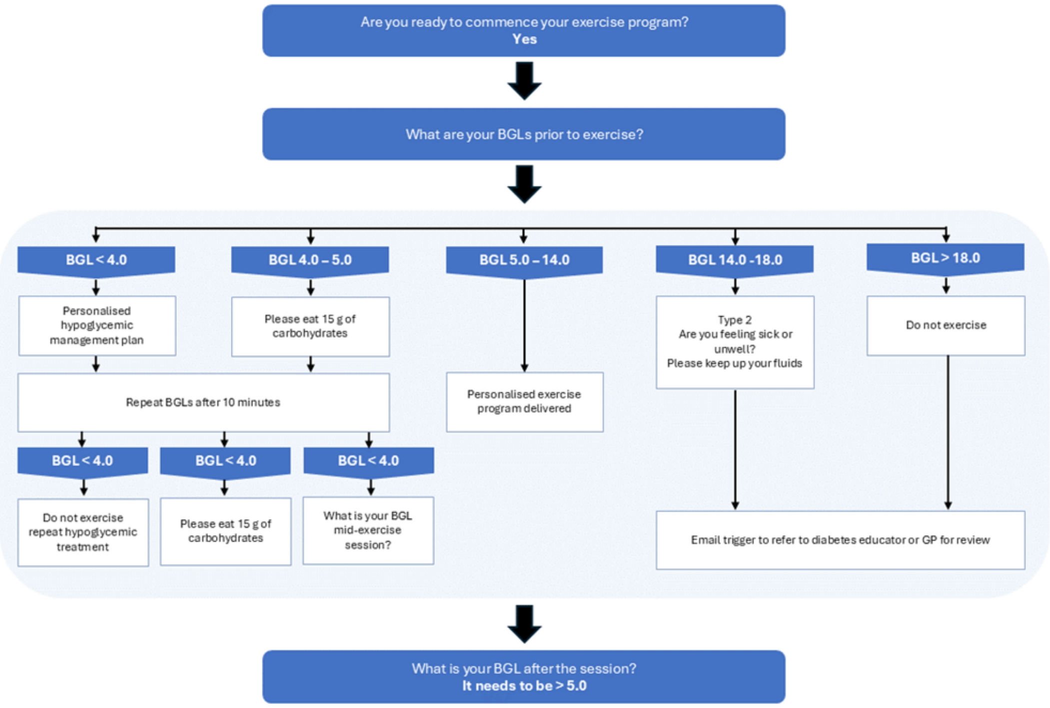
The DVA content was prepared and uploaded using the "Buddy Link" portal software (Great Australian Pty Ltd) [29]. Buddy Link allows HCPs to select existing, or create new, instructions and schedule these instructions to be broadcast (using both video and audio) to participants at specified times via the DVA device in their home. HCPs can also schedule questions to be broadcasted and review participant's responses which are recorded by the DVA. We have developed automated algorithms embedded within the Buddy Link software to allow the reporting of health outcomes such as BGLs and modify presented instructions automatically based on the reported data.

Each participant was provided with an Amazon Alexa Echo Show 8 ("Alexa") device delivered to their home via courier. The package included instructions on how to connect the Alexa device to a Wi-Fi network and how to initiate the preinstalled Alexa skill app ("TeleTrainer") to access the personalized content uploaded to Buddy Link. Both Buddy Link and TeleTrainer were developed and supported by Great Australian Pty Ltd.

The AEP prescribed a personalized, weekly exercise program for participants allocated to the intervention. Exercises were selected by the AEP using the health professional interface in Buddy Link and individually broadcast to participants via Alexa at specified times throughout the day, using video demonstrations and audio and written instructions based on Exercise & Sport Science Australia guidelines [30]. The exercise program used body weight or additional resistance such as weight plates, dumbbells, TheraBand, and weighted vests, if the participants had access to them (unless contraindicated). Participants performed up to 3 sets of 5 repetitions of 5 upper limb and lower limb exercises at a moderate intensity of approximately 4-6 on the 10-point modified Rating of Perceived Exertion scale [31]. Some examples of the exercises prescribed include chair squats, calf raises, and wall push-ups. Each participant was encouraged to increase the load of prescribed exercises each session while maintaining the desired intensity. Each exercise session was 20-30 minutes in duration. The protocol initially delivered 2 exercise sessions per week for the first 4 weeks of the intervention, 3 exercise sessions per week for the second 4 weeks, and 4 exercise sessions per week for the final 4 weeks. Following each exercise, Alexa broadcasted questions to determine whether participants completed their exercise, their self-perceived exertion, and if they had any other concerns (eg, pain or dizziness). Participants' responses to these questions were recorded and saved to the Buddy Link database, enabling the AEP to review weekly and modify or progress exercise prescriptions as required.

The DVA used a novel automated "decision to exercise tree" based on the current recommendations of the American Diabetes Association, as shown in Figure 1 [4]. Alexa provided BGL monitoring reminders using video, audio, and written instructions before and after each exercise session for the first 3 sessions (minimum) to establish BGL responses to each session, each week of the program. Participants were asked to report their BGLs to Alexa and the automated decision-to-exercise tree–adapted program content based on these responses. For example, the decision tree did not deliver exercise if participants had signs or symptoms of hypoglycemia, had self-reported BGLs less than 5 mmol/L, or were not feeling well enough to exercise. Instead, the decision tree would deliver audio and video instructions on how to self-administer a personalized hypoglycemia action plan. If self-reported BGLs less than 5 mmol/L, or greater than 14 mmol/L, were reported 3 sessions in a row, then the decision tree would recommend a referral to the participant's general practitioner or endocrinologist for completion of a Diabetes Management Plan.

Figure 1. Clinical decision-tree algorithm delivered by DVA. BGL: blood glucose level; DVA: digital voice assistant; GP: general practitioner.



An Accredited Practicing Dietician prescribed a healthy eating program delivered by the DVA to the intervention group for 12 weeks to increase whole grains, vegetable, and fruit daily intake in line with the Australian Dietary Guidelines [32]. In addition, generalized dietary educational videos tailored for T2DM management were displayed by the DVA. Examples include "meal planning," "making shopping lists using DVA," and "healthy snacking." The Buddy Link software was also accessed by study investigators to quantify the adherence of participant engagement with the educational videos.

The control group received a usual standard of care [33] and generic information on improving physical activity and nutrition sourced from Diabetes Australia [34] via weekly emails.

Outcome Measures

The primary outcomes related to feasibility with previously defined targets of ≥70% retention and completion of ≥66% (n=594) of prescribed exercise and dietary advice were determined based on the number of recorded voice responses from the DVA group. Adverse events were defined as health events that were considered possibly or probably related to the 12-week intervention and were measured using fortnightly phone calls by study investigators.

Secondary Measures

Accelerometer-Determined Physical Activity

Participants were provided with a wrist-worn ActiGraph GT9XLink accelerometer that was worn 24 hours per day, except while swimming or bathing, for 7 days at both baseline and post–12-week follow-up. Participants were also required to keep a diary to record wear times and reasons for not wearing their devices. These devices estimated average sedentary time (min/d), average light activity (min/d), average moderate activity (min/d), average vigorous activity (min/d), average very vigorous activity (min/d), average total moderate to vigorous activity per day (MVPA; min/d), and average number of steps per day.

Validated Questionnaires

Health-related quality of life was assessed at baseline and follow-up using the EQ-5D-5L [35,36]. This instrument contains 5 multiple-choice questions and a 100-point overall health state visual analog scale [35,36]. Self-care activities related to diabetes management were assessed using the DSMQ [37]. This instrument contains 16 questions, 6 relate to glucose management, 4 relate to dietary control, 3 relate to physical activity, and 3 relate to health care use [37]. Each subset is scored 0-3 with 0 not applying to participants and 3 being the most applicable [37]. All web-based questionnaires were administered by Qualtrics.

DVA System Usability

After the first week of use and again after follow-up, DVA participants were asked to complete a web-based System Usability Scale (SUS) [38] administered by Qualtrics. The SUS is a Likert scale of 10 items which projects a globalized subjective assessment of usability. SUS was administered to allow for a subjective evaluation of Alexa's usability by participants. Throughout the trial participants also received fortnightly emails inviting them to report any technical errors they may be experiencing with Alexa via a web-based form.

Data Analysis

Descriptive data were reported for feasibility outcomes. Each of the secondary outcomes was compared between groups using analysis of covariance adjusted for baseline values. Standardized effect sizes (Cohen *d*) were calculated for each secondary outcome. Alpha criterion level was set at P=.05. As this study was only a feasibility trial it may be underpowered to detect any significant changes, as such multiple hypothesis testing (Bonferroni correction) was taken into account [39]. All analyses were conducted using Stata (version 16.0; StataCorp).

Ethical Considerations

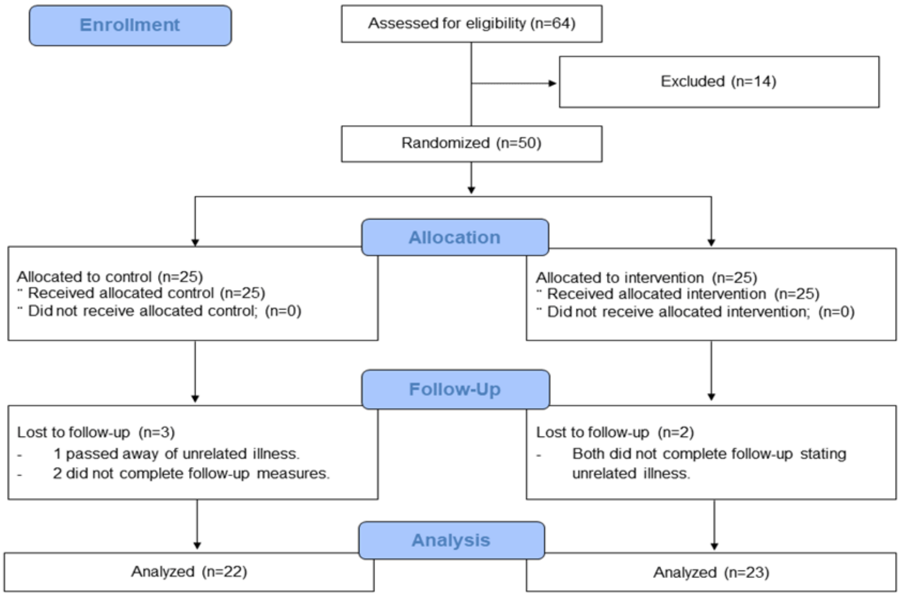
This study was approved by the Deakin University Human Research Ethics Committee (HREC 2021-009) and registered with the ANZCTR (Australian New Zealand Clinical Trials Registry; 12621000307808). Written informed consent was obtained from all participants. All the data has been anonymized and no compensation was provided to participants.

Results

Overview

A total of 64 potential participants were initially screened to recruit 50 eligible (self-reported BMI>30) men and women with obesity treated with oral hypoglycemic agents for T2DM, with equal numbers (n=25 each) randomly allocated to the DVA or control group (Figure 2).

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) flowchart of participation throughout this study.



Participant Demographics

Table 1 summarizes baseline demographic characteristics. The mean age of the 50 participants was 66 (SD 5; range 50-75) years and included 29 men and 21 women. Over half (n=30, 60%) of the participants in both groups were educated at a university level or higher, and around half (n=33, 46%) were currently retired. All participants in both groups were obese (self-reported BMI>30) and reported at least 1 chronic disease in addition to T2DM.

Table 1. Baseline demographics of the digital voice-activated intervention and control groups.

Baseline demographics	DVA[a] group (n=25)	Control group (n=25)

[a] DVA: digital voice assistant.

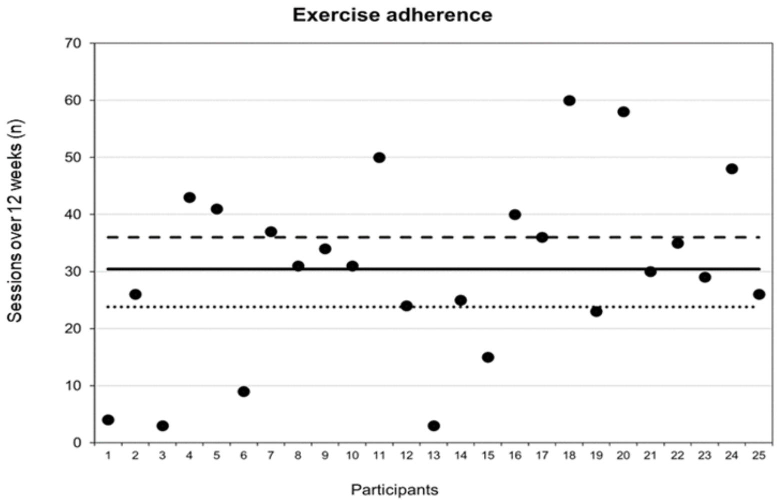
[b] Coronary heart disease included angina, stroke, peripheral vascular disease, and heart attack.

[c] Migraine, reflux, diverticulitis, hyperthyroidism, adenomyosis, polymyalgia rheumatica, epilepsy, sleep apnea, and peripheral neuropathy.

Primary Outcomes at 12-weeks—Adherence and Retention

Study retention was 90% (45/50), with 5 participants lost to follow-up (controls: n=3; DVA: n=2); 1 participant passed away due to unrelated causes, 2 participants withdrew (at weeks 5 and 9) due to unrelated illnesses, and 2 participants were lost to follow-up. The mean adherence of the DVA group to the prescribed exercise sessions was 85% (SD 43%; range 8%-167%). Overall, the 25 participants completed a total of 761 (84.5%) of the 900 total prescribed exercise sessions over 12 weeks (Figure 3). In total, 19 (76%) out of the 25 DVA group participants met the a priori exercise adherence target of 66%, inclusive of 9 (36%) participants who achieved ≥100% (n=900) exercise adherence (ie, initiated more exercise sessions than prescribed). Throughout the 12-week intervention, 24 (96%) out of 25 participants watched a total of 420 nutrition education videos. The mean adherence to the prescribed number of nutrition videos was 73% (SD 46%; 95% CI 61%-85%) over 12 weeks.

Figure 3. Individual participant adherence (●) to prescribed exercises over 12 weeks with the mean prescribed sessions highlighted by the dashed (--) line, mean observed adherence by the solid (—) line, and the target adherence by the dotted (. . .) line.



At 12 weeks, there was a total of 448 (49.7%) BGLs recorded out of the minimum prescribed 900 recordings. The mean BGLs self-reported by participants was 7.40 (SD 1.09) mmol/L, the normal preprandial blood glucose range was 4-7 mmol/L, and normal postprandial blood glucose range was 5-10 mmol/L [34]. Given there were no instances of BGLs lower than 5 mmol/L or higher than 14 mmol/L, the clinical decision-tree algorithm referred participants to their assigned exercise program on each occasion. Furthermore, no participants reported any other study-related adverse events across the 12-week intervention in both groups.

Secondary Outcomes

Accelerometer-Determined Physical Activity

Table 2 summarizes changes in secondary outcome measures for both groups. Regression coefficients represent the differences in change for these outcomes between groups over 12 weeks. After 12 weeks and accounting for multiple hypothesis testing, there was a significant decrease in average sedentary time (min/d) in the DVA group with a mean difference of –67 (SD 23; 95% CI –113 to –21) minutes per day when compared to controls (Table 2). This represented a medium to large effect size (*d*=–0.6). Furthermore, the DVA group's average moderate activity (min/d) and average MVPA (min/d) had medium to large effect sizes (*d*=0.6 and *d*=0.7 respectively) when compared to controls (Table 2).

Table 2. Baseline and 12-week values for secondary outcomes with adjusted regression coefficients (95% CI); *P* values for the mean differences in change between the groups and standardized effect sizes.

	DVA[a] group, mean (SD)		Control[b] group, mean (SD)		Estimated difference in groups after intervention (95% CI)[c]	*P* value	Standardized effect size

[e] n=23.

[f] n=22.

[g] DSMQ: Diabetes Self-Management Questionnaire.

[h] n=20.

[i] n=24.

[j] MVPA: moderate to vigorous activity per day.

[k] Indicates significant difference in change between groups (*P*<.05).

DVA System Usability

At 12 weeks, the mean SUS score reported by the DVA group was 70.4 (SD 16.9; Table S1 in Multimedia Appendix 1). This exceeds the value consistent with “average” usability (n=68) for this instrument. Mean scores from the specific SUS components indicated that participants generally disagreed that they would need the assistance of technical support to use the system and that it was complex or difficult to use. Furthermore, participants generally agreed that they were confident in using the system and that most people would be able to learn the system quickly.

Validated Questionnaires

There were no significant differences between groups at 12 weeks for measures of health-related quality of life (EQ-5D-5L and visual analog scale) and diabetes self-care management (DSMQ) (Table 2).

Discussion

Principal Findings

This pilot feasibility RCT demonstrated that a 12-week home-based exercise intervention delivered and monitored by DVAs was feasible and safe for older adults with obesity and T2DM. This was demonstrated by the high adherence and study retention with no intervention-related adverse events and an above-average SUS score. Secondary analyses demonstrated that the DVA intervention reduced sedentary time and increased MVPA relative to participants receiving generic advice (control).

Few studies have previously assessed remotely delivered, home-based lifestyle interventions for older adults with chronic conditions including T2DM [26,40,41]. Our recent pilot study [26] used an Alexa device to deliver a 12-week home-based exercise program to 15 older adults living alone. We found an overall adherence to the prescribed exercise of 115% as participants completed more than their prescribed exercise sessions, and no participant reported any adverse event related to intervention [26]. Our study also observed excellent adherence to prescribed exercise (mean 85%, SD 43%) and no adverse events related to the intervention. It is possible that the decision to exercise tree provided confidence for participants to exercise and contributed to the lack of adverse events in terms of hypo- and hyperglycemic occurrences. This novel exercise delivery approach was well adhered to indicating that it is feasible for home-based exercise programs for the management of T2DM in older adults. A study reported on the design and application of an intelligent digital assistant to remotely support 20 older adults (aged ≥65 years) with T2DM in making lifestyle changes and improving medication adherence [42]. This digital assistant differed from Alexa as it was an app powered by a Unity (Unity Technologies) software engine allowing for the construction of a female 3D model, capable of speech articulation and emotional expression through animation [42]. Furthermore, lifestyle changes were based on a rule-based component behavioral model where the digital assistant worked to modify the behavior of participants by providing counseling and education on aspects of physical activity and then assigning tasks for participants to complete to reinforce the desired behavior [42]. This differs from our approach where an AEP prescribed a personalized exercise program to support self-management in older adults with T2DM. The previous study reported a mean system usability (SUS) of 73.8 (SD 13.3) out of 100, suggesting good to excellent usability of the software [42]. The improved system usability may indicate that the integration of automation into a digitally delivered, lifestyle intervention may reduce burdens on HCPs and be acceptable to patients.

While limited studies have examined outcomes related to the feasibility of using DVA devices to deliver lifestyle interventions while monitoring BGLs in older adults with T2DM, other trials have investigated similar feasibility outcomes to our study using other asynchronous digital devices [43,44]. Koot et al [43] examined the feasibility of a mobile lifestyle management program (GlycoLeap; Holmusk, Inc) to improve blood glucose monitoring, dietary advice, physical activity, and diabetes self-management in 100 older adults (mean age 54 years) with T2DM for over 6 months. The mean adherence to completing at least 1 web-based health lesson was 33% [43]. This differs from our own study as we observed high adherence throughout the intervention. Older adults with T2DM may find a DVA-delivered program more engaging than a mobile-based lifestyle program, however future, long-term studies are required to further understand patterns of participant adherence over longer periods of time.

Following the 12-week intervention, we reported a decrease in the average sedentary time (min/d) and an increase in average moderate physical activity time (min/d) and total MVPA (min/d) in the DVA compared to the control group. A study investigated the use of a mobile and web-based tool to deliver a lifestyle intervention to 199 older adults (mean age 58 years) with T2DM in primary care for over 9 months [44] and reported significant improvements in MVPA/day (mean difference 10.6 min, 95% CI 4.9 to 16.3) compared to control participants who received only standard T2DM care [44].

Our study observed an increase in MVPA of around 30 minutes over a much shorter period; some possible explanations for this may be that the participants in this study were healthier than participants in the previous study or that DVA delivery may have been more engaging. Analogous future studies are required to better understand the use of DVAs in this population. Another study explored the effects of web-based home exercise on physical activity levels in 65 older adults (mean age 53 years) with T2DM for over 8 weeks [45]. Similarly to our study, participants were required to self-monitor and report their BGLs before and after exercise sessions [45]. After 8 weeks, the web-based group was found to have significantly improved their average number of steps (30.5, SD 34.9; *P*=.01) compared to the control group [45]. However, we observed a net difference of >1000 steps per day, indicating DVAs may be more acceptable and effective in improving physical activity levels in older adults with obesity and T2DM.

We found no significant changes between groups in the DSMQ. A study [46] examined the use of digital modalities for improving the self-management of T2DM in 115 older adults, in which they investigated the first 3 months of a 12-month digitally delivered intervention consisting of telemonitoring and telephone-based coaching to improve diet, physical activity, and self-diabetes management [46]. The main findings from this study were that participants in the intervention group had improved glycemic control as evidenced by significantly decreased hemoglobin A_{1c} (mean difference=–0.36, SE 0.17; *P*=.04 between groups) and improved DSMQ scores (mean difference=1.13, SE 0.23; *P*<.001 between groups) [46]. This study demonstrates that DSMQ scores can be improved through digital modalities in older adults with T2DM, and the lack of differences in our study may be explained by the smaller cohort, or perhaps the use of standardized rather than personalized coaching.

To date, no previous studies have used DVAs to self-monitor BGLs in older adults with T2DM. A review of 58 papers investigated the use of digital technology in supporting the self-management of T2DM and found that it is effective, scalable, and also acceptable to both patients and HCPs [47]. Furthermore, a qualitative systematic review of 13 papers found similar evidence but suggested that both patients and HCPs were more inclined to use digital technology if it was easily accessible and had a relatively simple learning curve [48]. Our study implemented a simplistic modality for participants to self-report BGLs to Alexa and the DVA group participant's self-reported BGLs were consistently within a "fit to exercise" range (mean of 7.40, SD 1.09 mmol/L). This demonstrates that automated assessment of the appropriateness of exercise based on self-reported BGLs is feasible, but further studies are needed in less healthy older adult T2DM populations to fully explore the effectiveness of this model.

Remote diabetes support allows patients to better manage their T2DM and related chronic conditions and has been associated with a reduction in diabetes-related medical costs [49].

Strengths and Limitations

The strengths of this study were the high level of adherence to exercise, the novel implementation of a clinical decision-to-exercise tree considering BGLs before exercise, and the above-average system usability of the DVAs. The limitations of our study must be acknowledged when interpreting the findings. The population appeared to be well educated and with well-controlled BGLs; thus, the results may not be generalized to all older adult populations with T2DM. Another limitation was that adherence to the lifestyle program, including the BGL monitoring, was self-reported by participants via Alexa, which may be susceptible to both overestimation and underestimation biases. Therefore, we suggest that this should be interpreted with caution and that future studies should include objective measures, including real-time BGL monitoring via continuous measuring.

Conclusions

In conclusion, this feasibility study indicates that it is safe and feasible for older adults with obesity and T2DM to participate in a home-based exercise program delivered and monitored remotely by HCPs using DVAs. Future large-scale, longer-term studies are warranted to explore the clinical- and cost-effectiveness of this digital health approach to support self-management of T2DM in older adults.

Abstract

Background: Osteoarthritis is a leading contributor to global disability. While evidence supports the effectiveness of Tai Chi in improving symptoms for people with hip/knee osteoarthritis, access to in-person Tai Chi classes may be difficult for many people. An unsupervised online Tai Chi intervention for people with osteoarthritis can help overcome accessibility barriers. The Approach to Human-Centered, Evidence-Driven Adaptive Design (AHEAD) framework provides a practical guide for co-designing such an intervention.

Objective: This study aims to develop an unsupervised online Tai Chi program for people with hip/knee osteoarthritis.

Methods: An iterative process was conducted using the AHEAD framework. Initially, a panel of Tai Chi instructors and people with osteoarthritis was assembled. A literature review was conducted to inform the content of a survey (survey 1), which was completed by the panel and additional Australian Tai Chi instructors to identify Tai Chi movements for potential inclusion. Selection of Tai Chi movements was based on 3 criteria: those that were appropriate (for people with hip/knee osteoarthritis aged 45+ years), safe (to be performed at home unsupervised), and practical (to be delivered online using prerecorded videos). Movements that met these criteria were then ranked in a second survey (survey 2; using conjoint analysis methodology). Survey findings were discussed in a focus group, and the Tai Chi movements for program use were identified. A draft of the online Tai Chi program was developed, and a final survey (survey 3) was conducted with the panel to rate the appropriateness and safety of the proposed program. The final program was developed, and usability testing (think-aloud protocol) was conducted with people with knee osteoarthritis.

Results: The panel consisted of 10 Tai Chi instructors and 3 people with osteoarthritis. The literature review identified Yang Style 24 as a common and effective Tai Chi style used in hip/knee osteoarthritis studies. Surveys 1 (n=35) and 2 (n=27) produced a ranked list of 24 Tai Chi movements for potential inclusion. This list was refined and informed by a focus group, with 10 Tai Chi movements being selected for inclusion (known as the Yang Style 10 form). Survey 3 (n=13) found that 92% (n=12) of the panel members believed that the proposed draft Tai Chi program was appropriate and safe, resulting in its adoption. The final program was produced and hosted on a customized website, “My Joint Tai Chi,” which was further refined based on user feedback (n=5). “My Joint Tai Chi” is currently being evaluated in a randomized controlled trial.

Conclusions: This study demonstrates the use of the AHEAD framework to develop an unsupervised online Tai Chi intervention (“My Joint Tai Chi”) for people with hip/knee osteoarthritis. This intervention is now being tested for effectiveness and safety in a randomized controlled trial.

Introduction

Osteoarthritis is a leading contributor to disability and chronic pain, with a global prevalence of 365 million in 2019 [1]. The knee is the most common lower limb site for osteoarthritis, followed by the hip [2]. Globally, it is estimated that cases of osteoarthritis will increase by 75% for the knee and nearly 80% for the hip by 2050 compared with 2020 [2]. People with hip and knee osteoarthritis often experience pain and impaired function, as well as comorbidities such as depression and anxiety [3,4].

All clinical guidelines for osteoarthritis recommend education and physical activity, including structured exercise, as the fundamental approach to treatment [5-7]. Tai Chi is specifically recommended as an exercise option for people with hip and knee osteoarthritis [5,7]. Tai Chi is a traditional Chinese, mind-body, land-based exercise that combines meditation with slow, gentle movements; deep diaphragmatic breathing; and relaxation [8]. Clinical trials indicate that Tai Chi is effective in improving pain, function, and quality of life for people with osteoarthritis [5,9-13]. With its meditative and mindfulness component, Tai Chi has also been shown to have broader benefits, such as improved psychological health, cognitive function, and sleep quality [14,15]. Tai Chi is generally performed in person in a group setting with demonstration and supervision from an instructor. However, this format can be difficult or inconvenient for many people to access, especially in regional or rural areas where there is a higher prevalence of people with osteoarthritis but Tai Chi classes may not be readily available [16].

An unsupervised online Tai Chi program may be a scalable way to help patients participate in Tai Chi in their own homes. Online exercise interventions have the potential to reach a wide audience regardless of location and at less cost to users and the health care system [17]. Since the COVID-19 pandemic, a number of Tai Chi schools and organizations now offer Tai Chi classes online [18-22]. These classes are generally conducted in a “synchronous” videoconferencing format with an instructor and require payment [23-26]. However, most Tai Chi programs are not specifically designed for people with osteoarthritis, which can make them challenging to perform correctly and safely [27]. Currently, there is no Tai Chi exercise program that is online, unsupervised, free, and tailored for people with lower limb osteoarthritis.

When designing interventions, the use of a theoretical framework is recommended to provide researchers with systematic and clear guidance [28,29]. The Approach to Human-Centered, Evidence-Driven Adaptive Design (AHEAD) is a 7-step framework that provides a practical guide for co-designing pragmatic and impactful health care interventions [30]. Using the AHEAD framework, this study aimed to develop an online, unsupervised Tai Chi program for people with hip and knee osteoarthritis.

Methods

Development of the online Tai Chi program followed the 7 steps of the AHEAD framework, which are (1) define the problem and assemble a team, (2) review evidence, (3) seek inspiration, (4) synthesize, (5) develop guiding principles, (6) ideate, and (7) evaluate [30].

Step A: Define the Problem and Assemble the Team

We defined the problem as the poor accessibility of evidence-based Tai Chi classes for people with osteoarthritis. To address this issue, we first assembled an advisory panel that included Tai Chi instructors and people with osteoarthritis. Tai Chi instructors were eligible to be part of the panel if they (1) were a member of a Tai Chi association in Australia and (2) had at least 5 years of experience teaching Tai Chi for adults (aged 45+ years) with musculoskeletal conditions. Potentially eligible instructors were identified by searching websites of Tai Chi associations. People with osteoarthritis were eligible if they had (1) self-reported symptomatic knee and/or hip osteoarthritis and (2) had participated in supervised Tai Chi exercise in the past year in Australia. It is suggested that around 10 people is an ideal size for a panel group discussion [31]. Therefore, we planned to recruit around 10 panel participants. Recruitment was conducted through email invitations to the Tai Chi instructors and email advertisements to our center’s consumer network. Interested instructors and people with osteoarthritis were asked to email the researchers and were followed up by phone to assess eligibility. A Plain Language Statement was provided to eligible panelists, and consent was obtained digitally through REDCap (Research Electronic Data Capture; Vanderbilt University). Gift vouchers of Aus $350 (US $235) were provided as an honorarium. To gain broader insights from the Tai Chi community, additional Tai Chi instructors were recruited Australia-wide to participate as nonpanel participants. Recruitment was done through the dissemination of study information by Presidents of Australian Tai Chi organizations, Facebook advertisements, and snowball sampling. Eligibility and consent procedures were consistent with panelist recruitment but with no remuneration provided.

Step B: Gather Information—Review Evidence

There are many different styles of Tai Chi, each with different forms (a series of connected movements executed in a certain order) [32]. To identify the style and movements of Tai Chi to be considered for the online program, 1 researcher (SZ) first conducted a literature search (by Ovid, PubMed, and Google) to identify systematic reviews and randomized controlled trials (RCTs) evaluating the effects of Tai Chi in people with osteoarthritis and of online Tai Chi programs in any condition. The research team (RKN, KLB, RSH, and JH) discussed the findings from the literature search through meetings, phone calls, and emails and proposed a draft list of Tai Chi movements for potential inclusion in the unsupervised online Tai Chi program.

Step C: Gather Information—Seek Inspiration

It was proposed by the Tai Chi instructor in the research team (JH) that the ideal number of Tai Chi movements to be included in an online program should be between 8 and 12, as it was thought more than 12 movements would be challenging to effectively learn and practice independently. To select the specific movements from those identified in Step B, 2 online surveys were conducted, involving both panel and nonpanel participants.

Survey 1

The purpose of this survey (conducted using REDCap software) was to identify which Tai Chi movements would be appropriate, safe, and practical for inclusion in the program. The survey asked participants to rate each identified Tai Chi movement (from Step B) against two criteria, which are (1) appropriateness of the movement for people with knee and/or hip osteoarthritis who are 45 years old and older when performed correctly, and (2) safety of the movement if performed at home unsupervised. Each movement was scored using separate 11-point numerical rating scales from 0 (not appropriate or safe at all) to 10 (completely appropriate or safe). Participants were also asked whether each Tai Chi movement would be practical to be delivered online using prerecorded videos that someone would watch at home (response options yes or no). Participants also provided feedback regarding Tai Chi exercise prescription, including the recommended length of each Tai Chi video session (response options 20, 30, 40, 50, and 60 minutes), weekly practice frequency (d/wk, range 1-7), and total weekly practice time (min/wk). Open-ended questions gathered additional suggestions for developing the program. The research team determined a priori that a Tai Chi movement would be retained for potential inclusion in the program if at least 70% of participants scored it at least 5 out of 10 for both appropriateness and safety, and it was deemed practical.

Survey 2

The purpose of this survey was to rank the Tai Chi movements retained from survey 1 so that 12 movements could be selected. Using a pairwise ranking technique (1000Minds) [33], participants were shown pairs of Tai Chi movements (selected based on those considered appropriate, safe, and practical from survey 1) and asked to identify which of the pair should take priority for inclusion in the program. The number of pairwise rankings required from each participant varied depending on their responses to the presented alternatives. The pairwise ranking process continued until the background mathematics established a ranked list of all Tai Chi movements for each participant and averaged over the sample.

Step D: Synthesize

To synthesize information gathered from the first 2 surveys, an online focus group was conducted with panel participants, facilitated by the researchers (KLB, SZ, RKN, and JH). Discussion topics included results of the first 2 surveys, practicalities of recording the online Tai Chi program, Tai Chi exercise prescription, and Tai Chi education content that would supplement the Tai Chi exercise program. The focus group discussion was recorded (both audio and visual) and transcribed verbatim. Notes and recordings were reviewed, replayed, and analyzed qualitatively to gather the panelist's perspectives and to identify areas of consensus for the design of the Tai Chi program.

Step E: Intervention Design—Develop and Apply Guiding Principles

The criteria of appropriateness, safety, and practicality were deemed as the guiding principles for this 12-week, online, unsupervised Tai Chi program. Based on the results from the first 2 surveys and focus group, a proposed 12-week Tai Chi program was filmed by the research team Tai Chi instructor (JH). Panelists were then sent the prototype video, through a final REDCap survey (survey 3). In this survey, they were asked to rate their level of agreement that the proposed program as a whole was (1) appropriate (for people aged 45+ years old with knee and/or hip osteoarthritis) and (2) safe (to be performed at home unsupervised). Each criterion was scored using a 5-point Likert scale from 1 (strongly disagree) to 5 (strongly agree). For the proposed program to be approved, 70% or more of participants were required to "strongly agree" or "agree" that the program was "appropriate" and "safe." Since all movements included in the program had already been judged to be practical, it was unnecessary to vote on this.

Step F: Intervention Design—Ideate (Brainstorm–Prototype–Test)

Finally, the 12-week, unsupervised, online Tai Chi program was filmed in a studio at the University of Melbourne. The produced videos were incorporated into a website prototype, "My Joint Tai Chi," which was constructed by the research team and 2 research assistants. The website was based on our other evidence-based unsupervised exercise programs for knee and/or hip osteoarthritis "My Knee Exercise" [34] and "My Hip Exercise" [35] and developed in accordance with recommendations outlined by the Health on the Net Foundation's Code of Conduct [36].

The website prototype underwent extensive usability testing with people with osteoarthritis, following a think-aloud protocol [37]. Volunteers from our previous osteoarthritis studies in Australia, who agreed to be contacted again, were invited through email to participate (by researcher SZ). Participants were eligible if they (1) had symptomatic knee osteoarthritis and (2) had no previous experience with Tai Chi exercise (in person or online) in the past 2 years. Purposive sampling was used to ensure diversity in age, sex, and symptom duration. A Plain Language Statement was provided, and consent was obtained digitally through REDCap. Participants received Aus $50 (US $35) gift vouchers as an honorarium.

Participants were scheduled for a 60-minute, one-on-one, online usability test with a researcher (SZ) through Zoom (Zoom Video Communications). During the usability test, participants were asked to share their screen and navigate the "My Joint Tai Chi" website prototype, as if they were commencing the Tai Chi program, while the researcher observed. Participants were encouraged to vocalize their thoughts on the website's design, content, and functionality, with the researcher asking open-ended questions for further feedback. Notes on usability were taken and sessions were audio and video recorded. Field notes and recordings were qualitatively analyzed to identify usability issues, which were addressed before the next participant. This iterative process continued until no further issues were identified.

Step G: Evaluate

The research team has designed and is currently conducting a 2-arm, parallel-design, superiority pragmatic RCT to assess the effectiveness of this unsupervised online Tai Chi intervention, ("My Joint Tai Chi"), compared with online osteoarthritis education control. Primary outcomes of self-reported pain during walking [38] and physical function [39] will be evaluated. A nested qualitative study has also been designed to explore the experience of people with osteoarthritis who use the "My Joint Tai Chi" intervention during the RCT. The RCT protocol and the results of the RCT will be published in separate subsequent papers.

Ethical Considerations

The Human Research Ethics Committee at the University of Melbourne approved this study (2023-25788-36959-4). All data collected in this study was de-identified and stored on secure university servers, accessible only to the researchers using a password.

Results

Overview

A summary of the development of the "My Joint Tai Chi" intervention using the AHEAD Framework is provided in Table 1 [30].

Table 1. Summary of the design of the "My Joint Tai Chi" intervention using the AHEAD[a] framework.

AHEAD framework domains	Intervention design stages
Define the problem and assemble the team (A)	• Problem: Poor accessibility of evidence-based Tai Chi classes for people with osteoarthritis • Team (n=17): Advisory panel including Tai Chi instructors (n=10) and people with osteoarthritis (n=3), and a research team including osteoarthritis researchers and/or physiotherapists (n=4; SZ, KLB, RKN, and RSH) and a Tai Chi instructor recruited from the panel.
Review evidence (B)	• Literature review identified Yang Style 24 form as a common and effective form of Tai Chi for osteoarthritis. Twelve weeks was the most common length.
Seek inspiration (C)	• Two surveys were completed by panel participants (Tai Chi instructors and people with osteoarthritis) and additional nonpanel Tai Chi instructors. • Survey 1 (n=35) rated Yang Style 24 form and modifications (total 33 Tai Chi movements) based on appropriateness, safety, and practicality. A total of 24 movements identified as appropriate, safe, and practical. • Survey 2 (n=27) produced a ranked list of the 24 movements retained from survey 1 (ranked based on most appropriate or safe to least appropriate or safe).
Synthesize (D)	• Met with the panel (n=12) to discuss results from surveys and additional Tai Chi program design considerations. This resulted in the adoption of the Yang Style 10 form.
Develop and apply guiding principles (E)	• Final survey with panel participants (n=13) rated a draft of the proposed program against the guiding principles of appropriateness (for people aged 45+ years with osteoarthritis) and safety (to be performed at home unsupervised). 92% (12/13) rated the program as both appropriate and safe.
Ideate (F)	• A 12-week Tai Chi exercise program was developed, produced, and housed within a website prototype called "My Joint Tai Chi". Usability testing was conducted with people with osteoarthritis (n=5) using a think-aloud protocol. Usability problems were identified, and the prototype was refined.
Evaluate (G)	• The final "My Joint Tai Chi" intervention is currently being evaluated in a 2-arm, parallel-design, superiority pragmatic RCT[b] (ACTRN12623000780651) and nested qualitative study. The methods and results of this RCT will be reported subsequently in separate papers.

[a] AHEAD: Approach to Human-Centered, Evidence-Driven Adaptive Design.

[b] RCT: randomized controlled trial.

Step A: Define the Problem and Assemble the Team

We recruited 10 Tai Chi instructors and 3 people with osteoarthritis (1 with hip and knee osteoarthritis and 2 with knee osteoarthritis only) as advisory panel participants and another 22 Tai Chi instructors as nonpanel participants. One Tai Chi instructor (JH) was recruited to join the research team (that comprised osteoarthritis researchers and physiotherapists) to provide professional opinions about Tai Chi during the development process. Participant demographic information is provided in Table 2.

Table 2. Demographic characteristics of participants in Step A.

Participant characteristics	Survey 1 participants (n=35)	
	Panel (n=13)	Nonpanel (n=22)
Tai Chi instructors, n	10	22
Sex, female, n (%)	6 (60)	11 (50)
Predominant style of Tai Chi taught, n (%)[a]		
Yang	9 (90)	19 (86)
Sun	5 (50)	5 (23)
Chen	2 (20)	1 (5)
Wu	1 (10)	1 (5)
Hao	2 (20)	0 (0)
Years of experience teaching Tai Chi, mean (SD)	24 (11)	16 (10)
Number of Tai Chi classes taught per week, mean (SD)	8 (6)	3 (2)
People with osteoarthritis, n	3	—[b]
Sex, female, n (%)	2 (67)	—
Age (years), mean (SD)	73 (2)	—
Years of symptom duration, mean (SD)	7 (3)	—
Years of Tai Chi practice, mean (SD)	7 (2)	—

[a] Some Tai Chi instructors taught more than 1 style of Tai Chi.

[b] Not applicable.

Step B: Gather Information—Review Evidence

Six systematic reviews and 14 RCTs were identified evaluating Tai Chi programs in people with osteoarthritis. Programs varied in length from 8 to 20 weeks, with 12 weeks being the most common [40-51]. The average Tai Chi exercise prescription was 3 Tai Chi sessions per week, each lasting 60 minutes [40-51]. Yang Style 24 form was the most commonly practiced [52]. This style was created in China in the 20th century and is known for its slow and graceful movements, with an emphasis on weight shifting in a wide stance [53]. It has been found to be effective in improving pain and physical function in people with osteoarthritis [54]. Hence, Yang Style was chosen as the foundational basis for the online Tai Chi program. There are 24 Tai Chi movements in the Yang Style 24 form. However, the Tai Chi instructor in the research team (JH) perceived some movements to be unsuitable for people with osteoarthritis and challenging to learn through online delivery, for example, movements that involve single-leg stance, maintained end-of-range hip and knee flexion, and multiple 180-degree turns. Therefore, the research team introduced 7 modifications and broke down certain movements, resulting in a total of 33 movements (Multimedia Appendix 1) for possible inclusion in the online program.

Four studies (2 feasibility trials, 1 longitudinal pilot study, and 1 RCT protocol) used telehealth-delivered Tai Chi for other chronic conditions such as long-term mobility disability, Parkinson disease, mild cognitive impairment, and cancer therapy–induced joint pain [23-25]. Programs were most commonly delivered synchronously using videoconferencing software Zoom (n=3). One study integrated Tai Chi training videos into a mobile phone app for people with Parkinson disease, which was connected to a clinician app for monitoring adherence [55]. Professional oversight through phone calls was also provided [55]. The Tai Chi for Arthritis program, endorsed by the US Centers for Disease Control and Prevention, does offer an online asynchronous course [56], but this has not been formally evaluated.

The research team determined that prerecorded videos of Tai Chi exercises would be the most convenient approach, allowing broader access without class scheduling or professional oversight. Moreover, it was decided to deliver the prerecorded Tai Chi videos by a dedicated website that also included osteoarthritis and Tai Chi education and exercise adherence support resources to allow for a potentially more effective multicomponent, osteoarthritis, digital, self-management intervention [57].

Step C: Gather Information—Seek Inspiration

Survey 1

All 35 participants (13 panel and 22 nonpanel) completed survey 1 (Multimedia Appendix 1). Out of the 33 movements, 24 (73%) achieved consensus (defined as at least 70% of participants rating it at least 5 out of 10 for appropriateness, safety, and considering it to be practical). For the 9 excluded movements, refer to Multimedia Appendix 2. Additional Tai Chi exercise prescription suggestions are summarized in Table 3.

Table 3. Tai Chi exercise prescription suggestions from survey 1 (N=35).

Tai Chi exercise prescription suggestions	Value
Length of each prerecorded video (min), n (%)	
30	17 (55)
20	9 (29)
40	2 (6)
50	2 (6)
60	1 (3)
Frequency of Tai Chi practice (d/wk), n (%)	
3	12 (40)
5	6 (20)
4	4 (13)
7	4 (13)
2	3 (10)
1	1 (3)
6	0 (0)
Weekly dosage of Tai Chi practice (total min/wk), mean (SD)	114 (60)

Survey 2

As 24 movements met the criteria in survey 1 (exceeding the 12 required), a 1000Minds survey was conducted for further prioritization. A total of 27 participants (13 panel and 14 nonpanel) completed survey 2, which produced a ranked list of movements (Multimedia Appendix 3) for potential inclusion. Kendall W was 0.124, indicating high variance and low agreement among participants [58]. Thus, this ranked list was used only as a guide to inform further discussions with the panel participants by a focus group.

Step D: Synthesize

Panel participants (12/13) were then involved in a 2-hour online focus group via Zoom. Suggestions provided during the focus group are listed in Multimedia Appendix 4. In summary, Tai Chi instructors advocated for the use of a recognized Tai Chi sequence, as opposed to solely relying on the ranked list of movements from the second survey (1000Minds). This is because the transition, stance, and flow between movements are vital in Tai Chi, rather than just presenting isolated "movements." It was decided to use the modified Yang Style 10 form (Textbox 1) for the program because 7 out of the 10 movements aligned with the top 10 ranked movements in survey 2 and it is a recognized Tai Chi sequence [54]. The other 3 moves were ranked 13th, 16th, and 20th out of the 24 moves in the results of survey 2 (Multimedia Appendix 3). Modifications were also discussed for certain Tai Chi movements to ensure suitability for people with osteoarthritis and little previous Tai Chi experience. It was also decided that each 12-week video should include 5-10 minutes of Qigong exercise for warm-up and cooldown (an ancient wellness practice that is performed with minimal footwork [59]). All panelists agreed on the program duration (12 weeks), and it was decided that the program should start with 30- to 40-minute sessions and progress to 40- to 45-minute sessions to build endurance. Incorporating explanations of the martial applications of each selected Tai Chi movement and the practicalities of recording the program were discussed. Finally, resources for those wanting to continue Tai Chi practice after completing the online program were also suggested.

Textbox 1. The Yang Style 10 form Tai Chi movements.

Movement name

- Commencement
- Repulse monkey
- Brush knee
- Part the wild horse's mane
- Cloud hands
- Golden rooster stands on one leg
- Cross hands and kick
- Stroke peacock's tail
- Embrace the tiger
- Closing

Step E: Intervention Design—Develop and Apply Guiding Principles

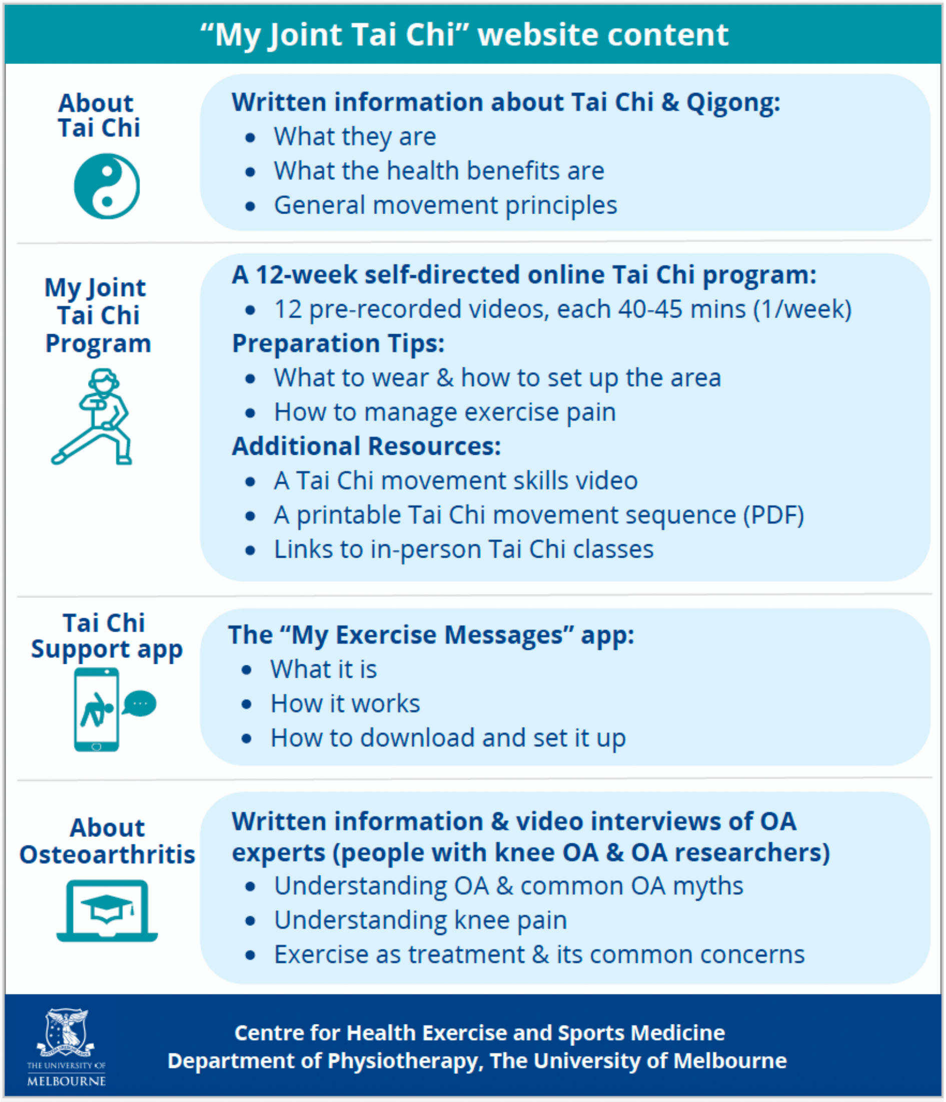
All panel participants (n=13) took part in the final survey that involved voting on the draft program's alignment with the guiding principles. A total of 92% (12/13) of participants rated "strongly agree" or "agree" to the draft 12-week Tai Chi program being (1) appropriate for people with knee and/or hip osteoarthritis and (2) safe to be performed at home unsupervised. The agreement reached the predetermined threshold (70%), and therefore, the draft online Tai Chi program was adopted as the final version.

Step F: Intervention Design—Ideate (Brainstorm–Prototype–Test)

"My Joint Tai Chi" Website

The 12 professionally filmed videos showing a Tai Chi instructor (JH) demonstrating the Tai Chi movements were housed on a website called "My Joint Tai Chi" (the website was built specifically for research purposes and was not yet widely publicly available). "My Joint Tai Chi" contains a home page with a video tutorial explaining how to use the website and four sections including (1) the Tai Chi program, (2) information about Tai Chi, (3) information about osteoarthritis, and (4) instructions on how to access an exercise adherence app to support engagement with the Tai Chi program. Figure 1 outlines the contents of the website, and further detail is provided in Multimedia Appendix 5. Still images of modified Yang Style 10 form in the "My Joint Tai Chi" program are provided in Multimedia Appendix 6.

Figure 1. Description of the content in the 4 discrete sections of the "My Joint Tai Chi" website. OA: osteoarthritis.



"My Joint Tai Chi" website content

About Tai Chi

Written information about Tai Chi & Qigong:

- What they are
- What the health benefits are
- General movement principles

My Joint Tai Chi Program

A 12-week self-directed online Tai Chi program:

- 12 pre-recorded videos, each 40-45 mins (1/week)

Preparation Tips:

- What to wear & how to set up the area
- How to manage exercise pain

Additional Resources:

- A Tai Chi movement skills video
- A printable Tai Chi movement sequence (PDF)
- Links to in-person Tai Chi classes

Tai Chi Support app

The "My Exercise Messages" app:

- What it is
- How it works
- How to download and set it up

About Osteoarthritis

Written information & video interviews of OA experts (people with knee OA & OA researchers)

- Understanding OA & common OA myths
- Understanding knee pain
- Exercise as treatment & its common concerns

THE UNIVERSITY OF MELBOURNE

Centre for Health Exercise and Sports Medicine
Department of Physiotherapy, The University of Melbourne

Usability Test

Five participants with osteoarthritis conducted website prototype usability testing. On average, they were 60 (SD 10) years old and had experienced knee pain for 2 (SD 1) years. Identified issues and implemented solutions are outlined in Multimedia Appendix 7. In summary, usability testing resulted in the redesign of the user interface and several pages for easier navigation. Page instructions were reworded for clearer and more explicit guidance.

Step G: Evaluate

The RCT evaluating the "My Joint Tai Chi" intervention is currently recruiting and expected to complete data collection in February 2025. The RCT has been prospectively registered (ACTRN12623000780651). The nested qualitative study is anticipated to commence data collection in July 2024. The RCT protocol will be published separately.

Discussion

Principal Findings

This study reports the systematic codevelopment of an unsupervised online Tai Chi intervention for people with osteoarthritis using the AHEAD framework. The intervention is a 12-week, web-based Tai Chi program that is complemented with educational information about osteoarthritis and Tai Chi and supported by an app to facilitate Tai Chi exercise adherence. Once the RCT evaluation is complete (and subsequently any required modifications are made), the finalized program will be released online for public access at no cost to the user. The program has the potential to boost participation in physical activity among people with osteoarthritis.

This study has several strengths. First, the use of the AHEAD framework provided a structured foundation for the transparent and thorough reporting of intervention design and intervention components. This approach addresses the previous lack of clarity in intervention development, with evidence showing that most Tai Chi studies do not meet the expected intervention reporting standards [60-62]. Second, by using an evidence-based, iterative, and robust process, we were able to incorporate opinions from a broad panel of Tai Chi experts and people with osteoarthritis (n=35 in total), along with physiotherapists and osteoarthritis researchers. To the best of our knowledge, only one other study has incorporated end-user feedback (n=14) into the design of an online, seated Tai Chi program for people with mobility disabilities [25]. However, that program was designed to include remote supervision, and its effectiveness has not been tested in an RCT [25]. Hence, no previous unsupervised online Tai Chi program has been codeveloped by such a large sample group nor subjected to rigorous evaluation. Third, since this Tai Chi exercise program was designed for people with knee and/or hip osteoarthritis, the panel also deemed it appropriate for people 45 years of age and older who do not have osteoarthritis. Hence, the Tai Chi exercise program videos developed could potentially be used as a strategy to increase access to Tai Chi exercise for a broader audience.

One limitation is that there were only 3 people with osteoarthritis out of a total of 35 participants involved in Step C (Seek Inspiration), indicating a potential underrepresentation of people with osteoarthritis. However, these 3 people provided constructive feedback in Step D (Synthesize), and an additional 5 people with osteoarthritis were involved in the final website usability testing in Step F. Another potential limitation is that we have developed an intervention that requires access to digital technologies and technological literacy. To fully gain the benefit from the "My Joint Tai Chi" program, the user is required to have a computer with internet access and preferably to have a mobile phone (to use the exercise support app). However, given that 94% of Australian households have a computer with 86% of them having internet access [63], and that 78% of Australian adults 65 years of age and older use a mobile phone [64], this suggests that the use of "My Joint Tai Chi" website is broadly accessible by most Australians.

Conclusions

A systematic design approach using the AHEAD framework was successful in developing this user-centered intervention and may serve as a guide for others developing unsupervised digital interventions. To our knowledge, "My Joint Tai Chi" is the first unsupervised online Tai Chi intervention designed for people with osteoarthritis. The program is now being evaluated in an RCT that will provide insights into the effectiveness and safety of the program compared with online osteoarthritis education control. The prerecorded Tai Chi exercise videos in the program can also be used to increase physical activity for people without osteoarthritis in the community at large.

Acknowledgments

We thank the research assistant (Bridget Graham) for help with designing the website. We thank the panel participants for their input into the "My Joint Tai Chi" development. Tai Chi instructor panelists were as follows (listed in alphabetical order based on surnames): Sam Au, Tara Brayshaw, Konrad Dorn, James Gao, Jin Song Han, Jenny Harrison, Suzette Hosken, Jenny Lucy, Su Rule, and Tunde Takacs. People with osteoarthritis panelists were as follows (listed in alphabetical order based on surname): Roger Corfield and Jennifer Leighton. SZ is supported by a PhD stipend from the Australian Government Research Training Program Scholarship. RSH is supported by a National Health & Medical Research Council Senior Research Fellowship (#1154217). KLB is supported by a National Health and Medical Research Council (NHMRC) Investigator Grant (#1174431). RKN is supported by a University of Melbourne Sir Randal Heymanson Fellowship.

Abstract

Background: Telemedicine is a potential option for caring for older adults with multimorbidity. There is a need to explore the perceptions about telemedicine among older adults with multimorbidity to tailor it to the needs of older adults with multiple chronic conditions.

Objective: This study aims to explore the perceptions about telemedicine among older patients with multimorbidity.

Methods: A qualitative study was conducted using semistructured interviews. The interview questions examined older adults' perspectives about telemedicine, including their expectations regarding telemedicine services and the factors that affect its use. Thematic analysis was performed using NVivo (version 12; Lumivero). The study was reported using the Standards for Reporting Qualitative Research guidelines.

Results: In total, 29 patients with multimorbidity—21 (72%) female patients and 8 (28%) male patients with a mean age of 69 (SD 10.39) years—were included. Overall, 4 themes and 7 subthemes emerged: theme 1—perceived benefit of telemedicine among older adults with multimorbidities, theme 2—appropriate use of telemedicine for multimorbid care, theme 3—telemedicine system catering to the needs of older patients, and theme 4—respect patients' decision to decline to use telemedicine.

Conclusions: Telemedicine for older adults with multimorbidity should focus on those with stable conditions. This can help increase access to care for those requiring continuous condition monitoring. A structured telemedicine program and patient-centered services can help increase patient acceptance of telemedicine. However, health care providers must accept the limitations of older patients that may prevent them from receiving telemedicine services.

Introduction

Background

The COVID-19 pandemic has led to the emergence of telemedicine as a viable alternative to traditional, in-person care. Telemedicine has the potential to provide convenient medical care for patients with disabilities, transportation limitations, or busy schedules, enabling them to receive care from home [1-3]. It has become an increasingly valuable tool for delivering care to patients with multimorbidity, who require regular monitoring or adjustments to their treatment plans [4,5]. An emerging care model illustrates the integration of a patient-centered approach for individuals and chronic care model with multimorbidity. The model offers comprehensive care across various patient aspects and uses a multidisciplinary approach to address the complexity of managing multimorbidity [6]. Telemedicine can provide remote consultations and monitoring, provide patient education, and facilitate continuity of care [7,8].

In many countries, telemedicine has been promoted in the post–COVID-19 era owing to comparable health outcomes and favorable cost-effectiveness compared with in-person visits [9]. In Thailand, telehealth projects have been launched by the National Broadcasting and Telecommunication Commission of Thailand and the Thai Ministry of Public Health to improve health care services' accessibility and quality [10]. As Thailand has become an aged society, with approximately 12 million people aged ≥60 years [11], telemedicine can help improve the quality of life of older adults by promoting healthy behavior, enhancing social functioning, and reducing depressive symptoms [12,13]. Telemedicine can also improve health for older patients, who often have multimorbidity, by helping to provide continuous medical care [14].

However, the lessons learned from using telemedicine during the COVID-19 pandemic have documented challenges for both older patients and health care providers (HCPs), as it was an unfamiliar mode of treatment compared with in-person service [15]. In addition, the literature suggests that older patients may prefer in-person visits owing to the frustration caused by technological challenges when using telemedicine [16]. However, their perceptions and preferences regarding telemedicine remain poorly understood. Therefore, the needs of older patients for telemedicine should be explored [17].

Moreover, there are gaps in understanding telemedicine for those with multimorbidity [6,18]. Many studies showed the effectiveness of telemedicine, but most focused on the use of telemedicine for a single disease [19-21]. Managing patients with multimorbidity is an increasing challenge in primary care practice [22]. In multimorbidity, there are many interactions such as disease-disease, treatment-treatment, and disease-treatment, which increase the complexity of management [23,24]. The rising question is what is the appropriate use of telemedicine in caring for older patients with multimorbidity [25].

Objective

Our study aimed to explore the perceptions about telemedicine among older patients with multimorbidity. By understanding the perceptions about expectations, preferences, and barriers regarding telemedicine, the results can be used to develop telemedicine strategies to support the management of multimorbidity in the older population.

Methods

Study Design

A qualitative study of older adults with multimorbidity attending a primary care outpatient clinic at a university hospital in Thailand was conducted in 2021. The study used the Standards for Reporting Qualitative Research guidelines, which is a list of 21 items considered essential for complete, transparent reporting of qualitative research [26].

Setting and Participants

The Family Medicine Clinic at the Faculty of Medicine, Chiang Mai University, is a primary care clinic that provides general medical care for chronic diseases. Approximately 80% of all patients are older adults (aged ≥60 y) with multimorbidity. Multimorbidity was defined as the patient's illness that includes the presence of multiple diseases or conditions, often with a cutoff of ≥2 conditions [27]. The most common conditions are hypertension, type 2 diabetes mellitus, and dyslipidemia. Approximately 90% of the patients had multimorbidity. Among those attending the clinic, the rate of controlled hypertension, type 2 diabetes mellitus, and dyslipidemia between August and October 2021 were 93.7%, 70.3%, and 79.8%, respectively.

Convenience sampling was used. Patients aged ≥60 years and diagnosed with at least 2 chronic conditions who were accessible and available were invited to participate in the study. The patients needed to have stable conditions, defined as being asymptomatic and not having any urgency or emergency conditions, according to the national clinical guidelines for managing hypertension [28], type 2 diabetes mellitus [29], and dyslipidemia [30].

Telemedicine Service

Telemedicine is the use of electronic information and communication technologies to provide and support health care when distance separates the participants [31]. In 2020, the Family Medicine Clinic in Thailand started a telemedicine service in response to the COVID-19 pandemic. After the COVID-19 pandemic, our facility continues to use telemedicine for delivering care to patients with chronic conditions. By considering patient safety, patients with moderate to well-controlled chronic conditions were approached to participate in the telemedicine service for continuous care [32]. In addition, it is essential to discuss with the patients the purpose of telemedicine and to address any limitations associated with its use [33]. In addition, the objective of telemedicine as ongoing care and limitations of telemedicine need to be discussed with the patients.

The clinic had adopted a published multimorbidity assessment checklist developed to help care for patients with multimorbidity

[6]. The 20-item assessment checklist (Simple Multimorbidity Assessment Checklist for Primary Care) incorporates patient-centered concepts into managing multimorbidity in primary care settings, including assessment of the patient, review of all diseases and conditions, review of all treatments, review of clinical practice guidelines, assessment of interactions, understanding patient context and concerns, finding common ground, setting individual care plan, and continuity of care and follow-up visits. The checklist was also extended for use in the telemedicine service for assessing patients who were suitable for telemedicine and health caregiving.

The telemedicine service was provided via video or audio call, depending on the patients' available devices and abilities. Physicians could collect patients' medical histories and evaluate emergency or urgent conditions during the consultation. If any patient had conditions that required further evaluation, they were advised to come to the hospital. If patients did not require any further in-person assessment, medications were prescribed and delivered to the patient's home via post.

Ethical Considerations

This study was reviewed and approved by the institutional ethics committee of the Faculty of Medicine, Chiang Mai University, Chiang Mai, Thailand (approval number 227/2021). All participants were informed about the research study and provided consent.

Data Collection and Analysis

Semistructured interviews were conducted between September and November 2021. The interview questions (Multimedia Appendix 1) focused on older patients' perceptions about telemedicine, including their preferences regarding expectations from telemedicine services, and factors that affect its use, using the Unified Theory of Acceptance and Use of Technology framework [34]. This framework illustrates a comprehensive understanding of all the factors that affect people's intentions to use the new technology. A research assistant, not involved in providing medical care, was trained in the interview method and interview questions by WJ and NB. Each interview lasted approximately 20 minutes and was conducted on-site. Interviewed information included baseline characteristics (age, sex, educational level, employment status, and their decision regarding telemedicine services) with permission for audio recording. Then, the interviews were transcribed verbatim. Data collection and analysis were performed iteratively by researchers. Recruitment ended when data saturation of the core analytic content had been achieved. Previous literature suggested that the sample size of 9 to 17 interviewees could help to reach saturation [35]. We further determined the sample size based on a previous study investigating the crucial factors for outpatient service selection among older adults. At least 16 patients were required to achieve data saturation [36]. Therefore, we considered collecting data from at least 16 patients until we achieved data saturation in the results [37].

Each transcript was evaluated multiple times to aid familiarization and understanding of the data. Descriptive analysis was used to describe the patient's characteristics. For qualitative analysis, 2 independent researchers (NB and WJ) conducted inductive thematic analysis [38]. The preliminary results were then interpreted and discussed with KP, SP, NN, and CA. Codes were then developed based on patterns in the data. The identified codes were compared and discussed for similarities and differences until consensus was reached regarding the emergent themes and subthemes. Data analysis was performed using NVivo (version 12; Lumivero).

Results

Overview

In total, 29 older patients with multimorbidity participated. Of the 29 participants, 21 (72%) were women and 8 (28%) were men. The mean age was 71 (SD 7.17) years. The 2 most prevalent underlying diseases were dyslipidemia (27/29, 93%) and hypertension (25/29, 86%). Most patients had completed primary school (11/29, 38%) or had a bachelor's degree (10/29, 35%). Of the 29 patients, 23 (79%) were retired and 6 (21%) were self-employed. Of the 29 patients, 18 (62%) patients were interested in using telemedicine, whereas 11 (38%) patients were not interested in telemedicine and rejected telemedicine when they were offered. Patients' characteristics are summarized in Table 1.

From the semistructured interviews, 4 themes and 7 subthemes emerged. The themes and subthemes are summarized in Textbox 1.

Table 1. Patients' characteristics (N=29).

Characteristics	Values
Age (y), mean (SD)	71 (7.17)
Sex, n (%)	
Female	21 (72)
Male	8 (28)
Chronic conditions, n (%)	
Dyslipidemia	27 (93)
Hypertension	25 (86)
Type 2 diabetes mellitus	9 (31)
Others	6 (21)
Number of chronic conditions, n (%)	
2	19 (66)
3	7 (24)
4	1 (3)
5	2 (7)
Educational level, n (%)	
No education	1 (3)
Primary school	11 (38)
Secondary school	5 (17)
Vocational certificate	1 (3)
Bachelor's degree	10 (34)
Master's degree	1 (3)
Working status, n (%)	
Retired	23 (79)
Self-employed	6 (21)
Decision regarding telemedicine, n (%)	
Accept	18 (62)
Decline	11 (38)

Textbox 1. Summary of themes and subthemes.

Theme 1: perceived benefit of telemedicine among older adults with multimorbidities

- Convenient to access without the need for travel
- Minimize the risk of COVID-19 transmission

Theme 2: appropriate use of telemedicine for multimorbidity

- Telemedicine for monitoring stable conditions
- Enhancing the self-management of chronic conditions

Theme 3: telemedicine system catering to the needs of older patients

- Telemedicine services should be as similar as possible to in-person care
- Telemedicine services should adopt a clear protocol that includes in-person visits
- Supporting the development of technological skills and providing resources

Theme 4: respecting patients' decision to decline to use telemedicine for various reasons

Theme 1: Perceived Benefit of Telemedicine Among Older Patients With Multimorbidity

Overview

The benefits of telemedicine were collected from older patients. They reported the reasons why telemedicine should be used and its benefits. These include eliminating the requirement for travel and reducing the risk of contracting COVID-19.

Subtheme 1: Convenient to Access Without the Need for Travel

The most mentioned benefit of telemedicine was eliminating the need for travel. Participants mentioned that telemedicine is convenient for accessing and receiving continuity of care. It can also save time and money, such as time spent in driving and finding parking. A patient mentioned that telemedicine reduces stress from long wait times at hospitals. It also eliminates the risk of driving accidents, especially in older patients with sensory problems owing to physiologic changes. In addition, there is no burden on family members or caregivers to come and drop them at the hospital:

> *...If we compare the advantages and disadvantages, there are more advantages, as it saves both time and cost. We don't have to drive, look for parking spots, or wait in line [to meet the doctor and receive medication]. The advantages are greater.* [Participant 13; female; aged 64 years; teacher; uncontrolled hypertension and obesity]
>
> *I like it because I don't have to go to the hospital. It's convenient. If I had to give [telemedicine] a score, it would be a ten because it's convenient for me. I don't have to drive there because I'm not good at driving right now. I have to ask my husband to take me there.* [Participant 5; female; aged 72 years; housemate; well-controlled hypertension, type 2 diabetes mellitus, and dyslipidemia]
>
> *Because we don't have to go to the hospital anymore. They send the medication to our house. It's difficult to go to the hospital now. We have to ask our children to take us, but everyone is working. I want to receive the medication at home because I take this medication regularly.* [Participant 26; female; aged 72 years; retired; well-controlled hypertension, type 2 diabetes mellitus, and dyslipidemia]
>
> *Sometimes, if I go to the hospital to see a doctor, I have to wait a long time, and it can be stressful. With video calls, I can talk for a long time.* [Participant 23; male; aged 76 years; retired; uncontrolled type 2 diabetes mellitus, well-controlled hypertension, and dyslipidemia]

Subtheme 2: Minimize the Risk of COVID-19 Transmission

Patients perceive telemedicine as a helpful way to reduce the risk of SARS-CoV-2 infection by avoiding contact with individuals with infection at the hospital. By not having to physically go to the hospital, there is no need to wait in crowded areas for a physician or medication after treatment, resulting in decreased rate of contact:

> *I don't have to go to places with many COVID-19 cases. My daughter also likes it because I don't have to take risks. Using telemedicine is very good for me.* [Participant 2; female; aged 72 years; self-employed; well-controlled hypertension, type 2 diabetes mellitus, and dyslipidemia]

Theme 2: Appropriate Use of Telemedicine for Multimorbidity

The participants felt that telemedicine should be used to care for patients with stable conditions in evaluating, monitoring, and providing health promotion. Participants also acknowledged the limitations of telemedicine in providing medical care, such as the inability to perform a complete physical examination or blood tests.

Subtheme 1: Telemedicine for Monitoring Stable Conditions

Patients feel confident in receiving telemedicine services when they have stable conditions because they have no abnormal symptoms, and the on-site care provided is only in the form of conversation to monitor their condition. Telemedicine services for those with stable conditions can resemble on-site care. Telemedicine services should include monitoring of clinical symptoms, vital signs, body weight, and behavioral factors. Consultation time is also required, so that patients can consult with their physician and inquire about their condition and receive follow-up care:

> *It's just like when we see a doctor at the hospital. If we meet the doctor, we ask questions like this. We can also ask online like this and see each other's faces; finding a doctor this way is good and convenient. The doctor called, and we talked. If we have any questions, we ask, and the doctor answers. It's just like going to see a doctor.* [Participant 18; female; aged 69 years; retired; well-controlled type 2 diabetes mellitus and osteoporosis]

However, some patients still believe that if they experience new or more severe symptoms, they prefer to receive treatment in an in-person setting for more detailed examinations or blood tests:

> *It's [telemedicine] comprehensive, but only if I do not have severe symptoms...However, if the patient has more severe symptoms..., it's uncertain how effective the treatment [received through telemedicine] will be.* [Participant 19; female; aged 66 years; retired; well-controlled hypertension and type 2 diabetes mellitus]
>
> *It's [telemedicine] good. Luckily, there have been no issues during this period. But if any problems arise, I still have to go see a doctor.* [Participant 15; female; aged 73 years; retired; uncontrolled type 2 diabetes mellitus and well-controlled hypertension]

Subtheme 2: Enhancing the Self-Management of Chronic Conditions

The patients perceive that they can take better care of themselves when telemedicine provides health care information specific to their health problems. Some patients suggested incorporating self-monitoring and health promotion features into the telemedicine platform. They believe in sharing self-management information with physicians to improve disease management, such as home monitoring of blood pressure and blood sugar levels. The platform could also provide specific knowledge for lifestyle modification, such as exercise videos or electronic brochures about food exchange lists. This enhances the potential for self-management:

> *I normally check and record my blood sugar and blood pressure at home. Sometimes, I forget to bring the records to the hospital. However, in telemedicine, when the doctor calls, I can inform them of my records.* [Participant 2; female; aged 72 years; self-employed; well-controlled hypertension, type 2 diabetes mellitus, and dyslipidemia]

> *I want to know more about blood pressure. We may think it's not a big deal, but actually, it's a silent danger. The doctor said it's a scary disease, and I want information on how to take care of this disease. It would be great if there were some tips on this matter.* [Participant 14; female; aged 66 years; government employee; uncontrolled hypertension and well-controlled type 2 diabetes mellitus]

> *If there is a LINE group [chat group], I would like to receive informative messages about health. Even seniors need to read news and information related to health, such as knowledge about [COVID] vaccines.* [Participant 21; female; aged 75 years; retired; well-controlled hypertension and type 2 diabetes mellitus]

Theme 3: Telemedicine Services Catering to the Needs of Older Patients

For an effective telemedicine service for older patients, it is crucial to address patient concerns and establish a clear management protocol based on their health status. Providing supporting resources, having good communication skills, and being aware of potential barriers arising from unfamiliarity with technology are also essential in meeting their needs.

Subtheme 1: Telemedicine Services Should Be as Similar as Possible to In-Person Care

When using telemedicine, patient concerns must still be evaluated, similar to in-person service. Some concerns may persist even after receiving telemedicine services. Presenting conditions can influence their physical or mental well-being, making it crucial for HCPs to thoroughly understand patients' illnesses to ensure appropriate management. Some patients feel that video call feels more similar to an actual on-site visit than audio calls because they can see the facial expressions and gestures of the HCPs:

> *Video calls would be better because the doctor can see the patient's face and how they feel at that moment, whether they are feeling stressed or not. With video calls, I feel closer [to the doctor] and more comfortable.... I usually don't share things within my family unless it's with the doctor. But with video calls, I feel more comfortable because I can see the doctor's face, knowing that they care about me. I just want the doctor to call me and ask what I want to share or talk about.* [Participant 1; female; aged 62 years; retired; well-controlled hypertension and type 2 diabetes mellitus]

> *With video calls, we feel close to each other. It feels like we're still talking to each other. It's good because we can talk to the doctor about anything comfortably. I think it's a good thing because patients can express themselves fully to the doctor.* [Participant 17; male; aged 76 years; retired; well-controlled hypertension and type 2 diabetes mellitus]

Subtheme 2: Telemedicine Services Should Adopt a Clear Protocol That Includes In-Person Visits

Patients express concerns that telemedicine might replace traditional, in-person care, leading to a lack of access to physical examinations, blood tests, and additional symptom management. They desire telemedicine to complement a comprehensive multimorbidity management program while still having the option to see physicians in person at the hospital:

> *Sometimes I want to meet with the doctor in-person to talk directly or ask questions. The doctor can know my symptoms if I communicate directly. If I say that it hurts here or it is swollen here, the doctor can touch it and examine it for evaluation. This is the basic step of diagnosing symptoms. I mean, I want to meet the doctor sometimes, but not frequently. It's not like I don't see the doctor for a year. I just want to see the doctor once or twice to feel reassured.* [Participant 16; female; aged 74 years; retired; well-controlled hypertension, type 2 diabetes mellitus, and dyslipidemia]

The support system of telemedicine services was crucial for patients' decision-making regarding whether to accept or decline the service. Most patients are willing to accept telemedicine owing to clear operational systems, including appointment scheduling, notifications, web-based payment, and medication delivery. However, some patients still have doubts about payment systems and medication delivery. In addition, patients receiving telephone-based care may have uncertainties about the authenticity of the HCP:

> *After a case manager added me on LINE [application], they gave me an appointment for a video call. A day before the appointment, a nurse called me and said the doctor would have a video call tomorrow. When the appointment arrived, they would call me and ask if it was convenient for the doctor to have a video call now. I answered that it was. Then, the doctor called me. It was a very good process.* [Participant 15; female; aged 73 years; retired;

> uncontrolled type 2 diabetes mellitus and well-controlled hypertension]

> *It's possible to send the appointment time through LINE in advance; for example, if the doctor would come in the afternoon, someone would call in the morning to inform. The doctor could then ask about the symptoms very well. It was done quickly, in just a moment.* [Participant 21; female; aged 75 years; retired; well-controlled hypertension and type 2 diabetes mellitus]

> *I asked about the cost of the medicine that sent text information by phone because I couldn't contact the finance department. It's very difficult.* [Participant 18; female; aged 69 years; retired; well-controlled type 2 diabetes mellitus and osteoporosis]

> *I don't know if they are doctors or not. To be honest, I don't know who is calling me. But if it's a video call, I can be more confident.* [Participant 13; female; aged 64 years; teacher; uncontrolled hypertension and obesity]

Subtheme 3: Supporting the Development of Technological Skills and Providing Resources

Most participants had limited technological skills and relied on their children to assist in using electronic telemedicine devices. Only a small minority were proficient in using such devices, with some preferring mobile phone calls over video calls owing to incompatible smartphones or unfamiliarity with more complex devices such as tablets or PCs. However, some older individuals expressed willingness to learn with proper support:

> *If necessary, I need to adapt. I have to learn to use additional equipment because I don't usually have a smartphone, so it might be difficult to learn. I can't even turn it on.* [Participant 9; female; aged 78 years; retired; well-controlled hypertension, type 2 diabetes mellitus, and dyslipidemia]

> *If it's time for telemedicine, I have to try to adapt and learn gradually.* [Participant 10; female; aged 71 years; retired; well-controlled hypertension, type 2 diabetes mellitus, and dyslipidemia]

Theme 4: Respecting Patients' Decision to Decline to Use Telemedicine for Various Reasons

Older patients often reject telemedicine owing to various obstacles. They face challenges related to age-related physiological changes, including forgetfulness and cognitive difficulties such as finding phones or using video calls despite instructions. In addition, some patients do not regularly use electronic devices, whereas others feel burdensome relying on their children for telemedicine assistance. A few patients are unable to receive telemedicine service owing to their routine work commitments. Therefore, HCPs need to understand these obstacles and respect their decisions for declining telemedicine:

> *I don't want to use telemedicine. It's not difficult for me to see a doctor in person. If you teach me something, I will forget in three months. For example, when I wanted to take a video, my grandchild had to teach me ten times, but when I got home, I couldn't remember. My memory has not been good for a few years.* [Participant 12; male; aged 68 years; self-employed; well-controlled hypertension and type 2 diabetes mellitus]

> *Sometimes I am not with my phone. Like when I went to a restaurant, I forgot my phone there and didn't realize it for three days. I think it's a problem related to age, but if I were newly retired at 60-65 years old, I would be fine. But now that I'm nearly 80, I have problems, especially with memory and internet use.* [Participant 23; male; aged 76 years; retired; well-controlled hypertension and type 2 diabetes mellitus]

> *If my child can help, that would be great. I need my child to be here because I don't know much. I'm forgetful, but I don't know if my child is available to help or not. I can't do it if I'm alone because I have to care for two other older people who are 90 years old. It's not easy for me because I have to take care of others as well.* [Participant 4; female; aged 63 years; retired; uncontrolled type 2 diabetes mellitus, well-controlled hypertension, and dyslipidemia]

> *I can participate, but I'm not familiar with it. I'm old and have never used LINE [chat application] before. Trying to learn it now may be difficult because my memory is not very good, and I tend to forget things easily. Although my grandchildren have computers and mobile phones, I don't want to bother them because they have to work all the time. If the doctor needs to call me, I have to ask my children. I don't know if they're available to answer or not.* [Participant 8; female; aged 71 years; retired; uncontrolled type 2 diabetes mellitus and well-controlled dyslipidemia]

Discussion

Principal Findings

Summary

In this qualitative study, participants perceived telemedicine as beneficial because it eliminates the need for travel and minimizes the risk of COVID-19 transmission. Older adults view telemedicine as a safe and effective way to manage stable chronic conditions. It is recommended to include health promotion in telemedicine services to enhance self-management. Regarding catering to older patients' needs, patients expressed that telemedicine should be presented as part of a continuous care program for multimorbidity, incorporating web-based monitoring with periodic in-person visits for physical examinations and laboratory screenings. Clear instructions, technological skills training, and access to resources such as equipment and caregivers are essential to make the program user-friendly for older patients. However, HCP should respect patients' decision to decline telemedicine owing to various obstacles that older patients may face when using it.

Patients accepted telemedicine as an effective method to improve access to health care for older patients. Some older patients face difficulties when coming to hospitals, such as finding transportation and parking space, long waits for the physician, and long queues for receiving medication [16,36]. This is in accordance with the literature that positive perceptions about telemedicine include cost savings [39]. During the COVID-19 pandemic, receiving treatment through telemedicine services also helped to reduce the risk of infection transmission by reducing the risk of overcrowding of patients and the risk of exposure for those who may not need to come to the hospital [40]. Telemedicine would be a necessary solution for addressing problems regarding access to care in the event of new pandemics.

Several studies have shown that telemedicine can effectively improve the health care outcomes of older patients, particularly those with chronic conditions such as diabetes [19], heart disease [20], and asthma [21]. A study found that telemedicine consultations reduced hospitalization rates among older patients with chronic heart failure compared with standard care [41]. Another study found that telemedicine consultations for older patients with chronic obstructive pulmonary disease improved symptom control and quality of life and reduced hospitalization rates [42]. There is evidence supporting that telemedicine services have the potential to enhance self-management among patients and their families, including improving medication adherence among older patients with chronic conditions and improving disease control and patient satisfaction [43,44].

Older patients, who often have >1 chronic condition, constitute a key group who use the health systems [45]. Owing to the situation in Thailand, it will be a superaged society in the next few decades [46]. The older adults would be the main target for health care delivery. There are potential opportunities in digital health such as telemedicine, emphasizing the management of chronic diseases in Thailand [47]. Cost-effectiveness was also another reason in the long run for telemedicine compared with an in-person visit [4,48]. On the basis of patients' perceptions obtained from our study and previous evidence supporting the health outcomes of telemedicine, we have the following 4 suggestions for enhancing telemedicine services tailored to the needs of older patients with multimorbidity.

Identify the Target Population as Individuals With Stable Chronic Conditions

Our study found that telemedicine is an accepted model for promoting continuous care for older patients with multimorbidity. In cases where patients have well-controlled chronic conditions and no abnormal symptoms, they can receive symptom monitoring and treatment through telemedicine [49]. Health care services for older patients with stable chronic diseases may not need to differ between telemedicine and in-person visits. The services should aim to monitor patients with stable conditions by regularly inquiring about their symptoms; offering self-care instructions at home (such as measuring blood pressure and blood sugar levels); and encouraging healthy behaviors such as medication adherence, maintaining a proper diet, and engaging in regular exercise. Telemedicine has the potential to replace nonurgent in-person medical visits for stable chronic diseases, as it can be used for symptom monitoring, detecting complications or disease progression, and prescribing medication delivery for stable chronic conditions [7,50].

Telemedicine Services Should Be Designed to Closely Resemble In-Person Visits With Scheduled Periodic In-Person Visits

Patients expressed concerns regarding the quality of care and maintaining the physician-patient relationship received through telemedicine. A previous study revealed that older patients perceived in-person visits as fostering a strong physician-patient relationship compared with telemedicine [16]. To address these concerns, telemedicine services should strive to deliver care that closely resembles an in-person visit in terms of the process and pattern of care. Telemedicine using video calls closely simulates an in-person visit over phone calls. It helps reduce medication errors, enhances diagnostic accuracy, and improves decision-making accuracy [51]. Telemedicine holds the potential to facilitate shared decision-making between patients and HCPs, thus promoting a patient-centered approach to care [52]. HCPs can also leverage telemedicine to provide education, promote behavior change, empower patients to take control of their health, boost their confidence, and ensure continuity of care [53].

Nevertheless, it is important to acknowledge the limitations of telemedicine. It is unable to perform comprehensive physical examinations and detailed laboratory tests, which means that it cannot fully replace in-person visits. Hence, it is crucial to integrate regular in-person visits with a physician at a hospital to adhere to standard medical practices. These in-person visits can be scheduled periodically on an annual basis, which can help instill confidence and satisfaction with the telemedicine services [54].

Integrated Support Systems for Telemedicine, Including Clear Protocols, Caregiver Assistance, and Electronic Health Literacy Training

When caring for older patients with multimorbidity through telemedicine, it is essential to establish a program that adheres to standard practices, incorporates clear protocols, and provides the necessary technical skills and resources. This will help ensure that telemedicine remains as a viable option beyond the COVID-19 pandemic, emphasizing ease of use and demonstrating its benefits. A well-defined service program enables patients to understand the process of care they will receive and empowers them to communicate their specific health needs [55]. In addition, telemedicine services for older adults may require assistance at various stages, including guidance for using tools such as smartphones, instruction for use, and involving caregivers in the process [56]. These supports could contribute to a smooth and more effective telemedicine experience for older patients and their caregivers.

Develop Alternative Services for Older Adults Who Cannot Use Telemedicine

Despite the potential benefits of telemedicine for the care of older adults, its use has some challenges and limitations. Some older patients may face various obstacles in using telemedicine, such as declining vision, hearing, and memory owing to aging; difficulty in learning new skills; unfamiliarity with technology; and feeling burdened to ask for support, which can lead to rejecting telemedicine services [56]. In addition, telemedicine is unsuitable for unstable patients requiring emergent management and detailed physical examinations that cannot be conducted remotely [57]. Some specific clinical contexts or onset of new symptom in multimorbidity, such as hemiparesis, require a comprehensive examination for critical diagnostic accuracy and severity evaluation. If possible, an in-person visit would be more appropriate [58]. Thus, in-person visits or other alternatives should be available [7].

Strengths and Limitations

The study has several strengths and limitations. The strength of this study lies in its structured approach to gathering insights about various aspects of telemedicine service tailored to the need of older adults with multiple chronic conditions. The study results can provide valuable guidance about preparing and delivering telemedicine services for this population. However, there are still some limitations to be considered. First, participants were recruited from a single health care facility. The results may be affected by the nature of the health care system and the educational level and digital literacy level of the population. Further studies from different settings and regions are needed to tailor telemedicine services to the needs of older adults with multimorbidity. In addition, future studies could explore more experiences of HCPs providing telemedicine services to this population and identify strategies to address their challenges and concerns. Next, we did not include uncontrolled conditions in this study, and we did not include health care professionals. Further studies may include other telemedicine users. Another consideration point that could influence the results of this study is gender. Gender is associated with differences in digital health care behavior and plays a role in the adoption of health technologies. For example, women exhibit high tendency to access health care services, book physician’s appointments, and search for nutrition-related information. In contrast, men are more likely to explore options related to smoking cessation and use health apps for monitoring sleep patterns and blood pressure than women [59].

As there are various guidelines for telemedicine management, the platform used depends on the facility in each hospital setting. Having many telemedicine providers may disrupt the continuity of care owing to regulation and personal data protection [60]. Furthermore, there remains an inequity in access to care in telemedicine for vulnerable population, such as older people. A strategy to promote electronic health education and provide the necessary equipment to ensure telemedicine equity is needed [61]. Therefore, the use of telemedicine should be tailored depending on the setting and needs of the population and health system.

To ensure the sustainability of telemedicine for older patients with multimorbidity, HCPs should consider patients’ needs, expectations, and abilities when designing telemedicine systems. Importantly, the findings also suggest that HCPs should respect the decision of older patients who decline to use telemedicine owing to multiple obstacles and find alternative ways.

Conclusions

The study highlights the importance of personalized and patient-centered care [62], where providers should understand older adults’ needs, preferences, and limitations to tailor telemedicine services for the population. The use of telemedicine for older patients with multimorbidity should focus on those with stable conditions. For this population, telemedicine can help increase access to medical services for patients who require continuous monitoring and care. A structured program incorporating periodic in-hospital visits can help increase patient acceptance of telemedicine. However, HCPs must also understand the limitations of older patients owing to various factors that may prevent them from receiving telemedicine services.

Abstract

Background: A number of studies document the benefits of face-to-face social interactions for cognitive functioning among middle-aged and older adults. Social activities in virtual worlds may confer similar if not enhanced cognitive benefits as face-to-face social activities, given that virtual interactions require the additional cognitive tasks of learning and navigating communicative tools and technology platforms. Yet, few studies have examined whether social activities in internet-based settings may have synergistic effects on cognitive functioning beyond those of face-to-face interactions.

Objective: This study examined whether internet-based social activity participation is associated with concurrent and later cognitive functioning, after adjusting for face-to-face social activity participation and sociodemographic covariates.

Methods: For cross-sectional analyses, we included 3650 adults aged 50 years and older who completed questions in the 2020 Health and Retirement Study about social activity participation, including specific internet-based social activities such as emailing or accessing social networks. Cognitive functioning was measured using the standardized cognitive tasks assessing working memory, episodic memory, and attention and processing speed. The longitudinal analyses included the 2034 participants who also completed follow-up cognitive assessments in 2022.

Results: Our results revealed that those with higher levels of internet-based social activity participation had higher levels of concurrent cognitive functioning than those with low levels of internet-based social activity participation, after adjusting for demographic and health-related factors and face-to-face social activity participation (b=0.44, SE 0.07; P<.001). More internet-based social activity participation also predicted better cognitive functioning 2 years later, even when adjusting for baseline cognitive functioning and other covariates (b=0.35, SE 0.09; P<.001).

Conclusions: Our findings suggest that greater engagement in internet-based social activities is associated with higher levels of concurrent cognitive functioning and slower cognitive decline in middle-aged and older adults.

Introduction

Social activity participation is strongly tied to multiple aspects of health and well-being in later life, including psychological well-being, depressive symptoms, physical health and functional limitations, and cognitive health [1-5]. Emerging research focusing on the cognitive benefits of social activity participation documents different aspects of social activity participation that are related to cognitive functioning, such as frequency (how often an individual engages in social activities) and variety (how many different types of activities an individual engages in social activities) [6]. For example, those who participate in social activities more frequently are likely to have enhanced concurrent cognitive functioning, slower age-related cognitive decline, and reduced dementia risk [7,8]. In addition to frequency of engagement, those who engage in a greater number of social activities show better later cognitive functioning than their socially inactive peers [6]. These social activities increasingly involve virtual interactions such as texting, video chats, or the use of other social media to stay connected [9]. Nevertheless, most research has focused predominantly on the benefits of face-to-face social activity participation on cognitive functioning [8]. This study investigated how engagement in a variety of internet-based social activities relates to cognitive functioning, especially for adults aged 50 years and above.

Communicating with others in virtual worlds can offer similar cognitive health benefits as face-to-face social activities [10]. For example, internet-based social activities such as posting status updates or liking others’ updates on Facebook are associated with high levels of cognitive functioning in adults aged over 55 years [11]. Emailing and texting, also forms of internet-based social connection, are related to a lower likelihood of cognitive impairment over 5 years in adults aged over 65 years [12]. Beyond engaging in any internet-based social activities, engagement in different types of internet-based social activities may also have cognitive benefits.

A variety of internet-based social activities may provide greater opportunities to learn novel information than engaging in fewer activities; moreover, it is related to greater hippocampal volume [13]. Novel information is also related to hippocampal neurogenesis and reduced age-related neural apoptosis, which are associated with cognitive functioning that relies on more than a single source of communication [14,15]. In addition, individuals can also share thoughts or feelings in a variety of virtual communities [16], which engage cognitive processes such as problem-solving and perspective-taking [17].

Unique aspects of internet-based social activities may boost the cognitive benefits of engaging in a variety of such activities. First, different types of internet-based social activities may require the use of various interactive tools such as internet searching or instant messaging. These different techniques and activities may be cognitively stimulating because they involve learning and memory [18]. Even simple internet searches are a neural exercise for middle-aged and older adults, activating multiple brain regions related to decision-making and complex reasoning [19]. Furthermore, content acquired through internet-based social activities is delivered in multiple formats such as sound, pictures, or videos [20]. Studies have demonstrated that the simultaneous presentation of information in visual and auditory modalities is associated with enhanced learning performance [21]. Moreover, each internet-based social activity may have its own function, offering an array of uses. For example, blogs or Facebook are used for information sharing, while Snapchat or Instagram is used for self-expression and self-documentation [22-24]. These findings about the use of different modalities and functions across various platforms suggest that internet-based social activity participation may be associated with better cognitive functioning.

Internet-based social activities may also benefit specific cognitive domains. Although research on the association between internet-based social activity participation and subdomains of cognitive functioning is still emerging, some studies provide initial evidence that benefits may particularly be related to memory. For example, internet use is linked to improved episodic memory, potentially through increased social contact [25]. Concurrent engagement in offline and internet-based social activities is also related to high levels of episodic memory [26]. This may be explained by people recalling previous social interactions and past experiences as well as by the processing and storing of new information, all of which are linked to episodic memory [27,28]. On the other hand, the relationship between internet-based social activity participation and executive functioning is more complex, as executive functioning encompasses a broad range of cognitive control processes such as reasoning, problem-solving, and attentional control [29]. Some studies suggest that learning to engage in internet-based social activities on laptop applications can enhance inhibition, but its relationship with working memory and attention and processing speed is less consistent [30]. Facebook users also exhibit higher scores in attention or inhibition, but not in working memory, than nonusers [11].

Studying technology use in the social domain for older adults may be particularly relevant because people are increasingly motivated to use technology for social motives as they age. According to socioemotional selectivity theory [31], people increasingly prioritize socioemotional goals with age. As a result, people are even more motivated to connect with others such as friends or grandchildren as they grow older, and thus, they are more likely to engage in internet-based platforms for socioemotional goals as opposed to nonsocial goals. While young adults may engage in internet-based social activities for various purposes such as self-representation or entertainment, older adults may be more motivated to engage in the virtual world for social reasons, such as maintaining interactions with their family, friends, or their community and receiving social support [32,33], which can be related to cognitive functioning [34].

For the aforementioned reasons, this study examined whether engagement in diverse internet-based social activities is positively related to concurrent and later cognitive functioning in middle-aged and older US adults beyond face-to-face social activities and whether this relationship varies by age. We hypothesized that internet-based social activity participation would be associated with high levels of concurrent cognitive functioning and slow cognitive decline across time, particularly in episodic memory. We also hypothesized that the relationship between internet-based social activity participation and cognitive functioning would be more pronounced in older adults. Data are from the Health and Retirement Study (HRS), a large national survey of adults aged 50 years and older. Information about technology use was first collected during the COVID-19 pandemic, a period when face-to-face interactions were limited and technology use among older adults increased [35].

Methods

Participants

The HRS is an ongoing project since 1992 that examines sociodemographic and psychological factors as well as health status to assess the well-being of US adults aged 50 years and older. The sample was recruited at the household financial unit level through a multistage area probability sampling method and required participants to complete an in-person interview and a telephone-administered short cognitive battery every 2 years [36]. From 2006 onward, a random 50% of participants were invited to complete a psychosocial survey returned to the researchers by mail. For the cross-sectional analysis, we used data from 2020 (n=3650), when survey questions about activity engagement in both internet-based and offline (face-to-face) settings in the self-administered psychosocial survey were first included. Data were collected from March 2020 through May 2021, amid the COVID-19 pandemic. For the longitudinal analysis, we included 2034 participants who completed cognitive assessments both in 2020 (wave 1) and 2022 (wave 2; collected from March 2022 through September 2023).

Measures

Cognitive Functioning

Cognitive functioning was assessed using the modified Telephone Interview for Cognitive Status [37,38]. The Telephone Interview for Cognitive Status measures episodic memory, working memory, and attention and processing speed with the following tasks: the immediate and delayed recall of a set of 10 words (episodic memory; range of 0 - 20), serial 7 subtraction (working memory; range of 0 - 5), and backward counting (attention and processing speed; range of 0 - 2). The scores for these 3 domains were summed together, with potential total scores ranging from 0 to 27, a method consistent with previous studies assessing overall cognitive functioningusing data from the HRS [39,40]. To address potential bias from missing cognitive data, the HRS imputed missing values in the 2020 dataset used in this study, using demographic factors (eg, birth year, years of education), wave-specific demographics (eg, age), economic status (eg, income), health factors (eg, chronic conditions, visual impairment), physical functioning (eg, instrumental activities of daily living [IADLs]), and prior cognitive functioning [41].

Internet-Based Social Activity

Internet-based social activity included the following 7 items: taking or sharing photos and videos; sending or receiving instant messages, text messages, or emails; writing or reading blogs, reviews, ratings, or comments on the internet; accessing a social network site like Facebook, Twitter, or Instagram; using other social media such as Linkedin to network with people; using WhatsApp, Snapchat, or similar apps to network with people; or connecting face-to-face with family and friends using an app (such as FaceTime or Skype). To calculate internet-based social activity scores, we first created binary variables indicating whether the participants reported having participated in such activity at least once a month or more (1=engaged at least once a month or more, 0=engaged less than once a month) and then summed these 7 binary composite variables, using a method consistent with the previous studies examining social activity variety [6,42]. Higher scores indicate more diverse internet-based social activities, with a possible range of 0 to 7.

Face-to-Face Social Activity

Face-to-face social activity included 11 items. Five items, indicative of socially oriented activities from prior research [43], included doing volunteer work with children or young people; doing any other volunteer or charity work; taking an educational or training course; going to a sporting, social, or other club event; and attending meetings of nonreligious organizations. The other 6 items, representing social activities in the previous literature [44], included caring for a sick or disabled adult; attending a religious service; doing activities with grandchildren, nieces, nephews, or neighborhood children; meeting up with children not living with the respondent; doing activities with other family members not living with the respondent; or meeting friends. We calculated the face-to-face social activity scores using the same method for internet-based social activity, with a possible range of 0 to 11. Higher scores indicate more diverse face-to-face social activities, following the existing studies on social activity variety [6,42].

Demographic and Health-Related Variables

We included the following demographic covariates in the model based on the previous studies on activity engagement [6,45]: age, sex (0=female, 1=male), race (0=racial and ethnic minority groups, 1=White), years of education (possible range: 0 - 17), working status (0=not working, 1=working), marital status (0=not married or partnered, 1=married). To capture subjective economic status, we included a question about participants' satisfaction with their financial situation (1=not at all satisfied, 5=completely satisfied). Two physical health-related factors were also included, one of which was IADLs (eg, difficulty with making phone calls, managing money, taking medications, shopping for groceries, preparing a hot meal), along with the number of chronic conditions (eg, hypertension, diabetes, cancer, lung disease, heart disease, stroke, arthritis). We also included an 8-item short form adapted from the 20-item Center for Epidemiologic Studies-Depression scale to measure depressive symptoms [46]. Participants indicated whether they had experienced any of the following during the past week with a yes (1) or no (0): felt depressed, felt that everything they did was an effort, slept restlessly, were happy (reverse coded), felt lonely, enjoyed life (reverse coded), felt sad, and could not get going.

Data Analysis

Using SAS 9.4, we conducted 2 separate linear regression models for overall cognitive functioning. Model 1 included only internet-based social activity and covariates as predictors. Model 2 incorporated face-to-face social activity in Model 1 to determine whether the effects were held after a measure of social activity without technology was included. Then, we ran a regression to examine whether internet-based social activity was related to a change in cognitive functioning, after adjusting for baseline cognitive functioning and face-to-face social activity and covariates, using cognitive functioning in 2022 as the outcome and including cognitive functioning in 2020 along with the covariates and social activity.

We also ran regression models to examine the relationship between internet-based social activity and each subdomain of cognitive functioning to determine whether effects varied across these domains. In addition, we explored whether age interacted with internet-based social activity in its association with cognitive functioning, reasoning that a 2-year change in cognitive functioning may be more likely to occur in older individuals. We also explored whether age was perhaps more sensitive to influences on cognitive functioning.

Ethical Considerations

This study used publicly available, deidentified secondary data from the HRS, which was approved by the University of Michigan Institutional Review Board and sponsored by the National Institute on Aging (NIA-U01AG009740). Therefore, institutional review board approval was not required.

Results

Characteristics of the Participants and Their Internet-Based Social Activity Participation

Participants in the cross-sectional sample (N=3650) were aged between 50 and 99 years (mean 67.68, SD 9.77) and most were female (2174/3650, 59.6%), White (2679/3650, 73.4%), not working (2579/3650, 70.7%), and married or partnered (2100/3650, 57.5%). Most participants were high school graduates with an average of 13.50 years of education and were, on average, satisfied with their current financial situation. Most reported good health, with a low average IADL score and few chronic conditions (3132/3650, 85.8%, had an IADL score of 0). On average, they engaged in 3.35 different types of face-to-face social activities and 3.50 types of internet-based social activities. Cognitive functioning ranged from 0 to 27 with an average score of 16.24 and an SD of 4.35. Table 1 presents additional demographic and health-related characteristics, along with details on social activities and cognitive functioning for the longitudinal sample and dropouts.

Table . Descriptive statistics in demographic factors, internet-based and offline social activity, and cognitive functioning.

	Cross-sectional sample (N=3650)	Longitudinal sample (n=2034)	Dropouts (n=1616)	Attrition analysis

[a] *t* test.

[b] Chi-square test.

The 7 types of internet-based social activities varied in their frequency, with the most frequent being sending or receiving instant messages, text messages, or emails (3049/3650, 83.5%) and the least being using social media platforms such as LinkedIn (611/3650, 16.7%) (Table 2).

Table . Number of participants engaging in various internet-based social activities.

Internet-based social activity	Participants (N=3650), n (%)
Sending or receiving instant messages, text messages, or emails	3049 (83.5)
Taking or sharing photos and videos	2360 (64.7)
Accessing a social network site like Facebook, Twitter, or Instagram	2323 (63.6)
Writing or reading blogs, reviews, ratings, or comments on the internet	2011 (55.1)
Connecting face-to-face with family and friends using an app such as FaceTime or Skype	1695 (46.4)
Using WhatsApp, Snapchat, or similar apps to network with people	713 (19.5)
Using other social media such as LinkedIn to network with people	611 (16.7)

Internet-Based Social Activity Participation and Concurrent Cognitive Functioning

Table 3 presents the results from our regression models testing our hypothesis that a greater variety of internet-based social activity use would be related to higher concurrent cognitive functioning. As indicated in Model 1, those who engaged in more diverse internet-based social activities had better overall cognitive functioning after adjusting for demographic and health-related factors (*b*=0.46, SE 0.07, *P*<.001). Results remained significant when we added face-to-face social activity participation (*b*=0.44, SE 0.07, *P*<.001; Model 2).

Table . Cross-sectional associations of internet-based social activity at W1[a] with cognitive functioning at W1 (n=3650). Age, internet-based social activity participation, and face-to-face social activity participation were standardized.

Parameter	Model 1		Model 2

Internet-Based Social Activity Participation and Later Cognitive Functioning

We then examined our prediction that greater variety in internet-based social activity participation in 2020 would be related to a slower decline in cognitive functioning over 2 years. Results from our longitudinal regression analysis revealed that those who engaged in more diverse internet-based social activities had higher cognitive functioning 2 years later, after adjusting for demographic and health-related factors as well as for cognitive functioning at baseline (*b*=0.36, SE 0.09, *P*<.001; Model 1 in Table 4). Results remained significant when we added face-to-face social activity participation (*b*=0.35, SE 0.09, *P*<.001; Model 2 in Table 4).

Table . Longitudinal associations of internet-based social activity at W1[a] with cognitive functioning at W2[b] (n=2034). Age, internet-based social participation, and face-to-face social activity participation were standardized.

Parameter	Model 1		Model 2

[c] When examining the relationship between face-to-face social activity participation and cognitive functioning, excluding internet-based participation, face-to-face social activity participation was not associated with change in cognitive functioning across time (*b*=0.08, SE 0.07; *P*=.27).

[d] Not applicable.

Additional Exploratory Analyses

When we examined the longitudinal association of internet-based social activity participation with changes in subdomains of cognitive functioning, those who participated in more diverse internet-based social activities had better later episodic memory (*b*=0.35, SE 0.08; *P*<.001), but not working memory or attention and processing speed, after adjusting for the baseline cognitive functioning (Table 5). In addition, we explored possible age differences in the association of social activity participation with later cognitive functioning, but the interaction effect of age and internet-based social activity participation was not significant for overall concurrent cognitive functioning (Table 6).

Table . Longitudinal associations of internet-based social activity at W1[a] with subdomains of cognitive functioning at W2[b] (n=2034). Age, internet-based social participation, and face-to-face social activity participation were standardized.

Discussion

Building on the importance of social activity in the real world, we examined the impact of a variety of social activities in virtual worlds on cognitive health. We found that greater engagement in internet-based social activities was associated with high levels of concurrent and later cognitive functioning, particularly in episodic memory, even after adjusting for face-to-face social activity, a relationship that did not vary by age.

Internet-Based Social Activity Participation With Cognitive Functioning

People have raised concerns that virtual social activities may not provide the same mental stimulation as face-to-face interactions, due to factors such as reduced social cues from the absence of facial expressions or voice tones [46]. The implication of these concerns is that less social stimuli would provide less cognitive stimulation. Yet, research finds that virtual communication offers a variety of different types of cues and multiple sensory stimulation [20]. For example, video-based communications involve similar verbal and nonverbal cues to face-to-face social activities [47]. Dynamic animations or videos also provide visual and auditory cues [48,49], which may enhance one's engagement with the environment. In addition to potential cognitive stimulation from communicating with others in these virtual worlds, internet-based social activity includes other tasks involving cognitive processing, such as recollecting, retrieving, and reminding functions [30]. Moreover, internet-based social activity participation may be a channel to exchange social support, which further relates to cognitive functioning [7]. Platforms like Snapchat or Instagram enable sharing moments across generations, while blogging fosters a sense of belonging and social support by connecting individuals with shared interests [50,51], all of which can be potential psychological mechanisms for cognitive benefits and may be reasons why engaging in virtual social activities was associated with high levels of both concurrent and later cognitive functioning in this study.

When examining the subdomains of cognitive functioning, engagement in diverse internet-based social activities was only related to episodic memory. Engagement in social activities in virtual worlds may facilitate learning and remembering new information, which has been related to better episodic memory in another study [52] and is consistent with our findings. On the other hand, activities included in this study, such as posting, messaging, and sharing photos, have not been associated with executive functioning in previous studies [30], similar to our null effects within this subdomain. A recent study, however, suggests an indirect relationship between internet-based social activity participation and executive functioning, as seen in individuals who receive social support through sustained use of internet-based social media [34]. We do not have the data to examine this indirect relationship, but future studies should examine the possibility of indirect effects of virtual social activity participation on executive functioning.

The relationship between internet-based social activity participation and cognitive functioning did not vary by age. Previous research raised concerns that older adults may derive fewer benefits from internet-based social activities because they are likely to have potential physical limitations restricting engagement in technology use in social interactions [53]. Yet, our results indicate that the cognitive benefits of internet-based social activity participation were consistent across age even without adjusting for health-related factors. In addition, the potential mechanisms that may link participation in internet-based social activities and cognitive functioning may be comparable across ages, as internet users of all ages tend to participate in various social networks [54].

Associations of Face-to-Face Social Activity Participation With Cognitive Functioning

Face-to-face social activity participation was also related to concurrent cognitive functioning, but not to later cognitive functioning, when internet-based participation was excluded from the model. Our results contrast previous findings indicating cognitive benefits of face-to-face social activities [8]. One potential reason why we failed to find a difference is that the effect size of the relationship between face-to-face social activity participation and cognitive functioning may be very small. Another reason may be that people who may experience cognitive decline or other cognitive issues may receive more social support from others and thus obscure the association. Finally, these data were collected during a time when face-to-face interactions were more limited than usual. Social activities outside the home, such as clubs, educational courses, or volunteer work, were strictly restricted during the COVID-19 pandemic. This may have led to a limited engagement in face-to-face social activities regardless of individuals' interests or motivations for engaging in them and may have contributed to the weaker association observed with cognitive functioning.

Another consideration is that cognitive health benefits of face-to-face social activity may be especially notable when individuals are involved in these activities consistently over an extended period of time [6]. Studies have supported the importance of sustained social activity participation by demonstrating that the relationship between face-to-face social activity and cognitive functioning was stronger when examining the participation across time rather than participation at the baseline [55]. We did not measure how long participants had been engaging in each of these activities.

Importantly, this study focused on cognitive functioning, one aspect of health, among older adults. Our findings suggest that virtual social activities, as opposed to face-to-face activities, were related to a slower decline in cognitive functioning over 2 years; however, other aspects of health may have a different pattern of results. For example, several studies on the health benefits of internet-based and face-to-face social activity participation have found that only face-to-face interactions are related to better emotional well-being [56]. In addition, several studies find that social interactions via technology such as emailing or texting cannot replace face-to-face interactions in combating loneliness [57], emphasizing the significance of face-to-face social interactions for other health outcomes, such as emotional health.

Limitations and Future Directions

This study has limitations that can be addressed in future studies. Internet-based social activities used in this study may not encompass all social activities in the virtual world. Further studies could examine a broader range of such activities, such as playing interactive computer games. Moreover, the item "taking or sharing photos and videos" may capture 2 distinct activities: taking photos or videos and sharing them. Since sharing involves social interaction, those who only took photos may not be engaging socially. We examined whether excluding this item from internet-based social activity impacts its relationship with cognitive functioning, and the results remained consistent. Although we used items with social components, future studies could explore which internet-based activities necessarily involve social interaction and how they relate to cognitive functioning. In addition, we used data that were collected during the COVID-19 pandemic, and as we mentioned, engagement in various internet-based social activities may have health benefits when in-person interactions are limited—benefits that may not appear when people are less socially restricted. Future studies could examine the relationship between internet-based social activity participation and cognitive functioning under other circumstances. Lastly, other psychological or sociodemographic factors, such as motivations for learning, could yield different patterns of the relationship between engagement in a variety of internet-based social activities and cognitive functioning. Further studies could explore this relationship across different backgrounds, such as in individuals with different levels of motivations or self-control.

Conclusion

Social activities through internet-based platforms, such as sharing moments or communicating with others, were related to higher levels of concurrent and future cognitive functioning in late adulthood when examined during the COVID-19 pandemic. This study contributes to the existing findings on the importance of social activity participation by promoting the role of engagement in diverse social activities in internet-based settings. Given that middle-aged and older adults are highly motivated to interact with their friends and family members, they may be more likely to use and benefit from technology that provides them with a way to maintain social connections.

Abstract

Background: Intergenerational friendship, a mechanism of social support, is an effective intervention to reduce the increasing risk of social isolation (SI) and develop companionship in the older adult population. The COVID-19 pandemic provided a unique opportunity to examine the psychosocial intervention of befriending via technology use as a primary form of contactless socialization.

Objective: The study aims to explore the effectiveness of the befriending intervention through a contactless, intergenerational service-learning project on older adult emotions, especially boredom and loneliness as the key attributes of SI, and on students' attitude toward companionship.

Methods: During the months of January to April 2022 , undergraduate students enrolled in a health administration course with a special focus on culture were asked to be involved in a contactless, intergenerational service-learning project (n=46). In this study, contactless intervention meant communication using the telephone and apps such as FaceTime and Zoom. Students were paired with older adults to have at least a 30-minute weekly conversation, for 8 weeks, via telephone or an internet-based app such as FaceTime. Students were asked to write a half-page diary after each interaction and a 1-page reflection at the end of the fourth week and at the end of the service-learning project. At the completion of the project, the researchers also surveyed the older adults to assess the impact of the project using a 5-item open-ended questionnaire. Following a heuristic approach and content analysis, student artifacts (110,970 words; 118-page, single-spaced Microsoft Word document) and the older adult surveys were analyzed using MAXQDA, (VERBI GmbH). Qualitative data were extracted to assess the impact of service learning on SI by measuring the attributes of boredom and loneliness among 46 older adults. Students' attitudes toward companionship were also assessed using data from their diaries and reflections.

Results: Overall, three major constructs were identified: (1) meaningful engagement, defined as feeling safe, having increased confidence, and having reduced boredom; (2) internal motivation to participate in the weekly interaction, defined as discussion about daily life experience, level of happiness, and ability to exert personal control over the situation; and (3) intergenerational befriending, defined as perceived benefits from the friendly nature of the interaction, ability to comfortably connect with students, and positive feeling and attitude toward the student.

Conclusions: The contactless, intergenerational befriending intervention reduced boredom and loneliness among older adults and enhanced positive attitude and confidence among university students. Students helped older adults to develop digital skills for the use of apps and social media. Older adults showed interest in the intervention and shared their daily life experiences with the students, which helped to reduce the gap between generations. Findings indicate the effectiveness of an intergenerational service-learning intervention on SI reduction and increased positive attitude among college students.

Introduction

Background

The growing surge of the aging population has shone a spotlight on social isolation (SI). With increasing age, an increasing proportion of older adults experience chronic boredom and feelings of loneliness [1]. In addition, COVID-19 confinement and quarantine disturbed their lifestyle behaviors, making the aging population susceptible to high levels of stress and depression. SI is exacerbated when people are living alone, especially vulnerable older adults, experiencing the loss of family or friends, having comorbid or chronic illnesses, and facing sensory impairments. Even in residential settings and older adults' living facilities, many older adults struggle to maintain their autonomy, self-determination needs [2], and competence as they are often disconnected from the broad community or dependent on unskilled nursing staff who lack social competence and training [2,3]. An intergenerational service-learning approach to befriending these individuals is an effective intervention to enhance their psychosocial well-being [4]. This approach demonstrates the importance of using reflective writing assignments to help university students deconstruct and reconstruct images, beliefs, and paradigms about older adults [5]. In addition, it is where the young individuals relate to older adults to discuss or share their life stories or day-to-day experiences to alleviate boredom, an attribute of SI [6].

Although SI is a global epidemic implying the absence of meaningful human relations and social connectedness, befriending is a psychosocial tonic to building social relationships and intergenerational friendships [7] that might reduce boredom and depression and significantly enhance the quality of life among older adults [8] and youth. The feeling of companionship is augmented when an intergenerational conversation is conducted purposefully, thereby negating the exacerbating consequences of SI such as boredom or even the feeling of loneliness. These negative subjective experiences result from discrepancies between an individual's desires and perceptions about the quality of social relationships [9].

Intergenerational conversations are a gateway to enduring socialization for older adults and students [9]. The quality of life is enhanced as both generations engage in purposeful activities in a safe and friendly environment [8] to the satisfaction of each other's psychosocial needs and well-being. Long-lasting intergenerational conversations can create a bonding between the older adult and the student, and it enhances the level of patience and builds social competence in youth, which are essential attributes to become skilled health care professionals in long-term care [10]. The social support provided by students can foster emotional health for the isolated, frail, older adult who is no longer at the center of a network of friends and acquaintances. Older adults with social connections have a high quality of life under social support [11], are motivated to work and engage in social activities, and have an inclusive attitude that promotes a healthy lifestyle [12]. Hence, they have low risk of conditions such as depression, additive behaviors, or dementia [13]. With social connectedness, even in living alone situations, these individuals have life satisfaction, with high cognitive stability [10,14].

Facets of SI

SI is one of the most disruptive transformations that exacerbate the quality of life, affecting human behavior, perceptions, and experiences [10,15]. It is a condition that leaves one with feelings of boredom and loneliness that are detrimental to physical and mental health [7]. Loneliness among older adults is the subjective, distressed feeling of being alone or separated, whereas SI is the objective physical separation from the community [14,16]. In addition, boredom is an emotion that often triggers negative thoughts such as self-harm and anxiety, and it is profound when the surrounding environment is mostly empty [17]. Hence, boredom, compounded by the feeling of loneliness over a prolonged period, may result in depression [18], which is a mental disorder that can be controlled in a timely way by identification of the needs of individuals and restoration of successful attention in meaningful activities such as intergenerational conversations. More than 56 million adults aged ≥65 years live in the United States, accounting for approximately 16.9% of the nation's population [19]. In this population, >7 million (13%) are socially isolated. Of those 7 million individuals, 1.3 million are severely socially isolated [5,7]. The crucial drivers of boredom [18,20], namely, lack of recreational opportunities; limited personal contacts; immobility; prescribed home office; and, especially, COVID-19 quarantine and isolation have dissuaded the everyday lives of older adults, triggering anxiety and monotony [4,16,21].

Boredom across the population increased significantly owing to the COVID-19 pandemic containment measures [22], and so did the behavioral intention to find information, access services, and connect socially [23]. For older adults, there is evidential increase of the benefits of technology interventions for social connectedness [10,24]. This may have helped the contactless, intergenerational, service-learning intervention to become especially effective, facilitating the feeling of companionship and social support that is felt bilaterally and actively by both parties [25].

Intergenerational Service Learning

Intergenerational service learning is an experiential learning, which is a course-based, credit-bearing, educational experience in which students participate in an organized, service-learning activity that meets identified community needs. Students reflect about the service activity to gain further understanding of a course content [26]. With an intent to develop a sense of companionship or friendship between both parties, the intergenerational service-learning intervention brings the socially isolated older adults back on the periphery of social activities as they engage in conversations with college students [27]. Recurrent interactive sessions are useful to enhance the level of subjective well-being among older adults and connect them to the social network [28].

Alternatively, the service-learning sessions provide a broad appreciation of discipline and an enhanced sense of civic responsibility to the students while connecting them in purposeful activity with community members [29]. Requesting students to write diaries and reflections regarding their interactions with older adult adults is a key component of service learning [25,29]. Although it is less likely to see older individuals readily embracing service-learning sessions involving students or even social media sites when compared with young adults, adoption rates for contactless interactions with students among individuals aged ≥65 years have approximately doubled in the United States in the past 4 years [14,30].

Intergenerational Befriending Approach

This study used an approach that aims to bolster a long-lasting, genuine connection or relation between generations, especially college students engaged in service learning and older adults who are socially isolated [31]. This connection is based on shared experiences of daily living, which is reflected in the recurrent interaction based on the multicultural project. Although the intergenerational connection may develop over a contactless platform, it fosters a sentiment of compassion and empathy through focused interactions that add purpose and engagement for participants. The befriending idea is based on reciprocity and what benefits the older adult in a relationship [32]. The interactions are mostly based around topics that are meaningful to the older adult [10,33] and benefit the student to understand the biases of ageism. The idea is to make the older adult feel valued and cared for in a relation that is free from any kind of service delivery, obligation, or family ties [26,34].

Contactless Socialization

The quality of life comprises components such as health; well-being; peaceful existence; living in harmony; social engagement; life satisfaction; and keeping oneself busy with hobbies, volunteer service, or work [8,35,36]. The older adults were subjected to a harsher reality during the pandemic than younger adults as old age was affirmed as a risk for COVID-19 complications [37]. This contention promoted contactless socialization through contactless service-learning sessions via SMS text message, FaceTime, and emails that connected the older adults to wide social networks [38]. Although user confidence remained as a dominant issue when using technology such as a smartphone or tablet for interaction needs [39], the willingness and interest of older adults let students train them on the use of technology. The training also facilitated the use of mobile health and telemedicine among older adults, which greatly enhanced their health-related quality of life [40]. Hence, technology-based, contactless, service-learning sessions provided safe interaction for both parties, fostering social support and technology skill augmentation for the older adults [41]. Simple telephonic calls were used to build intergenerational friendships [13,38] connecting student helpers with their clients through personal life experience, interpersonal interaction, collaboration, and understanding [42].

Study Purpose

The study aimed to explore the effectiveness of the befriending intervention through a contactless, intergenerational, service-learning project on older adult emotions, especially boredom and loneliness as the key attributes of SI, and on students’ attitude toward companionship.

Our approach was to forge an alliance and create an affective bond between the young student and the older adult to facilitate the possibility of friendship as they shared their life experiences and students engaged in technology training activities for the older adults regarding the use of apps and social media sites. The relationship that develops through befriending is seen as central to the experience while hypothesizing the facts that befriending would foster psychosocial well-being among older adults and that students’ attitudes toward older adults would become more positive throughout the service-learning course.

Methods

Study Setting and Recruitment

The research design was based on qualitative data analysis [43]. Data were collected through the survey of older adults and dialogues included in journal entries submitted by 46 undergraduate students enrolled in a Health Administration course. This core or required course had a special emphasis on cultural competency and diversity. The study followed 46 older adults, aged between 64 and 82 years, via intergenerational service-learning sessions during the months of January to April 2022. The older adults were recruited from residential facilities in Good Samaritan Society, Denton, Texas; Schertz Senior Living, Texas; Knowles Home, Nashville, Tennessee; Aguadilla Seniors, Puerto Rico; and Guadalajara Senior Center, Mexico. We selected these locations because these are the largest centers for older adults known to the researchers, and we asked the older adults in these centers to invite other participants known to them to participate in the study, to expand the sample size.

The inclusion criteria for older adult participants consisted of the following: those who (1) were interested in socialization activities, (2) were aged >65 years, (3) could read English, and (4) were willing to participate in the study. The exclusion criteria were the following: older adults who (1) were aged <65 years, (2) were already engaged in >1 socialization activity, and (3) did not pass the “attention check” in a meeting with the researcher conducted before the intervention to assess their interests and identify careless respondents, thereby improving the data quality. The inclusion criteria of student participants were the following: all students enrolled in the health administration course irrespective of age or involvement in socialization activity. No exclusion criteria for students were determined.

Data Collection Procedures

The service-learning sessions are an essential component of the undergraduate Health Administration course that has culture as a major topic. The course introduces undergraduate students to the historical and cultural development of health care in contemporary American society. During the months of January to April 2022 a total of 46 students were paired with 46 older adults from the abovementioned communities. Once a week, the students communicated with their assigned older adult partners and engaged in an unscripted conversation for at least half an hour, for a total of 8 weeks. Of the 46 pairs, 29 (63%) pairs engaged in telephonic conversations and 17 (37%) pairs engaged in internet-based conversations via casual calling app, such as FaceTime or Zoom. The risk of COVID-19 contamination restricted all possibilities of in-person meetings.

As part of service learning, students were required to create an artifact diary to document each conversation. Students were also asked to write a 1-page diary after each interaction with their older adult partners and 2 reflections. On the basis of the duration of the project, students were expected to write 8 diaries and 2 reflections, once at the end of their fourth interaction and then again at the end of their eighth interaction. The conversations were recorded by the students with their smartphones or technology used for internet-based interaction such as Zoom and then transcribed by the students.

As part of the study, older adults were surveyed (paper-based, 5-item open-ended questionnaire) by the researchers to determine their interest in conversation to reduce SI and evaluate the effectiveness of the project. This 1-time survey was mailed with return envelopes to the older adults at the end of the eighth interaction with students. Survey questions were open ended, so that older adults could write their answers. The students' transcribed conversations, diaries, and reflections and the older adults' answers to the open-ended questions in the survey were all used in the qualitative data analysis.

The open-ended survey questions for the older adults included the following: (1) Did you find the conversation interesting? If your answer is yes, please write a few lines what was interesting in the conversation. (2) Would you like to participate in our project again next semester?

The whole idea of the project was to provide a useful framework for befriending that may facilitate and create a meaningful bond between the young student and the older adult [44,45]. All questions were composed from previously validated survey instruments and contextualized for use in this study (refer to sources in Table 1). To assess older adult emotions, especially boredom and loneliness as the key attributes of SI, students focused on conversations (refer to definition in Table 1) based on life satisfaction and digital skill training in the context of meaningful engagement [46,47], internal motivation to participate in the intervention for both older adults and students [47-49], and human feelings in the context of intergenerational befriending or companionship [46,49,50]. Thus, in Table 1, we have presented 3 major constructs: meaningful engagement, internal motivation to participate, and intergenerational befriending.

Table 1. Study constructs, definitions, and sources.

Construct	Definition	Sources
Meaningful engagement	• Frequency of socially interactive activities • Feeling of reduced boredom • Cohesive interaction (confidence and safety)	Questions about satisfaction with life, contextualized from the studies by Diener et al [46] and Gierveld and Tilburg [47]
Internal motivation to participate	• Discussion about daily life experience • Level of happiness • Ability to exert personal control over the situation	Questions about social isolation and motivation, contextualized from the studies by Kozma and Stones [48], Gierveld and Tilburg [47], and Russell [49]
Intergenerational befriending	• Perceived benefits from the friendly nature of interaction that develops mutual trust • Ability of the older adults to comfortably connect with students • Positive feeling and attitude of the students	Questions about human feelings, contextualized from the studies by Diener et al [46], Russell [49], and Golden et al [50]

Ethical Considerations

This contactless, intergenerational, befriending interventional study was approved by the institutional review board (protocol number 2022-7046) of the Texas State University. Written informed consent was obtained from all participants (students and older adults) before the intervention. Participants had the option to exit the intervention after reading the informed consent information or to provide consent to participate in the study. The confidentiality of the participants was properly protected during the intervention and data analysis. The study data were fully deidentified. All records pertaining to the intervention were securely protected in the university database with protected passwords, which were only accessible by the researchers. As this study was not grant funded, participants (undergraduate students and older adults) were not compensated for participating in this study.

Data Analysis

The older adults' survey was mailed to the 46 older adult participants, and 21 (46%) returned the completed survey. Students' diaries and reflections were collected at the end of the intervention (46/46, 100%), and all the files were used for data analysis. The qualitative data used in the study to extract the constructs and subconstructs were obtained from the 21 older adults' surveys and 46 students' diaries and reflections. Our analytic data included all the 110,970 words in a 118-page, single-spaced Microsoft Word document.

Following a heuristic approach [51] and content analysis, the data were coded using the qualitative text analysis software, MAXQDA by numbering each line of the dialogue [52]. The "Advanced Coding Method" in MAXQDA Standard was used for content analysis with major keywords that were allocated to data segments. The "Lexical Search" function located the keywords in all the text that define the 3 major constructs as identified in Table 1. Once the keywords of befriending, SI, boredom, socialization, engagement, and motivation were identified, the thematic coding of the relevant texts was performed using MAXQDA's visual tool, "One Code Model." We explored the frequency of words and terms used in the sources and analyzed their semantic contexts in a quantitative way. A differentiated word frequency analysis was performed using the "MAXDictio Module" [52]. The data were then classified into several groups to reveal trends and patterns of response to each question in the survey and in each topic of conversation between the older adults and students from the student dairies and reflections. Topically similar codes were grouped together and then narrowed by code segments using the option "Subcode Statistics" in the context menu of the "Code System" of MAXQDA. For example, the code "intergenerational befriending" was further subcoded as "comfortability," "positive emotions," and "perceived benefits." Finally, using the MAXQDA function "Analysis Summary Grid," thematic compilations were presented in "Participant Comment Tables."

The use of heuristic inquiry [51,52] helped us to discover the nature of social phenomena, especially the intergenerational bonding that developed between participants, as we systematically coded the data. Owing to the complex nature of the emerging themes related to befriending and self-expression, heuristic inquiry appeared to be the most convenient method of sense making for this study. The heuristic depictions of the artifacts involved a synthesis of intuition and tacit understanding of researchers [53]. This understanding characterized the idea of befriending experience. The concepts that emerged from the study included relationship building, empathy, social interactions, and capacity for additional relational networks outside the family.

Results

In the older population of 46 adults, of which 19 (41%) were men and 27 (59%) were women, 3 main constructs were identified: intergenerational befriending, meaningful engagement, and internal motivation to participate in the program. According to the older adult participants, the perceived benefits of the friendly nature of intergenerational interaction were mainly the heightened feelings of comfort and reduced boredom. For both the student and older adult participants, trust in the interactions bolstered the positive emotions, enhancing the feeling of safety and social affinity. Table 2 displays the number of times the older adults' and student participants' specifics about the scope of befriending and engagement to reduce boredom. Meaningful engagement was described as "reduced boredom," "feeling safe," and "increased confidence." For a total of 253 times, the older adult participants mentioned that they were purposefully engaged, 96 times they reiterated their feeling of happiness, 58 times about feeling safe, and 98 times that there was an impressive increase in their level of confidence. Similarly, students mentioned 201 times that they were meaningfully engaged in the project, 91 times they felt happy, 55 times that they did not feel bored in the conversations with older adults, and 97 times about the increased level of confidence.

Intergenerational befriending was summarized as "comfortability" and "positive emotions." The older adult participants specified 97 times that they benefited from the program and that they made new friends. For many older people, "engagement to reduce boredom" specified 97 times, was the main reason for participating in these conversations. Intergenerational sessions enhanced the motivation level of the older adults 277 times, with improvement in emotional health or positive emotions (specified 80 times). Having company was more of an antidote to reduce boredom (specified 90 times). The discussions about daily life experience led to emotive bonding and friendship. For the students, the befriending experience (specified 201 times) enhanced the feeling of comfort (specified 70 times) and positive emotions (59 times). Both the students and older adult participants looked forward to the sessions and considered it as a reason to get up in the morning.

The intergenerational service-learning intervention mainly covered two activities: (1) discussions about daily life experience to reduce the gap between generations and (2) digital training to help older adults to use social media sites and apps such as Facebook or Uber. The main attributes of SI targeted in this study, namely, boredom and loneliness, were minimized to some extent with the befriending approach as people felt safe and happy as they interacted with the students. Importantly, older adults were extremely interested in the technology training from students regarding how to use social media sites and apps such as Facebook and Uber. Tables 3 and 4 reflect the confirmatory statements of the older adults and students toward the valuable "befriending" component that engaged older adult participants substantially with the undergraduate college students in digital training and motivated them to share their life experiences safely. The attributes of hesitation and fear, which were noticed in the initial stages, turned to compassion, trust, respect, empathy, honesty, and warmth in the later stages, which are the most essential attributes of friendship.

The positive attitude and the dedication of the students toward the project helped the older adults to find social support and feel safe. On most occasions, activities were based upon the interest of the older adults. The opportunities for social interaction were possible as students were proactive and flexible with time and the needs of their older adult partners. The results revealed the importance of students' positivity to support the older adults and the increased level of motivation for spontaneous interactions. The students created a friendly environment, or that of companionship, where the older adults had confidence that the discussions were appropriate based on their choices and preferences.

Another key finding was that older people define boredom and comfort differently and that there is a difference between the students' perceptions and older adults' perceptions related to interactions to alleviate boredom. Although befriending through these sessions cannot compensate for the loss of an attachment figure, such as a close friend, spouse, or a significant other, which is common in old age, people with poor social skills are likely to have trouble in developing and maintaining relationships. Negative perceptions about age and aging, at societal and individual levels, have adverse effects on older adults' health and well-being. Ageism, which means negative attitudes toward older adults, or unrealistic expectations about the intergenerational sessions can leave both the older adults and the young individuals with unmet social needs, resulting in increased boredom. Hence, the befriending approach must be understood from the individual's subjective point of view.

Table 2. Constructs and subconstructs identified from the intergenerational service-learning intervention.

Name of the constructs and subconstructs	Number of times specified by older adults (n=786), n (%)	Number of times specified by students (n=557), n (%)
Intergenerational befriending	256 (32.6)	179 (32.1)
Comfortability	79 (10.1)	70 (12.6)
Positive emotions	80 (10.2)	59 (10.6)
Perceived benefits	97 (12.3)	50 (8.9)
Internal motivation	277 (35.2)	177 (31.8)
Feeling of happiness	96 (12.2)	91 (16.3)
Discussion about daily life experiences	181 (23)	86 (15.4)
Meaningful engagement	253 (32.2)	201 (36.1)
Feeling safe	58 (7.4)	49 (8.8)
Increased confidence	98 (12.5)	97 (17.4)
Reduced boredom	97 (12.3)	55 (9.9)

Table 3. Comments of older adults about the key constructs.

Key construct	Comments
Meaningful engagement	• "Like to talk about you and the multicultural sensitivity project in the Zumba classes three times a week, and ballet classes twice a week." [Participant 2] • "Feel glad, I seem to have more control on anger unlike before, we have opportunities for social interaction and there is less counterproductive behavior." [Participant 45] • "She plays for the university's basketball team. Since the university is so close to where I live, I get to attend all her games and is eternally grateful for this." [Participant 5] • "The student group hosts a couple of social events every day, so there is always an event to attend and enjoy. Some of these events include- bingo, bible studies, stretching class, and physical fitness classes as well." [Participant 42] • "She is physically very active, I enjoyed our zoom discussion last week, me and my husband, engaging in either yoga, meditation, or going on 30-minute walks." [Participant 16]
Internal motivation to participate	• "Family reunion was over; it was a good day of our weekly conversation and i-phone training." [Participant 39] • "Grateful to be able to wake up each morning and do the things that I enjoy, like art and seeing family and talking to my student friend over the phone." [Participant 3] • "Like to talk to you about school, do you enjoy the simple pleasures in life like cooking?" [Participant 28]
Intergenerational approach to befriending	• "Now look forward to our weekly conversations and app training sessions." [Participant 40] • "I don't get to see my grandchildren as often as I would like, so having a person of the younger generation to talk to weekly reminds me a lot of them." [Participant 25]

Table 4. Comments of students about the key constructs.

Key construct	Comments
Meaningful engagement	• "At first the project was challenging, towards the end I felt relaxed, as I came to know the older adult partner more closely." [Participant 9] • "She explained it so well, I never thought before that smoothie making could be so simple." [Participant 11]
Internal motivation to participate	• "She loves everything about her life. Our hobbies are the same. She is blessed to be healthy at her age, and she wouldn't change a thing." [Participant 12] • "My grandmother used to tell me similar things, to be able to wake up each morning and enjoy breakfast with family." [Participant 1]
Intergenerational approach to befriending	• "Feels nice to be in an interesting conversation and write diaries." [Participant 46] • "So happy to help someone who sees her grandchild in me." [Participant 45]

Discussion

Summary

The befriending intervention delivered through the service-learning sessions promoted reciprocity and social support that enhanced the quality of life by fostering positive emotions and reduced boredom and loneliness. The intergenerational service-learning program fostered discussions about daily life experience that reduced the gap between generations and promoted companionship [54]. The proactiveness and dedication of the students for their project helped the older adults to find social support and feel safe and created a bonding between the generations with long-lasting friendships.

Meaningful Engagement

Through this specific intergenerational service-learning experiment, we found that most older adults try to keep themselves occupied through personal hobbies; talking to family over the phone; and occasionally, even work. Meaningful engagement was depicted well through the comments of older adult participant 42 who was happy and well engaged in programs and activities administered by the university such as telephone-based befriending and contactless luncheons with students. For these participants, social interaction through the service-learning program enhanced connectivity and reduced the risk of losing the motivation to maintain an active and healthy lifestyle. The conversations reduced the feelings of boredom and isolation that adversely affected their emotional health. These sessions helped the older adult to reengage in community networks and participate freely in cohesive neighborhood environments with other members of the older adult living facility. Older adult participant 2 found these sessions to be meaningful and interesting, explained the importance of these sessions to friends and community, and constantly spoke about the interactions in the Zumba and ballet classes 2 to 3 times a week. The intergenerational service-learning conversations toward the end of the project showed a heightened level of comfort for both the older adults and the youths and made the older adults feel that they are cared for while in conversation. Hence, they were not bored in their conversation with the students.

Internal Motivation to Participate

For the older adults, there is the need of a companion to share life experiences [55], which is profound when separated from the family owing to relocation, death of family members, or retirement [56]. The befriending activity reduced the boundaries between the 2 people involved, and the student befriender was asked to undertake tasks that the older adult wanted to do, such as using technology or having contactless visits during family reunion. This created a sense of internal motivation for older adult 40 to participate in the interactions. As students helped the older adults to interact with their family and share life stories, these interactive sessions fostered companionship that was of interest to the older adult and a reason for the student to find meaning and value in the conversations. Following the comments of older adult participant 25 and student participant 45, we found discussions about spouses to children and grandchildren and, for some, even to great grandchildren. All familial connections showed the importance of social support and motivated both parties in conversation on a day-to-day basis. Student participant 12 prayed for the well-being of his older adult partner and felt happy as he discovered a common hobby to talk about. Older adult participant 39 described her spouse returning from rehabilitation and mentioned that a welcome home party with her spouse's family resulted in her having a good day. Older adult participant 5 revealed that she is eternally grateful to be able to attend her befriender's basketball games; the joy and motivation to be able to socially connect seemed to have a positive effect on her well-being.

Intergenerational Approach to Befriending

Although several of the older adults in this study had various outlets to socialize such as hobbies, calling a friend, and family visits outside the intergenerational service-learning sessions, they still expressed appreciation toward the students for their time and companionship, which fulfilled the idea of befriending that we aimed for in this study. Student 45 noted that the older adult was nervous at the beginning but eventually looked forward to their weekly conversations, further mentioning that having someone from the young generation to talk to reminded her about her grandchildren whom she does not get to see often. In another instance, student participant 46 would write down events worth mentioning every week to discuss during the call. The overall evaluation of the intergenerational conversation was positive; older adult 40 wrote in the survey that she valued the ability to talk, listen, and share information with another human being whom she could trust and rely on. The befriending approach within these sessions appeared to expose the similarities between 2 different generations as the weeks passed. For example, student 28 revealed that he felt lucky to share the same religious and spiritual beliefs as the older adult partner. Similarly, student 42 stated that she and her older adult partner shared the same type of church. Most of the student's reflections revealed the idea of reliability, compatibility, intimacy, and reciprocity in the conversations, which had a positive effect on promoting friendship and reducing boredom and loneliness for both parties. In addition, the program improved the youth's social skills and assumptions related to one's privacy and safety.

Limitations

This study has some limitations. Several students reported being unable to communicate with their partners at the beginning of the project owing to difficulty with older adults' digital literacy, inability to answer phone calls or read SMS text messages, or inability to use apps such as Zoom or FaceTime. This ruled out the possibility of Zoom focus groups. In-person focus groups were also not possible owing to COVID-19 socialization restrictions. In some cases, there was dropout of older adults from the project owing to sickness or other health conditions. Although the authors clearly explained to the older adults that the service-learning project was completely contactless, some of them still preferred face-to-face interaction, which was not possible because of COVID-19 restrictions. Furthermore, student notes may not be free from bias. The findings from this study have limited generalizability because we used a sample of students from 1 course, and the results may not be applicable in other study settings. Variables such as overall health, stress, stigma, comorbid conditions, socioeconomic status, and discrimination were not considered while assessing older adult surveys or student artifacts in the study.

Conclusions

The need to feel important and be included in a large social group is vital regardless of age. The need is perhaps more during the later stages of life when one has more physical and mental challenges and is confined in living situations with very limited social networks. The effects of service-learning sessions on boredom and loneliness among older adults promoted interest in intergenerational practice to reduce SI and improved the feelings of companionship among both students and older adults as a long-term outcome of the intervention. Students identified the intergenerational component as a highlight of the health administration course, which increased their awareness of gerontological issues and knowledge about working with aging populations. The intervention enhanced students' attitude toward companionship and gerontological practices via intergenerational befriending opportunities and digital training sessions. As students developed an interest in service-learning programs through frequent interactions with older adults, the social interaction component in the program amplified social connectivity via contactless interactions, phone conversations, and digital training sessions for older adults. Consequently, it reduced the risk of losing the motivation to maintain a self-image and an active and healthy lifestyle among older adults. This study was designed for periodic or postpandemic follow-up of the participants experiencing SI. Our results showed that older adults wished to maintain their social connectedness and access to technology and digital networks. Driven by a desire to communicate and access information that stemmed from the need to connect to friends, family, or other internet-based services such as mobile health or social media, older adults showed appreciation and gratitude toward the youth for taking an interest in their lives and, often, would look forward to their weekly conversations.

Acknowledgments

This study received no external funding. The authors are grateful to all the older adult study participants for their time and support in the study. The authors are grateful to Dr Stan Ingman for his assistance with the recruitment phase. The authors are also grateful to Dr Gayle Prybutok for helping with qualitative data analysis.

Data Availability

The institutional review board of this study does not allow data sharing because the data protection statement is an integral part of our institutional review board approval. Therefore, our data will not be made available.

Authors' Contributions

KS was involved in conceptualization, methodology, validation, formal analysis, investigation, resources, data curation, writing, and original draft preparation. ZR and NL wrote and prepared the original draft. All other authors reviewed and edited the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Older people are particularly vulnerable to social isolation and loneliness, which can lead to ill-health, both mentally and physically. Information and communication technology (ICT) can supplement health and social care and improve health among the vulnerable, older adult population. When ICT is used specifically for communication with others, it is associated with reduced loneliness in older populations. Research is sparse on how the implementation of ICT, used specifically for communication among older people in social services, can be performed. It is recommended to consider the determinants of implementation, that is, barriers to and facilitators of implementation. Determinants related to older people using ICT tools are reported in several studies. To the best of our knowledge, studies investigating the determinants related to the social services perspective are lacking.

Objective: This study aims to explore the determinants of implementing the Fik@ room, a new, co-designed, and research-based ICT tool for social interaction among older people, from a social services personnel perspective.

Methods: This study used an exploratory, qualitative design. An ICT tool called the Fik@ room was tested in an intervention study conducted in 2021 in 2 medium-sized municipalities in Sweden. Informants in this study were municipal social services personnel with experience of implementing this specific ICT tool in social services. We conducted a participatory workshop consisting of 2 parts, with 9 informants divided into 2 groups. We analyzed the data using qualitative content analysis with an inductive approach.

Results: The results included 7 categories of determinants for implementing the ICT tool. *Being able to introduce the ICT tool in an appropriate manner* concerns the personnel's options for introducing and supporting the ICT tool, including their competencies in using digital equipment. *Organizational structure* concerns a structure for communication within the organization. *Leadership* concerns engagement and enthusiasm as driving forces for implementation. *The digital maturity of the social services personnel* concerns the personnel's skills and attitudes toward using digital equipment. *Resources* concern time and money. *IT support* concerns accessibility, and *legal liability* concerns possibilities to fulfill legal responsibilities.

Conclusions: The results show that implementation involves an entire organization at varying degrees. Regardless of how much each level within the organization comes into direct contact with the ICT tool, all levels need to be involved to create the necessary conditions for successful implementation. The prerequisites for the implementation of an ICT tool will probably change depending on the digital maturity of future generations. As this study only included 9 informants, the results should be handled with care. The study was performed during the COVID-19 pandemic, which has probably affected the results.

Introduction

Older people are especially vulnerable to social isolation and loneliness, particularly because they are exposed to risk factors such as living alone and experiencing chronic illness [1]. There is robust evidence linking loneliness and isolation with physical decline; morbidity; increased mortality; and cognitive and mental health problems, such as depression and dementia; and increased risk of suicide [2-7]. Several studies point toward an increase in loneliness during the COVID-19 pandemic with *stay-at-home* orders and recommendations for social distancing [8-11], and the impact is particularly severe among people aged ≥80 years [12]. Information and communication technology (ICT) can supplement health and social care and improve health in the vulnerable, older population [4,13]. ICT is a part of welfare technology, which in one way or another, improves the lives of those who need it. When technology is used specifically for communication with others, it is associated with reduced loneliness [4,13-16] and increased well-being and life satisfaction [4] in older populations. Technology can improve social connectedness among older adults. The specific effectiveness rates favor ICT and videoconferencing [13]. Chen and Schultz [15] identified 4 important mechanisms for reducing social isolation using ICT: staying connected to other people, such as family and friends; gaining social support; participating in interesting activities; and boosting self-confidence. Studies show that ICT can support and maintain the social relationships and healthy and independent lives of older people at the individual level and should be prioritized as an early and preventive intervention in social services [17]. However, the use of ICT has been shown to decrease after 6 months of use [15,16]. Only few studies have investigated how the implementation of web-based social activities in social services can be performed. Thus, there is a need for sustainable, structured, and well-planned solutions for the implementation of ICT in social services.

To make ICT useful for older people, social services must consider the determinants for its implementation, that is, barriers to and facilitators of implementation. Determinants related to older people are reported in several studies. A literature review including 59 papers identified determinants related to this specific population's adoption of technology, such as perceived usefulness, potential benefits, user friendliness, ease of learning, perceived costs and savings, knowledge about existence, availability in the market, technical support, social support, perceived emotional and psychological benefits, and relevance with their previous experiences [18]. Other identified determinants related to older people are gaps in ICT literacy, fear of making mistakes when learning the ICT tool [19], privacy concerns, technical difficulties, lack of user-friendly options designed specifically for an older population, and lack of experience in using technology [20,21]. However, implementation of ICT does not depend on the older people alone. Social services personnel have an important role in introducing ICT to older people and to support its use [22]. Thus, ways of working to introduce and support the use of ICT among older people need to be implemented in the social services and other services they offer. To the best of our knowledge, determinants of implementing an ICT tool for social interaction among older people related to the social services personnel perspective are lacking.

The readiness and maturity to adopt digitalization and new ways of working vary among the social services provided by Swedish municipalities, for example, in residential care services and home care services. Few older people receive access to welfare technology services despite the benefits [23]. It is a large step for an organization to move from a limited project to implementation in their organization. Konttila et al [24] identified determinants of importance for digitalization in health care but not specifically for the care of older people, related to professionals' knowledge, skills, attitudes, and experiences and organizational and collegial support. One of the proposals from the Swedish Ministry of Health and Social Affairs [23] is that studies are needed to implement models for welfare technology in social services. A systematic review focused on facilitators and barriers that influence the implementation of welfare technology for older people, from the perspectives of older individuals, people with disabilities, informal caregivers, health and care personnel, organizations, infrastructure, and technology [25]. Overall, 6 themes of determinants were identified: capacity, attitudes and values, health, expectations of effects, shared decision-making, and identity and lifestyle. These determinants are within different levels in an organization and are consistent with other determinant frameworks for implementation [26,27]. However, most of the included papers in the systematic reviews of determinants for digitalization and implementation of welfare technology for older people [24,25] involved various types of technology, such as technology for smart homes, mobile devices in medicine and public health, self-care, medication, and surveillance systems, whereas ICT used specifically for communication among older people was not included. This study aimed to explore the determinants of implementing the Fik@ room, a new, co-designed, and research-based ICT tool for social interaction among older people, from a social services personnel perspective.

Methods

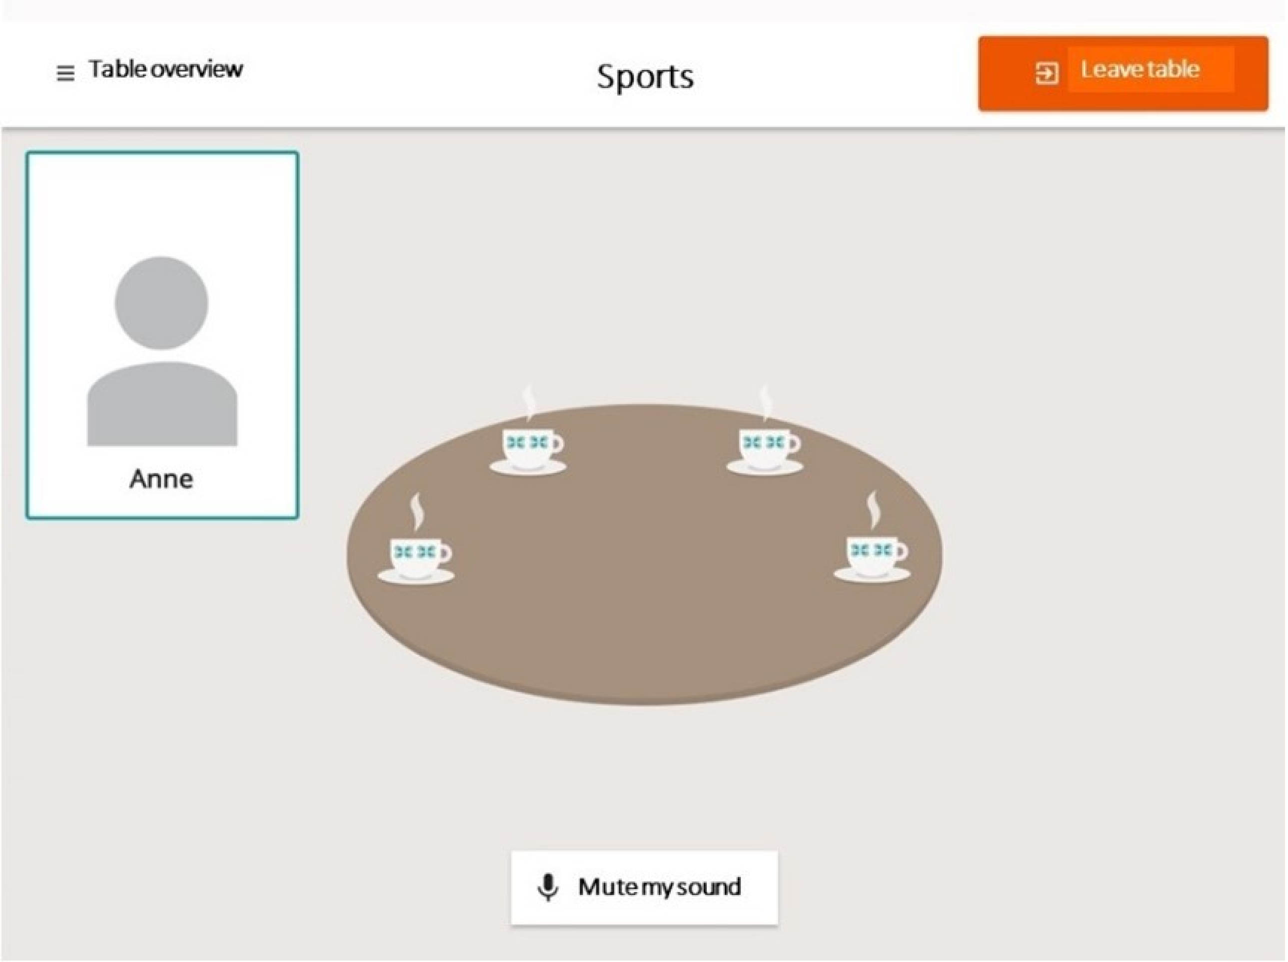
Design

This study used an exploratory, qualitative design [28,29]. An exploratory design is appropriate for conducting studies in a field that is relatively underexplored and hence, an inductive approach was adopted [30].

The Fik@ room: An ICT Tool for Social Interaction Among Older People

The Fik@ room is a research-based ICT tool, in the form of a web platform for safe web-based social interaction, created and developed by researchers in coproduction with older people aged ≥60 years, municipal health and social care personnel, and an IT company, based on focus group interviews and workshops. The content and design of the Fik@ room was based on the needs and wishes expressed by older people [31]. The older people who participated in the development process in 2019 and 2020 expressed the importance of knowing that others visiting the Fik@ room were equal, that is, experiencing loneliness, and access to the Fik@ room was protected by an individual password. This log-in procedure contributes to increase the safety and the feeling thereof for the older people. All older people with access to the Fik@ room have received personal log-ins from a contact person from the municipality. People who received log-ins were older people who had experienced loneliness or social isolation [31]. The Fik@ room consists of digital coffee tables with seating for up to 4 people at each table (Figure 1). The older people can start conversations regarding topics of their own choice using video, voice, or chat. They can also post messages to each other on a bulletin board. In the Fik@ room, older people can meet new friends and socialize as a way of forming routines in their everyday lives. The Fik@ room focuses on meeting peers (people in the same situation) and offers the opportunity to meet and discuss subjects related to users' interests. This foundation improves the quality of conversations in the Fik@ room and increases independence, participation, accessibility, and options for users to form their own social interactions as part of their everyday lives, which is associated with better quality of life for older people [17]. The Fik@ room is available on Google Play Store and Apple App Store (for iPad devices) but will not be available for logging in without permission from an authorized gatekeeper such as personnel in the municipality.

Figure 1. Illustration of a digital coffee table within the Fik@ room. The conversation theme of this table is sports, and in this example, only 1 person is attending.



Informants and Settings

The ICT tool was tested in an intervention study performed in May and June 2021 in 2 medium-sized municipalities in the middle of Sweden. The 2 municipalities were chosen because they are coproduction partners of the University and were both involved in the development of the Fik@ room. Informants in this study were social services personnel, with experiences of the intervention study and thus the implementation of this specific ICT tool in social services: municipal social services managers and social services personnel who recommended the ICT tool to older people in the intervention study (Table 1). The informants were chosen using a purposive sampling technique to capture different perspectives and experiences from the stakeholders in the implementation process, which provided the process with experience-related information and theory-based knowledge. In total, 9 informants from the 2 municipalities agreed to participate, who were basically all the people involved in the implementation process. Municipality 1 had an ongoing digitalization project running in parallel with the intervention study. This means that the municipality was appointed by The Swedish Association of Local Authorities and Regions as 1 of 10 model municipalities, which would function as a model for the digitalization of care for older people. These 10 municipalities received extra financial support to enable time for knowledge dissemination. Together with The Swedish Association of Local Authorities and Regions, they support other municipalities with knowledge about digital services and welfare technology. Municipality 2 was not involved in the parallel, ongoing digitalization project.

Table 1. Characteristics of the informants and settings.

Characteristics	Municipality 1 (n=6)	Municipality 2 (n=3)
Sex of the informants, n (%)		
Male	2 (33)	0 (0)
Female	4 (67)	3 (100)
Profession of the informants, n (%)		
Manager	2 (33)	1 (33)
Developer	1 (17)	0 (0)
Occupational therapist	0 (0)	1 (33)
Technology supporter[a]	2 (33)	0 (0)
Guide for older people[b]	1 (17)	1 (33)
Ongoing digitalization project	Yes	No

[a] Technology supporters were IT experts, employed in the municipality, who prepared the iPad devices for the older people in the intervention study by installing SIM cards and connecting them to the network and installing the Fik@ room app.

[b] Guides for older people were social services personnel with experience in IT, employed in the municipality, who worked at the meeting places for older people and supported the older individuals regarding the use of the iPad and the Fik@ room app.

Data Collection

Participatory workshops with 2 researchers acting as workshop leaders provided a valuable opportunity to learn together and discuss several perspectives. The informants both generated and analyzed data through a structured process for data collection and analysis that includes a combination of individual and group activities, inspired by the effect modifier assessment (EMA) method [32]. The EMA method consists of workshops and subsequent analyses. The workshop leaders facilitate the collection of information on past significant events; in this study, the event in focus was the introduction of the Fik@ room to older people. The method facilitates a combination of individual and group activities, which implies that all experiences from each informant is used and then developed in a group discussion. In this study, semiquantitative estimations were not used because all the determinants (barriers and facilitators) were considered important regardless of how many people had experienced them. The workshop guide (Multimedia Appendix 1) could be considered as a semistructured interview guide, but the workshop informants interactively influenced the interview guide by deciding what events and in what way the events are discussed. Each informant participated in 1 or 2 participatory workshops in August and September 2021, in groups of 3 to 6 participants. Each workshop began with casual conversation to help the informants feel at ease and more comfortable in the setting. The researchers served as workshop leaders to encourage a flow of discussion. To create a comfortable environment for the informants, the workshops were conducted separately for each municipality, ensuring that all the informants within a workshop were familiar with one another. The participatory workshop consisted of 2 parts. The first part focused on the determinants for implementing the ICT tool, and the workshop activities involved the identification of possibilities, obstacles, and challenges that were experienced during the intervention study. The first workshop leader (JF) asked the informants to individually note the possibilities, obstacles, and challenges on a paper in front of them and, thereafter, facilitated a group discussion regarding the same questions. The second workshop leader (CE) asked clarifying questions during the workshop and summarized the discussion at the end of the workshop. The second part started with a review of the first part, followed by the same individual and group processes as the first part, focusing on scenarios for the development of methods to support the implementation of the ICT tool. The workshop activities were regarding how to overcome the obstacles and reinforce the possibilities identified in the first part of the participatory workshop.

The workshops were performed using a web-based video communication tool, Microsoft Teams (Microsoft Corp). Municipality 1 performed the 2 parts of the workshop in separate sessions (2 hours each), and municipality 2 performed both the parts in the same session (2 hours). The informants' professions were requested at the beginning of the first workshop. The workshops were video recorded using the Microsoft Teams video platform.

Data Analysis

The data were analyzed using qualitative content analysis with an inductive approach [33]. The recordings were transcribed verbatim. The text was read several times for familiarization. Meaning units related to the determinants for implementing the ICT tool for social interaction among older people from the perspectives of the social services personnel were identified, coded, and grouped into subcategories and categories according to similarities. Examples of the abstraction of categories from meaning units are shown in Table 2. The identification of meaning units and categorization were performed by the first author. To validate the analysis, part of the categorization was also performed by 2 other authors (CE and PvHW) separately. In addition, the analysis was regularly discussed and validated among all the authors during the process to achieve consensus.

Table 2. Examples of the abstraction process: meaning units, codes, subcategories, and categories.

Meaning unit	Code	Subcategory	Category
...That they [the personnel] have a login so when they are there, they [personnel and older person] can talk to each other at a table [within the ICT[a] tool] just like we did.	Be able to log in to the ICT tool	Be able to show the tool	Be able to introduce the ICT tool in an appropriate manner
If it had been as usual [before the pandemic] then we would have done the same at home visits, and it would have been much easier because then you can show this leaflet, talk about it, and sell it in a better way, so it would have been much better.	Easy to show in person	Be able to show the tool	Be able to introduce the ICT tool in an appropriate manner
The pandemic, of course, because it has not been possible to visit people. They have not wanted to let us in, and not even homecare staff have been able to visit some people. They have declined home care and arranged help in another way because they do not want to expose themselves to the coronavirus.	The pandemic hindered in-person visits	Be able to show the tool	Be able to introduce the ICT tool in an appropriate manner

[a] ICT: information and communication technology.

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki [34] and Swedish Ethical Review Act [35]. However, according to the act, ethics approval by the Swedish Ethical Review Authority is not needed when, for example, sensitive personal data are not collected (ie, when interviewing staff to determine how they perform their work), as in this study. However, the intervention study (in which older people were study participants) has obtained ethics approval by the Swedish Ethical Review Authority (Dno 2020-06640). Participation was voluntary, and all informants provided their verbal consent after receiving verbal and written information. Furthermore, they were allowed to withdraw at any time without consequences.

Results

Overview

The results included 7 categories of determinants for implementing the ICT tool: be able to introduce the ICT tool in an appropriate manner, organizational structure, leadership, digital maturity of the social services personnel, resources, IT support, and legal liability (Textbox 1). The results are presented using the categories as headings, and the subcategories are italicized in the text.

Textbox 1. Categories and subcategories of determinants for implementing the information and communication technology (ICT) tool for social interaction among older people.

Be able to introduce the ICT tool in an appropriate manner

- To tailor the information
- Be able to show the ICT tool
- To let the user practice
- The personnel need to have knowledge about the ICT tool

Organizational structure

- A system for effective communication
- Clear roles

Leadership

- The manager’s engagement
- Enthusiasts

The digital maturity of the social services personnel

- The personnel’s digital skills
- The attitudes among the personnel varied

Resources

- Costs
- Time
- Access to transport

IT support

- Accessibility
- Follow-up system

Legal liability (no subcategories)

Be Able to Introduce the ICT Tool in an Appropriate Manner

Older people need to be informed about the existence of the ICT tool. Reaching all potential users with information about the tool was a challenge that the informants did not know how to address. They found that written information sent via mail reached many potential users and was easy to distribute. However, when introducing the ICT tool to an older person, the informants found it important *to tailor the information*, for example, the amount of information that the older person was able to receive, according to their knowledge and attitude toward ICT. Knowing the person and meeting in person facilitated tailoring compared with written information and web-based meetings:

> *I have to know how to structure the conversation with the person I am calling, and I also have to do that when I call the person because I have to hear what status the person has, how should I handle the person, i.e., how should I structure my conversation so that I establish good communication with the person. I must choose my conversational tone mode, how I present it, and how I tell it, a lot is about structuring the conversation and I have to do that immediately when I get in touch with the person.* [Informant 4]

When introducing the ICT tool, the informants found it important to *be able to show the tool*. To enable this, the personnel also needed to have the prerequisites to log in to the ICT tool, which was not always a matter of course. The personnel also needed to have access to their own account, and the program needed to be installed in their digital equipment. To reduce older people’s fear of digital tools, the informants found it important *to let the users practice* using digital tools in a playful manner. Getting acquainted with digital equipment, such as tablets or computers, through playing games, watching movies, or reading newspapers can improve the ease of use of other digital tools such as the ICT tool. Some meeting places for older people offered these practices and integrated digital tools into their daily services. During the COVID-19 pandemic, in-person visits were not always possible but were considered a prerequisite for showing and practicing the ICT tool:

> *To dare to use the tablet...to use it for something they are familiar with, read the newspaper or whatever it may be, as a first step. It may not be the ICT tool that is the first step, but it may be the next step when they have learned to use the tablet. A game can be a little*

> *easier or reading the newspaper can be an easier way to start using it and then you take the next step.* [Informant 7]

To be able to provide information regarding the ICT tool, *personnel need to have knowledge about it*. The informants perceived the written information regarding the ICT tool as useful for understanding the purpose of the tool. However, it was difficult to inform older people about a tool without knowing how it looked or how it worked. Having both seen and tried the tool made the personnel more confident when informing older people about it:

> *It was great that we got to try the ICT tool first, because it also makes it easier when you are out with the user to show them how it works because you actually know what the picture looks like, how the sound sounds, what happens with the sound if we sit too close to each other. So, I thought it was great, you need to try it first.* [Informant 6]

Organizational Structure

When implementing the ICT tool, the informants perceived it as important to have *a system for effective communication* within the organization. A secure electronic communication system regarding personal data worked appropriately for communication among different parts of the organization regarding lists of potential users, who to call, who would visit whom, information needed for home visits, and so on. After the personnel had visited an older person, they used the same system for feedback about the visit and to document whether further support was needed. The informants also highlighted the importance of feedback among different levels within the organization, such as to the management team by whom new decisions could be made:

> *Lists were created so that we had a structure on which we had called, who would go to whom, all the information needed to make a home visit and even be able to write when you had been there, and it was a completed project...So, it was a very good structure in the lists.* [Informant 3]

> *Spontaneously, I would say that some structure will be required for the recruitment of these [older] people.* [Informant 2]

The informants expressed that *clear roles* facilitated the implementation of the ICT tool. Clarity about whom to ask regarding a special issue, whom to ask for support, and so on makes the work more efficient. Similarly, the person who holds the role knows what duties come with the role. They experienced that the implementation was facilitated if the selected personnel performed the introduction, skills training, and support of the ICT tool:

> *I thought a bit about this regarding whom to contact and so on. It should be incredibly clear, both for our users but for the employees as well. They should not have to think "who are we to contact to get support for this?" but there must be somewhere very, very clear so it can be done quickly, so that you do not have to run around and look and waste time looking for who to contact.* [Informant 7]

Leadership

The informants expressed that *the manager's engagement* was important to the implementation, and it became obvious when engagement was lacking. A manager who was open to the ICT tool and interested in its implementation spread their engagement to the rest of the working group. According to the participants, another success factor was having *enthusiasts* or champions as leaders. These were selected personnel with a clear mandate within the organization who had extra knowledge about ICT, who worked actively regarding its implementation, and who regulated the entire process:

> *That it is someone who owns the question, who has the question on their table, who is the one who then ensures that it is followed up, and the continuity of the whole thing I think is very important.* [Informant 6]

The Digital Maturity of the Social Services Personnel

The implementation of the ICT tool was affected by *the social services personnel's digital skills*. According to the informants, some of the personnel did not know how digital equipment worked, such as a tablet, which hindered them from informing others about and supporting the use of the ICT tool:

> *The personnel couldn't use a tablet either, you had to give them basic instructions on how to press the button to start it up. Of course, there were also those who were very talented. But you might think that it is only the older people that don't have the skills, but it is actually the personnel too.* [Informant 3]

The informants expressed that *the attitudes among the social services personnel varied*. Some were very interested, and the implementation was conducted smoothly. In other parts of the organization, the personnel did not even talk about the ICT tool. The informants thought that an ICT tool that can be used by both older people and personnel would create great interest among the personnel compared with a tool that can be used only by older people. For example, the personnel could conduct lectures or discussions about health-related subjects, such as diet and exercise, within the ICT tool. The informants thought that this digitalization investment had a positive impact on personnel's attitudes toward digital tools, which provided synergies and paved the way for the implementation of this specific ICT tool:

> *Yes, but what if we can have a table where we can talk about health and diet, and those who want to can come in and hear, listen, or participate in discussions.* [Informant 2]

Resources

Implementation requires resources of various types. In this case, the informants highlighted resources regarding *costs*, *time*, and *access to transportation*. They expressed concern about the *costs* that would be required to gain access to the tool and support. The implementation of the ICT tool would be at the expense of something else. According to the informants, a payment model based on different fees, depending on what is included, may facilitate implementation:

> *If you start from the scenario that it is the municipalities that in some way buy a license or something similar for the ICT tool, then the payment model itself could be for a lower amount if the municipality itself, so to speak, moderates what is said and not, and perhaps a higher amount then if it is a company who would be responsible for it.* [Informant 5]

Implementation takes *time*, and some of the most time-consuming parts, as mentioned by the informants, were sending and following up on information letters, delivering tablets, creating log-ins, and showing users what to do. The informants felt that time had been allocated at different levels (eg, to key individuals within the digitalization investment area of the model municipality):

> *It does not matter what we are going to do, time is required. And if you have decided to make a change like this, you should be aware that time is needed. So, it is obvious that it is something that really needs to be considered if it would be implemented somewhere else as well. That you actually make sure you have that time and resources, it costs to implement something, but in the end, it can generate so much more.* [Informant 7]

Access to transportation is a prerequisite for home visits. The informants experienced that there are always cars available as a means of transportation for home visits.

IT Support

The *accessibility* of the support, both for the users and personnel, was perceived as important for implementing the ICT tool. Contact information needed to be available, and it was preferable if all support could be reached using the same contact method (eg, the same phone number or email address). In addition, time needs to be allocated for support. According to the informants, support not only involved direct contact with the user but also involved communication with and recurring feedback between the supporters and the personnel. Support could be provided through various forums to increase accessibility, such as during home visits, at meeting places for older people, or at the public library. Support could also be provided via other digital media, which hindered accessibility, as the requested support was sometimes related to the difficulties in handling the digital equipment itself and, thus, also the digital support. During the COVID-19 pandemic, the accessibility of support was particularly limited, as digital support could not be received owing to some users' lack of skills, and the older people did not accept home visits owing to the risk of spreading the infection:

> *What needs to be strengthened is time, it is the key that we have talked about. It was also what was difficult, but we also saw that what still worked well was when there was allocated time for various steps: time to be at home with the user to practice and provide support and follow-ups, but also time for communication with personnel and recurring feedback: to ask how it works out. So, I think that resources and time really need to be strengthened, then you have all the prerequisites to succeed.* [Informant 6]

The personnel lacked a *follow-up system* for support. They expressed a need to be able to follow up regarding whether the user had used the ICT tool to facilitate implementation. It was not possible to assess whether the older person understood how to use the ICT tool after a short introduction. The informants suggested that it should be possible to obtain information about the number of log-ins on the ICT tool to be able to follow up with users who have few log-ins:

> *It would be interesting to get feedback on if these users have not been in at all. Then you could have maybe called them and asked: How are you? Do you want more help?* [Informant 9]

Legal Liability

The informants expressed doubts about whether the municipalities complied with the legislation if the ICT tool was offered by the municipality and used inappropriately, such as the use of racist statements. There was a concern that the municipality cannot guarantee that nothing inappropriate is said within the ICT tool without some form of supervisory function. Therefore, it was proposed that a moderator of the ICT tool could perform that function:

> *If the municipality buys it, we stand as some form of guarantor, we also have a responsibility not to release that freely, but to have some form of moderating function that can support what is said. Because racist statements may be used, for example, and then we also have a responsibility to take care of it.* [Informant 5]

Discussion

Principal Findings

The results included 7 categories of determinants for implementing the ICT tool. *Being able to introduce the* ICT *tool in an appropriate manner* concerns the personnel's options for introducing and supporting the ICT tool, including their competencies in using digital equipment. *Organizational structure* concerns a structure for communication within the organization. *Leadership* concerns engagement and enthusiasm as driving forces for implementation. *The digital maturity of thesocial services personnel* concerns the personnel's skills and attitudes toward using digital equipment. *Resources* concern time and money. *IT support* concerns accessibility, and *legal liability* concerns possibilities to fulfill legal responsibilities.

Comparison With Previous Studies

Determinants of implementing ICT tools related to older people have been reported in several studies and systematic reviews [18-21]. The novelty of our study lies in its knowledge about the determinants of implementing a new, co-designed, and research-based web platform, customized specifically for older adults, from a social services personnel perspective. The determinants identified in this study are concretized to increase the understanding of specific factors that influence the implementation of an ICT tool for social interaction among older people. Damschroder et al [27] and Flottorp et al [26] highlighted several domains of determinants, including factors related to the implemented intervention itself (in this case, the ICT tool) and patient factors. These 2 domains are not presented in our results but are reported in a related article [22]. The social services personnel's view about the determinants identified in this study were mainly related to the interaction between the personnel and older individual, and organizational factors. Our findings differ from those of other studies describing older people's views about determinants, which were mainly related to their own capacity, attitudes, and health-related benefits and the usefulness and ease of learning the technical tool [18-22]. However, the interaction between the professional and the older individual relates to strategies for supporting older people to overcome barriers mentioned as determinants by the older people themselves. Thus, although the determinants mentioned by social services personnel and older people differ, they are logically interconnected. The 7 categories of determinants reported in this study correspond to the following domains reported in the paper by Flottorp et al [26]: individual health professional factors; professional interactions; incentives and resources; capacity for organizational change; and social, political, and legal factors. Some of the factors within these domains were not mentioned as determinants by the informants in our study, such as the continuing education system, assistance (external) for organizational change, contracts, and political stability. As they were not mentioned by the informants, we interpreted them to be of less importance in this specific case.

Most of the identified determinants in our study were related to contextual factors at different levels, which confirms that contextual determinants play an important role in implementation [36]. Nilsen and Bernhardsson [36] highlighted contextual factors as determinants at the micro (interaction between the professional and patient), meso (the organization), and macro (influences from the wide environment) levels. The micro-meso-macro framework for analysis is a useful way of understanding the determinants of implementation, as implementation is a multilevel phenomenon [37]. In this study, the contextual determinants mostly involved the micro (*be able to introduce the ICT tool in an appropriate manner*) and meso levels (*organizational structure*, *leadership*, *resources*, and *IT support*). Only 1 category was identified at the macro level (*legal liability*). The Lancet and Financial Times Commission on Governing Health Futures 2030 [38] recommends interventions at the macro level to facilitate the digitalization of health and social care to achieve future health and well-being. From the perspective of the personnel, the impact of the identified determinants likely differs. As macrolevel determinants were not mentioned by the informants to the same extent as microlevel and mesolevel determinants, it could be assumed that macrolevel determinants were not perceived to have as great an impact as micro- and mesolevel determinants on the implementation of the ICT tool.

A category of determinants that we identified, *the digital maturity of the social services personnel*, was related to individual health professional factors according to the checklist by Flottorp et al [26] and, in particular, knowledge, skills, and cognition. A lack of digital competence has been identified across all professions within social services in Sweden, and the development of the personnel's competence is stated to be a success factor when implementing welfare technology in social services [23]. Konttila et al [24] recommend that learning how to use technical devices should be integrated into the personnel's daily work by providing education and sufficient time for learning. In previous studies, knowledge and skills primarily focused on digital and technical aspects. However, our results in the category, *be able to introduce the ICT tool in an appropriate manner*, also emphasize the importance of the personnel's pedagogical knowledge and skills in teaching older people how to use an ICT tool. This introduces additional demands on the personnel that must be considered when implementing an ICT tool in social services.

Our results are consistent with the barriers to and facilitators of the implementation of welfare technology identified by Zander et al [25]. All our identified determinants correspond to the themes reported by Zander et al [25] regarding capacity, attitudes, and values. In addition, we identified enthusiasts, as part of the *leadership* category, as an important driving force for implementation, which was not explicitly mentioned by Zander et al [25]. However, similarity can be seen with the theme of participation, as Zander et al [25] discussed the importance of involvement in the development, decision-making, and implementation processes as a facilitator of implementation. A theme of determinants that Zander et al [25] identified but were not identified in our results was expectations. Expectations were seen as a barrier to the implementation of welfare technology and were related to fear that the technology would affect the quality of care, threats to professional identity, and fear of losing jobs. It is possible that the ICT tool in our study was not perceived as a threat against the personnel's professional role, as it did not directly affect the quality of care or replace the care provider. It is also important to remember that the technology used in the literature review by Zander et al [25] did not include ICT used specifically for communication among older people, which can explain the differences in the results.

According to our results, enthusiasts seemed to be an important facilitating determinant for implementation. Enthusiasts can also be described as champions or local opinion leaders, depending on whether they are appointed by the management or considered informal, educationally influential leaders appointed by peers [39]. In our results, we interpret enthusiasts more consistently with the definition of champions. However, it remains unclear whether the enthusiasts only function through managerial status and process or also function through social influence, such as an opinion leader. To support implementation, the evidence for the role of local opinion leaders is more robust than that for champions, and it seems that involvement of local opinion leaders is an effective implementation strategy [39,40]. To understand the impact mechanisms of enthusiasts, the role and significance of enthusiasts need further clarification.

One of the 2 municipalities included was a model municipality for the digitalization of care for older people, which contributed to an important difference between these municipalities. The informants from the model municipality expressed the determinants by describing their own experiences as facilitators (eg, their experiences regarding how a system for effective communication among personnel facilitated the implementation of the ICT tool). The other municipality talked about the same determinant as a barrier, that is, the lack of a system for effective communication. It was obvious that the digitalization project positively influenced the implementation of the ICT tool, which also confirms the importance of determinants related to the organization. Although the ICT tool was supposed to be easy to use for older people [31], it is still important to have an organizational structure to support the older people in using the ICT tool. Previous studies highlight the importance of a shared vision within the organization for the implementation and involvement of leadership [25]. These determinants were perceived by the informants in the model municipality. They also experienced other facilitators identified in previous studies, such as a system for communication, clearly defined roles, enthusiasts, access to IT support, and resources that facilitated the implementation [24,25]. Digital maturity appears to be great in the model municipality, which also affected the implementation of the ICT tool.

Implementation is more likely to be successful if implementation strategies are chosen based on an assessment of determinants (facilitators and barriers) of implementation [40]. However, when selecting the implementation strategies, consideration must also be given to the effectiveness of different strategies based on well-designed studies and systematic reviews, the phases—implementation or maintenance—of the actual implementation process [41], and the theoretical underpinnings of the implementation [42,43]. Our findings can contribute to increasing the understanding of the complexity of implementing an ICT tool for social interaction among older people in municipal settings and guide the choice of implementation strategies.

Several studies have explored the determinants of using ICT tools, often in relation to older people. ICT tools can mean different types of technology that are used in health and social care and used by older people outside health and social care. Most ICT tools studied are not designed specifically for older people [18-21,23-25]. In this study, determinants are explored in relation to the Fik@ room, a specific ICT tool for social interaction among older people, developed for and in coproduction with older people. As ICT tools involve large variety, it can hinder the transferability of our results. Therefore, it is important that the readers themselves are aware of the type of ICT tools that are studied.

Strengths and Limitations

As determinants for improving professional practice have been identified at different levels [26,41], we wanted to include the informants involved in the implementation of the ICT tool in different ways. The combination of informants working with leadership and informants working directly with the older people in different ways enabled a comprehensive understanding of the determinants of the implementation of an ICT tool for social interaction among older people in municipal settings. It would have been desirable to have more informants from municipality 2. Although the study only included 9 informants, these informants had specific experiences pertinent to the study’s aim by being involved in the intervention study that introduced the Fik@ room to older people. Taken together with the specific phenomenon in question and a narrowly defined objective, the data were considered to have sufficient information power [44].

The use of participatory workshops inspired by the EMA method [32] contributed to a systematic approach to data collection and opportunities to learn from each other. The combination of individual and group activities meant that all experiences from each informant were used and developed in group discussions, which contributed to multifaceted and rich data. By including a second part of the workshop, focusing on how to overcome obstacles and reinforce the possibilities identified in the first part of the workshop, we were able to further use the informants’ thoughts and experiences.

Owing to the COVID-19 pandemic, the workshops were performed using the web-based video communication tool, Microsoft Teams. Although conducting qualitative studies over the internet facilitated the informants’ participation, it also involved some challenges [45]. A challenge was the informants’ familiarity with technological hardware and software. In this case, the informants had access to a reliable internet connection and a computer with a microphone and camera. The video communication tool, Microsoft Teams, was chosen because the informants were already familiar with this program because it was used in their organizations. All the informants (9/9, 100%) used digital communication tools in their daily work and were familiar with how to communicate using them. Another challenge is that web-based interviews seem to generate short responses and less contextual information [45], which could also apply to web-based workshops. Compared with in-person workshops, web-based groups need to be small, and 4 to 6 participants are recommended [45]. Therefore, we included a maximum of 6 informants in each workshop group. It might be a limitation that the informants in the workshops knew each other. A power imbalance might have occurred between managers and employees, which might have limited the issues that were raised for discussion during the workshops. However, the opinion of the 2 researchers participating in the workshops was that the informants spoke freely regarding the barriers to and facilitators of implementing the ICT tool. The fact that the implementation of the ICT tool was a project might have stimulated the informants to speak more freely than they might have done if the ICT tool was implemented as compulsory working task.

An exploratory design was considered appropriate for conducting research in this relatively underexplored field and thus, we adopted an inductive approach [30]. The choice of design was made to stimulate an open and creative discussion to enable the identification of new areas of determinants. In hindsight, a deductive approach would also have been possible to use because our results proved to be consistent with the checklist by Flottorp et al [26]. However, the use of the inductive approach contributed to a deep understanding of the determinants of implementing an ICT tool for social interaction among older people.

The findings present the determinants for the implementation of an ICT tool for social interaction among older people in municipal settings, but the determinants related to the ICT tool itself and older people are presented in a related article [22]. This division may complicate the possibility of obtaining an overall picture of the current determinants of importance for the implementation of the ICT tool. To make this easy for the reader, we refer to the related article by Gusdal et al [22] in the text.

The careful description of the data collection process and illustration of the findings with quotations increased the confirmability of the findings. Trustworthiness was strengthened through regular discussions among the authors during the analyses. The agreement between our findings and those of previous studies regarding the determinants of implementation in general [26] and implementation of welfare technology for older people in particular [25] increases the credibility of our findings, which is an important strength of our study and indicates wide transferability of the findings to the implementation of other ICT tools for older people in other contexts. However, the trustworthiness and transferability of the study results should be considered with caution because there were only 9 informants from 2 municipalities involved. Despite the small sample size, the study revealed important aspects to be considered when implementing ICT tools in municipality social services.

This study was conducted during the COVID-19 pandemic. The purpose was not to relate the results to the situation of older people specifically during the pandemic. However, the pandemic has probably affected the results in different ways. The problem of loneliness among older people increased during the COVID-19 pandemic [9-12], which increased the need for new solutions for communication among older people. This may have affected the attitude of both the older people and the personnel participating in this study toward ICT tools. The difficulties with meeting older people in person are also strongly associated with the restrictions during the pandemic and might have affected the results as the personnel did not have the prerequisites to meet older people and introduce the ICT tool (and the hardware) in the same way as without the pandemic and physical restrictions. Therefore, determinants with a direct connection to the pandemic are not as relevant during periods without a pandemic.

Conclusions

The ICT tool discussed in this study will be used by older people in their homes for the purpose of social interaction. Although the ICT tool is for use by older people in their homes, with limited involvement of others, the results show that the implementation involves an entire organization at different levels. Specifically, the following may be required: ability of the personnel to introduce and support the ICT tool, including their competencies in using digital equipment; structure for communication within an organization; leadership as a driving force; sufficient resources; and possibilities to fulfill legal responsibilities. Regardless of how much each level within the organization comes into direct contact with the ICT tool, all levels need to be involved to create the necessary conditions for successful implementation. The prerequisites for the implementation of an ICT tool will probably change depending on the digital maturity of future generations. As this study only included 9 informants, the results should be considered with caution. The study was performed during the COVID-19 pandemic, which has probably affected the results.

Acknowledgments

The authors wish to thank Ulrika Florin, PhD in innovation and design, for the valuable input regarding the design and prerequisites of this study. The authors also thank all the study informants for sharing their experiences. This study was supported by internal research funding from Mälardalen University, Eskilstuna and Västerås, Sweden.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

JF, CE, AKG, RMJP, and PvHW were involved in the methodology of the study. JF and CE conducted the workshops. JF conducted the content analysis and wrote the original draft. CE, AKG, RMJP, and PvHW supported the analysis and contributed to reviewing and editing the paper.

Conflicts of Interest

Coauthors CE, AKG, RMJP and PvHW own equity in the Fik@ room, a company that might benefit from this study’s findings. The company was founded after the data collection of this study and aims to make the Fik@ room available for its target audience. The first author (JF) led data analysis and manuscript preparation to ensure objectivity in the research.

Abstract

Background: Digitalization in the German health care system is progressing slowly, even though it offers opportunities for improvement of care. In nursing homes, most of the staff's work is paper based. Following the pandemic, there has been a decrease in the use of telemedicine applications. To ensure long-term implementation, the views of users, in this case nurses, are of interest.

Objective: This cross-sectional study was conducted to describe which digital applications are already being used at inpatient care facilities, the attitude of nurses toward telemedicine, and for which areas the use of telemedicine in the facilities is considered appropriate by the participants.

Methods: All inpatient care facility staff in Schleswig-Holstein were invited to participate in the survey from August 1 to October 31, 2022. The questionnaire consists of 17 determinants that ask about the attitude, use, and possible applications of telemedicine. In addition to a descriptive analysis, the influence of the general attitude toward telemedicine on various determinants was examined using the Fisher exact test for nominal variables and Spearman correlation coefficient for metric variables.

Results: A total of 425 caregivers participated in the survey. Of these respondents, 10.7% (n=41) currently used video consultations, and 76.1% (n=321) of the respondents were in favor of video consultations being practiced in training. Furthermore, 74.8% (n=312) of the respondents would attend a training on telephone medical consultation. Respondents indicated that video consultations have a small added value compared to asynchronous telemedicine (eg, sending photos). However, video consultations were perceived as somewhat less time-consuming than other communication channels. Video consultations are perceived as most useful for clarifying urgent problems. The respondents estimated that one in five paramedic calls at their facilities could be reduced through telemedicine approaches. It was important to the participants that telemedicine is as simple as possible and that there is a high level of data security.

Conclusions: Although many caregivers have a positive attitude toward telemedicine and perceive its advantages, communication channels such as video consultation are still used infrequently in care facilities. To promote the use of telemedicine applications, it is important to emphasize their benefits. The presumed saving of paramedic calls thus represents a benefit, and it is crucial to train caregivers in the use of telemedicine to avoid uncertainties in dealing with the newer technologies. It is important to give them enough time and repetitions of the training.

KEYWORDS

eHealth; telemedicine; nursing home; pandemic; Germany

Introduction

The digitalization of the German health care system offers opportunities for the improvement of care. For instance, established communication channels in paper-based form can be eliminated and faster communication between different providers can be strengthened [1,2]. Areas with less access to care can be supported by digital applications [2-4]. The benefits of telemedicine recognized by health care stakeholders include providing better access to care and further communication options [1,5,6]. Telemedicine applications may also help to reduce avoidable ambulance callouts and hospitalizations [7,8].

The term telemedicine is, based on the definition of the German National Association of Statutory Health Insurance Physicians, defined as follows: telemedicine includes applications that can be used for consultation, diagnostics, or therapy over a geographical or temporal distance. This can be done through a wide variety of applications such as video consultation, email, or an app [9].

Nevertheless, digitalization in the German health care system is progressing slowly. Approximately 70% of nursing staff still used paper-based methods. This causes incomplete documentation and is time-consuming [10]. A study from Germany shows that telemedicine applications, such as video consultations, simplify communication between doctors and nurses. Due to flexibilities in time and location, video consultations enable a faster exchange between the doctor and the nursing home [5,11]. Since there is a shortage of nursing staff and a chronic lack of time, the question arises as to why digitalization is not promoted more in this area of care.

In the first year of the COVID-19 pandemic, rapid implementation of telemedicine, and video consultations in particular, was predicted [12]. Nursing homes struggled with isolation rules (eg, shortage of protective clothing). To maintain continuity of care, telemedicine applications were often used during this time [1]. However, it is also apparent that telemedicine applications are being used less after the pandemic, including in nursing homes [13-16].

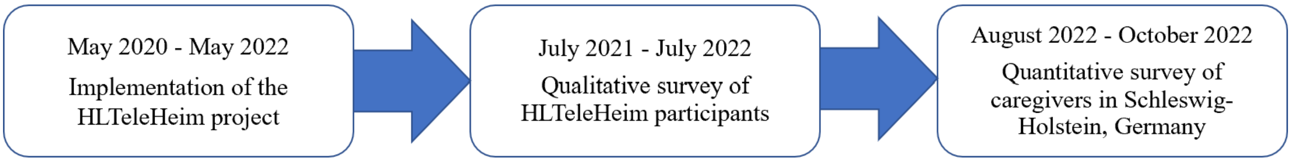
To successfully implement a telemedicine application in the long-term, it is necessary to explore the attitude of the nursing staff toward telemedicine. In this way, these expectations and perceptions toward telemedicine can be used to tailor the implementation process [13]. Therefore, this cross-sectional study aimed to explore the attitude of caregivers working at inpatient care facilities toward telemedicine, which applications are already used, and what is considered useful.

Methods

Study Design and Population

In the federal state of Schleswig-Holstein, Germany, the project (HLTeleHeim) was influenced by observations of the challenges in primary care during the COVID-19 pandemic when nursing homes and palliative care providers were performing video consultation with general practitioners, specialists, pastors, or family members. The aim was to support the care of residents during access restrictions in care facilities in the early phase of the SARS-CoV-2 pandemic. The equipment and the training on how to use it was free for the participants [9,13]. Figure 1 provides a better overview of the project's timeline.

Figure 1. Timeline of the study and evaluation.



For this cross-sectional study, all 567 inpatient care facilities in Schleswig-Holstein were contacted by mail. The letters contained information about the survey as well as 10 questionnaires and return envelopes. People 18 years or older who were active in providing care could participate in the inquiry. The questionnaires were mailed on August 1, 2022, and could be returned until October 31, 2022. On September 1 and October 1, 2022, reminders were sent to the nursing homes. From September 1, 2022, a web-based version was created on SurveyMonkey as an alternative to the paper-based questionnaire, which should have enabled as many nurses as possible to participate in the survey. Access via a QR code and link to the web-based survey was sent with the first and second reminders. The survey was carried out anonymously; it was not possible to conclude which person or care facility the completed questionnaire originated from.

Ethical Considerations

The study is a low-risk study since it is not an experimental study. The data were treated in accordance with the General Data Protection Regulation (European Union) 2016/679. Only employees of the study have access to the data contained in the questionnaires, and the data is protected from unauthorized access. Third parties do not have access to the original documents.

The participants were provided with written information before completing the questionnaire and informed that by submitting the questionnaire they were agreeing to participate in the study. They were also notified that it is not possible to subsequently delete the data received, as it is collected anonymously. The participants did not receive any compensation for participating.

The survey of nurses received a positive ethics vote by the ethics committee of the University of Lübeck (22 - 095).

Questionnaire

The questionnaire was developed based on interviews with nurses, physicians, and app developers from a preliminary project and the existing literature [13,17]. It consisted of 17 determinants; the whole questionnaire can be viewed in Multimedia Appendix 1. Those questions aimed to find out which telemedicine devices are used, whether the respondents had received training on the subject during their education, what the general attitude toward telemedicine is, and for which areas telemedicine devices would be suitable to use. It was also intended to find out which factors (eg, data protection aspects or costs) are particularly relevant in relation to telemedicine. Respondents were also allowed to write their comments on the topic in a free-text section. The questionnaire was pilot-tested for comprehensibility. Therefore, carers from the researchers' private circle of acquaintances were asked to complete the questionnaire and explain in a discussion round how the questions were perceived and what changes they would suggest. The paper-based questionnaire contains the same questions as the web-based questionnaire, so all responses were analyzed together.

Analyses

Data analysis was conducted using the IBM SPSS Statistics 28 program. A descriptive analysis of the data was performed. In addition, the influence of the general attitude toward telemedicine on various determinants was examined. For this purpose, the variable attitude toward telemedicine was summarized as a dichotomous variable. Values 1 - 3 (mostly positive to very positive) were defined as a positive attitude and values 4 - 6 (mostly negative to very negative) as a negative attitude. The prerequisites for a chi-square test were not fulfilled; therefore, the Fisher exact test was used for nominal variables. For metric variables, Spearman correlation coefficient was calculated. The original variable of the attitude toward telemedicine with 6 expressions was used for this purpose; furthermore, the age variable was created based on the year of birth variable. The significance level was set at .05.

Results

A total of 425 caregivers participated in the survey—22 of them completed the web-based survey. Table 1 shows the sociodemographic data of the sample.

In the open question for which scenarios the use of video consultation would also be useful, the following points were indicated: ordering medications and bandages, electrocardiograms, specialist consultations, discussions between physicians and residents, communication with guardians, new admissions, avoidance of hospitalizations, contact with training institutes, and clarification of queries. Three participants responded that video consultations would not be useful in general.

Table 2 shows the current use of telemedicine in nursing homes and for which areas the use of video consultation would be useful.

Table 3 illustrates the general attitude toward telemedicine, how the participants deal with the video consultation, and which aspects are particularly relevant to them.

Table . Sociodemographic data of the participating nursing staff from Schleswig-Holstein (N=425).

Variable		Participants
Age (years), mean (SD)		43.7 (12.2)
Sex, n (%)		
	Female	309 (72.8)
	Male	105 (24.6)
	Missing	11 (2.6)
Active in care, n (%)		
	Yes	330 (77.6)
	No	84 (19.8)
	Missing	11 (2.6)
Certified nurse (n=322), n (%)		
	Yes	268 (63.1)
	No	54 (12.6)
	Not active in care	90 (21.2)
	Missing	13 (3.1)
Work experience (years), mean (SD)		16.1 (10.6)
Location of the nursing facility, n (%)		
	Rural	226 (53.2)
	Urban	186 (43.7)
	Missing	13 (3.1)

Table . Current use and benefits of telemedicine of the participating nursing staff from Schleswig-Holstein (N=425).

Question		Yes, n (%)	No, n (%)	Missing, n (%)
During the last 12 months, the possibilities for using telemedicine have been...				
	...addressed within the team?	112 (26.4)	309 (72.7)	4 (0.9)
	...addressed by the residents?	36 (8.5)	383 (90.1)	6 (1.4)

	...routine house calls?	158 (37.2)	259 (60.9)	8 (1.9)

Table . Attitude and relevant aspects of telemedicine of the participating nursing staff from Schleswig-Holstein (N=425).

Question		Score[a]		Missing, n (%)
		Median	IQR	
How is your general attitude toward telemedicine?		2	2-3	11 (2.6)
If you use video consultations				
	How confident do you feel in using them?	2	2-3	8 (1.8)
	In your experience, how big is the additional benefit a video consultation offers compared to sending an image for health issues relating to a resident? (*n*=37)	3	2-4	6 (1.4)
	How would you rate the time aspect of video consultations compared to previous forms of communication? (*n*=37)	3	1-3.5	6 (1.4)
How relevant is/are...				
	...personal contact with doctors to clarify a question for your work?	1	1-2	2 (0.5)
	...personal contact with doctors for the residents?	1	1-2	2 (0.5)
	...digital communication for your work?	2	1-3	4 (0.9)
	...the cost-to-revenue aspect for you?	3	2-4	20 (4.7)
	...easy usability of a telemedicine workstation for you?	2	1-3	7 (1.6)
	...low costs for hardware and software for you?	3	1-4	20 (4.7)
	...clearly structured organizational processes for you?	2	1-2	9 (2.1)
	...data security aspects for you?	1	1-2	7 (1.6)
	...software compatibility with the information system for you?	2	1-3	16 (3.8)
	...it for you to have a contact person for IT issues?	1	1-2	10 (2.4)
How big was the influence of the COVID-19 pandemic on your day-to-day work in terms of the use of digital media?		2	1-4	8 (1.9)
How big is the influence of the staffing ratio for you when using videoconferencing systems?		3	2-5	21 (4.9)

[a] 1=very high/positive/relevant; 6=very low/negative/irrelevant.

When asked how much time the participants could spend per shift familiarizing themselves with topics such as telemedicine, an average of 28 (SD 26, median 30, min-max 0-180) minutes was determined. When estimating how long it would take to familiarize themselves with a telemedicine workplace, an average of 47 (SD 76, median 30, min-max 0-1000) minutes was reported.

On average, the emergency service was alerted 5 (SD 9, median 3, min-max 0-135) times per month per area of operation in the nursing homes. Among these, the nurses estimate that on average 1 (SD 2, median 0, min-max 0-15) of these emergency operations could be spared by telemedicine.

Looking at the Fisher exact test, there are differences ($P<.001$) between the positive and negative responses to the questions

"Do you think video consultation should be practiced in training?" and "Would you attend training on medical telephone consultation?" There were differences in the questions about whether video consultation is considered useful for conversations between residents and relatives (*P*=.002) and routine examinations (*P*=.03). Those with a negative attitude were more likely to answer "no" to these questions. There were no differences between the groups in the questions about whether video consultation is considered useful for discussing laboratory results and for new findings. There was a difference (*P*<.001) in the question about whether video consultation is considered useful for follow-up checks. Those with a positive attitude were more likely to answer "yes" to these questions, while those with a negative attitude were more likely to answer "no." Furthermore, there was a difference (*P*=.003) in the question about whether video consultation would be useful to clarify urgent questions. Those with a positive attitude were more likely to answer "yes" to this question. There were no differences in attitudes toward telemedicine based on the location of the nursing facility. In both rural and urban facilities, about 80% had a positive attitude toward telemedicine.

The calculation with Spearman ρ showed no correlation (0.079) between age and attitude toward telemedicine (*P*=.11). There was a significant (*P*<.001) negative correlation (−0.274) between attitude toward telemedicine and opinion of how many emergency service calls can be reduced per month.

Discussion

Principal Findings

This cross-sectional study aimed to describe which telemedicine devices are already being used at inpatient care facilities and to determine the attitude of nurses toward telemedicine and for which areas the use of telemedicine in the facilities is considered sensible by the nurses.

The survey shows that the telephone and the fax machine are the most frequently used digital tools among nurses in Schleswig-Holstein. Video consultations and messaging apps, on the other hand, are currently used less. According to the PraxisBarometer 2021, video consultations are used by 20% of contract physicians (in Germany there is no obligation to use telemedicine [18]). This may influence the use of video consultations in care facilities [19]. The higher use of the telephone in contrast to video consultation could be explained by the fact that telephone calls are currently faster to execute and that many questions can be answered through a telephone call [20]. This was not asked in the study and could be the subject of further research.

Few participants were educated in using video consultation in their training, but many consider training to be useful. This indicates that training should focus more on digital topics, such as how to conduct video consultations. This is in line with observations from other countries. In the United Kingdom, there is also a need for more training in online communication skills [21]. Further work is needed to determine whether training should and can be adapted in Germany. The large variance in the responses as to how much time is presumably required for familiarization indicates that the training and familiarization times must be individually adapted to the needs of the nurses.

Notably, video consultations are considered more useful for urgent cases and questions than for regular visits. Participants also noted that telemedicine applications could save around 1 emergency ambulance call per month. This is also consistent with observations from other studies [7,8]. In past research, video consultations were considered useful, especially for frequently needed follow-up appointments [5], for instance in the treatment of depression. However, this study was conducted with doctors and not with nurses. There seem to be different views on the appropriateness of video consultations [6,22]. Furthermore, it is noticeable in the survey that for the use of video consultations, more organizational/administrative topics are considered useful, such as ordering medication or communication with training facilities, than direct patient care. It was not possible to determine why nurses prefer video consultation for administrative activities, which could be further researched.

The general attitude of the participants was positive toward telemedicine. Nevertheless, personal contact with physicians was relevant for the respondents. Particular care should always be taken to ensure that video consultations are only used where they really can support care and not completely replace personal contact [11]. The age of the respondents and the location of the care facilities did not influence their attitude toward telemedicine. Therefore, younger people are not the only age group interested in using telemedicine [19,23].

According to the respondents, the COVID-19 pandemic had a strong influence on their use of digital media. This is consistent with other literature. The increased use may be attributed to the fact that in some cases digital solutions were better than no contact at all [24-28]. Whether this influence was perceived positively or negatively cannot be determined. A decrease in video consultations after the relaxation of restrictions during the pandemic has already been seen in physicians' practices [15,19]. Additionally, whether the influence will be long-lasting could not be determined.

Data protection and a contact person in case of technical problems are very important for the respondents. The compatibility of the systems is also a relevant point for the caregivers. Furthermore, a telemedicine workstation should be as easy to use as possible. The cost aspect is somewhat less relevant for the caregivers themselves. This would presumably be an aspect that is more relevant at the institution level, but this was not addressed in this study. In a possible implementation of telemedicine applications in full inpatient care facilities, these points should be taken into consideration to achieve more success [7,11]. Likewise, efforts should be made to ensure that nurses have enough time to familiarize themselves with telemedicine workstations [8,16]. The respondents in this study suspected that familiarization would take more time than they had available. General attitudes toward telemedicine should also be considered, as the study showed that respondents who were positive about telemedicine were more likely to consider attending further training on the subject, among other things. It is important to keep demonstrating the benefits of telemedicine applications to maximize the motivation to use them [27,29]. Uncertainties about new technologies should be addressed so that people feel comfortable and confident using them [30]. Additionally, the implementations should be designed for the relevant facilities so that they can be used as easily as possible, and familiarization provides more benefits [31]. New applications cannot be implemented if there is no acceptance from the nursing staff [29,32,33].

Strength and Limitations

A strength of this study is that all 567 full inpatient care facilities in Schleswig-Holstein were contacted. It is not possible to conclude how many institutions participated, as the questionnaires were sent anonymously, and the response rate could not be determined. Since significantly more paper-based questionnaires were completed than web-based questionnaires, it is possible that more people could have been reached if more questionnaires had been sent out per facility. Despite the anonymity of the questionnaires, it is possible that the participants were biased toward answers they perceived to be desirable. In addition, recall bias, especially for the question about emergency services, was possible and must be considered in the interpretation of our data. It is also important to consider that people who are interested in the topic of telemedicine were more inclined to participate in the survey [34,35].

Conclusion

Attitudes toward telemedicine among nurses in full inpatient care facilities were generally positive. However, newer telemedicine applications, such as video consultation or messaging apps, are infrequently used. The need for telemedicine is seen mainly for acute issues. For the future practice of telemedicine, related content and training should be included in the education of future caregivers. When implementing telemedicine, the specific needs of the users must be considered to be successful. For example, regular customized staff training could be helpful in this regard. Furthermore, caregivers need to be given time for this training. Finally, caregivers need to be involved in the training content.

Acknowledgments

We gratefully acknowledge the voluntary participation of all nurses in the study.

Abstract

Background: Technology has been identified as a potential solution to alleviate resource gaps and augment care delivery in dementia care settings such as hospitals, long-term care, and retirement homes. There has been an increasing interest in using real-time location systems (RTLS) across health care settings for older adults with dementia, specifically related to the ability to track a person's movement and location.

Objective: In this study, we aimed to explore the factors that influence the adoption or nonadoption of an RTLS during its implementation in a specialized inpatient dementia unit in a tertiary care rehabilitation hospital.

Methods: The study included data from a brief quantitative survey and interviews from a convenience sample of frontline participants. Our deductive analysis of the interview used the 3 categories of the Fit Between Individuals, Task, and Technology framework as follows: individual and task, individual and technology, and task and technology. The purpose of using this framework was to assess the quality of the fit between technology attributes and an individual's self-reported intentions to adopt RTLS technology.

Results: A total of 20 health care providers (HCPs) completed the survey, of which 16 (80%) participated in interviews. Coding and subsequent analysis identified 2 conceptual subthemes in the individual-task fit category, including the identification of the task and the perception that participants were missing *at-risk* patient events. The task-technology fit category consisted of 3 subthemes, including reorganization of the task, personal control in relation to the task, and efficiency or resource allocation. A total of 4 subthemes were identified in the individual-technology fit category, including privacy and personal agency, trust in the technology, user interfaces, and perceptions of increased safety.

Conclusions: By the end of the study, most of the unit's HCPs were using the tablet app based on their perception of its usefulness, its alignment with their comfort level with technology, and its ability to help them perform job responsibilities. HCPs perceived that they were able to reduce patient search time dramatically, yet any improvements in care were noted to be implied, as this was not measured. There was limited anecdotal evidence of reduced patient risk or adverse events, but greater reported peace of mind for HCPs overseeing patients' activity levels.

Introduction

Background

The increasing demands for efficiency and improvements in the delivery of care have prompted interest in the use of tracking technologies as a solution to monitor the movements of patients, providers, and equipment across health care settings, including hospitals and long-term care homes. As an example of this type of technology, real-time location systems (RTLSs) can be used to identify the physical location of people or assets across time and space [1,2]. RTLS technologies are local positioning systems that typically consists of a wireless device attached to objects or worn by people, with environmentally embedded reference points that receive wireless signals from these wireless devices. Software connected to this wireless network can provide continuous real-time visualizations of the location data on a facility map. RTLS installations have been studied in a wide variety of health care settings to monitor individuals' movements (eg, residents or patients and health care providers [HCPs]) [3-5] and assets (eg, surgical equipment) [6] and, more recently, to collect health data [3,7-9]. These systems are particularly well suited for monitoring movement and reducing the risk of unaccompanied exit (eg, elopement); however, RTLS data have also been used to inform clinical decision-making processes and to monitor health status or the effects of an intervention [10]. Similar systems using wireless geolocation have already been successfully implemented in other sectors, such as insurance [11] and telecommunications [12], but present novel challenges when deployed in health care settings, particularly when they are used to generate personal and life-space data from vulnerable populations [13,14].

In the context of dementia care, interest in RTLS has been driven by the desire to evaluate cognition and health status more objectively and to enable the prediction of patient decline from changes in patterns of movement [7]. Other potential benefits of RTLS may include allowing greater freedom of movement within secure units and reducing the risk of unaccompanied exits (eg, elopement). A recent review by Grigorovich et al [2] identified barriers and enablers to implementing RTLS in people with dementia. Barriers to implementation included the following: a lack of motivation for providers to engage due to issues, such as perceptions of low value in use; technology infrastructure and maintenance challenges, such as a lack of on-site technical support and maintenance; and myths and stories about the technology and its purpose that are shared informally due to a lack of understanding about the systems and poor communication about how they work. In contrast, enablers of implementation included the following: being sensitive and adapting to local workflows, policies, and technologies; usability and user-centered design of the RTLS system; frequent communication with care providers; and establishing policies, frameworks, governance, and evaluations to assess the utility and improve the quality of the installation. The review found a striking lack of evidence to support the use of RTLS technologies to improve the quality of residents' lives or the workflow of HCPs. RTLS adoption in acute care settings has been slow, with concerns regarding provider privacy pitted against the goal of patient safety and efficiency [3].

Objectives

While many technology adoption models are in use [4] and have provided considerable insight into the adoption of digital technologies in the health care domain [5,6], to date, no study has specifically examined the implementation of an RTLS in a tertiary dementia care setting. To better demonstrate the potential barriers and enablers of RTLS adoption in a clinical setting, we used the Fit Between Individuals, Tasks, and Technology (FITT) framework developed by Ammenwerth et al [8]. The FITT framework suggests that the adoption of new technology in a clinical environment will depend on the *fit* between the attributes of the users (eg, computer literacy and education), the attributes of the technology (eg, user interface and functionality), and the attributes of the clinical task (eg, degree of complexity and workflows) [8]. The framework can be used predictively [9] or retrospectively to identify "deltas" between the expectations of a technology's implementation in a clinical setting and its actual relevance in the workflows and to its users [15]. The FITT framework's strength is its emphasis on the interaction between the individual and the task, with the understanding that harmonization will positively impact the implementation and adoption of novel technologies. In this study, we aimed to identify the factors that influence the adoption or nonadoption of an RTLS during its implementation in a secure inpatient unit for persons living with dementia in a rehabilitation hospital.

Methods

Study Design

This partially mixed methods concurrent study [16] included a brief preinterview survey followed by an in-depth semistructured interview. We chose this study design due to the exploratory nature of the research and the combination of quantitative and qualitative data that provides a deeper and more comprehensive understanding of the topic [17,18].

Study Setting

This study was conducted in a 20-bed secure inpatient dementia care unit of a large urban rehabilitation hospital in Ontario, Canada. Patients were admitted primarily from long-term care homes to receive specialized assessment and a personalized care plan to manage agitation, aggression, and other behaviors that interfere with the quality of life and safety of individuals living with dementia and their caregivers (eg, formal and informal). The unit comprised a team of interprofessional care providers (eg, nurses, physiotherapists, occupational therapists, recreation therapists, and geriatric psychiatrists) with expertise in addressing the range of physical, mental, and emotional challenges often associated with dementia. As the unit was a secure unit, the team was familiar with using technology to help monitor patients' health status and movements. For instance, the unit used the WanderGuard elopement prevention system (Securitas Healthcare), which alerted providers if patients attempted to leave the unit unaccompanied.

Participants

Participants in this study were HCPs who regularly worked on the unit where the technology was implemented (eg, nursing aides, nurses, allied health professionals, and unit leadership). There were approximately 40 frontline staff members who interacted with patients, in addition to an advanced practice nurse and a unit manager. HCPs working on the unit were exposed to the RTLS and were individually able to decide to engage with the technology. The participants were recruited via an email distributed by the unit manager to all HCPs and by word of mouth during training sessions, team meetings, and daily report huddles.

RTLS Intervention

The implemented RTLS was a commercially packaged ultrawideband live monitoring system installed to locate and track patients on the unit. The hardware consisted of wall-mounted beacons that created a local Wi-Fi mesh and wearable tags that provided location data within the networked area. The wearable tags were fitted to patients on the unit as nonremovable bracelets. All participants' substitute decision makers were provided with an opportunity to consent (or refuse) to have the patient wear the bracelet and to separately consent (or refuse) to have the location data collected and stored for research purposes (eg, development of clinical algorithms).

In the nursing station, a tablet app provided a view-only dashboard of the unit map and a live feed of patient locations. The tablet was locked to "kiosk mode" after log-in, thus preventing the app display from timing out. We held in-service training sessions to familiarize HCPs with the app's layout and functions, including how to read the map and search for patients. Although the RTLS can be used in various ways (eg, nursing call bell), no other features were enabled in this study; the system was exclusively used to locate patients. The RTLS location data were stored on a secured and sectioned client cloud server approved by the Health Insurance Portability and Accountability Act.

Ethical Considerations

This study was approved by the University Health Network (UHN) Research Ethics Board (#20-6277) and the Wilfrid Laurier University Research Ethics Board (ID# 6767) and was conducted in accordance with the principles of the Declaration of Helsinki. The survey participants reviewed a web-based consent form, had an opportunity to contact the study team with any questions, and indicated their informed consent to participate through the UHN REDCap (Research Electronic Data Capture; Vanderbilt University) e-consenting process. Then, a personalized link was sent from the REDCap system via email for participants to complete the preinterview survey. Upon completion of the interview, HCPs received a gift card valued at CAD $20 (US $14.8).

Data Collection

Following installation, a research study team member (LS) held training sessions for HCPs to explain how the bracelets worked to track patient location and how to use the nursing station tablet and app. During the training sessions, HCPs were verbally informed that they would receive an email inviting them to participate in the study. Approximately 6 weeks after installation, HCPs were invited via email to participate in the study, which included a short survey followed by a more in-depth, semistructured interview. The survey (facilitated via the UHN-managed REDCap servers) took approximately 5 minutes to complete and included questions regarding their sociodemographic characteristics and attitudes toward the use of technology when caring for patients with dementia. These attitudinal questions asked HCPs regarding their perceptions of the following: (1) their comfort with technology generally and location-tracking technology in particular, (2) the appropriateness of using location-tracking technology on patients with dementia, (3) whether they planned to use the location-tracking system installed in their unit, and (4) the appropriateness of technology to monitor HCPs. Furthermore, staff were invited to provide free-text comments regarding why they planned to use or not use the technology. After completing the survey, the participants were contacted to participate in the semistructured phone interview. The interview comprised 12 primary questions (Multimedia Appendix 1), asking about their past experience (if any) using RTLS, expectations and goals of the system, user experiences with the system, and how they perceived the system to impact their care of patients. The interviews lasted approximately 1 hour and were audio recorded. The interviews continued until saturation was achieved.

Data Analysis

Qualitative analysis was conducted using NVivo (version 12; Lumivero). Anonymized interviews were transcribed verbatim. Transcripts were read by all the research team members (LHL, AG, JM, KN, and AB) to gain a comprehensive understanding of the content. Several team meetings were held to review the transcripts and develop a coding strategy. We used inductive and deductive analytic techniques, such as systematic coding and constant comparison to fit data with existing literature and to identify conceptual categories and insights [19]. After the first round of independent coding, the team met to ensure the optimal categorization of utterances within themes and subthemes. Each interview was coded by at least 2 team members. Group discussions and consensus were used to resolve any disagreements in coding.

Our deductive analysis of the interview data was informed by the FITT framework developed by Ammenwerth et al [8] and included the following categories: (1) individual and task, (2) individual and technology, and (3) task and technology. The FITT framework suggests that the adoption of new technology in a clinical environment will depend on the "fit" between the attributes of the individuals (eg, computer literacy), the attributes of the technology (eg, user interface and functionality), and clinical task attributes (eg, degree of complexity) [8]. The individual category represents not only the individuals using the technology but also groups of users (eg, HCPs) and considers constructs such as the physical settings in which they operate, thus representing any nontask phenomenon that may influence uptake and use of the technology. The technology category includes components of a digital application, such as hardware, software, and network infrastructure, or analog tools, such as paper-based care plans or manuals, used to complement a particular technology. The task category represents the clinical work and work-related processes that occur within a particular care setting.

Results

Participant Demographics

A total of 20 HCPs completed the preinterview survey. The survey's primary purpose was to characterize the participant sample and allow the study team to determine whether the diverse range of HCPs on the unit was represented in the interview process. Of the 20 HCPs who completed the survey, 16 (80%) completed interviews, a sample size deemed sufficient given the exploratory nature of the single-site study and relative professional homogeneity of the sample population that allowed us to achieve saturation (Table 1) [20]. The participants who completed the survey and interview were predominantly female individuals (16/20, 80%), aged <50 years (16/20, 80%), and provided direct patient care (eg, nursing and support staff and allied health staff; 14/20, 70%).

Table 1. Participant demographics (n=20).

Measure and item	Surveys (n=20), n (%)	Interviews (n=16), n (%)
Sex		
Female	16 (80)	14 (88)
Male	4 (20)	2 (12)
Age group (y)

[a] OT: occupational therapist.

[b] PTA: physiotherapy assistant.

All the participants who completed the survey agreed or somewhat agreed with the statements that they were "satisfied with their job," were "confident in their ability to learn a new technology," and were "familiar with location-tracking technology and how it works" and "agreed" or "somewhat agreed" that location-tracking technology was "acceptable when tracking the movements of persons living with dementia" (Table 2). There was less concordance of opinion regarding the use of location-tracking technology to monitor the movement of providers; 12 (60%) of the 20 respondents reported that its use would be "somewhat or completely unacceptable," and 4 (20%) reported its use as "somewhat or completely acceptable" (Tables 3 and 4).

Table 2. Survey question responses (N=20).

Questions	Agree, n (%)	Somewhat agree, n (%)	Neither disagree nor agree, n (%)	Somewhat disagree, n (%)	Disagree, n (%)
"I am satisfied with my job."	15 (75)	5 (25)	0 (0)	0 (0)	0 (0)
"Overall, I find technology is useful in my job."[a]	15 (79)	1 (5)	3 (16)	0 (0)	0 (0)
"I feel confident in my ability to learn how to use new technology."	17 (85)	3 (15)	0 (0)	0 (0)	0 (0)
"I am familiar with location-monitoring technology and how it works."	14 (70)	6 (30)	0 (0)	0 (0)	0 (0)

Rarely	1 (5)
Never	0 (0)

[a] RTLS: real-time location system.

[b] SDU: special dementia unit.

Interview Results

Interview data were analyzed and reported in 3 categories that correspond to the FITT framework [8]. The quality of the fit between these constructs depends on each of their characteristics and their alignment and the ability of management or the technology adoption team to influence the adaptation of the task, the technology, or the individual to improve the quality and success of the implementation.

Individual-Task Fit

Overview

This category represents individual attributes, including individual users, user groups, the organization, and the working processes involved in completing the task, which in this case was using the RTLS to locate a patient in the unit. The ostensibly simple task of locating patients within a locked unit is complicated, given that many are mobile and some exhibit motor agitation, where restlessness keeps them in constant motion [21]. Using coding and subsequent analysis, we identified 2 conceptual subthemes: (1) characterization of the task and (2) the association between locating and monitoring patients for HCPs.

Characterization of the Task

In the first subtheme, participants identified the characteristics of the task, particularly the time-sensitive nature of some activities; for example, medication administration, which benefits from real-time monitoring, or conversely, the inability to locate a patient promptly when needed. One provider noted that the task of locating patients was more complicated with this specialized population as follows:

> *Because our patients are confused, and they have no concept of their own place or their own room, majority of them, they wander around the unit.* [P5]

Legacy closed-circuit television cameras that streamed video in real time to monitors located at the nursing desk only allowed the visualization of public spaces (eg, hallways). A provider articulated the difficulty with locating a patient using this existing system, as follows:

> *[T]here's no cameras in the patient rooms. Only in the hallway. Like [in] the public spaces...but not in the patient room. So, if you can't see them in like the more public spaces, then you would actually have to get up and search every single room because the patients might not be in their room...They could be in someone else's room, they could have fallen asleep on someone else's bed, maybe they're in someone else's bathroom.* [P21]

Furthermore, many HCPs shared that the task of locating patients manually made other tasks, such as medication administration, more complex:

> *Like if you wanted to give medication, [if] we couldn't find, um, patients, we have to go and look for them in room by room.* [P6]

Moreover, we conducted this study during the COVID-19 pandemic, during which patients who tested positive or were symptomatic of infection had to be isolated on the unit. While external doors were locked, most internal doors were not, particularly in patient rooms. The task of maintaining isolation for new patients, those who were exposed, or those who tested positive for COVID-19 in this unit was challenging, as they had difficulty remembering and understanding the need for isolation and physical distancing. HCPs had to monitor patients every 15 minutes to ensure that they stayed isolated and had to use a variety of strategies to encourage patients to remain in their rooms (eg, placing stop-strip door banners across the unit and stop signs on closed doors and sitting outside their rooms). Hallway cameras were perceived as inadequate for the task of supporting isolation, and providers felt that they did not allow for an anticipatory response when a patient was either moving from their bed or toward a restricted hallway or room.

In addition, this theme included the individuals' need to track items other than human or physical assets in a dynamic space. One HCP stated that putting tags on nurses could help them locate each other when one of their patients required assistance. Another suggested that they would be useful for quantifying direct care hours provided by different providers.

Similarly, some participants suggested that the RTLS may be helpful for monitoring assets such as patient's phones and walkers that are often misplaced. This is particularly important for assistive technologies, such as walkers, that support mobility and activities of daily living. One HCP noted as follows:

> *Someone who always uses their walker or, you know, always misplaces it...especially a lot of our patients now have, you know, like, personal items such as cell phones...and they've been misplaced and we're always looking for it.* [P8]
>
> *Especially with our...patient...group right now, a lot of them have their own cell phones. A lot of them, they put it in their pockets and a lot of the provider don't really track where they are. So, when the patients are looking for it, we're the ones who have to go around and look, you know, in the bag, in the laundry, in their closet.* [P8]

Association Between Locating and Monitoring Patients for HCPs

The second individual-task subtheme accounted for an HCP's perception that the act of locating or knowing the location of a patient on the unit was strongly associated with a better standard of care by helping to mitigate potentially "risky" events. One HCP noted as follows:

> *It gives me more stress if every time I keep on looking for my patient, I couldn't get my things done right away, 'cause I have to find them and always making sure that they're safe.* [P12]

Being unable to identify when one patient entered another patient's room was a common concern noted by HCPs:

> *So once in a while, we do our rounds, but if a patient sneaked into somebody's room, how would I know, until I really look at who is in bed?* [P5]
>
> *We cannot find them because they wander around, you know, they...pace and...they are so intrusive, they go to other, uh, patients' rooms.* [P6]

A number of HCPs noted that "distractions" would often interrupt the process of physically locating a patient on the floor, for example:

> *Another patient come(s) up to you and need(s) something, then you have to find someone else to help you.* [P21]
>
> *I would be finding one patient and then I would be distracted and go to another nurse who needed me.* [P14]

The same HCP mentioned that the task is never just a "straight search" and that their presence on the floor would be noted by other patients and staff, and they would be drawn into monitoring or supporting interactions in support of patients or their colleagues.

Task-Technology Fit

Overview

This category of the FITT framework represents the working processes involved in completing the task (locating a patient) and how they interact with the RTLS (consisting of the bracelet, the wall-mounted beacons receiving the ultrawideband signal, the app on the tablet at the nursing desk, and the software application). The task-technology fit category consisted of three subthemes: (1) reorganization of the task, (2) personal control in relation to the task, and (3) efficiency and resource allocation.

Reorganization of the Task

Reorganization of the task was expressed by HCPs as the ability to locate and monitor patients in real time without having to go into each patient room. HCPs using the technology started their search at the nursing station, where they interacted with the tablet to identify the location of the patient and then proceeded directly to the patient, rather than conducting a random search. Providers found this beneficial for several reasons, including using the tablet to “spot-check” to see where a patient was or being able to directly find a patient when they wanted to:

> *The purpose as I see it, is to be able to locate the patient when you need to locate a patient, whether it’s because of double checking that they haven’t eloped or you’re trying to locate them for a therapeutic reason or for you know, I think this is the big one was like family members coming to visit and they wanted, you know, to find their loved one.* [P4]

Furthermore, we found evidence of evolving work routines or stable actions that achieved work across time and space through adaptive routinization that supported HCPs use and adoption of the technology. However, adjustment of the technology (eg, tablet number and location) or routine (eg, shift change and anticipating interpatient altercations) to achieve a successful implementation was still clearly a work in progress at the time the interviews were conducted:

> *It’s been so new, it’s hard for us to remember that we have this...the more people are talking about it, the more that we’re remembering, “Oh we could use this instead of you know, running about the unit searching for patients.”* [P3]

> *Habitually, I would start the lap- and then realize that I’m wasting time, cut through the care station, find them on the monitor and then, yeah. So, it-it-it did change the fact that I-I wouldn’t do more than one lap before realizing that I could go use it.* [P8]

> *Right at shift change, I’m not gonna go in there and push through the nurses, trying to do their shift change to look at the monitor. I’ll just do a couple extra laps until I find them because it’s a reasonably small unit.* [P8]

Personal Control in Relation to the Task

The second subtheme in the task-technology fit category was the recognition of personal control in relation to the task of locating patients. The HCPs perceived that they had more control by being able to decide how and when to find patients using the app. For example, if they were in the nursing station performing another task, they were also able to see or locate a patient at a glance on the tablet. Examples of this narrative are as follows:

> *Instead of walking around three times around the entire unit, I know exactly where my patient is. I also can monitor them, uh, remotely.* [P5]

> *Especially, uh, at night-time it’s a lot better because, uh, we know that, uh, which patient is, uh, in the room and which one is out. When we are sitting in the nursing station, we can say like this...patient has come out of the room and is in a hallway or he has woken up.* [P6]

> *At night, like I wanna see which patients are asleep, or awaken, are awake, like, if the bed alarms don’t work.* [P13]

Efficiency and Resource Allocation

Efficiency and resource allocation were identified as a subtheme in the task-technology fit category. The HCPs stated that they were saving time and resources through their ability to find a patient directly using the app. They shared that a room-by-room search of the unit could potentially take up to 15 minutes each time as their patients were very mobile, which was challenging as they were also likely to be distracted by another patient during their search:

> *It saves me time from going from room to room because these patients, normally they walk around and go to other people’s rooms so where you least expect them to be that’s where they sometimes are. And, um, if you think they’re gonna be in their room, most times you’re wrong. They’re in somebody else’s room away from-- Maybe the other corner, you know, so it saves your time when you use this device. You located them faster.* [P11]

HCPs further reflected that the time they saved using the app to locate patients could potentially be used for accomplishing other tasks. For example, 2 providers stated as follows:

> *When time is saved, then I can invest that time more on patient care, and all the things that I can do with extra time.* [P13]

> *You still have to physically go look for the patient, but at least it does narrow it down for you.* [P4]

However, the location of a singular tablet installed at the nursing station may pinpoint a patient in 1 location only to find that they had moved by the time the HCPs reached there. Finally, the technology was considered helpful in locating multiple patients when the providers needed to run a group activity:

> *If I run groups, and I want to get, you know, specific patients of a certain group—um, then I would, you know, go to iPad and see where they are.* [P8]

Individual-Technology Fit

Overview

Individual-technology fit represents the relationship between the attributes of the individuals and the attributes of the technology and, in this study, comprised the most populous coding category for the interview data. The "individual" construct in the FITT model represents the HCP, who uses the technology to locate a patient; the patient, who wears the bracelet; the users as a group; and the organization, in which the technology is installed and the "tasks" and work processes are occurring. A total of four subthemes were identified in the individual-technology fit category: (1) privacy and personal agency, (2) trust in the technology, (3) user interfaces, and (4) perceptions of increased safety.

Privacy and Personal Agency

The subtheme of privacy and agency has multiple perspectives, given that while HCPs were the "users" of the technology, patients were the ones wearing the bracelet and being tracked. In alignment with the survey data, HCPs felt that patients on the unit had a limited right to privacy due to their perspective that these patients required close supervision to reduce their risk of harm (eg, preventing them from a fall or an altercation with another resident). This perception was expressed in narratives that suggested that patients with dementia lose their right to privacy (and conversely, their right to refuse to be monitored using the bracelet) as their cognitive impairment and behavior presents a risk to themselves, their family, and the organization:

> *There is no privacy for patients with dementia, with behaviors...privacy means that you are putting them in, uh, at risk.* [P6]

However, HCPs recognized that other patients (eg, those without dementia) had a right to privacy and may thus find the use of RTLS to monitor them unacceptable:

> *I don't know about the patients on other floors if...it's monitoring every move...they don't wanna be like, to know that they've gone to the washroom, you know? These just—these are- these are things they might not like.* [P6]

Despite HCPs belief that patients in the unit waived their right to privacy in return for what they believed to be better care and safety, in general, providers believed they were "entitled to their own privacy" (P16) and did not agree with the concept of using location tracking for HCPs. In particular, HCPs were worried that if the ability to track staff was initiated by management, it could be used to sanction them:

> *So, tracking staff, they would be depending on the culture, and I think just general trust of senior leadership. Like, are you tracking if I'm taking too many breaks, if I'm doing my job correctly?* [P21]

Those who personally felt that there may be value in tracking the movements of staff acknowledged that other HCPs might not agree but variously supported the tracking of providers to help locate each other, gather supporting data as it relates to workload monitoring, and build more efficient units. For example, they suggested that tracking providers' movements may be useful for showing how much they move in a day, how often they are in patient rooms, how many staff members are required to assist a patient, and for how long:

> *Cause I think we don't estimate that correctly.* [P22]

The potential risks associated with the collection and storage of patients' data were not a focus of concern; providers did not reflect on data use and storage until prompted during the interviews. Furthermore, providers made assumptions that the location data were kept on internal hospital servers; while for this study all data were stored on hospital secure servers, this is unusual and had to be negotiated with the equipment vendor who retained data on proprietary servers. One HCP stated as follows:

> *I would hope the security, or the data is secure and, um, only, you know, used for the study purposes.* [P3]

Another wondered if the data could be used for alternative purposes that they were not aware of:

> *I don't know that information is being used for some other sinister reason I don't know. Like whether they trust us with that information.* [P4]

Trust in the Technology

The subtheme of an individual's trust in the technology relates to the reliability of the system—that the technology was working when required—and how it was used or adopted as a result. However, HCPs displayed a tolerance for unreliability in this product, likely because there were workarounds; that is, the providers could revert to walking the unit to find a patient, which made the consequences of unreliability minor:

> *Okay. So, you have a little bit of a clue that there's something wrong with the bracelet if it's not moving then?* [Interviewer]
>
> *Yeah. Especially when the bracelet, uh, is on the screen in one location and patient is physically on a, in a completely different location.* [P5]
>
> *Okay. Do you think that it not working, um, will influence how you trust the system or how you use it?* [Interviewer]
>
> *Uh, no, because it doesn't happen often, it's just once in a while malfunction.* [P5]

User Interfaces

The individual-technology fit category includes a subtheme of how patients and HCPs interfaced with the technology. Many HCPs shared that some patients "fidgeted" with or attempted to remove the bracelets. When asked to expand on this, HCPs explained that "some patients do remove, like they have catheter or other bracelets, they remove it. It's just, uh, one of their behaviors" (P13). In response to a patient removing their RTLS bracelet or trying to remove it, providers reported that they would attempt to redirect the patient or move the bracelet to another location on their body (eg, an ankle) despite acknowledging that such attempts to remove the bracelet might be an expression of their desire to not wear the bracelet at all:

> *Sometimes we don't understand, but of course they're showing that they don't like it.* [P15]

Despite acknowledging this, HCPs did not explore the reasons why patients attempted to remove their bracelet. However, one provider did report that they would remove the bracelet if "the patient states exactly that he knows what the bracelet is and he states like, 'I don't want to be monitored'" (P13).

Furthermore, providers mentioned that the patient-technology interface was a tool for maintaining patients' dignity while wearing the bracelet, considering their lack of agency over whether they wore the tracking device. The bracelet esthetic mimicked something other than a surveillance device. For example, one provider reported that a patient "referred to the bracelet...as their Apple watch and it was kind of cool that they had a nice new watch, which was beautiful" (P07). She suggested that this was beneficial and stated as follows:

> *In the future, if it could even mimic a watch or have a watch face on it, that it, you know, when it goes into screensaver or whatever becomes a watch face, then it would be even more patient-friendly, user-friendly, right?"* [P7]

Similarly, another HCP stated as follows:

> *Even people with dementia want to feel ready for the day and wear important pieces like a watch, carry a wallet. Wearing such pieces give dignity and acknowledges that people still have purpose.* [P14]

Perceptions of Increased Safety

Another subtheme related to how providers supported and justified the use of the system by discussing potential (but not yet implemented) enhancements to the safety of patients. Specifically, providers felt that the technology might allow them to intervene or react more efficiently to a presumptive risk with the potential to avoid injury. One person in the study expressed an interest in using the RTLS to reduce the use of restraints, while others mentioned their desire for proximity alarms that would alert providers when patients who are "having an altercation" are in close proximity to each other and allow them to intervene. The narratives of this theme include the following:

> *In terms of safety, like interactions with other...other patients...like you could, you know, set up some kind of parameters that alert the staff when my patient X gets within vicinity of patient Y.* [P20]
>
> *I think maybe even physically if you see that a patient has entered the washroom, an alert could go off into the care station. Um, there's often times where I'll find someone in there and they're either beginning the process on their own and need help, or they are finishing the process and it's become messy and there's no way for us to know...But if an alert goes off in the care station, so and so has entered the bathroom, then whoever's in the care station can respond to that before it gets messy.* [P07]

Discussion

Principal Findings

In this study, the introduction of an RTLS with restricted functionality of tracking the location of people and assets within a secure inpatient unit for persons living with dementia represents one of the most elementary implementations of a single technology to achieve a single task. The successful adoption of the technology was uncomplicated, and its uptake by HCPs was thus predictably swift. We aimed to investigate the factors influencing the adoption or nonadoption of the RTLS technology. We found that the successful adoption of the RTLS was due to the strong fit between the technology and the task, which was locating the patients more efficiently, and the strong individual and task relationship on the unit.

First, we summarize the results of the interactions between the 3 pillars of the FITT framework to explain the success of the implementation and identify the factors that influenced the adoption of the technology. Second, we address related issues that warrant consideration for similar and more complex implementation.

Evaluating the FITT of the RTLS Implementation

The strong individual and task relationship on the unit was supported by an organization whose labor force was stressed due to the global pandemic and shortages and allied health and nursing HCPs who were aware of the challenges of ensuring that mobile individuals living with dementia were safe without constant one-to-one supervision. Individual providers who were responsible for locating patients in real time for events such as medication rounds, check-ins, patient visitors, and meals relied on installed closed-circuit television camera feeds. These cameras streamed to monitors mounted above the nursing station desk, providing real time but restricted line-of-sight hallway identification of patients and providers. However, the patient had to be in a hallway and remain in the same place long enough to be visualized. Depending on the patient, a care provider may need to search >1 bedroom to find a patient [22]. Providers' anticipation of negative outcomes, both personally and to the patient from less than round-the-clock monitoring or to respond to risky behaviors such as interpersonal altercations or elopement, was a strong motivator not only to continue with what was described as an inefficient and time-consuming process but also to find and adopt a more efficient solution. As demonstrated in the narratives, the strong fit between the RTLS technology and the task was perceived as a clear benefit to staff and, as such, an influencing factor of technology uptake. When staff perceive that using the technology is the best fit for the completion of their tasks, they are more likely to adopt its use [23]. With this type of technology, Doshi-Velez et al [22] identified that being able to find patients more efficiently provides nursing staff with a strong motivation to use RTLS technology. Our HCPs provided examples of the perceived limitations of the current method of completing the patient locating. The time and energy required to find patients by "roaming" the halls were not generally perceived as a valuable use of time. Similar to research by Griffin et al [3], the HCPs appreciated the efficiencies that the technology afforded them (eg, the ability to "multitask" by reviewing the tablet app at the nursing station while completing another task, such as charting). HCPs mentioned that this was especially helpful during night shifts when HCP-to-patient ratios were lower (eg, fewer HCPs were responsible for more patients). Although HCPs were universally appreciative of reducing patient search time, they mentioned the indirect value of HCP "walkarounds" in the facility during patient searches. This informal "rounding" on the unit and attending to "distractions" over time and space was suggested by one participant as an opportunity for HCPs to intervene early or to prevent risky events or behaviors.

As the RTLS technology in this study passively *surveils*, it is neither predictive nor prescriptive; therefore, while it may help identify potential issues (eg, a patient alone in a bathroom or exiting the facility), with the functionality activated for this pilot, the system still required a provider to identify an issue (by visualizing patient location on the tablet), judge the potential risk, and determine if they needed to respond in person. The transactional (locating task) and anticipatory (monitoring task) use of the technology were both highly suited to the task of reducing risk for the individual, the institution, and the patient and provided peace of mind to visiting care partners who may perceive that the providers were more aware of the presence of their family or loved one.

Another influencing factor for adoption was the fit between the individual and the technology, partly due to the intrinsic capacity of the HCPs. We conducted foundational preinstallation training on the operation and use of the RTLS, and the HCPs were comfortable with workflow changes as a result of being a research-intensive facility (eg, by way of social influence and facilitating conditions), which has been found to be beneficial for the adoption of technology [24,25]. In addition, as found in the preinterview survey, the HCPs self-reported a positive attitude toward technology in general and the RTLS in particular. However, the fact that the technology was introduced to the staff as a pilot research project may have impacted its adoption. One HCP noted that if it had been presented as the de facto and permanent new method of locating patients, they would have been more invested in it.

Similar to Griffin et al [3], the HCP's confidence in the RTLS system was based on trust. This included trust that the organization would not implement a system that did not secure patient location data, that the RTLS was reliable and presented accurate information, and that the organization's trust in them as professionals should preclude the expansion of RTLS technology to monitoring staff for any reason. Similarly, the trust extended to the reliability that the system would be functional when needed. While the implementation of the RTLS presented few technological issues, beyond unplugged beacons, frozen screens, and drained bracelet batteries, that were unable to be managed by the on-site research coordinator (in addition to its fit with the unit workflow and operations), other issues emerged that are noteworthy.

Perceptions of Safety

The decision to pilot or implement RTLS is frequently promoted as it has the potential to enhance unsupervised freedom of movement and improve the physical safety of persons living with dementia. Similar to the findings reported by Hall et al [26], the HCPs in our study identified that the primary rationale for using RTLS in this population was enhanced physical safety rather than freedom of movement. Providers alluded to technology-enhanced patient safety, yet it was difficult for them to articulate measurable outputs of related safety improvements compared to current interventions. It is important to distinguish between the "potential" of the technology's capabilities and the actual functionality that helps realize improved safety. In reality, the functionality of the installed technology for our study was not "smart" nor was it predictive or responsive; unless a human was monitoring the app the moment a patient was at risk, there was no intervention or lessening of risk. The installed off-the-shelf technology in this study had both geofencing alerts and call button features but required human monitoring and sufficient staffing to respond and therefore were not enabled. Installations that enable these types of alerts (related to being outside a restricted area, experiencing a fall, or being in a location that suggests more risky behaviors) must be monitored to allow for a response in real time. This has resource implications related to technology (eg, mobile phone apps or tablets that allow remote monitoring rather than using a fixed desktop application) and human resources (eg, alerts must be responded to); thus, additional staff must be recruited to monitor, investigate, and respond to alerts anywhere on the floor at any time. Infrastructure and funding challenges and labor force shortages must be addressed to encourage more widespread exploration of the value and use of technologies such as RTLS in long-term care.

Training and Adoption

HCPs in the study were oriented to the tablet app through training sessions, which focused on the features of the technology and its basic use, whether they voluntarily chose to use the location map app or not. The tablet was located beside the legacy surveillance camera feed, serving as a reminder of its availability. During the training sessions, those who were using the technology shared use cases and examples of when and how they found the system useful. At the start of the project, HCPs explained that their confidence in the system would be heightened if they could trust that it reliably showed the real location of patients and that the patients were unable to interfere with its operation. By the end of the study, most HCPs were using the tablet app based on their perception of its usefulness, its alignment with their comfort level with technology, and its ability to help them perform job responsibilities. As the pilot implementation progressed, "superusers" emerged [27,28], who were early adopters and who strongly advocated for its usefulness and value in the unit. Superusers often spontaneously helped others troubleshoot or navigate the RTLS and quickly identified alternative uses for the technology (eg, as asset tags). In one case, we downloaded a patient's activity reports (a management feature of this particular RTLS), which helped to identify that they walked an extraordinary distance daily, allowing providers to integrate changes into the care plan (eg, encouraging rest times and increased caloric intake). Furthermore, some HCP users identified that the technology would be potentially more helpful if it were available on their phones or if there were more tablets accessible throughout the unit at different locations.

The setting for this study was a locked inpatient unit that already used sensors fitted to each patient to prevent their unaccompanied exit from the unit. Within the unit, the patients were free to move as they wished or were able to. As a short-stay unit, its focus was on stabilizing or addressing behaviors and facilitating patients' return to the community. Unlike a long-term care home where residents' mobility is often compromised, many of the patients in this unit were ambulatory; the organization's interest in preserving patients' dignity and aligning their values with those of patients by allowing their free movement in the unit had operational implications, such as unsupervised interactions between patients and increased provider time in seeking out patients for treatment and well-being checks. It is unsurprising that organizations are moving to replace what they believe to be non–value-added tasks performed by providers with technology-enhanced solutions such as RTLS [29]. Patients' resistance to wearing the bracelet was reduced for some patients perceived the technology similar to an Apple Watch, which they described as "cool." Providers suggested that to avoid dissent, further disguising the transponder, what Sannon and Forte [30] describe as "dignity in design" where aesthetics are considered along with utility, would provide more dignity to their patients when the organization and substitute decision makers' values (to create a safe and risk-free environment) supersede patients' right to privacy.

During the training of HCPs on the RTLS and in our research interviews, we noted a lack of in-depth discussion regarding the complexities and potential challenges associated with implementing monitoring technologies in a health care setting [26]. This approach, while simplifying the training and implementation process, may have allowed staff to focus on its potential to enhance patient safety but failed to engage the HCPs, care partners, and, where feasible, patients in a dialogue about the implications and challenges associated with its deployment, such as its impact on privacy. Hall et al [26] suggested that for technology implementations to be successful, they must involve substantive discussions to anticipate and address these challenges. Such inclusive conversations involving all stakeholders in the decision-making process are crucial for a more effective implementation of novel technological systems.

In the survey, all participants identified that using this technology to track persons with dementia was either somewhat (16/20, 80%) or completely (4/20, 20%) acceptable. During the interviews, the staff did not initiate any ethical concerns. Prompted questions related to the ethical use of ubiquitous monitoring technologies that collect sensitive biometric data, the creation of a surveillance culture, and the responsibility of organizations to respect the rights and dignity of susceptible individuals when using these technologies were not identified as a care priority by staff in the interviews. This finding has considerable risks and implications that have been explored in more detail elsewhere [2].

In the survey, the HCPs demonstrated a mixed level of acceptance of the RTLS being used to monitor HCP movement. This finding was echoed in the interviews, where HCPs expressed a hesitancy to use the technologies on themselves despite overall satisfaction with their work; this is consistent with previous studies [3,31], where workforce monitoring was viewed as a lack of management-worker trust, a manifestation of the blame culture, and a foot in the door where monitoring for quality of care (eg, time spent with patients or handwashing) would be the first step to its use for individual performance tracking (eg, length of breaks and productivity). The shift of health care administration, toward the adoption of more scientific management where standardization, removal of inefficiencies, and process improvement, supports the notion that RTLS might be used in this fashion [32]. Overt messaging from the management that the monitoring in this study was limited to patients supported its successful adoption and implementation.

HCP Workload and Technology Support

Technology has increased the amount and complexity of information that employees are expected to process and has enabled HCPs to access unlimited amounts of information to do their jobs [33]. In the health care environment in which provider resources are scarce, workloads are high. Some HCPs on the floor did not use the RTLS (and did not volunteer to participate in our study); those who participated cited its simplicity, reliability, and ability to reduce their perceived workload as the reason for their continued use of the technology, rather than the rationale of safety as the rationale for adoption. Workload presented a challenge in relation to troubleshooting technological issues with the RTLS. Although providers were comfortable with the RTLS, none moved into a role where they were able to troubleshoot simple technological issues. Most cited the lack of time, the availability of a low-cost alternative (walking around), and the presence of a research team for technological support; however, this support was not available 24/7.

Limitations

The generalization of findings from data collected at a single location during one technology implementation has limitations. However, our focus on exploring the perspectives of HCPs working in an environment that provides specialized dementia care was both a strength and a limitation. The perspectives of the organizational decision makers on the rationale for adopting and implementing the RTLS technology in the unit were outside the scope of the study. These findings will be important to explore in future research on the adoption of RTLS in dementia care settings.

Providers' self-reported comfort with the installed RTLS was evident in the preinterview questionnaire responses and after providers were trained and had used the technology. Furthermore, the unit under study is a teaching and research-intensive hospital that frequently involves providers in technology-enabled research studies. The uniqueness of the unit may have impacted the self-reported providers' job satisfaction where, particularly during the pandemic, restricted access to the unit and the limited number of patients and providers offered some immunity from the ongoing pandemic pressures related to staffing shortages, frequent outbreaks, and increased workloads, which were experienced in other congregate settings for people living with dementia [34].

The staff members on the unit were acquainted with the principal investigator and the research coordinator of this study, who conveyed the study's purpose to the participants, responded to staff inquiries, and obtained participant consent. To ensure impartiality, the study team used deductive analysis of the data and applied the FITT framework as a standardized approach to analyze the data. This framework is a well-established and widely used approach in the literature, which helped to reduce the potential for researcher bias in data interpretation. Furthermore, the fact that the unit uses other technology, such as the elopement prevention system, suggests that staff members are accustomed to using technology in their daily work routine. This familiarity with technology may have helped to reduce any bias toward or against the RTLS technology used in this study.

Another limitation relates to the small scale of this study. Although the number of participants was sufficient to reach saturation with respect to our research questions, it is insufficient to generalize beyond the specific context of the featured location-tracking technology, its functionality, and the hospital-based dementia care setting in which it was implemented.

Conclusions

Similar to many novel technologies in the nascent stages of their adoption, evidence to support the utility and effectiveness of RTLS in improving the safety and quality of care in health care organizations and patients' experience is limited. While HCPs were able to reduce their self-reported patient search time dramatically, sometimes by half, any improvements in care were implied or perceived. While no participants self-reported evidence of reduced patient risk, reduced adverse events, or improved outcomes, they described greater perceived peace of mind for the staff responsible for oversight. As stewards of resource-constrained pragmatic organizations, decision makers in the health care sector will weigh the risks of RTLS adoption related to personal privacy, overreliance on untested technology, and cost against the benefits of ubiquitous monitoring of human and equipment assets, performance management, and automation of location tasks to improve staff efficiency. The decision to adopt novel technologies necessitates examination policies, workflows, and resource commitments beyond the initial purchase costs of the hardware, software, and training to identify technologies and adoption processes that best fit the organizational context and the tasks it must perform.

Abstract

Background: Because of the relationship between independent living and activities of daily living, care teams spend significant time managing assisted living residents' toileting problems. Recently, the TrueLoo was developed as a connected toilet seat to automatically log and monitor toileting sessions.

Objective: This study aimed to demonstrate the validity of the TrueLoo to (1) record and identify toileting sessions with regard to stool and urine events; (2) compare the results with the person-reported, standard-of-care methods; and (3) establish metrics of user acceptability and ease of use in a assisted living facility population.

Methods: We used two phases: (1) initial development of the TrueLoo algorithms to accurately identify urine and stool events and (2) evaluation of the algorithms against person-reported, standard-of-care methods commonly used in assisted living facilities. Phase 2 analyzed data over a 3-day period from 52 devices. Participants' age ranged from 63 to 101 (mean 84, SD 9.35) years. Acceptability and ease-of-use data were also collected.

Results: Regarding the development of the TrueLoo algorithm for urine assessment, sensitivity and specificity of 96% and 85% were observed when evaluating a gold-standard labeled data set, respectively (F_1-score=0.95). For stool, sensitivity and specificity of 90% and 79% were observed, respectively (F_1-score=0.85). Regarding the TrueLoo algorithm in assisted living settings, classification performance statistics for urine assessment revealed sensitivity and specificity of 84% and 94%, respectively (F_1-score=0.90), and for stool, 92% and 98%, respectively (F_1-score=0.91). Throughout the study, 46 person-reported instances of urine were documented, compared with 630 recorded by the TrueLoo. For stool events, 116 person-reported events were reported, compared with 153 by the TrueLoo. This indicates that person-reported events were captured 7% (46/630) of the time for urine and 76% (116/153) of the time for stool. Overall, 45% (32/71) of participants said that the new toilet seat was better than their previous one, 84% (60/71) reported that using the TrueLoo was easy, and 99% (69/71) said that they believed the system could help aging adults. Over 98% (69/71) of participants reported that they would find alerts related to their health valuable and would be willing to share this information with their doctor. When asked about sharing information with caregivers, 66% (46/71) reported that they would prefer the TrueLoo to send information and alerts to their caregiver, as opposed to the participant having to personally communicate those details.

Conclusions: The TrueLoo accurately recorded toileting sessions compared with standard-of-care methods, successfully establishing metrics of user acceptability and ease of use in assisted living populations. While additional validation studies are warranted, data presented in this paper support the use of the TrueLoo in assisted living settings as a model of event monitoring during toileting.

KEYWORDS

activities of daily living; toileting habits; bowel movements; elder care; smart toileting; monitoring technology

Introduction

The global population is aging rapidly, and by the year 2050, the number of people aged 60 years and older will drastically increase to over 2 billion [1]. Concurrent with this increase in the number of older individuals, life expectancy is projected to increase in the coming decades [2]. However, as is often the case with advanced aging, this increased life expectancy will almost certainly be associated with accompanying morbidities and their associated costs to individuals and health systems [3,4].

These aging demographics will increase the burden of care in assisted living facilities. As part of their regular responsibilities, care staff in these facilities spend significant time and effort documenting and managing their residents' toileting habits and events [5,6]. This also means they play a key role in the assessment and prevention of toileting-related issues.

While toileting measurement and assistance is an important part of management in assisted living facilities, there is little evidence on how these individuals actually manage bowel problems and the quality of the interventions performed [7]. Furthermore, to track these events and monitor for issues, staff often rely on human reporting. This can come in the form of second-hand information from the resident or the staff member's own memory when recording multiple residents' toileting habits at once near the end of a shift; as a result, these methods are incomplete and prone to error.

Because of the relationship between independent living and activities of daily living [8], care teams spend a significant amount of time managing residents' bowel and bladder problems. Besides common bladder issues such as urinary tract infections [9], bowel problems such as constipation [10], diarrhea [11], and fecal incontinence [12] are highly prevalent among assisted living residents and present several challenges for care staff with regard to monitoring and reporting. Furthermore, these types of events cannot be identified without proper monitoring and recording of toileting events. Recently, the TrueLoo (TL; Toi Labs) was developed as a connected toilet seat to automatically log and monitor toileting sessions, removing the burden from the patient or facility staff. Reporting and monitoring stool and urine characteristics is shown to notably improve the quality of care that residents in assisted living facilities receive, especially those living with multiple comorbidities [13]. The TrueLooprovides concurrent monitoring of toileting sessions, providing caregivers with data to improve their clinical decision-making through evidence-based technology.

Previous investigations and review papers have evaluated the efficacy, practicality, and use of smart toilet seats as a model to longitudinally monitor individual toileting habits. Initial work provided evidence of usability and proof of concept for such a design through the use of a colorimetric assay tracing red-green-blue values from images of urinalysis strips [14]. They also included cameras to collect "analprints" used as unique identifiers. However, there were limitations related to device scalability as well as privacy from upward facing cameras; nevertheless, this was important work to demonstrate functionality of the process [14]. Further work demonstrated the ability to use an image-based data set to classify stool according to the well-established Bristol Stool Form Scale [15], demonstrating the feasibility of using such a technique to automatically evaluate samples [16]. However, while the groundwork for using smart toileting technology has been demonstrated, no data currently exist demonstrating the efficacy and applicability of accurately capturing and evaluating toileting events in a real-world setting.

Therefore, the purpose of this retrospective study was to demonstrate the validity of the TrueLooto (1) record and identify toileting sessions with regard to stool and urine events; (2) compare the results with the person-reported, standard-of-care methods; and (3) establish metrics of user acceptability and ease of use in a assisted living facility population. We hypothesized that the TrueLoowould demonstrate significant improvements in the event capture of toileting sessions compared with the current reporting systems, while being well accepted in the target population.

Methods

Ethical Considerations

This was a retrospective analysis, and all procedures were approved by the Western Institutional Review Board (TLSD-001); the study was conducted in accordance with the Declaration of Helsinki.

Subject Demographics and Recruitment

The participants in the study were aged between 63 and 101 (mean 84, SD 9.35) years. All study participants were from a skilled nursing facility located in Dallas, Texas. Of the 52 participants, 27 (52%) were female. The eligible participants were contacted by community staff, and all individuals who agreed to participate in this investigation were provided with an extensive overview of the product and its capabilities; there were no residents who declined participation. The use of the technology was noted in each resident's care plan, and community staff were extensively trained by Toi Labs on the capabilities of the product. Finally, Toi Labs provided additional materials to the community to distribute to residents and their families to address concerns about privacy protocols, product overview questions, or other questions regarding the reporting system.

Inclusion and Exclusion Criteria

This study was conducted as a retrospective analysis, and, as such, there was no participant consent required. However, to participate in the original commercial program, each participant was required to meet all of the following inclusion criteria: (1) willing to participate and provide consent for the program, (2) aged 55 years or older, (3) a resident of the assisted living facility where the data were collected, and (4) had regular access to a TrueLoo.

Additionally, participants satisfying any of the following exclusion criteria were precluded from participation in the study: (1) unwilling or unable to accept the requirements associated with installing the TrueLooin their residence, including power and Wi-Fi connectivity, and (2) used certain types of toileting assistance devices that, at this time, are not compatible with the TrueLoo(eg, padded toilet seat risers).

Study Design

This study was conducted in two phases:

1. Development of the TrueLoo algorithms to accurately identify urine and stool events
2. Evaluation of the algorithms against the real-world person-reported, standard-of-care methods commonly used in assisted living facilities

It is suggested that traditional methods for developing robust evidence are incongruent with the agile approach commonly used in software development, as there is often an incongruence between the length of traditional registered controlled trials and the development and update cycle for software [17]. Given the agreement that more traditional approaches present fundamental limitations for proper evidence generation for digital health solutions, this 2-phase approach allowed for the controlled development of the algorithms from real-world data collected as part of a commercial program and then analyzed and evaluated retrospectively for efficacy.

For phase 1, details surrounding the development of the initial algorithm for identifying stool and urine events are described below. For phase 2 (real-world data collection), participants were enrolled independent of symptoms, disease diagnosis, or state. Furthermore, in an effort to attain real-world applicability, there was no stratification of the population by sex, age, race, or disease severity. Each participant was monitored in their residences within their respective community. For each resident, a TrueLootoilet seat was installed in their private bathroom along with an initial health assessment to collect demographic information and any preexisting conditions. During this phase, 52 devices were deployed and reviewed for a 3-day period. Data were collected on each of the 52 participants using the TrueLoo.

Measures

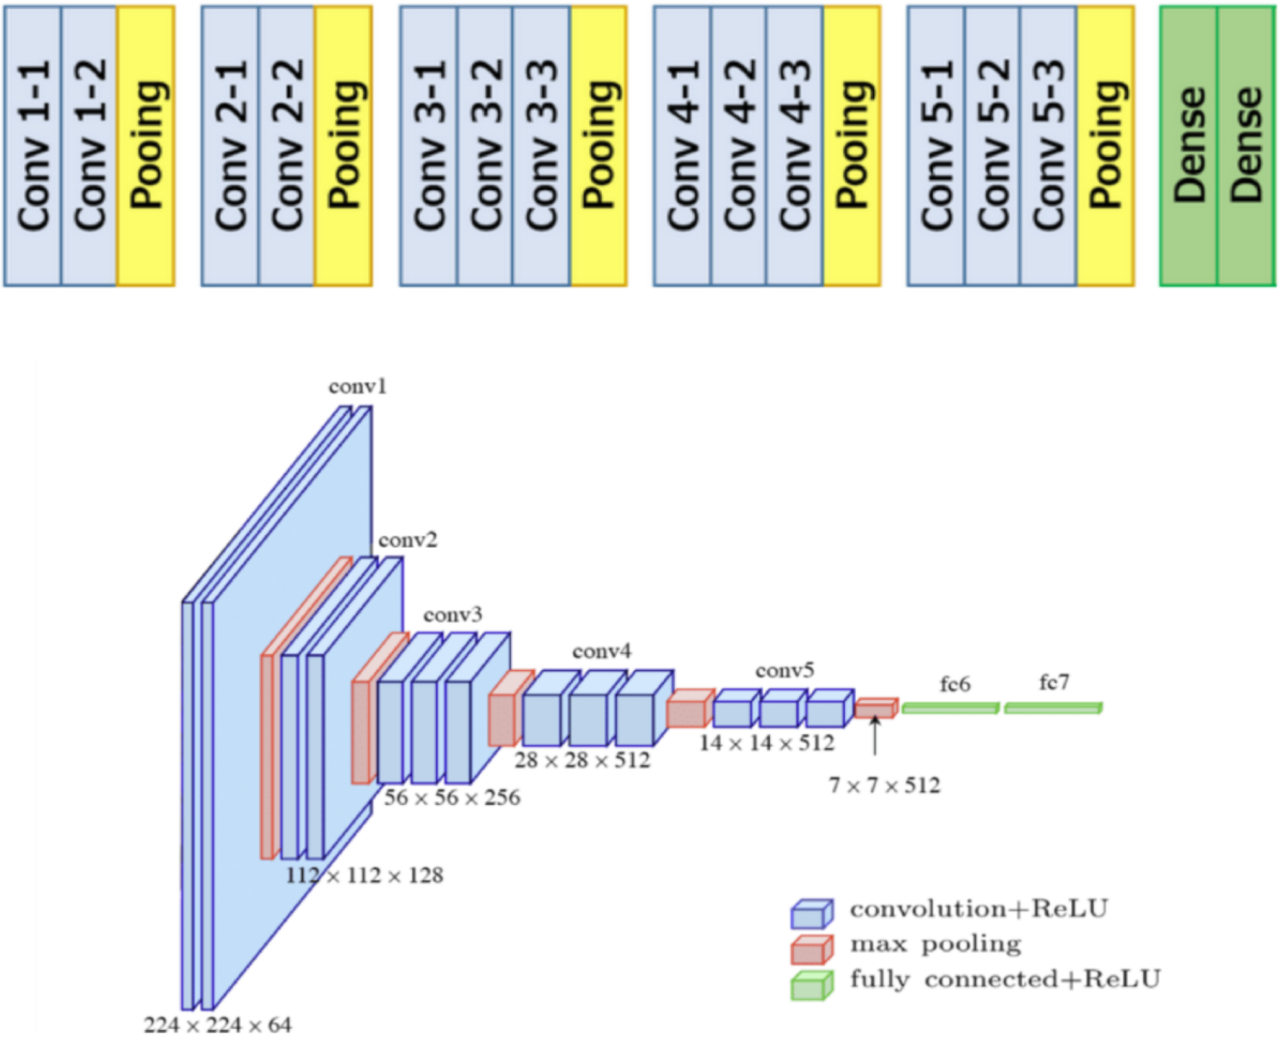
Development of the TrueLooAlgorithm for Identifying Urine and Stool Events

To verify urine and stool events that were accurately captured in the development of the algorithm, a panel of board-certified, gastroenterologist, subject-matter experts were first enlisted to create a “gold-standard” database. The subject-matter experts created a rule set for image annotators, who were trained to accurately identify image content. These image annotators provided our ground truth and produced a labeled data set that was then used to train the machine learning algorithms before being run on the full data set. The applied labels were used to create digital biomarkers for toileting event imagery. As of this investigation, more than 10,000 sessions (times people have used the toilet) were labeled, with more than 40,000 images. A session was activated when a user is in proximity to or sitting on the toilet seat. Each session comprises multiple images that depict the physical characteristics of urine and stool seen throughout the session in a time series.

The TrueLoo algorithms were developed using an existing large image model that is pretrained to extract fundamental image features such as shapes, colors, and textures. This model is then trained on proprietary image data collected by the TrueLoo that have been human annotated with label taxonomy of over 20 contextual labels that include relevant health metrics such as the Bristol Stool Scale and nonhealth metric such as toilet cleaning. The labeled data set is used to refine the large image model to create the proprietary TrueLoo algorithms.

A classic deep learning network structure was used for the neural network architecture, as illustrated in Figure 1. The network consists of 5 convolutional blocks with max pooling for feature learning and extraction, followed by 2 dense layers. A sigmoid activation function on the final layer is used for the final multilabel classification task and a binary cross-entropy loss function. This architecture has been very successful in traditional image classification tasks, and pretrained weight configurations based on classic benchmarks are readily available, making it an ideal candidate for fine-tuning and transfer learning.

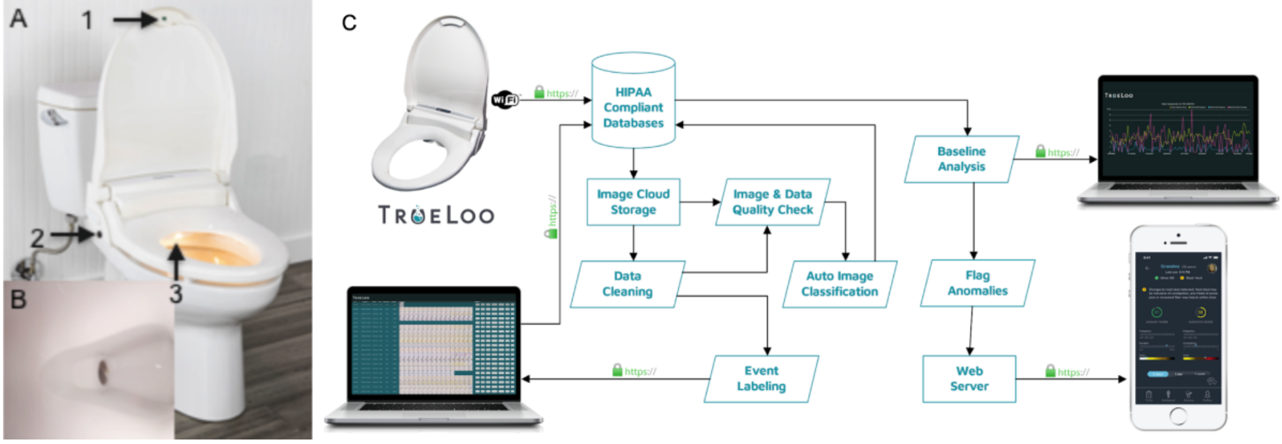
Figure 1. Convolutional neural network architecture. Conv: convolutional block; ReLu: rectified linear unit.



Detailed Working Description of the TrueLoo Technology

The TrueLoo consists of 2 parts: a hardware component that is delivered as a replacement toilet seat and a software system for analysis and reporting. Figure 2A shows a photograph of the TrueLoo seat with features called out and an image (example in Figure 2B) captured from the optical system. The TrueLoo seat has 2 user presence sensors: a contact sensor bound to the seat with no visible sign to the user and a noncontact time-of-flight distance sensor (Figure 2A.1) that activates when the user does not sit on the seat (ie, standing while urinating). By using the 2 sensors, the system distinguishes between standing and seated events as well as nonevent classification. The rear housing is used to mount the optical system and support electronics. The bowl is illuminated (Figure 2A.3) uniformly by red-green-blue-white LEDs to control color balance and some narrow band imaging illuminating with only 1 color. This allows for consistent imaging conditions for all currently encountered toilet geometries. Not shown in the image is the red-green-blue 8-megapixel manual focused camera and needed control and communication electronics. The system is powered by a single-board computer with integrated Wi-Fi communications for transmitting the images. The TrueLoo seat has a guest button (Figure 2A.2) to disable the system if a guest needs to use the toilet. The guest button automatically resets after each use. No images are recorded from guest events; however, they are registered in the database as an activation of the TrueLoo. Not shown in the figure is the cable routing using a conduit to fix the cable to the wall and connect the unit to power using a wall mount type AC-DC transformer at the outlet allowing for a long cable run with a low-voltage thin wire; this setup does not require a new outlet or the replacement or recharging of batteries. The seat is fixed to the toilet using a standard commercial mounting system for replacement toilet seats. After the TrueLoo seat is installed, it requires minimal to no ongoing maintenance, other than ensuring that the optics stay clean.

Figure 2. The TrueLoo platform and associated dataflow. (A) Image of TrueLoo installed on a toilet: (1) user presence sensor for risers and male standing urinating; (2) multifunction guest button: excludes guests who may use the toilet; (3) bowl illumination, optical system that scans the contents of the toilet bowl. (B) Example frame captured by TrueLoo. (C) TrueLoo software block diagram; data captured by TrueLoo is uploaded to HIPAA-compliant databases and data flow begins. HIPAA: Health Insurance Portability and Accountability Act.



When a user activates the TrueLoo by sitting on the seat or standing in front of the toilet, the system activates an event and immediately starts imaging at 1.2 frames per second. The TrueLoo continuously captures images of the bowl for the duration of time the user is seated or standing in front of the device. Immediately after the event is finished the images are transferred via Wi-Fi to Health Insurance Portability and Accountability Act (HIPAA)–compliant servers for storage and analysis (Figure 2C). Duplicate images are not uploaded but are registered to ensure correct time sequencing and more.

Because of the non–battery power and Wi-Fi connectivity configuration, data could be logged and monitored to ensure that the device was connected and working properly. The device can save approximately 1 week of data locally and resume uploading data if and when a Wi-Fi connection is compromised. This capability provides added capture and integrity in the event of a prolonged Wi-Fi outage.

Tracking of Toileting Events in Assisted Living Facilities

As previously mentioned, person-reported methods of bowel movement and urinary event tracking are considered the standard of care in assisted living settings. For phase 2 of this study, the same annotators retrospectively labeled toileting images captured through a commercial engagement, creating a real-world ground truth data set. We then analyzed recorded TL-captured events through the algorithm developed in phase 1, comparing them with the person-reported events captured by facility staff, broken down into urinations and bowel movements.

The current practice for reporting toileting events among facility staff involves documentation at the end of a shift, sometimes manually (pen to paper in a chart), or other times in the electronic medical record. The analysis done was for a community that reports this information in the electronic medical record. The data recorded in bowel and bladder logs are often inadequate, with limited description. For example, the logging for urination only allows facility staff to notate “Void? Yes or No.” Many of the entries are listed as “Not Applicable.”

Bowel elimination questions include (1) the size of bowel movement (small, medium, large, resident not available, resident refused, and not applicable), (2) consistency of bowel movement (formed or normal, loose or diarrhea, constipation or hard, putty like, resident not available, resident refused, and not applicable), and (3) bowel continence (continent, incontinent, no bowel movement, continence not rated due to ostomy, resident not available, resident refused, and not applicable).

The TrueLoo system automatically classifies on an established scale based on the Bristol Stool Scale [15]. The following classifications were used to inform the TrueLoo algorithms: separate, hard lump nut-like stool; soft blobs with distinct edges; sausage-like stool with surface cracks; lumpy, sausage-like stool; smooth, sausage-snake stool; fluffy, mushy stool with ragged edges; and watery liquid, no solid stool.

Most of the data captured by the TrueLoo are supplemental when benchmarked against the information recorded by facility staff through the logs. As seen in our analysis, although the elimination questions in the electronic records have the potential to capture the characteristics of stool and urine, they are not accurately completed by care staff, if at all.

Data Safety and Integrity

Protocols are included as a part of the TrueLoo implementation’s standard process to ensure that privacy is maintained at all times through the data collection process.

1. The TrueLoo imaging system faces down into the toilet bowl and is designed specifically to scan stool and urine; it does not capture any body parts.
2. User information is completely deidentified, from data capture to analysis.
3. The seat itself does not carry the name or location of the user.
4. All deidentified data are stored internally—none of the data that are viewed or used are associated with any sort of identifier—and are completely anonymized.

Secure servers and connections allow reports to only be shared with onsite care teams tasked with caring for the user. The reports can be shared with outside care partners (such as physicians) or families. Toi Labs’ team members review and validate reports to ensure compliance of privacy protocols and offer the best service and care to users.

Information is not identifiable on capture. Multiple protocols are in place throughout data capture to ensure that the data remain completely deidentified. No TrueLoo seat or its data are directly linked to a resident's name or room number. This information is secured internally and is only used when providing reports to care teams. Otherwise, all data that are captured and uploaded are deidentified and anonymized. Secure servers and connections allow reports to only be shared with onsite care teams tasked with caring for the user. Upon the authorization of the user or their responsible party, the reports can be shared with outside care partners or families as they see fit. The reports are not distributed to anyone outside of the circle of care of the user.

Participant Satisfaction and Acceptability

At the end of the study, a survey about user satisfaction was provided to all participants to evaluate acceptability and comfort with the use of the TrueLoo. This survey can be found in Multimedia Appendix 1.

Data Analyses

Python version 3.9 (Python Software Foundation) and R version 4.1.3 (R Foundation) were used to conduct all analyses. Descriptive statistics were calculated for age and sex. For the development of the initial algorithms, sensitivity, specificity, precision, recall, F_1-scores, and receiver operating characteristic (ROC) area-under-the-curve (AUC) were calculated to evaluate the classification performance of stool and urine events. Bootstrapping was used to calculate 95% confidence intervals for AUC.

For evaluation of the algorithm in real-world evidence (RWE) settings, sensitivity, specificity, precision, recall, F_1-scores, and ROC analyses were performed. Overall results were compared with the person-reported events as a percent to determine effectiveness to the standard of care.

Results

Data Characteristics

Throughout the period involved in the study's retrospective analysis, a total of 645 toileting sessions were recorded by the TrueLoo. Of the 645 total recorded events, 630 included urine and 153 included stool. There was overlap between the number of sessions containing both urine and stool. In this investigation, the average age of the participants was 84 (SD 9) years, with 52% (27/52) of the participants identifying as female. All of the individuals in the setting in question used the TrueLoo for the 3 days as planned. No participants declined the use of the TrueLoo.

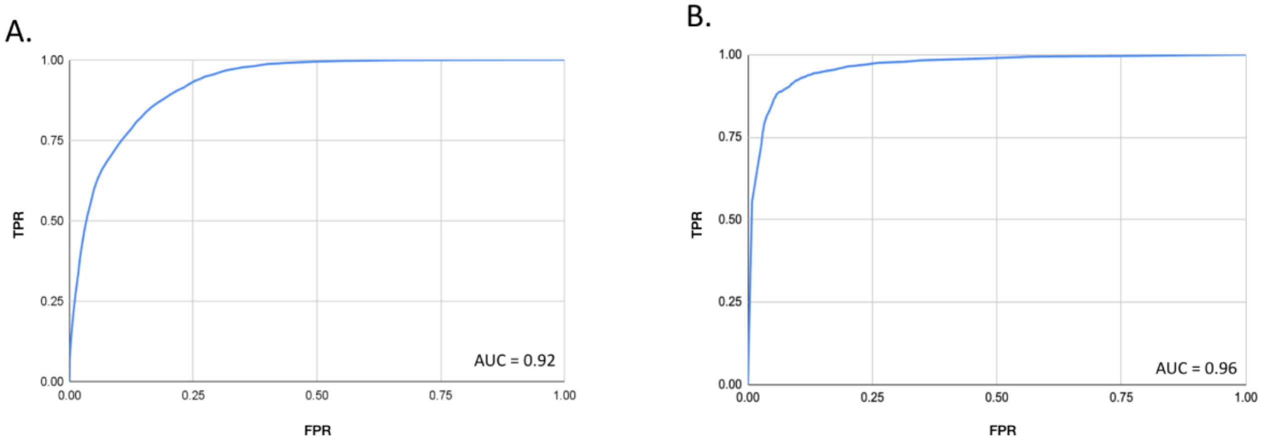
Development of the TrueLoo Algorithm for Identifying Urine and Stool Events

With regard to the development of the TrueLoo algorithm, classification performance statistics for all urine and stool events can be found in Table 1, and ROC curves can be found in Figure 3. For urine assessment, AUC was 0.92, with sensitivity and specificity of 96% and 85% observed, respectively. For stool, AUC was 0.96, with sensitivity and specificity of 90% and 79% observed, respectively.

Table 1. Classification performance of the TrueLoo algorithm for detecting urine and stool events.

Event	Precision	Recall	Sensitivity	Specificity	F_1-score
Urine	0.94	0.96	0.96	0.85	0.95
Stool	0.80	0.90	0.90	0.79	0.85

Figure 3. Receiver operating characteristic area-under-the-curve (AUC) analysis for the TrueLoo algorithm to identify (A) urine and (B) stool events. fpr: false positive rate; tpr: true positive rate.



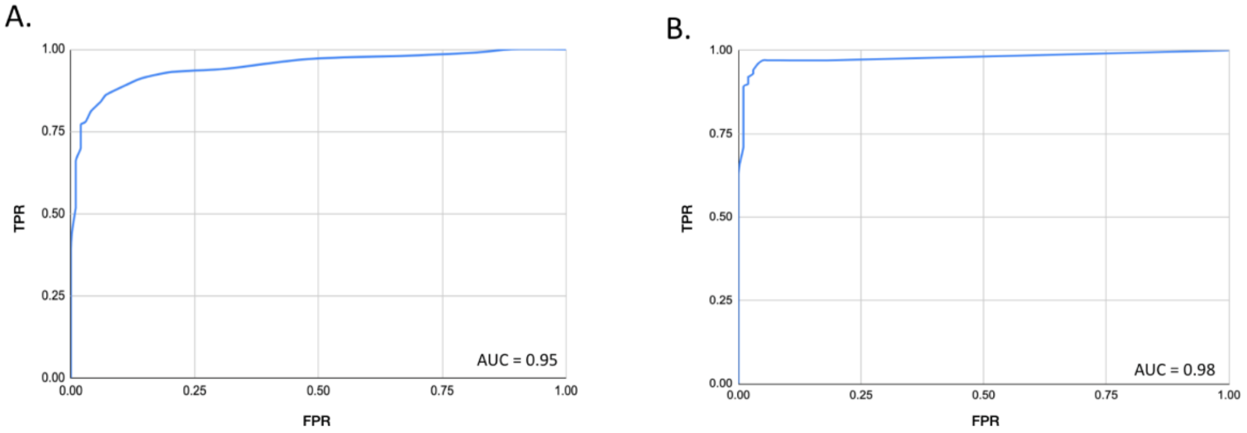
Toileting Sessions Compared With Standard of Care

With regard to the evaluation of the TrueLoo algorithm in RWE settings, classification performance statistics for all events can be found in Table 2, while ROC curves can be found in Figure 4. For urine assessment, AUC was 0.95, with sensitivity and specificity of 84% and 94% observed, respectively. For stool, AUC was 0.98, with sensitivity and specificity of 92% and 98% observed, respectively.

Table 2. Classification performance of TrueLoo for detecting urine and stool events in assisted living settings (real-world evidence analysis).

Event	Precision	Recall	Sensitivity	Specificity	F_1-score
Urine	0.97	0.84	0.84	0.94	0.90
Stool	0.91	0.92	0.92	0.98	0.91

Figure 4. Receiver operating characteristic area-under-the-curve (AUC) analysis for the TrueLoo algorithm in real-world evidence settings (ie, standard of care) to identify (A) urine and (B) stool events. fpr: false positive rate; tpr: true positive rate.



To compare the TrueLoo with the person-reported standard of care, we compared the number of reported instances in the skilled nursing facility with the number of events recorded by the TrueLoo. Over the course of the study, there were 46 person-reported instances of urine documented, compared with 630 by the TrueLoo. For stool events, there were 116 person-reported events compared with 153 events reported by the TrueLoo. This indicates that, when compared with the TL, person-reported events were captured 7% (46/630) of the time for urine and 76% (116/153) of the time for stool.

Survey Feedback on Acceptability and Ease of Use

A high degree of user satisfaction was found in the exit survey. Overall, 45% (32/71) of participants said the new toilet seat was better than their previous seat, while 46% (33/71) said it was the same. Importantly, 84% (60/71) of participants reported that using the TrueLoo was easy and required no effort; 99% (69/71) said they believed that the monitoring system had the potential to help aging adults.

With regard to the transmitting and interpretation of data, 99% (69/71) of participants reported that they would find alerts related to their health valuable and would also be willing to share this information with their doctor. When asked about sharing information with caregivers, 66% (46/71) reported that they would prefer the TrueLoo to send information and alerts to their caregiver, as opposed to the participant having to personally communicate those details.

Discussion

Principal Findings

The purpose of this retrospective study was to demonstrate the validity of the TrueLoo to (1) record and identify toileting sessions with regard to stool and urine events; (2) compare the results with the person-reported, standard-of-care methods; and (3) establish metrics of user acceptability and ease of use in a assisted living facility population. Our hypothesis that the TrueLoo would accurately identify urine and stool events, as well as capture more toileting sessions than were captured via the standard of care, was confirmed. We also confirmed our hypothesis that this method would be well accepted by residents.

Ability to Record and Identify Toileting Sessions

In this investigation, the TrueLoo algorithm demonstrated high sensitivity, specificity, and accuracy for detecting urine and stool events in real-world settings. Toileting issues such as urinary tract infections [9], constipation [10], diarrhea [11], and fecal incontinence [12] are highly prevalent among assisted living residents; however, if regular monitoring of toileting events are not accurate, it becomes difficult to identify and manage these conditions. Being able to manage these clinical events begins with the identification and monitoring of toileting; if it cannot be tracked, it cannot be measured and therefore cannot be improved.

Previous research investigating the use of smart toileting technology provides an initial look into the feasibility and proof of concept related to successfully executing this type of monitoring model [14-16]. However, these designs and models were limited as it pertains to real-world applicability. Early work used a colorimetric assay tracing red-green-blue values from images of urinalysis strips as well as upward facing cameras to collect “analprints” used as unique identifiers [14]. Based on the recommendation by Ge et al [18], “To enhance data quality, devices should be designed in ways that are physically or psychologically unobtrusive so as not to influence normal toileting behavior,” this initial model becomes problematic as the process can be intrusive and pose risks to data privacy.

Comparison of TrueLoo With Traditional Standard of Care

The standard of care (facility staff manual reporting) requires an individual to remember each event, manually track the event, and recall specific details about the event that would be relevant to a clinical issue. While this is theoretically feasible, it is unrealistic to expect these individuals to remember specific details and document each event without error throughout the course of a shift. Furthermore, expecting patients to remember and accurately report their own events is difficult due to recall bias and the natural discomfort of discussing one’s own toileting habits [19], especially if the events are different or unusual. This can be combined with the fact that, perhaps unsurprisingly, residents in seniors living facilities report that noninvasive methods of care are preferable to more invasive methods when it comes to the development of toileting programs [19,20]. This concept that there is a reluctance to openly discuss excreta [21,22] has hampered the development and acceptance of smart toilets; however, the use of smart toileting technology, such as the TL, creates a way to seamlessly integrate toileting analyses as part of routine monitoring, serving as a gateway to the digitalization of health care in the home [18].

Through this investigation, we found that facility staff underreport toileting events when compared with the TrueLoo. Given the active versus passive nature of the 2 methods, this is unremarkable, provided the limitations naturally inherent on the time and resources of human monitoring. Not only are facility staff dependent on their own timing for successfully monitoring a resident’s toileting habits, but they are also highly reliant on residents being honest about their own habits in the instances when they cannot be monitored or observed directly [13]. Furthermore, it appears that staff tend to log these data points in batches, often from memory. For example, most sites use a shift system where their staff are working from 6:00 to 14:00 hours, from 14:00 to 23:00 hours, and from 23:00 to 6:00 hours. Based on a single day of data provided by the site from their self-reporting logs (Multimedia Appendix 2), the majority of toileting events are reported toward the end of their respective shift. This is especially evident in the later evening shifts where the majority of reports from the 14:00-23:00 shift were reported from memory within a 2-hour time span. The level of cognitive load required with this method, in addition to their other responsibilities [7], is highly prone to error.

Many assisted living residents require more complex and advanced care compared with the general population, and evidence supports the fact that nursing home clinical outcomes are heavily reliant on geriatric approaches and care leadership. Proper care of these residents requires a multidimensional and specialized approach from facility staff [23,24]; however, recognition for this type of skill and the effort involved is frequently undervalued, thus leading to staff turnover and vacancies [25]. Furthermore, the high prevalence of toileting issues among nursing home residents indicates that there is demonstrable potential for improvement within this population. Such issues among residents are largely related to remediable factors, which can potentially be prevented or improved [7], and current nursing home practices do not adequately address these challenges. Providing a passive monitoring toileting solution that captures these types of data automatically, analyzes them, and transmits them back to the facility can reduce time and discomfort required for staff. This would allow an already underappreciated group [25] to focus on alternative needs in their respective facilities, removing burden and potentially increasing staff morale and attitude. The latter is, perhaps, most important because previous research from assisted living settings has shown that attitudes of care staff toward their organization, residents, and families have a significant effect on the quality of care provided to the residents [26].

Clinical Relevance in Real-World Settings

As discussed above, current standard-of-care methods are error prone and inconsistent. This inconsistency of monitoring potentially creates a larger issue for identifying critical conditions associated with greater costs and health care needs. Residents in assisted living facilities are at significant risk of developing issues such as urinary tract infections [9] and bowel problems such as constipation [10], diarrhea [11], and fecal incontinence [12], to name a few. These issues cannot be consistently identified without proper monitoring of toileting events. For example, when evaluating the prevalence of inpatient falls in a Michigan community hospital, 45.2% were related to toileting-based issues [27]. Importantly, 82.3% of patients who fell had completed a fall risk assessment before the incidents, indicating minimal relationship between fall assessment and actual falls. These results were further confirmed in a secondary data analysis conducted on 281,865 high-risk falls assessments collected in a multisite study where toileting issues were the third most powerful predictor of falls after “falls in the last 6 months” and “confusion” [28]. Furthermore, a retrospective analysis of falls related to nighttime toileting over a 1-year period found that 34% of falls were related to toileting-related issues [29]. Finally, a cross-sectional report evaluating the association between toileting and falls in older adults admitted to an emergency department discovered that the rate of recurrent falls was significantly higher in a toileting-related falls group than a non–toileting-related falls group [30]. As such, it is critical that toileting issues be addressed upstream to prevent larger, related issues from occurring. The use of the TrueLoo to accurately, consistently, and passively track toileting habits and related issues may provide the necessary feedback to ensure that residents receive the care and attention required to prevent falls from occurring, instead of requiring active response after the fall occurs.

Acceptability and Ease of Use

There are an ever-growing number of technological solutions offering potential benefits for older adults. However, despite the potential benefits, older adults regularly demonstrate lower adoption rates compared with their younger peers [31-33]. In the older adult population, perceived value, confidence in the ability to learn the technology, and the perceived impact on quality of life are reported to be some of the most robust predictors of willingness to adopt technology [34]. In this investigation, 84% (60/71) participants reported that using the TrueLoo was easy and required no effort (ability to learn) and 99% (69/71) said they believed that the monitoring system had the potential to help aging adults (perceived impact). Additionally, 99% (69/71) of participants reported that they would find alerts related to their health valuable and would also be willing to share this information with their doctor, and 66% (46/71) reported that they would prefer the TrueLoo to send information and alerts to their caregiver, as opposed to the participant having to personally communicate those details (quality-of-life improvements). These data points triangulate to the TrueLoo being not only efficacious but also successfully adopted as a passive monitoring intervention in this age group.

Strengths and Limitations

The strengths of this study include the process of initially developing the algorithm for identifying stool and urine events against a gold-standard labeled data set and then retrospectively analyzing it in an RWE setting. This methodology allowed for the ability to generate real-world insights into how the TrueLoo could most effectively be used in assisted living facilities. Additionally, the ability to get direct feedback from the end users provides subjective validation, in addition to the efficacy of the TrueLoo to evaluate sessions. There is often a disconnect between clinical efficacy and practical use, which prevents new technology from being properly implemented. While RWE designs are powerful for real-world practicality, there are associated limitations. In this study, there was a lack of ability to control certain parameters (monitoring and reporting habits of facility staff) and collect certain data points (detailed health reports) on the participants. Ameliorating these limitations would change facility workflows, therefore affecting the validity of real-world efficacy. As such, we accept these limitations but recommend that this study be followed up with additional controlled investigations into the clinical efficacy of the TrueLoo. Such controlled investigations would also allow for the evaluation of other indications such as loose or bloody stool or cloudy urine. Given the clinical applicability of these indications, they are a recommended next step for future research.

Conclusions

In this retrospective validation and acceptance study, we demonstrated the validity of the TrueLoo to record toileting sessions compared with the standard-of-care methods, while categorizing them into clinically relevant events. Additionally, the TrueLoo successfully established metrics of user acceptability and ease of use in assisted living populations. While additional validation studies are warranted, the data presented in this paper support the use of the TrueLoo in assisted living settings as a model of session monitoring during toileting.

Acknowledgments

We would like to acknowledge all of the staff and participants at the locations evaluated in this investigation. We are grateful to them for their participation and helpfulness through this process.

Conflicts of Interest

At the time of the publication, VK, PS, THL, and GK were employees at Toi Labs, receiving salary, stock options, and benefits. PC worked in a consultancy role and received stock options. JG has no conflicts of interest to report at the time of this publication.

Abstract

Background: Persons living with dementia experience autonomy loss and require caregiver support on a daily basis. Dementia involves a gradual decline in communication skills, leading to fewer interactions and isolation for both people living with dementia and their caregivers, negatively impacting the quality of life for both members of the dyad. The resulting stress and burden on caregivers make them particularly susceptible to burnout.

Objective: This study aims to examine the efficacy of Communication Proches Aidants (COMPAs), an app designed following the principles of person-centered and emotional communication, which is intended to improve well-being in persons living with dementia and caregivers and reduce caregiver burden.

Methods: In this implementation study, volunteer caregivers in 2 long-term care facilities (n=17) were trained in using COMPAs and strategies to improve communication with persons living with dementia. Qualitative and quantitative analyses, semistructured interviews, and questionnaires were completed before and after 8 weeks of intervention with COMPAs.

Results: Semistructured interviews revealed that all caregivers perceived a positive impact following COMPAs interventions, namely, improved quality of communication and quality of life among persons living with dementia and caregivers. Improved quality of life was also supported by a statistically significant reduction in the General Health Questionnaire-12 scores (caregivers who improved: 9/17, 53%; z=2.537; P=.01). COMPAs interventions were also associated with a statistically significant increased feeling of personal accomplishment (caregivers improved: 11/17, 65%; t_{15}=2.430; P=.03; d=0.61 [medium effect size]).

Conclusions: COMPAs intervention improved well-being in persons living with dementia and their caregivers by developing person-centered communication within the dyad, increasing empathy, and reducing burden in caregivers although most caregivers were unfamiliar with technology. The results hold promise for COMPAs interventions in long-term care settings. Larger group-controlled studies with different populations, in different contexts, and at different stages of dementia will provide a clearer picture of the benefits of COMPAs interventions.

Introduction

Background

Dementia is a progressive or chronic syndrome, affecting memory, reasoning, orientation, understanding, calculation, learning ability, language, and judgment; it represents a greater impairment of cognitive function than might be expected, while being the main cause of disability and dependence among older people [1]. Dementia is the consequence of diverse diseases, the most common being Alzheimer disease [1].

According to the World Health Organization, 55 million individuals worldwide live with dementia, making it one of the main causes of disability and social deprivation among older adults [2]. These figures are set to rise over the next few years, with an estimated 78 million people expected to be living with dementia by 2030. The report states that support for the care of people living with dementia and help for caregivers need to be stepped up urgently. As dementia progresses, it has an impact on the autonomy of the person affected. At the advanced stage, persons living with dementia can no longer live at home because they are no longer able to carry out everyday tasks (eg, dressing, eating, and washing), and this is often difficult to manage for those around them.

Person-Centered Communication and Dementia

Dementia is characterized by a progressive deterioration of cognitive functions and particularly affects language [3]. As the disease progresses, persons living with dementia will experience increasing communication deficits that impact all aspects of life. Frequent communication breakdowns lead to feelings of frustration that can trigger reactive behaviors known as behavioral and psychological symptoms of dementia (BPSD) [4]. Communication breakdowns complexify care, increase caregiver burden, and decrease the quality of life (QoL) for persons living with dementia and caregivers [5,6]. In the later stages of dementia, sustaining a simple communicative exchange (eg, greetings or short conversation between the caregiver and the person living with dementia) is practically impossible. Because they are unable to express their needs or understand others, persons living with dementia often express frustration [7] and generally require more attention than other older adults, which also contributes to increasing the burden on caregivers and decreasing QoL [8,9].

The literature shows that communication is a key component of quality care [10-13] and a core component of person-centered care, promoting positive social interactions around topics of the life story of persons living with dementia [5]. Person-centered care, considered state of the art in dementia care [14], recognizes the individual as a person and aims to respond to the individual’s feelings, preferences, and needs [15,16]. Furthermore, person-centered care precludes perceiving the person living with dementia exclusively as a person with illness, and such perception contributes to cognitive decline, adds to communication difficulties, and contributes to depersonalization [13]. A person-centered nondirective approach considers the person’s lifestyle, culture, and history, including their likes and dislikes, preferences, and interests, while always considering the person’s point of view [5].

In sum, communication breakdowns contribute to depersonalization and weakening of person-centered care [17], requiring continuous adaptation from the caregiver. In contrast, person-centered care develops leadership in caregivers, prompting management changes toward a more personalized philosophy of care.

Impact of Communication on Care

Communication deficits in the context of dementia have negative impacts on several aspects of the caregiver and resident relation within a long-term care (LTC) setting. More specifically, the progressive nature of the illness entails frequent communication breakdowns, which generate frustration in both the caregiver and the person living with dementia (referred to as the dyad) [5,6]. Indeed, most persons living with dementia show signs of frustration when they cannot understand a conversation or make themselves understood [7,18]. Frustration increases emotional tension, which in turn contributes to the caregiver’s burden [9]. Poor-quality interactions also increase the risk of agitation and apathy in persons living with dementia [8]. While the quality of communication within the dyad is known to modulate caregiver burden [9], it also affects person-centered care, both of which are essential to QoL [19,20]. Greater burden and a higher prevalence of anxiety disorders are observed in caregivers working with persons living with dementia [21,22]. Burden is described along 2 dimensions: objective burden, which refers to the degree of dependence of the person living with dementia and the presence of BPSD, and subjective burden, which is associated with the physical, social, and emotional dimensions of caring, as well as the resources available to the caregiver [23]. A systematic review by Queluz et al [24] grouped professional caregiver needs into 3 main themes: emotional health, formal or informal help received from third parties, and need for information about dementia and associated care.

Several variables related to the physical and social environment in which communication occurs can create living conditions that promote or hamper QoL in caregivers and persons living with dementia [20]. These include the quality of caregivers’ engagement in care (ie, a positive attitude), enjoyable communication as reflected by personalized exchanges [25], and social activities [26]. In addition, the progression in communication deficits often results in avoidance of communication within the dyad, a factor that contributes to accelerating cognitive decline and triggering BPSD, which are particularly disruptive in LTC settings [27]; it also impacts caregivers’ QoL [28]. A review by Scott-Cawiezell et al [29] on 995 staff members has shown that improvements are required to achieve open, accurate, and timely communication in nursing homes. More specifically, according to McCormack et al [30], while some staff members know of residents’ preferences, this information is not routinely communicated to all staff members in a facility. By sharing information about communication topics and strategies facilitating person-centered communication with each resident, caregivers may become more efficient in providing care and less exposed to communication breakdowns and the resulting increase in their burden. Moreover, according to Kolanowski et al [31], available communication systems do not consider the time and resource constraints of nursing homes.

There is a strong consensus on the need to empower caregivers and give them strategies so that they can optimize communication with persons living with dementia [28]. Particularly in the context of LTC residences, the evidence shows that adopting a person-centered care approach significantly influences quality of care and the QoL of both caregivers and persons living with dementia, by improving care compliance and reducing caregivers' burden [26,28]. Moreover, the literature shows that personalized, emotionally relevant contents facilitate person-centered care, preserve personhood, and prevent dehumanization and isolation of persons living with dementia [5]. Sharing complete information with the persons living with dementia and their families, ensuring participation of persons living with dementia and their families in decision-making, and securing the collaboration of persons living with dementia in policy and program development are among the key elements of person-centered care [32]. Thus, while communicating with persons living with dementia in the provision of care, it is important to consider the unique life history, feelings, cultural background, values, and preferences of each person. This consideration is a challenge for a caregiver in an LTC setting who meets a person living with dementia in the advanced stages when they are unable to tell their life story. Communication tools that consider this important aspect of person-centered care while fitting into the reality of LTC settings (including tight schedules, resources, and constraints, together with administrative investment in nursing leadership) are therefore required to achieve beneficial changes.

Sustaining person-centered care and communication between persons living with dementia and their caregivers, especially in LTC settings, requires adapted communication tools. It was with this purpose that our team designed Communication Proches Aidants (COMPAs; it also refers to the compass, the instrument that orients sailors in troubled seas).

COMPAs was designed to support person-centered communication between persons with severe communication impairments and their caregivers, professional or informal. It is based on the concept of person-centered communication, as reflected by its personalized audiovisual content in line with the life trajectory, preferences, interests, and culture of the persons living with dementia. Through coviewing, it engages the person living with dementia and the caregiver in a form of dialogue beyond words as they share verbal and nonverbal expressions of joy and well-being. Unlike the purely transactional communication that is characteristic of basic care [17], COMPAs puts the person living with dementia at the center of communication, thereby providing a unique framework for person-centered care in the context of dementia.

In sum, the person-centered care approach acknowledges the person living with dementia as their own person. Communication is an essential tool in the implementation of this approach and the maintenance of personhood [33]. Persons living with dementia have trouble expressing their needs, which often leads to the perception that they have no awareness, and their interactions lack mutuality [33]. However, persons living with dementia need meaningful interactions [34], and caregivers need adequate communication tools to meet the care and social needs of persons living with dementia. Unfortunately, caregivers lack sufficient communication training and adapted tools to support social communication in order to overcome the communication deficits of persons living with dementia. Furthermore, LTC settings are environments where there are multiple, often changing, caregivers who revolve around the persons living with dementia. Technology could play a crucial role in care for persons living with dementia. According to Koo and Vizer [35], technology facilitates daily activities, maintains social interactions, supports autobiographical memory, and promotes leisure activities, all while allowing storing and monitoring the clinical status of individuals. Overall, technology could improve the QoL of persons living with dementia, reducing the BPSD and burden on caregivers [35].

Technology and Communication

Overview

Although the evidence shows that technology is relevant for promoting social interactions [35-37], there is a need for rigorous studies on the use of digital tablets in the context of persons living with dementia and their caregivers. Specifically, a scoping review on this topic points to the benefits of technology for intergenerational communication [38], in particular, by means of suggested conversation topics related to the life trajectory of the person living with dementia, which generate positive emotions; however, the review acknowledged that little attention is paid to higher-level needs, such as self-esteem and preserving personhood [35]. Regarding the use of tablets, evidence shows that persons living with dementia may enjoy using tablets at all stages of dementia [38,39]. Hung et al [40] has pointed out the utility of tablets in the context of one-on-one, small-group, and large-group activities, thereby facilitating relationship building and resident engagement and helping caregivers gain better knowledge of the interests and abilities of the persons living with dementia. Furthermore, a recent review [37] has identified a series of apps that could potentially prevent and overcome communication barriers. However, none of these apps were designed to promote person-centered communication or were tested in an LTC setting. Finally, a recent scoping review [35] on the use of technology in LTC has shown some positive impacts on behavior engagement and mood in LTC residents. Importantly, the authors highlight that this finding is not specific to persons living with dementia, who are generally excluded from such studies, while pointing out the importance of examining the impact of technology use specifically in this population [35].

In sum, technology offers some promise for supporting communication in persons with dementia. However, there is limited empirical research on the use of technology to support communication between caregivers and residents in LTC residences [35,41], and only 1 study examined the caregivers' perspectives on the ability of mobile apps to support caregiver-resident communication [36]. The consensus in the literature is that more research on the use of communication apps involving persons living with dementia in LTC settings is imperative [35]. Moreover, there is a need for evidence-based apps specifically designed to promote person-centered communication in cases of advanced dementia when the possibilities of verbal communication are very limited.

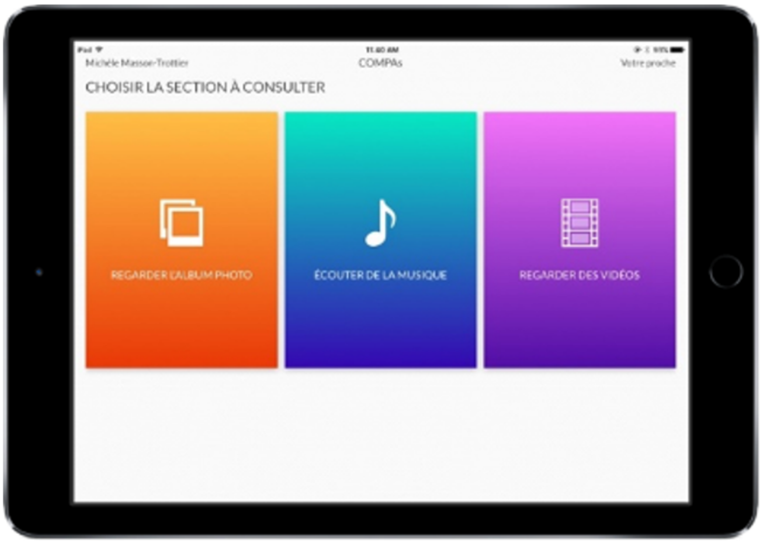
COMPAs App

COMPAs is an evidence-based app available on digital tablets to facilitate portability and participation of persons living with dementia. It is designed to support person-centered care between persons living with dementia and their caregivers. This app integrates knowledge from proven therapies [6,15,42-46] and has the advantage of combining these concepts in a single medium [47]. COMPAs is a secure platform that collects photos, music, and videos that have marked the life of the persons living with dementia. It was designed by speech language pathologists (SLPs) and media experts and offers an intuitive environment to promote positive communicative moments; its content is fully customizable to reflect the relevant life events of each person living with dementia and is constantly adaptable as the person's dementia evolves.

With COMPAs, caregivers gain secure access to personalized libraries of audiovisual materials that are selected according to residents' personal preferences, cultural background, and life history. Specifically, photographs, music, and videos can be uploaded to a secure space through the tablet or the COMPAs website, allowing families to remotely add content to enrich their loved one's COMPAs space. Apart from the content provided by the family, the COMPAs artificial intelligence module provides access to personalized internet content related to the person's life history (eg, places where the person lived, favorite sports, animals, and hobbies). Caregivers can also add music pieces (from music libraries available on the tablet or through a Spotify account) as well as excerpts from movies or shows available on YouTube, while family caregivers can safely add personal videos. A "like" allows users to highlight particularly meaningful content. Before closing COMPAs each time, the caregiver is given a short multiple-choice questionnaire, which gathers a more personal perspective on the COMPAs session, while providing a means to follow up its effects and share relevant information on session outcomes with the members of the team. Coviewing sessions with COMPAs have been shown to facilitate person-centered care, the gold standard in dementia care. Studies conducted during the COVID-19 pandemic showed that COMPAs sessions triggered emotional communication, characterized by shared verbal and nonverbal exchanges related to positive emotions, while increasing social engagement between persons living with dementia and caregivers [47]. Finally, by adding likes to specific music, videos, or photographs in the residents' personalized space and writing comments, caregivers can share information with the team about the best communication strategies and topics to sustain person-centered communication.

The application was initially developed in French; however, because it uses little written language and is very intuitive, neither language impairments nor language barriers prevent its use by speakers of other languages (see Figure 1 showing the app's interface).

Figure 1. Communication Proches Aidants (COMPAs) interface.



The rationale behind COMPAs lies in the person-centered care approach and emotional communication. Its personalized, meaningful content reduces the impact of communication deficits by encouraging nonverbal and emotional communication. Regulation of positive emotions has been shown to optimize care in the context of dementia, while favoring trust and promoting well-being for the person living with dementia [48] and the caregiver [49].

Pilot work by our team has shown that COMPAs allows caregivers and LTC residents to enjoy moments of person-centered interaction, breaking the vicious circle of noncommunication, thereby reducing both residents' isolation and caregivers' burden. COMPAs's theoretical background and our pilot findings offer some promise regarding the app's potential to support person-centered communication between persons living in LTC residences and their caregivers.

Purpose of the Study

In light of these pilot findings and considering the need for evidence-based technology tools to support person-centered communication between persons living with dementia and their caregivers in LTC settings [35,41], the purpose of this study was to test the use of COMPAs in LTC settings. Specifically, we implemented COMPAs in the context of LTC daily routines and measured its effects on the communication between residents and caregivers, caregivers' burden, and the QoL of persons living with dementia and caregivers.

In line with the literature, and considering the rationale underlying COMPAs, it was expected that interventions with COMPAs would achieve the following:

1. Improve the quality of communication between the person living with dementia and the caregiver, as measured through improvements in questionnaire scores and semistructured interviews.
2. Enhance the QoL of the persons living with dementia, as measured through improvements in questionnaire scores and semistructured interviews.
3. Reduce the burden on caregivers, as measured through improvements in questionnaire scores and semistructured interviews.

In addition, we anticipated that COMPAs would be adapted to the LTC environment. This had been assessed through participant adherence and satisfaction with the use of COMPAs in this study.

Methods

Study Design

This study used a pretest-posttest experimental design, with a COMPAs intervention administered over 8 weeks. The total duration of the study, including recruitment and assessments, was 14 weeks. The timeline depicted in Figure 2 shows the various stages of the COMPAs study.

Figure 2. Study timeline.

Participant Selection Process, Inclusion, and Exclusion Criteria

Caregivers

In total, 17 caregivers were recruited. The inclusion criteria were being a caregiver at the Paul-Bruchési LTC Center in Montreal, Québec, Canada, or Saint-Victor LTC center in Amiens, France, and caring for a person living with dementia who presented communication impairments as described in their chart or perceived by the caregiver. There were no exclusion criteria for caregivers. However, 1 participant from the Saint-Victor center was subsequently excluded from the study analyses, as only quantitative data were available for this participant; consequently, 16 caregivers completed the study. Most of the caregivers included in this study were women (14/17, 82%). Caregivers were between the ages of 24 and 57 years and had between 1 and 29 years of work experience in the health sector. Before this study, none of the caregivers had used a digital tablet, and only some used a smartphone (4/17, 22%) at work, although they were all familiar with these technologies since more than half of them used a digital tablet (10/17, 59%) or a smartphone (15/17, 88%) at home. Of the 22 caregivers who attended the information session and were not included in the study, 3 (14%) were not able to participate because they were transferred to another workplace, 1 (4%) refused to participate for personal reasons, and 1 (4%) left on parental leave.

Residents

The inclusion criteria were having an assigned caregiver enrolled in the project and experiencing communication difficulties, as identified by a caregiver, in the context of a diagnosis of major neurocognitive impairment, whether isolated or in combination with hearing and visual loss, or other conditions that can challenge communication, including a linguistic barrier. To make the samples as representative of the LTC population as possible, there were no exclusion criteria for persons living with dementia. A total of 17 residents participated in the study; they were aged between 61 and 96 years. Most of the residents (11/17, 65%) had a diagnosis of dementia (mixed dementia: n=6, 35%; Alzheimer disease: n=3, 18%; vascular dementia: n=1, 6%; severe dementia: n=1, 6%; and Lewy body disease: n=1, 6%). Other diagnoses were hippocampal atrophy (n=1, 6%), generalized anxiety (n=1, 6%), and cancer (n=1, 6%). Most of the residents (n=12, 71%) included in this study were women and still had some ability to express themselves verbally in isolated words or short utterances, with fluctuating comprehension of short sentences (n=15, 88%), including due to hearing limitations (n=6, 36%).

Recruitment Process

The recruitment process for caregivers was on a voluntary basis. Specifically, the project was presented by the research assistant (RA) and the laboratory director (Ana Inés Ansaldo) during a staff meeting. The purpose of the presentation was to stimulate interest in the study and to introduce COMPAs to the staff members. Staff members were asked to contact the head of the LTC unit to express their interest in participating in the study. Each caregiver identified a resident with whom they wanted to improve communication. The research team then asked the residents if they were interested in participating.

Ethical Considerations

Ethics approval was obtained from the Centre de recherche de l'Institut universitaire de gériatrie de Montréal (CRIUGM) Ethics

Committee (approval number CER-18-19-14), and informed written consent was obtained from the residents or their representatives in cases of incapacity. Caregivers were invited to sign consent forms with the RA after they had expressed interest to participate in the study.

Pre-Experimental Phase

Information Session

The first week of the study was dedicated to describing the project's purpose, the procedures, the measurement tools, and COMPAs's characteristics and use.

Training Sessions on COMPAs Use

Caregivers received two 30-minute training sessions on COMPAs during the daily planned team meetings. Facilitated by an SLP or a trained RA, the training session focused on COMPAs's rationale and principles and a demonstration of its use by the trainer. There was a hands-on practice session at the end of the training.

Pre-Experimental Measures

The measures administered to caregivers included questionnaires investigating QoL (General Health Questionnaire-12 [GHQ-12] items) [50] and the burden at work (Maslach Burnout Inventory [MBI]) [51]. The RA also administered measures related to residents, including an overview of residents' communication deficits (*Grille d'évaluation des difficultés de communication dans la démence* [GCOM]) [52] and a QoL questionnaire (*Qualité de vie dans la démence de type Alzheimer* [QDV-DTA]) [53]. Information on the residents' and caregivers' age, sex, and other sociodemographic data was also collected, as was information on residents' neurocognitive disorders from their medical charts.

The GHQ-12 was used to acquire data on the caregivers' general QoL. It includes 12 questions, scored on a 4-point Likert scale where 1=not at all, 2=not more than usual, 3=a little less than usual, and 4=a lot more than usual. In the standard scoring system, scores of 1 or 2 are given 0 point, and scores of 3 or 4 are given 1 point. The overall score is the sum of 0 and 1 points. If the sum is higher than 2, it is considered problematic.

The MBI measures caregiver burden at work. It comprises (1) an emotional exhaustion score (9 questions; scores of <17, 18-29, and >30 denote low, moderate, and high emotional exhaustion levels, respectively); (2) a depersonalization score (5 questions; scores of <5, 6-11, and >12 denote low, moderate, and high empathy loss, respectively); and (3) a personal achievement score (8 questions; scores >40, 34-39, and <33 denote low, moderate, and high achievement levels, respectively). Caregivers were asked to rate their own scores on this test.

The GCOM measures the severity of communication difficulties. The caregiver is asked to score communication behaviors for each resident (eg, "The person has word-finding difficulties") on a Likert scale ranging from 1 (always) to 4 (never); it is also possible to select "does not speak enough for me to judge." All scores are added up to give a final communication score. The QDV-DTA measures residents' QoL. It consists of 13 questions, with higher scores indicating better QoL.

Setting Up Personalized COMPAs Libraries

Before the intervention, the RA completed a personal history with the residents' representatives. The caregivers, along with an SLP or a trained RA, created a personalized communication space for each resident by adding significant personal content such as personal photos, images, videos, and music selected based on their life history questionnaire and the information provided by the residents' representatives.

Experimental Phase

Caregivers used COMPAs for 8 weeks in the context of their daily LTC routine (eg, family visits; recreation time; birthday celebrations; and situations triggering reactive behaviors, such as personal care or specific interventions). COMPAs sessions could be very short (2-5 minutes) or longer (up to 20 minutes). They consisted of coviewing sessions (ie, resident and caregiver) during which personalized material in the resident's library was presented by the caregiver, with the purpose of eliciting positive emotions and triggering verbal and nonverbal exchanges within the dyad, according to the principles learned during the training sessions.

Caregivers were instructed to ensure that residents always used their hearing and visual aids during COMPAs sessions. Furthermore, following caregivers' comments, we made adaptations such as using personal hearing amplifiers or Bluetooth speakers to improve listening to the music. In addition, since COMPAs is a person-centered approach, we encouraged caregivers to focus on the person's strengths and therefore used more photos and videos with people with hearing loss and more music and audio clips with those with visual loss.

Caregivers could modify the number and duration of COMPAs sessions according to what was possible for them (eg, workload and residents' status), as long as they respected a minimum of 15 minutes a day, at a time they considered appropriate. During the first 2 weeks of the intervention, with the purpose of facilitating COMPAs use, the SLP and the trained RA provided direct support to the caregivers on the telephone, by email, or during visits to the LTC facility. All caregiver shifts were covered so that everyone had the chance to ask questions. Indirect support (by telephone and email) was available throughout the 8-week duration of the intervention.

Postexperimental Phase and Measures

Following the 8 weeks of COMPAs intervention, the same measures administered before the experiment were administered by the RA to the caregivers and residents. Semistructured interviews with the participating caregivers were also completed: individual, semistructured 20- to 40-minute interviews were conducted with the caregivers in person, and on the Zoom (Zoom Video Communications Inc) platform. Only the interviewer and the caregiver were present at the meeting. The questions came from an interview guide developed by the last author (CD), based on interview guides from previous studies [54,55]. The interview consisted of open-ended questions and began with a very general question ("Could you please talk about your experience with COMPAs in the last few weeks?"). Uncertainties arising from participants' answers were elucidated with follow-up questions. At the end, the interviewer also asked the caregiver if they wished to provide any additional information. Overall, 17 interviews were conducted with the 17 participants.

Data Analysis Plan

Quantitative Analyses

Data analyses include quantitative and qualitative approaches. Primary outcome measures are scores on the GHQ-12 [50] and the BMI [51] with caregivers and scores on the GCOM [52] and QDV-DTA [53] with persons living with dementia. The 4 outcome measures were used as dependent variables, and the 2 measurement points before and after the COMPAs intervention were considered as independent variables. The results were entered in paired sample 2-tailed *t* tests with an α of .05 to define significance. The paired-sample *t* test allows to control for individual variables that potentially affect outcome measures. Furthermore, paired-sample *t* tests are suitable to analyze data from small samples, as in this study. When the assumptions of the paired-sample *t* test were not fulfilled (ie, difference scores were not normally distributed and within-participant variability was not consistent), a nonparametric alternative, the Wilcoxon signed-rank test, was used. For all measures, outliers were detected by inspection; criteria to exclude data from analyses were set at values >1.5 box lengths from the edge of the box plot.

Qualitative Analyses

The qualitative measures involved a qualitative content analysis approach [56], as described by Intissar and Rabeb [57] and Vallée et al [58]. To analyze data from semistructured interviews with caregivers, MAXQDA software (VERBI GmbH), a qualitative analysis program for discourse content analyses was used [59]. The interviews were audio recorded and manually transcribed verbatim by BD and JD, and the interjudge validity was assessed, followed by thematic coding. The corpus of the interviews was read multiple times separately by 2 authors to achieve a full understanding of the data. Transcripts were coded individually by 2 authors (CD and JD), and multiple meetings took place to reach intercoder reliability. Each author separately generated codes, following which they met to discuss them and reached consensus on the coding tree, which was further discussed with the last author (CD) of this manuscript. Quotations presented in this paper were translated from French into English. Caregivers were assigned numbers from P1 to P17.

Results

Quantitative Findings

Caregivers

Outlier values were detected in the difference scores for the GHQ-12, the MBI-depersonalization score and the MBI-personal achievement score. All data points >1.5 box lengths, each associated with a different participant, were removed from this specific analysis. The differences between the MBI-emotional exhaustion score, MBI-depersonalization score, and MBI-personal achievement score scores were normally distributed (*P*=.39, *P*=.29, and *P*=.74, respectively). Thus, paired-sample *t* tests were used to analyze these differences. The results are presented in Table 1. In contrast, the GHQ-12 scores were not normally distributed (*P*=.02), and therefore, a Wilcoxon signed-rank test was used to analyze these differences. The results are presented in Table 2. Data are presented as mean (SD), unless otherwise stated.

To determine whether the use of COMPAs by caregivers in LTC settings influenced their scores on the GHQ-12 questionnaire, the Wilcoxon signed-rank test was used to measure QoL scores. The difference scores were approximately symmetrically distributed, as assessed by a histogram with a superimposed normal curve. Of the 17 caregivers who participated in this study, 9 (53%) showed a decrease in score difference, 7 (41%) showed a tied score, and 1 (6%) showed an increase in score difference. There was a statistically significant change (mean –0.88, SD 1.26; median –0.5, IQR 2.50) between GHQ-12 scores at T3 (mean 1.50, SD 1.67; median 1, IQR 3.0) and at T14 (mean 0.63, SD 1.09; median 0, IQR 1.5; $z=2.54$; $P=.01$). At T14, 1 (6%) caregiver's score had worsened, 9 (53%) had improved, and 7 (41%) remained the same.

A 2-tailed paired-sample *t* test was used to determine whether COMPAs influenced caregivers' scores on the MBI-emotional exhaustion scale, MBI-depersonalization scale, and MBI-personal achievement scale. No significant change from T3 (mean 19.29, SD 13.20) to T14 (mean 18.00, SD 12.67; $t_{16}=–0.62$; $P=.55$) was found on the MBI-emotional exhaustion scale. Specifically, at T3, 10 (59%) caregivers scored a low level of emotional exhaustion, 4 (24%) scored a moderate level, and 3 (18%) scored an elevated level. At T14, 10 (59%) caregivers were at a low level, 4 (24%) at a moderate level, and 3 (18%) at an elevated level; scores had worsened for 7 (41%) caregivers, improved for 9 (53%), and remained the same for 1 (6%).

There was also no significant change on the MBI-depersonalization scale (T3: mean 7.75, SD 4.84; T14: mean 6.88, SD 5.06; $t_{15}=–1.01$; $P=.33$). At T3, 5 (29%) caregivers had a low level of empathy loss, 9 (53%) had a moderate level, and 3 (18%) had a high level. At T14, 8 (47%) caregivers scored a low level of empathy loss, 5 (29%) scored a moderate level, and 4 (24%) scored a high level; 9 (53%) caregivers had improved, 5 (29%) had worsened, and 3 (18%) remained at the same level.

Regarding personal achievement, according to the MBI-personal achievement scale, there was a significant change following COMPAs use (T3: mean 37.24, SD 10.21; T14: mean 38.71, SD 9.2; $t_{15}=2.43$; $P=.03$; $d=0.61$ for a medium effect size). Specifically, at T3, a total of 9 (53%) caregivers scored a high level of personal achievement, 4 (24%) scored a moderate level, and 4 (24%) scored a low level. At T14, 9 (53%) caregivers scored a high level of personal achievement, 4 (24%) scored a moderate level, and 4 (24%) scored a low level; 5 (29%) caregivers had worsened, 11 (65%) had improved, and 1 (6%) remained the same.

Residents

A paired-sample *t* test was used to determine whether there was a statistically significant mean difference between residents' overall scores on the QDV-DTA and the GCOM before and after the use of COMPAs by caregivers in the LTC setting. There were no outliers in the data or in the QDV-DTA differences or in the GCOM differences, as assessed by the inspection of a box plot for values >1.5 box lengths from the edge of the box.

The assumption of normality was not violated, as assessed by the Shapiro-Wilk test for the QDV-DTA or the GCOM (*P*=.78 and *P*=.78, respectively). The results did not reveal any significant change in the overall score on the QDV-DTA (QDV-DTA: preintervention mean 33.42, SD 3.92; postintervention mean 34.58, SD 5.42; t_{11}=0.84; *P*=.42) or the GCOM (GCOM: preintervention mean 16.42, SD 10.08; postintervention mean 20.67, SD 12.92; t_{11}=1.89; *P*=.09). However, 2-tailed *t* tests revealed a significant worsening for the following questions in the GCOM: "They tend to repeat something that someone just said" (*P*=.03); "They use filler words ('thing,' 'whatchamacallit') instead of precise words ('pencil,' 'balloon')" (*P*=.04).

Although the QoL questionnaire and the GCOM did not show a significant change, the semistructured interviews with all caregivers (n=17) revealed that they felt COMPAs had a positive impact on the lives of persons living with dementia (please refer to the *Qualitative Findings* section). Some caregivers described these positive impacts as positive emotions during nonverbal communication revealed by a positive facial expression in the person living with dementia or the simple fact that the person living with dementia started dancing while using COMPAs.

Qualitative Findings

The qualitative analyses of semistructured interviews with the caregivers regarding the effects of COMPAs use with persons living with dementia in the LTC setting highlighted 3 main themes: capacity of COMPAs to elicit positive emotions, decrease in caregiver burden, and versatility of COMPAs.

Eliciting Positive Emotions

The interviews highlighted COMPAs's capacity to elicit positive emotions in persons living with dementia and caregivers. This increase in positive emotions led to an increase in feelings of joy, pleasure, and happiness.

Persons With Dementia

Caregivers (16/16, 100%) reported on COMPAs's capacity to elicit positive emotions in persons living with dementia, who had expressed well-being and the pleasure they got from their COMPAs session both verbally and nonverbally via changes in their facial expression (eg, smiles and eye contact):

> *This nonverbal person's face would light up.* [P6]

Almost all caregivers discussed the positive effects of personalized content on persons living with dementia: how pictures or music from their past can evoke positive memories (15/17, 88%) and positive emotions (16/17, 94%). Persons living with dementia enjoyed reminiscing and sharing former moments of their life with their caregivers:

> *COMPAs calms them, and does them good too, because it reminds them of memories, good memories, there are pictures of their kids, their pet, their house.* [P14]
>
> *I would say cheerfulness. They were happy to see the pictures, listen to their favorite music.* [P17]

Caregivers

Caregivers (14/17, 82%) reported that using COMPAs gave them joy, pleasure, and overall positive effects on their daily lives. They said that they looked forward to using COMPAs with their patients and appreciated these moments in their week:

> *To me, it is my moment of pleasure, when I am working.* [P5]
>
> *It was good for them but for me too because I felt their well-being.* [P17]

Some of the caregivers (14/17, 82%) said that simply seeing the enjoyment of the persons living with dementia gave them pleasure too:

> *Yes, I would see that it brought them joy, so it brought me pleasure too.* [P14]

Caregivers also reported on how they appreciated the effects of the app on the persons living with dementia. They valued COMPAs's capacity to contribute to the well-being of persons living with dementia:

> *It's great, because we give the resident the chance not to feel lost, and without this tool, you can't really do it.* [P10]

Decrease in Caregiver Burden

The analysis highlighted how COMPAs gave caregivers a solution to deal with their everyday struggles, helped them feel empowered, and resulted in better bonds with the residents.

COMPAs was used as a tool and, in some cases, as an excellent way out of difficult situations involving persons with dementia, such as opposition, disorientation, and apathy. Caregivers (12/17, 71%) saw COMPAs as a solution that worked with residents who had required more attention. They were grateful to have an effective solution in these types of cases:

> *Interviewer: Did you have the impression of having a solution?*
>
> *P13: Yes, exactly, now I have a solution.*

P2:But, with some residents, the device also helps us to do the tasks.There are some cases that are more difficult, but with the device, it improves our interaction with certain residents a bit.

The implementation of COMPAs also contributed to caregivers' feelings of personal achievement in the workplace. Caregivers (15/17, 88%) felt more useful and believed that they made a real difference in the lives of the persons living with dementia, as they could go beyond providing primary care. Caregivers enjoyed learning about the residents, their lives, and their personal tastes, and they felt empowered by having an additional clinical role:

> *It lifts you up, in your work...you are not only there to help them with comfort care or to feed them.* [P10]
>
> *I can say it adds something good to the atmosphere, it adds more...How can I say this...I could say particularly with PWDs, it makes us want...with people who communicate less. It is like us; it makes us want to reach out to those people.* [P6]

Caregivers (11/17, 65%) discussed how COMPAs enabled the development of more personalized relationships with persons living with dementia. They felt closer to the residents and more interested in them. Spending more time with persons living with dementia helped caregivers to create a bond and spend quality time with them despite the communication difficulties:

> *P9: ...just spending fifteen minutes with them, it was a moment of joy and relaxation. Because I was also learning plenty of things.*
>
> *Interviewer: Do you mean that it provided you with joy to spending time with them?*
>
> *P9: Yes, exactly. We never take enough time; we do not take the time to talk to them.*

Caregivers (11/17, 65%) also said that COMPAs allowed them to have better interactions with the residents. They talked about better-quality exchanges, and generally enhanced communication, including communication by the persons living with dementia themselves:

> *We can communicate with the device.* [P14]
>
> *Even their speech is more fluent.* [P10]

Versatility of COMPAs

Caregivers highlighted the flexibility of COMPAs, as it could be used for different reasons, in different settings, and for different durations.

COMPAs was implemented in different ways by different caregivers. They could adapt it to their working conditions, and over time, they incorporated the tool into their daily routine. Some caregivers used it while providing grooming care:

> *And there are moments, like grooming care, that are a bit stressful, I would put his music on, and we sang, we danced in front of the mirror, and we giggled.* [P13]

Some used it in a group setting, while others used it individually. Some caregivers had a fixed time in their day dedicated to COMPAs, while others used it at different times depending on the situation:

> *A big asset of COMPAs, is that in fact, we can use it at any time of day.* [P11]

The duration of a COMPAs session also varied between caregivers, ranging from 5 minutes to around 20 minutes:

> *When I have five minutes, ten minutes, I would take the iPad, go to the room, and we listened together. Sometimes when I have more time, l stay longer.* [P4]

Challenges for Caregivers

Caregivers reported some issues during the implementation of COMPAs. Lack of time, technological issues, and the responsibility for or availability of the device were mentioned as challenges.

Lack of Time

Close to half of the caregivers (8/17, 47%) stated that they lacked the time to use COMPAs. They commented that it was not always easy to take the time to conduct a COMPAs session because of workload or when time permitted, the resident might be unavailable:

> *The evening shift, it is hard to find the time to enjoy it.* [P3]
>
> *It was hard in the mornings with grooming care: there is too much work to do it properly. However, we would do, I would do one in the morning from time to time.* [P15]

Technological Issues

The participants encountered some technological issues during the implementation. Caregivers (3/17, 18%) discussed how the bugs could disrupt their sessions, making the residents lose interest in the content presented:

> *The videos did not work. I would have liked to do it with Mrs. B, watch videos, but it was not working.* [P17]

Responsibility for and Availability of the Device

Caregivers (6/17, 35%) raised the issue of being responsible for an iPad. Being responsible for a valuable object was a concern for them. In other cases, the iPad was locked, and a nurse had to make it available to the caregiver (5/17, 29%). Their busy schedules made it difficult for them to access the device when they needed it.

Challenges for Residents

A few residents (6/17, 35%) faced some problems while using COMPAs. Confusion, negative emotions, and disinterest were mentioned as challenges for residents.

Caregivers reported that some of their residents considered the app to be an intrusion; they did not understand how their personal information came to be in the attendant's hand:

> *P10: People like Mrs. G, this dementia, well, for her, it's not positive, because it's difficult, she starts questioning. She wonders what is going on.*
>
> *Interviewer: You think Mrs. G., it makes her wary?*
>
> *P10: Mrs. G., she did it once and it was very hard to do it again, because she takes it as an intrusion.*

Others were troubled by not being able to recognize the pictures shown to them. Negative emotions could also be elicited by the content:

> *A little bit of melancholy at times.* [P12]

Caregivers (4/17, 24%) reported that some residents were disengaged from COMPAs. This disinterest was related to the device, the redundancy of the content, or the resident's attitude:

> *Well, there were some residents who weren't even slightly interested.* [P13]
>
> *Some residents weren't interested in watching the screen or were troubled by the screen.* [P13]

Discussion

Principal Findings

The purpose of this study was to implement and validate the effect of COMPAs, an app designed to elicit positive emotions triggering communication between persons living with dementia and their caregivers in an LTC setting.

Using a combination of quantitative and qualitative methods, the main results of the study validate our hypotheses. Specifically, the qualitative results from the semistructured interviews show that COMPAs improved person-centered communication between caregivers and persons living with dementia; its use resulted in more verbal and nonverbal exchanges in different contexts (eg, personal care and dedicated time). In particular, caregivers reported an improvement in the quality of exchanges and a more personal care relationship. Moreover, the use of COMPAs was associated with an improvement in QoL for both persons living with dementia and caregivers. The caregivers reported that COMPAs elicited positive emotions in persons living with dementia, contributing to emotional communication and helping the caregivers see the person living with dementia beyond the illness. In so doing, COMPAs supported person-centered care and communication between persons living with dementia and their caregivers. In addition, statistically significant results were observed in the form of increased caregiver empowerment, as reflected by the accomplishment score in the MBI. Caregivers also described COMPAs as a solution that helped them create opportunities to develop meaningful bonds with persons living with dementia, easing the caregiver communication burden. Finally, COMPAs was deemed well suited to the LTC context, particularly due to its versatility. These results were observed although 40% (7/17) of the caregivers were not accustomed to using an iPad, which provides evidence for the versatility of COMPAs in empowering even caregivers with limited technological literacy.

Quality of Communication Between Persons Living With Dementia and Caregivers

The GCOM showed some deterioration in specific oral expression components for persons living with dementia, which is expected in the context of progressive conditions. Interestingly, the COMPAs intervention was associated with stable general communication skills in residents. This may be a result of the GCOM's poor sensitivity to the communication patterns characterizing advanced neurocognitive disease, or it might reflect the benefits of daily stimulation with COMPAs in reducing morbidity, despite the progressive nature of neurocognitive disease [7]. The results on the GCOM also highlighted the positive nonverbal communication markers of well-being and positive emotions that COMPAs induced in residents, including smiling; raising eyebrows; touching the caregiver's hand while coviewing; smiling, dancing, or singing to personalized music; and laughing with the caregiver. These findings highlight the app's efficacy in promoting person-centered communication between LTC residents with dementia and their caregivers. They also attest to the benefits of COMPAs training, which increases caregivers' awareness of nonverbal and emotional aspects of communication. These findings are in line with those of previous work showing that integrating communication strategies into care and using elements of a patient's life story in informal discussions enhance meaningful communication between caregivers and LTC residents [6]. Moreover, the results of the semistructured interviews showed that following the COMPAs trial, caregivers focused more on nonverbal and emotional person-centered communication and less on verbal and transactional communication. These results reveal the importance of combining a good tool with suitable training in order to promote awareness of all dimensions of communication and the potential facilitators and barriers [31].

Studies conducted during the COVID-19 pandemic also found that COMPAs had positive effects on communication between caregivers and persons living with dementia in an LTC setting, even during periods of extreme isolation [47]. Specifically, caregivers reported that residents showed increased engagement, as opposed to apathy, together with verbal and nonverbal expressions of joy, well-being, and calmness while using COMPAs, despite major public health restrictions and the use of personal protective equipment [47].

Residents' and Caregivers' QoL

Caregivers' QoL

The results on the GHQ-12 showed that caregivers' QoL increased following COMPAs use, and so did their sense of personal accomplishment (measured by the MBI-personal achievement scale). More specifically, an improvement in the feeling of personal accomplishment was observed in the level of energy that the caregiver felt when working closely with the resident. This is in line with the findings of previous studies showing that significant communication between persons living with dementia and caregivers is associated with a better QoL [60,61].

The analyses of semistructured interviews show that caregivers described COMPAs-supported interactions with residents as pleasant times, moments of relaxation, and even as therapeutic for them. Thus, caregivers saw COMPAs as a solution to their struggles with persons living with dementia: a quick and effective way out of the challenges they faced in managing difficult behaviors (eg, apathy and agitation) and engage in more natural communication. It was probably this factor that led to the association between reduced caregiver burden and COMPAs use. Similar findings were reported in previous work showing the relationship between caregiver burden and the quality of communication [9,62]. Furthermore, there was a decrease in the score of the MBI-depersonalization scale for over half of the participating caregivers (9/17, 53%). This may have been related to the personalized COMPAs content, which helps caregivers appreciate the person beyond the disease and become aware of the individual traits of the persons living with dementia including their history, culture, tastes, and preferences, that is, the opposite of depersonalization.

The caregivers expressed their satisfaction with knowing more about the person they were caring for, spending more time with them, getting to know their life story better, and seeing the residents happier in this context. Indeed, personalized content is shown to be relevant in facilitating communication among persons living with dementia [63]. Thus, improving the quality of communication had positive effects on the dyad and helped to establish an empathic relationship. As a result, caregivers felt valued and satisfied with their work:

> *It lifts you up in your job: you're not there just to help them with their comfort care or feed them.*

Using COMPAs empowered the caregivers, and this is probably a key reason for reduced caregivers' burden.

Residents' QoL

The QDV-DTA scores did not show any significant changes in the residents' QoL. However, caregivers reported that COMPAs triggered positive expressions in the residents, demonstrated by their nonverbal communication. They viewed COMPAs as a tool helping residents change their routine, remember positive times, break out of their isolation, and feel well. They considered COMPAs to be a valuable tool to support meaningful communication, thus supporting social engagement in persons with dementia. During the semistructured interviews, caregivers mentioned COMPAs's ability to support a meaningful activity, which meant persons living with dementia were involved in stimulating activities. In light of the literature, residents' QoL is promoted by social contacts, a good relationship with the caregiver, and the caregiver's involvement in providing care [26,28]. These factors are also associated with better self-esteem in persons living with dementia, an essential component of their well-being [5] and dignity [17]. Furthermore, it is essential to address the socialization needs of persons living with dementia and provide person-centered care [64]. In line with this literature and considering the verbal and nonverbal manifestations of well-being in residents documented by caregivers in the semistructured interviews, the results of this study prove the relevance of COMPAs for communication and QoL. They illustrate the value of orienting communication around emotional content linked to the residents' own life trajectory, which improves interactions in the dyad, and in turn promotes positive relationships [16,33].

Burden on Caregivers

QoL at work refers to various factors such as satisfaction, mental health, and stress level [65]; these 3 factors contribute to caregiver burden. More specifically, stress arises when caregivers fear not having the necessary resources to face the physical and psychological challenges that they may encounter in geriatric care. The reduction in caregiver burden and increased personal achievement found in this study may be related to several factors. One is the fact that caregivers received a training session on communication strategies and barriers in LTC. Thus, the literature shows that training on strategies for communicating with persons living with dementia improves caregivers' communication skills and is associated with a decrease in their burden [61].

Another factor that may have contributed to reducing caregiver burden is reflected by the results on the MBI and by the thematic analyses concerning the stress and frustration associated with communication barriers [9], all of which were reduced in this project. Specifically, the quantitative results on the MBI following 8 weeks of COMPAs use showed a significant reduction in the burden score, concurrently with a significant improvement in the personal achievement score and a reduction in feelings of tiredness. Hence, COMPAs was a resource for caregivers, allowing them to feel more accomplished and less exhausted at work. These effects are also illustrated by the semistructured interviews; caregivers reported that adding COMPAs to their daily routine did not result in work overload.

In fact, caregivers noticed the positive effect of COMPAs on the residents and wanted to continue using the app, although they occasionally mentioned not having time to use COMPAs to their satisfaction or to add material to the libraries. The key will be to find more time in everyday life situations for caregivers to use COMPAs and to simplify the addition of personalized material. We are currently working on these 2 elements to meet these needs.

In sum, the results on the MBI and semistructured interviews show that COMPAs reduced caregiver burden, a factor that is associated with more relaxed care, which in turn further reduces their burden [66,67]. Furthermore, the emotional component of COMPAs interventions contributed to the expression of empathy, which is also known to reduce caregivers' burden.

Strengths and Limitations of the Study

To our knowledge, this is the first study to explore the implementation of a communication-based app in the context of LTC settings. The qualitative results of this study demonstrate COMPAs's effectiveness in positively influencing the lives of persons living with dementia and caregivers in an efficient and timely manner. It should be noted that COMPAs's positive effects on caregivers might perhaps be influenced by a selection bias; they volunteered for the study, and therefore, they might have a positive bias toward the method and would not necessarily be representative of the target population. However, according to the LTC administrators, the caregivers' demographic profile in the sample was representative of the vast majority of caregivers in Québec and Canada, mostly immigrant women aged between 20 and 60 years. Following the launch of the project, more caregivers saw the benefits and told the research team that they wish they had enrolled. Future studies could explore COMPAs's effects and adherence in a larger community of caregivers as a function of cultural background, age, gender, and technological literacy, among other things.

Finally, we acknowledge that the statistical significance of the quantitative results is limited. This may be a consequence of the small sample size and the diversity of residents' clinical profiles. Hence, although we find medium effect sizes, these results should be considered as only a tendency. Future studies with larger samples of participants are required to confirm these results and test the generalizability of these findings in broader populations, including family caregivers of persons living with dementia in LTC residences or other LTC populations without dementia but with severe communication impairments following stroke, or severe sensory impairments in the context of behavioral disturbances, or major psychiatric disorders.

COMPAs interventions proved to be suitable for implementation in LTC residences, as caregivers could choose the duration, time, and modality of their sessions with persons living with dementia. Caregivers could adapt the app to their working conditions, making COMPAs a versatile tool that can be modulated to the users' needs.

The literature shows that technology is underused to support the communication between caregivers and persons living with dementia in LTC settings [37], and no available evidence was found to support the use of apps for such communication. This study provides evidence that COMPAs is suitable to support person-centered care in the caregiver-LTC resident dyad. To our knowledge, this is the first app that supports communication through a person-centered care approach and that is fully customizable to the person living with dementia.

Although the information gathered from caregivers in the questionnaires and the semistructured interviews is an effective way to understand COMPAs's effects on persons living with dementia, we acknowledge that the perspectives of persons living with dementia were not included. Including them in the research team entails ethical and logistical challenges [68,69]. To be in line with the person-centered care approach, future studies should include their point of view [32]. The research team created the personalized libraries, which saved time for the caregivers, who were overloaded with everyday work, but persons with dementia could be more involved in choosing the material. This will be done in future studies.

In a context where human resources and time are limited, it will be important to develop efficient ways to create user-friendly personalized libraries. Future work will focus on improving the COMPAs interface by adding artificial intelligence modules that will assist in more efficiently creating sophisticated personalized libraries.

Conclusions

COMPAs proved to be effective in improving communication between caregivers and residents while reducing the burden on caregivers and improving both groups' QoL.

The evidence shows that COMPAs facilitates person-centered communication. Positive emotions generated in residents resonate in caregivers, stimulating empathy and well-being in the dyad. This state of shared well-being promotes social engagement, defocuses attention from impairments and disabilities, and fosters exchanges between the dyad and what they share. The impressive gains in relevant outcome measures obtained with residents and caregivers underscore the relevance of COMPAs in LTC settings. Large-scale studies are necessary to validate the observed tendencies and optimize COMPAs's potential benefits in persons with living dementia in LTC settings and their caregivers, while examining its use with other susceptible populations presenting communication deficits. Studies could also explore the barriers to technology use in caregivers and persons living with dementia and ways to overcome them; they must also consider the ethical issues related to technology use with susceptible populations, including privacy and security, to identify best practices for safe implementation of technology in dementia care.

Acknowledgments

The authors are grateful to all the residents and caregivers who participated in the study and to the administrators and members of the research team whose cooperation made this study possible.

This work was supported by the Spark Program of the Center for Aging Brain Health Innovation, powered by Baycrest.

Introduction

Individuals with heart failure (HF) have a high burden of health care utilization, costs, and morbidity in the year following hospitalization for an acute HF exacerbation. Frailty, which has been described as increased vulnerability to adverse events, is common among those with HF and increases with age [1]. Health systems worldwide are integrating automated tools within electronic health records to measure frailty. However, using longitudinal data to measure frailty and better predict outcomes among those with HF has rarely been considered [2-5]. We sought to evaluate the predictive value of adding longitudinal data to a standard frailty index (FI) and evaluate predictions of 1-year outcomes in patients with HF.

Methods

Study Design

This was a retrospective cohort study that used national Veterans Health Administration (VA) data. Veterans aged ≥50 years with an index hospital admission for HF from 2016 to 2019 were included. We excluded veterans with <2 primary care visits in the 3 years before their date of admission to indicate regular use of VA care. We included those with documentation of ejection fraction. We used the validated VA FI, which captures 31 deficits in health based on *International Classification of Diseases, Tenth Revision*, and Current Procedural Terminology codes [6]. We estimated the FI for each preceding year, without overlap. We fit a linear line to 3 calculated FIs for each year prior to the index date of admission and reported the slope and intercept individually. This method provided a 3-year longitudinal estimate of frailty at admission. We used 1-year all-cause mortality following the index date of admission as the primary outcome. We reported the area under the curve (AUC) for predicting outcomes, using logistic regression. We estimated two AUCs: (1) FI at the time of admission (AUC_{FI}) and (2) FI at time of admission plus slope and intercept ($AUC_{\text{frailty trajectory (FT)+FI}}$). Changes in the AUCs were reported as the percentage of improvement ($\Delta_{AUC} = 100\% \times [AUC_{FT+FI} - AUC_{FI}]/AUC_{FI}$). We recursively calculated the AUCs and Δ_{AUC} by including patients whose FIs at admission were <0.1 and, at each step, increased the FI level by 0.01 to 0.4.

Ethical Considerations

The study protocol was approved by the Research & Development Committee of the Michael E. DeBakey VA Medical Center and Baylor College of Medicine Institutional Review Board (institutional review board number: H-464220).

Results

In total, 54,774 veterans were included (age: mean 73.3, SD 10.1 y; BMI: mean 30.1, SD 7.5 kg/m^2; male: n=53,899, 98.4%; White: n=30,406, 55.5%; Table 1). Figure 1 shows the AUC_{FI} and AUC_{FT+FI} across the distribution of frailty ranges, from prefrail (FI: 0.1-0.2) to frail; an FI of 0.2 is equivalent to an accumulation of 7 deficits among 31 variables, and the Δ_{AUC} is also displayed. For all veterans across all FI thresholds, the AUC improved by at least 4.1% when adding the FT to the FI. The highest Δ_{AUC} (24%) was observed for FIs of 0.13 to 0.16, and it decreased to ≤10% for FIs of ≥0.2.

Table . Characteristics of patients (N=54,774) with an index admission to the Veterans Health Administration for heart failure from January 1, 2016, to January 1, 2020.

Characteristics		Patients
Admit year 2016, n (%)		12,875 (23.5)
Admit year 2017, n (%)		13,585 (24.8)
Admit year 2018, n (%)		14,082 (25.7)
Admit year 2019, n (%)		14,232 (26)
Age (y), mean (SD)		73.3 (10.1)
	<65, n (%)	9776 (17.8)
	65 - 75, n (%)	22,772 (41.6)
	≥85, n (%)	22,226 (40.6)
Sex, n (%)		
	Male	53,899 (98.4)
	Female	875 (1.6)
Race, n (%)		
	White	30,406 (55.5)
	Black	9340 (17.1)
	Other[a]	15,028 (27.4)
Hispanic ethnicity, n (%)		2093 (3.8)
BMI (kg/m^2), mean (SD)		30.1 (7.5)
	≥30, n (%)	24,352 (44.5)
Frailty status (frailty index), mean (SD)		0.35 (0.11)
	Robust (<0.1), n (%)[b]	297 (0.5)
	Prefrail (0.1 - 0.2), n (%)[b]	5715 (10.5)
	Frail (>0.2), n (%)[b]	48,762 (89)
All-cause mortality, n (%)		
	30-day mortality	2848 (5.2)
	1-year mortality	14,460 (26.4)
	All-time mortality	37,027 (67.6)
Time to death (mo), median (IQR)		18.2 (5.6-36.4)
HFrEF[c], n (%)		27,223 (49.7)
HFmEF[d], n (%)		4546 (8.3)
HFpEF[e], n (%)		23,005 (42.0)
Living in a CLC[f], n (%)		1808 (3.3)

[a] “Other” includes Asian, American Indian or Alaska Native, Native Hawaiian or other Pacific Islander, and unknown.

[b] Standardized frailty status cut points drawn from validated studies [6].

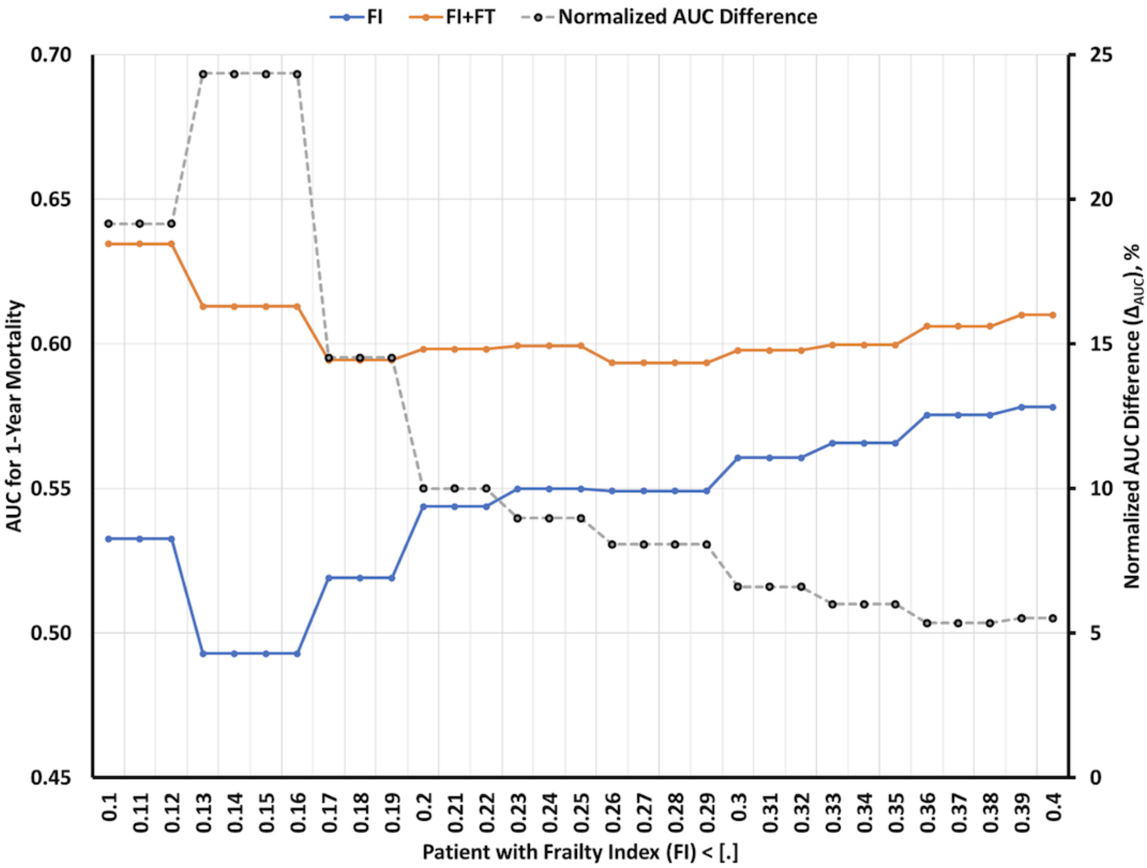
[c] HFrEF: heart failure with reduced ejection fraction of <40%.

[d] HFmEF: heart failure with modified reduced ejection fraction of 40%-50%.

[e] HFpEF: heart failure with preserved ejection fraction of >50%.

[f] CLC: community living center.

Figure 1. AUCs for patients who were admitted, for the first time, to the Veterans Health Administration for heart failure from January 1, 2016, to January 1, 2020, and had an FI of 0.1-0.4 (as shown on the x-axis in increments of 0.01). We compared the AUCs of FIs (in blue; AUC_{FI}) versus the AUCs of FIs and FTs combined (in orange; AUC_{FI+FT}). The percentage of improvement in AUCs resulting from the addition of the FT to the FI was reported in black (Δ_{AUC}) and calculated by using the following formula: ΔAUC= (AUCFI+FT−AUCFI)AUCFI ×100. AUC: area under the curve; FI: frailty index; FT: frailty trajectory.



Discussion

In a national cohort of veterans who were admitted to the VA for HF, the addition of longitudinal FT data resulted in a clinically significant (up to 24%) improvement in 1-year mortality prediction when compared to a standard FI alone among patients in the prefrail range. In contrast, we observed a modest (at least 4.1%) improvement in 1-year mortality prediction in the overall population. Enhancing AUC prediction for patients in the prefrail range is clinically important, as interventions that mitigate frailty may be most impactful in this population [7]. Patients with prefrailty may benefit from interventions (eg, cardiac rehabilitation) that improve frailty status and cardiovascular outcomes [1]. These findings enrich our understanding of the importance of FT in patients at lower FI levels, and a previous study compared the importance of FIs to that of FTs alone [5]. These results may not generalize to nonveteran populations. The sample was predominately male but did include a diverse population in terms of race, ethnicity, and geographic distribution. In summary, methods for calculating frailty provide useful predictions of adverse outcomes among adults with HF. The addition of longitudinal frailty data improves predictions for patients with HF and prefrailty. These findings aid clinician and health system decision-making, as this population benefits most from interventions that slow or prevent frailty progression, and suggest that longitudinal data for modeling FT provide additional evidence for tailoring interventions to patients with HF who may benefit most from tailored interventions.

Abstract

Background: With countries promoting generic drug prescribing, their growth may plateau, warranting further investigation into the factors influencing this trend, including physician and patient perspectives. Additional strategies may be needed to maximize the switch to generic drugs while ensuring health care system sustainability, focusing on factors beyond mere low cost. Emphasizing affordability and clarifying other prescription considerations are essential.

Objective: This study aimed to provide initial insights into how patient severity, composite adherence, and physician-patient relationships impact generic switching.

Methods: This study used a long-term retrospective cohort design by analyzing data from a national health care database. The population included patients of all ages, primarily older adults, who required primary-to-tertiary preventive actions with a history of hospitalization for cardiovascular diseases (*ICD-10* [*International Statistical Classification of Diseases, Tenth Revision*]) from April 2014 to March 2018 (4 years). We focused on switching to generic drugs, with temporal variations in clinical parameters as independent variables. Lifestyle factors (smoking and drinking) were also considered. Adherence was measured as a composite score comprising 11 elements. The physician-patient relationship was established based on the interval between physician change and prescription. Logistic regression analysis and propensity score matching were used, along with complementary analysis of physician-patient relationships, proportion of days covered, and adherence for a subset of the population.

Results: The study included 48,456 patients with an average follow-up of 36.1 (SD 8.8) months. The mean age was 68.3 (SD 9.9) years; BMI, 23.4 (SD 3.4) kg/m^2; systolic blood pressure, 131.2 (SD 15) mm Hg; low-density lipoprotein cholesterol level, 116.6 (SD 29.3) mg/dL; hemoglobin A_{1c} (HbA_{1c}), 5.9% (SD 0.8%); and serum creatinine level, 0.9 (SD 0.8) mg/dL. Logistic regression analysis revealed significant associations between generic switching and systolic blood pressure (odds ratio [OR] 0.996, 95% CI 0.993-0.999), serum creatinine levels (OR 0.837, 95% CI 0.729-0.962), glutamic oxaloacetic transaminase levels (OR 0.994, 95% CI 0.990-0.997), proportion of days covered score (OR 0.959, 95% CI 0.948-0.97), and adherence score (OR 0.910, 95% CI 0.875-0.947). In addition, generic drug rates increased with improvements in the HbA_{1c} level band and smoking level ($P<.01$ and $P<.001$). The group with a superior physician-patient relationship after propensity score matching had a significantly higher rate of generic drug prescribing (51.6%, SD 15.2%) than the inferior relationship group (47.7%, SD17.7%; $P<.001$).

Conclusions: Although physicians' understanding influences the choice of generic drugs, patient condition (severity) and adherence also impact this decision. For example, improved creatinine levels are associated with generic drug choice, while stronger physician-patient relationships correlate with higher rates of generic drug use. These findings may contribute to the appropriate prescription of pharmaceuticals if the policy diffusion of generic drugs begins to slow down. Thus, preventing serious illness while building trust may result in clinical benefits and positive socioeconomic outcomes.

Introduction

Background

Many high-income countries with mature health care systems are actively expanding the use of generic drugs [1,2]. However, as generic drug use reaches a certain level, growth may slow (eg, Japan: 71.2% in 2018, annual rate of 5.45%; 77.8% in 2020, annual rate of 1.15%) [3,4]. Therefore, additional strategies may be required to maximize the switch to generic drugs with the sustainability of the health care system in mind, focusing on factors other than the conventional low cost. Specifically, it is important not only to emphasize the affordability of generic drugs but also to clarify other prescription considerations. For further promotion, the biological quality of generic drugs must be ensured, and their long-term health economics must be evaluated. Furthermore, both medical practitioners and patients must have a good understanding of the clinical characteristics and health care economics of generic drugs. Addressing the concerns of all stakeholders is crucial for optimizing prescriptions. This discussion should particularly focus on patient factors, including intrinsic adherence and physician-patient relationships.

The factors influencing the prescription of generic drugs can be classified into 3 major categories: patients, physicians, and regulations. While many studies have focused on physicians and regulatory factors, majority of the research on physicians is based on questionnaire surveys assessing their trust and knowledge of generic drugs, particularly among doctors and pharmacists [5-13]. Regarding regulatory factors, numerous studies have discussed the socioeconomic significance of the low prices of generic drugs against the backdrop of the medical insurance system [7,10,11,14,15]. However, patient characteristics have received less attention; although some reports have analyzed these factors as part of treatment outcome evaluations, few studies have specifically focused on how patient characteristics influence the selection of generic drugs [16].

Another theme related to the study of the factors influencing the prescription of generic drugs is the scattered outcome evaluation. Regarding this topic, relatively more study designs tend to compare clinical outcomes and patient compliance (eg, the proportion of days covered [PDC]) between brand names and generic drugs [17-30]. In addition, the analysis may address therapeutic inertia, which is characteristic of this theme. Studies tend to target diseases, such as cardiovascular diseases (CVDs) [17-22] and pain syndromes, for which generic drugs have been introduced as an alternative for expensive brand-name drugs. In this light, research on the factors influencing generic drug prescriptions is closely related to medical innovation (drug discovery) and the sustainability of the health care system (health insurance).

Aim of This Study

Many studies have investigated the biological quality and economic use of generic drugs. However, as mentioned earlier, research on patient characteristics as limiting factors in generic drug prescriptions is lacking. For instance, few studies have explored the impact of complex diseases (severity) and inherent adherence on the switch to generic drugs. Most existing research has used the PDC as a surrogate for adherence, and no studies have analyzed widespread adherence (overall health-related behaviors), including disease prevention. In addition, while the impact of physician attitudes on PDC has been reported [13], no reports related to the patient-physician relationship for PDC or generic drug rates have been found.

In this context, we previously published a study suggesting that the selection of generic drugs could improve long-term life prognosis and reduce medical costs, influenced by composite adherence using drug dispensing data based on doctors' prescriptions [26]. In the previous study, multivariate analyses were conducted to identify factors affecting long-term changes in the prognosis and clinical indicators from both public benefit and economic efficiency perspectives. The findings indicated that patient severity plays a significant role in the decision to switch to generic drugs. In addition, it was hypothesized that the patient-physician relationship, grounded in adherence, also plays a role in generic drug switching. Therefore, this study aimed to verify these hypotheses.

Thus, we conducted a study focusing on patient characteristics, primarily older adults, as a factor influencing generic prescribing. The study aimed to provide preliminary insights into how patient severity, composite adherence, and the patient-physician relationship impact the switch to generic drugs.

Methods

Application of Findings From Data Science

This study is a continuation of our previous study [26] on the development of a validation and prediction model for the long-term prognostic impact of adherence on health care costs and clinical outcomes in circulatory diseases. This was a long-term longitudinal multicenter retrospective cohort study.

In a previous study, we developed a predictive model of integrated health care resource consumption (Adherence Score for Healthcare Resource Outcome [ASHRO]) that incorporated patient health behaviors and examined their association with clinical outcomes. Predictive models, including neural networks and random forest learning (artificial intelligence), were used in that study. Adherence, measured by the ASHRO score, was considered a broad concept encompassing moral and public interest perspectives [26]. This adherence score was also selected as a key factor in this study owing to the socioeconomic implications of drug prescriptions, which form the context of this research.

In the previous study, the examination of the basic model by machine learning was summarized as follows: Traditional empirical statistical methods, which involve obtaining a dataset with results, predictors, and fit coefficients, were not optimal for this exploratory study's multivariate analysis on large samples. Consequently, we used machine learning techniques, specifically random forests, and K-fold cross-validation, to select and integrate explanatory variables and establish weights from the previous study.

Random forests are machine learning techniques used for classification and regression that can help minimize overfitting [27,28]. The advantage of medical big data is their ability to efficiently handle large samples with thousands of input variables. In addition, random forests can accommodate various data scales (eg, blood pressure and glomerular filtration rates have different normal ranges) and remain robust even when unrelated variables are included [29,30].

The study developed a basic prediction model for medical and long-term care costs using random forests. We included over 100 variables related to medical practices, clinical tests, and preventive activities as explanatory factors. Machine learning was used to evaluate parameter integration and feature importance by randomly selecting multiple sample sets and feature variables using the bootstrap method (sampling with replacement).

Data Sources and Populations

Data Sources

A previous study that developed a composite adherence score used a national health care database (Kokuho Database) that individually links health checkups, health insurance claims, and long-term care insurance data. This study used the same data source, and extracted a cohort from it.

The Kokuho Database is a large-scale repository that includes self-employed and retired individuals covered by National Health Insurance. It provides long-term medical and care insurance data, with a personal collusion rate between medical and long-term care information exceeding 99%. The regions included in the database accounted for 6.1% of Japan's total population. In addition to the demographic trends and social structures, the main conditions of medical and long-term care generally reflect the average level in Japan. The data were managed and analyzed as part of the Health Economics Big Data of the University of Tokyo.

Data from each patient, anonymized under a unified identification, included basic characteristics, medical expenses related to hospitalization, outpatient care, dispensing, and dentistry; diagnostic information; breakdown of medical treatments; frequency of medical examinations; hospitalization duration; nursing care costs and required care level; usage frequency and duration; health checkup guidance content; laboratory and biological test results; and the number of unhealthy behaviors. We excluded samples with missing data to address potential bias in the large dataset.

Although the long-term care insurance system operated by the Japanese government focuses primarily on long-term care, it also covers chronic care. Nursing care is a key indicator of "functional impairment" and is a crucial metric, particularly in geriatric research. The system classifies daily living abilities using the nursing care level, which measures the degree of care required [31]. This classification includes 7 categories: "two stages of support required" and "five stages of nursing required"; higher numbers indicate greater severity. These care categories were scored and analyzed in this study.

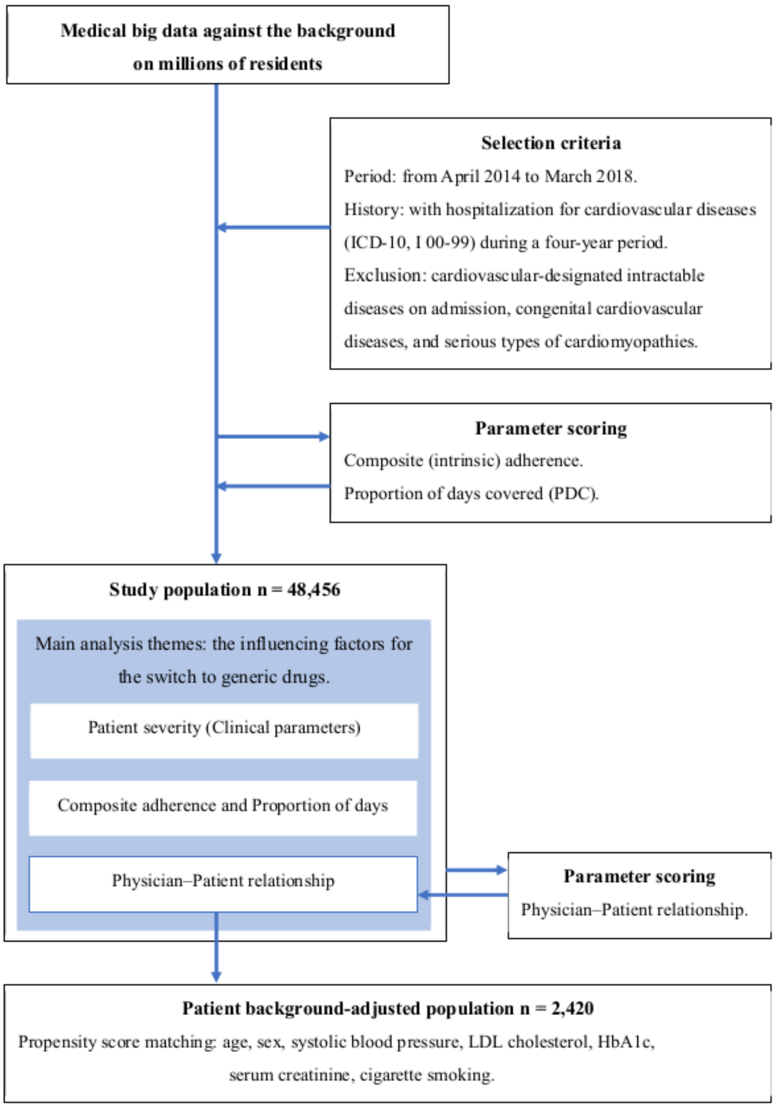
Data Populations

The study cohort comprised patients of all ages requiring preventive actions from first-to-tertiary levels, with a history of hospitalization for CVDs (*ICD-10* [*International Statistical Classification of Diseases, Tenth Revision*] codes I00-I99) from April 2014 to March 2018 (Figure 1) [32]. The cohort predominantly included older adults. This single-gate, multicenter retrospective observational study used real-world population data from an area with over 3 million residents. Exclusion criteria included cardiovascular intractable diseases upon admission, congenital CVDs, and serious types of cardiomyopathies [26,33].

As this was a longitudinal study, missing data at follow-up due to participants' death or relocation were censored. Furthermore, we adjusted for patient background using the basic characteristics of sex and age, clinical indices of cardiac function, renal function, endocrine metabolism, and lifestyle habits, such as smoking, to reduce bias in the analysis of physician-patient relationships.

Sex differences in CVD are well-documented, with female generally having a lower incidence of ischemic heart disease than men [34]. In addition, coronary artery disease in female often develops later in life, with many cases involving cumulative risks, such as hypertension and dyslipidemia [35]. The population composition in this study reflected these trends.

Figure 1. Flow chart of the study cohort setting. The propensity score method was used to compare the level of generic rates according to patient-physician relationship. LDL: low-density lipoprotein; HbA_{1c}: hemoglobin A_{1c}; ICD: International Classification of Diseases.



Definition of Key Indicators

Concept of Adherence Indicators

In our previous study, adherence was developed as a broad concept to discuss the behavioral changes in social groups and factors intrinsic to individual patients. Against this background, adherence is considered a composite measure. The 11 components comprising the final composite adherence (ASHRO) included indicators related to health promotion, prevention of disease severity, rational resource consumption behavior (moral hazard), medical attitude behavior, and public behavior (Multimedia Appendix 1) [26].

The following 11 indicators were calculated as the ratio of the difference between the mean value of the population and the mean value of each individual during the 1-year follow-up period after enrolment: number of health check-ups, units of rehabilitation intensity, number of guidance sessions, number of overlapping outpatient visits, clinical laboratory and physiological tests, inpatient days, number of outpatient visits, dispensing, PDC, and generic drug rate. This study used drug dispensing data based on doctors' prescriptions.

Composite adherence (ASHRO) was scored while ensuring a significant correlation with risk factors, such as systolic blood pressure, serum creatinine, low-density lipoprotein cholesterol (LDL-C), and hemoglobin A_{1c} (HbA_{1c}) levels, and the estimated glomerular filtration rate.

Overlapping outpatient services for the same diseases during the same period were similar. The generic drug rate is calculated as the proportion of prescriptions for generic drugs listed by the government, with the number of generic prescriptions as the numerator. The PDC was calculated based on the duration and continuity of prescriptions rather than individual medication adherence data. It is important to note that the PDC rate data reflect actual results, and the PDC score was incorporated into the ASHRO score. Each score serves a distinct purpose with different scales and interpretations.

Indicator of the Physician-Patient Relationship

In this study, we examined the relationship between physicians and patients. Although a questionnaire survey could be used to explain the relationship quantitatively, it was deemed unrealistic due to concerns about reliability from subjective judgments and the technical challenges or burden of integrating it with big data. Therefore, we extracted surrogate indices related to the relationship between doctors and patients from big data to prepare quantitative data matching actual clinical practice. Furthermore, we constructed a proxy index for trustworthy relationships using two elements: (1) change in the doctors or facilities for the same patient and (2) continuation of prescriptions at the same institution.

To examine this surrogate index, we proposed the following conditions hypotheses. First, a strong physician-patient relationship would be associated with fewer changes in physicians (eg, doctor shopping) [36]. Second, due to the characteristics of the cohort in this study, it was assumed that continuous (regular) medical care would be provided if the relationship was appropriate. Based on these hypotheses, we assessed the physician-patient relationship by evaluating the presence or absence of facility changes during the observation period and interval between consultations and classified the samples accordingly.

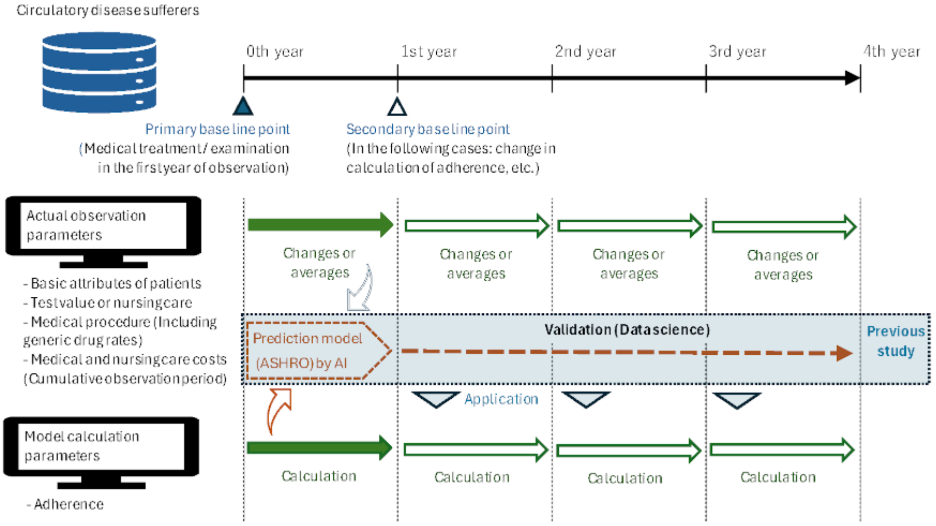
We categorized patients into 2 groups: those who experienced a change in facilities and those who did not, based on their visits for the same disease during the observation period. In addition, we considered information on the changes in the address. We labeled conditions with no change in the facility and a practice interval of 365 days or less as a superior relationship group (coded as 0) to indicate a strong physician-patient relationship. The other groups were considered as inferior relationship groups (coded as 1). The interval between treatments was set using a cutoff value derived from the receiver operating characteristic curve for a conservative assessment.

Statistical Analysis

Logistic regression analysis was performed to examine the influence of the clinical indicators on the choice of generic drug prescriptions. We also performed a logistic regression analysis to examine the complementary factors in the physician-patient relationship. Mann-Whitney *U* test was used to compare the percentage of generic drug prescription choices by high and low physician-patient relationships, and multiple regression analysis was performed to determine the relationship between PDC rate and other factors.

The influence of the clinical indicators on the choice of generic drug prescriptions was organized based on the relationship between the displacement (annual mean value) of each indicator and the generic drug rate. Change was calculated as the change from the previous year's value, either increasing or decreasing. The annual mean serum creatinine level was used as a surrogate because the progression mechanism was irreversible in the medium-term. The PDC and adherence indices were calculated based on 4 years of data; therefore, data on change were not used (Figure 2).

Figure 2. Timeline of this study and measurement methods for each parameter. This study was not an interventional study, so no fixed index time point was set. AI: Artificial intelligence; ASHRO: Adherence Score for Healthcare Resource Outcome.



A comparison of the levels of generic rates by patient-physician relationship was performed for the generic switch factor, adjusted for patient background using propensity score matching (PSM). Propensity scores for each case were calculated, and a 1:1 matching method was applied to align the sample numbers and ensure the data distribution and balance between both groups. It is important to note that because this study aimed to assess the influence of actual measured severity (laboratory values) on prescription choice, we did not perform background adjustment using PSM was not performed in the overall basic analysis. Categorical variables are expressed as numeric values (%), and continuous variables are expressed as mean (SD). The statistical significance level was set at 5%. The probability of an outcome occurring was organized in terms of odds ratios (ORs). The software used was SPSS Statistics for Windows (version 27; IBM Corp).

In Japan, medical policy has encouraged the prescription of generic drugs, resulting in a steady annual growth (average annual rate: 4.27%) [4]. We also performed an analysis that considered this growth trend, adjusting for the displacement of generic drug use rate over time.

Ethical Considerations

This study was approved by the Research Ethics Committee (2018167 N1: The Health Economics Big Data) of The

University of Tokyo Hospital and involved strict data confidentiality in accordance with the Helsinki Declaration and Japanese Government's Guidelines for Clinical Research Ethics and Reporting of Studies Conducted using the Observational Routinely Collected Data Statement.

Results

The findings of this study are as follows. For reference, we compiled a summary (list) of all results in an additional file (Multimedia Appendix 2).

Cohort Characteristics

A total of 48,456 patients were enrolled, with an average follow-up period of 36.1 (SD 8.8) months. The mean age was 68.3 (SD 9.9) years, and most patients were males (61.9%). At the baseline major health check-up, the BMI was 23.4 (SD 3.4) kg/m^2, systolic blood pressure was 131.2 (SD 15) mm Hg, triglyceride level was 120.8 (SD 5.2) mg/dL, LDL-C was 116.6 (SD 29.3) mg/dL, HbA$_{1c}$ was 5.9% (SD 0.8%), and serum creatinine was 0.9 (SD 0.8) mg/dL (Table 1).

Table 1. Cohort characteristics.

Parameter	Mean (SD)	Median (IQR)
Sample		
Patients, n	48,456	—[a]
Health check-up examination		
Age, years	68.3 (9.9)	69 (65-73)

HbA$_{1c}$[e] (%)	5.9 (0.8)	5.7 (5.5-6.1)
Follow-up period, months	36.1 (8.8)	44 (25-48)

[a] —: not applicable.

[b] HDL: high-density lipoprotein.

[c] LDL: low-density lipoprotein.

[d] GFR: glomerular filtration rate.

[e] HbA$_{1c}$: hemoglobin A$_{1c}$.

The superior physician-patient relationship group comprised 10,332 patients. The mean age was 70.03 (SD 10.10) years for this group and 66.26 (SD 8.47) years for the inferior relationship group. The proportion of males was 67.15% in the superior relationship group and 60.44% in the inferior relationship group.

After PSM, no statistically significant differences were observed between the 2 patient-physician relationship groups (inferior and superior groups): mean change in the systolic blood pressure was 8.9 (SD 5.6) mm Hg in the inferior group and 8.5 (SD 5.5) mm Hg in the superior group (*P*=.14), and the mean serum creatinine levels were 0.6 (SD 0.8) mg/dL and 0.7 (SD 1.1) mg/dL in the inferior and superior groups, respectively (P=.13) during the observation period (Table 2). The sample size was 1210 in each group.

Table 2. Adjusted backgrounds of physician-patient relationship groups using propensity score matching.

Parameter	Inferior group	Superior group	P value
Sample, n	1210	1210	—[a]
Age (year), mean (SD)	70.2 (6.6)	70.2 (6.8)	.44

[c] LDL: low-density lipoprotein.

[d] HbA_{1c}: hemoglobin A_{1c}.

[e] Cigarette smoking: binary (presence; 0, existence; 1).

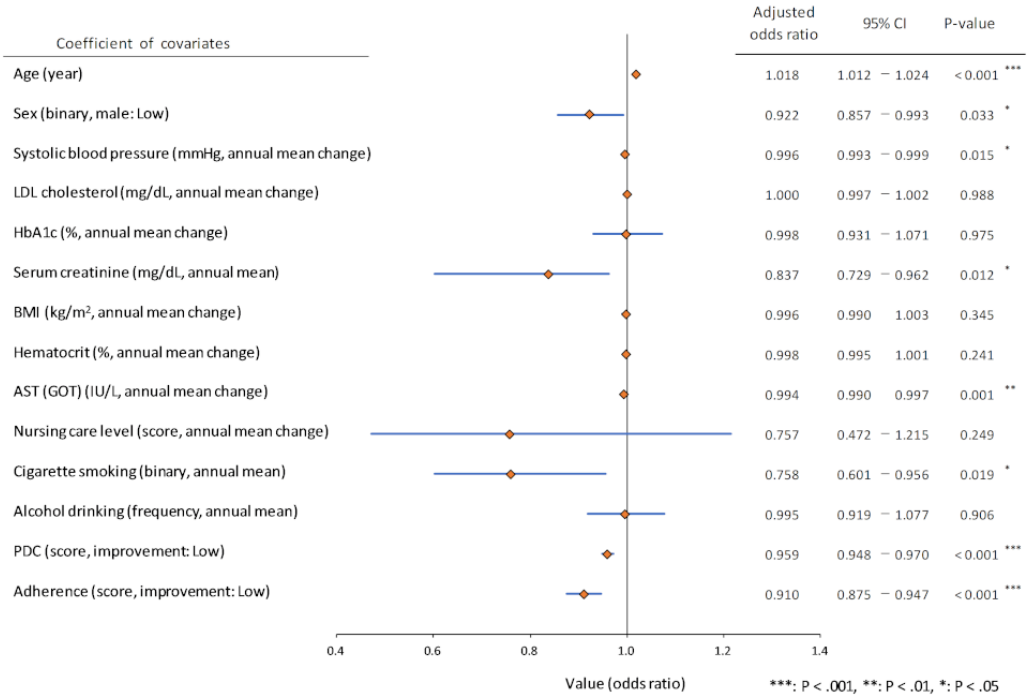
Clinical Factors Influencing the Switch to Generic Drugs

Logistic regression analysis was performed by switching to a generic drug as the variable and various clinical parameters related to CVD as independent variables. Significant predictors included systolic blood pressure (OR 0.996, 95% CI 0.993-0.999; P<.05), serum creatinine (OR 0.837, 95% CI 0.729-0.962; P<.05), aspartate aminotransferase (OR 0.994, 95% CI 0.990-0.997; P<.01), PDC score (OR 0.959, 95% CI 0.948-0.970; P<.001), and adherence (OR 0.910; 95% CI 0.875-0.947; P<.001), all of which demonstrated significant associations with generic drug switching (Figure 3). Smoking also significantly influenced generic drug switching (OR 0.758; 95% CI 0.601-0.956; P<.05). No significant differences were observed in the LDL-C and HbA_{1c} levels between the groups.

The analysis corrected the rising trend in the generic drug use rate in Japan; thus, the impact of each parameter did not change compared with the previously mentioned OR results (systolic blood pressure, 0.997 and serum creatinine level, 0.878).

We organized the relationship between the amount of displacement and cost of dispensing (a surrogate for generic drug rates: integral of the unit price and quantity of the prescription drug) to complement the results for the OR of systolic blood pressure. The results showed a statistically significant reduction in dispensing costs with a decrease in blood pressure (population mean difference between all pressure displacement ranges: P<.001; Figure 4). For reference, we analyzed the generic drug rate according to LDL-C level bands. No significant differences were observed between the normal LDL-C level band and the other bands (Figure 5). In addition, we analyzed the generic drug rates using the HbA_{1c} level band. A significant decrease was observed between the normal LDL-C level band and other bands (HbA_{1c}: 5%-5.6% vs 6%-6.4%, generic drug rate: 48.5% vs 47.4%; P<.01; Figure 6).

Figure 3. Clinical factors that influence the switch to generic drugs: logistic regression analysis. Nursing care is an indicator (degree of care) of the nursing care insurance system operated by the Japanese government. The level of nursing care is an index of the degree to which the older adults require nursing care. Depending on the physical and mental condition of the person being cared for, the condition will be classified into one of seven categories: “two stages of Support Required” or “five stages of Nursing Required”; the higher the number, the more severe the condition. Sex: binary (male: 1, female: 2), nursing care level: score (3 levels), cigarette smoking: binary (presence; 0, existence; 1), alcohol drinking: frequency (3 levels). LDL: low-density lipoprotein; HbA_{1c}: hemoglobin A_{1c}; BMI: body mass index; AST (GOT): aspartate aminotransferase (glutamic oxaloacetic transaminase); PDC: proportion of days covered.



Coefficient of covariates	Adjusted odds ratio	95% CI	P-value
Age (year)	1.018	1.012 − 1.024	< 0.001 ***
Sex (binary, male: Low)	0.922	0.857 − 0.993	0.033 *
Systolic blood pressure (mmHg, annual mean change)	0.996	0.993 − 0.999	0.015 *
LDL cholesterol (mg/dL, annual mean change)	1.000	0.997 − 1.002	0.988
HbA1c (%, annual mean change)	0.998	0.931 − 1.071	0.975
Serum creatinine (mg/dL, annual mean)	0.837	0.729 − 0.962	0.012 *
BMI (kg/m^2, annual mean change)	0.996	0.990 1.003	0.345

PDC (score, improvement: Low)	0.959	0.948 − 0.970	< 0.001 ***
Adherence (score, improvement: Low)	0.910	0.875 − 0.947	< 0.001 ***

Figure 4. Relationship between systolic blood pressure variation and dispensing cost (percentage to mean value) SBP: systolic blood pressure.

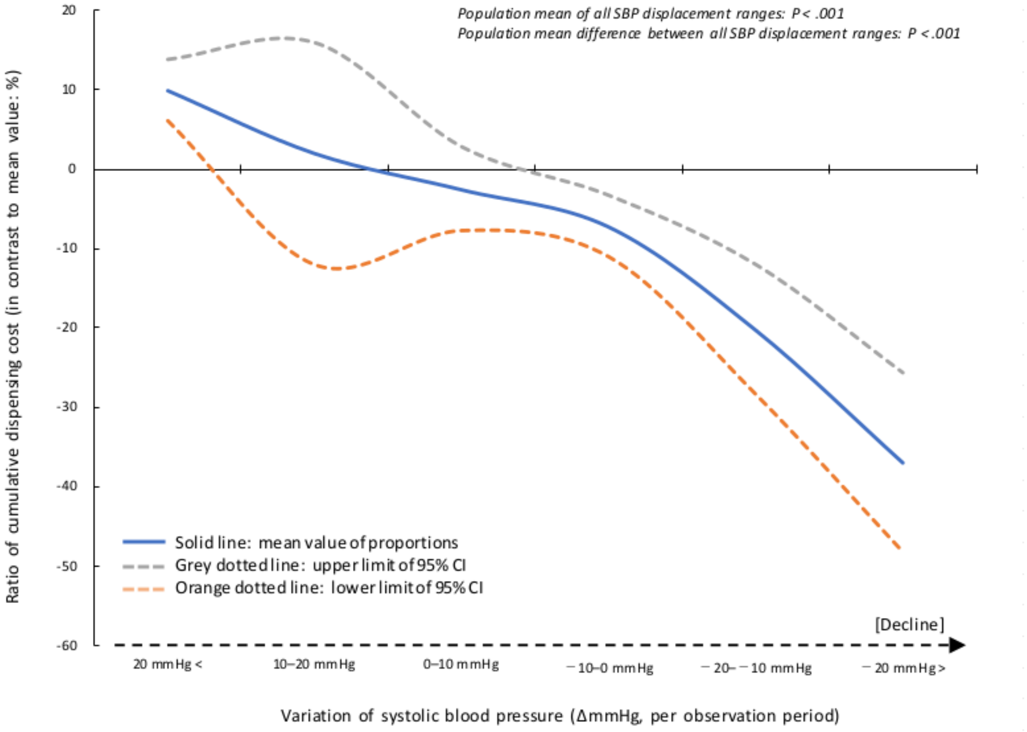

Figure 5. Generic drug rates at different mean low-density lipoprotein levels. Groups were compared using the Mann–Whitney U test, and no significant differences were detected. LDL-C: low-density lipoprotein cholesterol; NS: not significant.

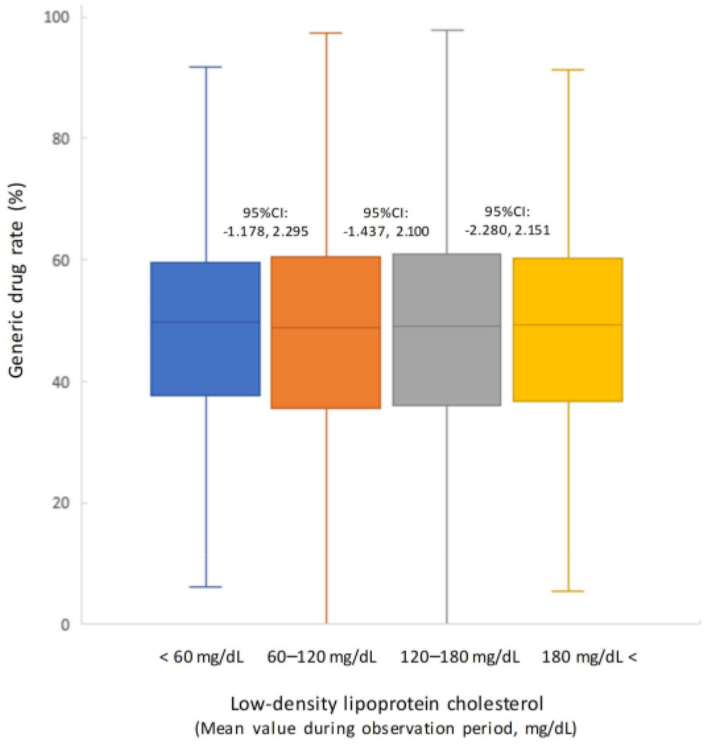

Figure 6. Generic drug rates at different mean hemoglobin A_{1c} levels. Groups were compared using the Mann–Whitney U test.

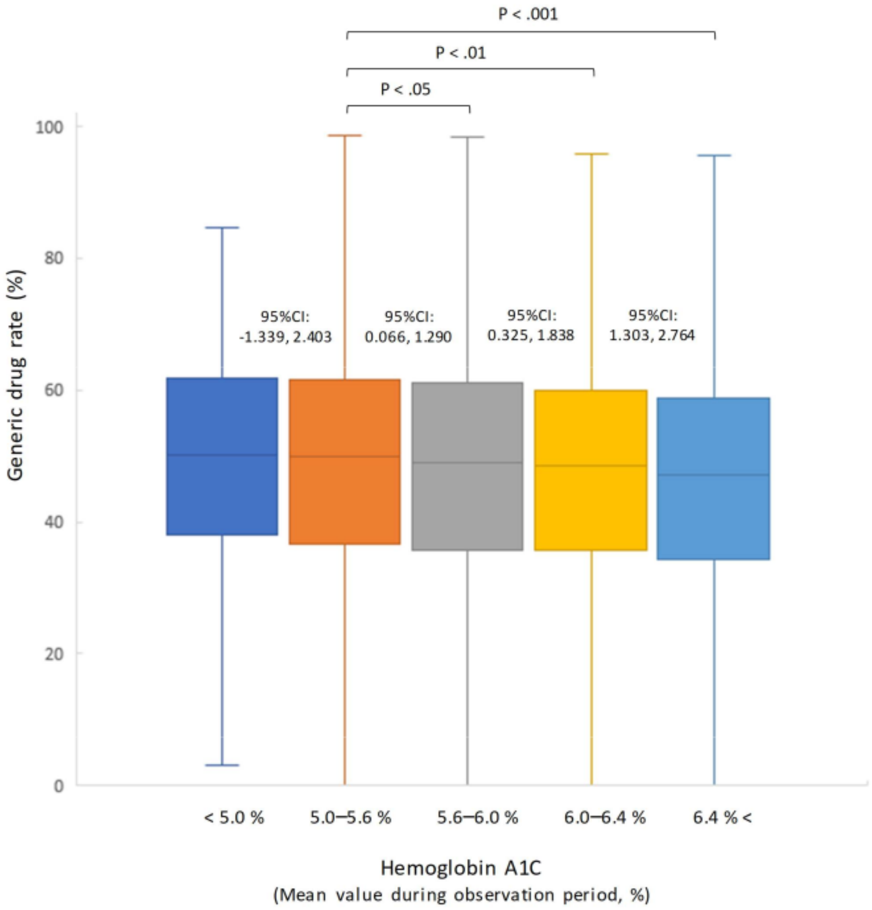

Physician-Patient Relationship and PDC as Adherence Indicators

When generic drug rates were sorted by physician-patient relationship after PSM, the superior relationship group had a significantly higher generic drug rate than the inferior relationship group (51.6%, SD 15.2% vs 47.7%, SD 17.7%; *P*<.001; Figure 7). The treatment interval cutoff value applied to the physician-patient relationship grouping (365 days) was a conservative estimate, as confirmed by the cutoff value derived from the receiver operating characteristic curve (494 days; area under the curve, 0.848; 95% CI 0.840-0.856; *P*<.001).

Multiple regression analysis with the PDC rate as the dependent variable revealed that an increase in the physician-patient relationship (standard partial regression coefficient:–0.254, *P*<.001) was a statistically significant factor for improving PDC (Table 3). The regression model (multiple regression equation, dependent variable: PDC rate) was statistically significant (*P*<.001, *df*: 10531).

Figure 7. Generic drug rate according to the physician–patient relationship after adjustment for patient background. Groups were compared using the Mann–Whitney U test. PSM: propensity score matching.

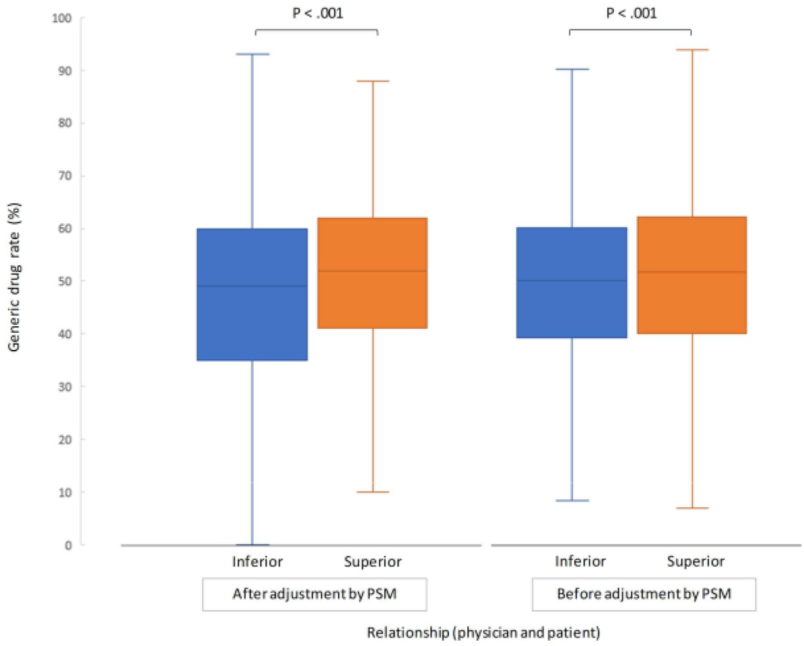

Table 3. Analysis of factors affecting the proportion of days covered rate: multiple regression analysis.

Parameter	Standard partial regression coefficient	*F* test value (*df*=10531)	VIF[a]	95% CI (partial regression coefficient)	*P* value
Relationship (binarization)[b]	–0.254	733.169	1.04	–0.018 to –0.016	<.001
Age (year)	0.136	214.004	1.03	0.000-0.001	<.001
Sex (binarization)[c]	–0.020	4.787	1.00	–0.050 to 0.003	.029
Constant term	—[d]	19.152	—[d]	0.006-0.016	<.001

[a] VIF: variance inflation factor.

[b] Relationship: binary (superior: 0, inferior: 1).

[c] Sex: binary (male: 1, female: 2).

[d] —: not applicable.

Logistic regression analysis with the physician-patient relationship as the dependent variable suggested that adherence (ASHRO: OR 1.025; 95% CI 1.021-1.029; *P*<.001) was a statistically significant factor in improving the relationship (Table 4). Age tended to improve the PDC rate (standard partial regression coefficient: 0.136, *P*<.001, Table 3) and physician-patient relationship (OR 0.982; 95% CI 0.977-0.986; *P*<.001; Table 4). The regression model (logistic regression, dependent variable: relationship) was statistically significant (*P*<.001).

Table 4. Analysis of the effect of attribute factors on physician-patient relationships logistic regression analysis.

Parameter	Standard partial regression coefficient	Standard error	Odds ratio (95% CI; partial regression coefficient)	*P* value
Age (years)	–0.064	0.002	0.982 (0.977-0.986)	<.001
Sex (binarization)[a]	0.024	0.044	1.145 (1.050-1.249)	.002
Adherence (score, improvement: low)	0.104	0.002	1.025 (1.021-1.029)	<.001

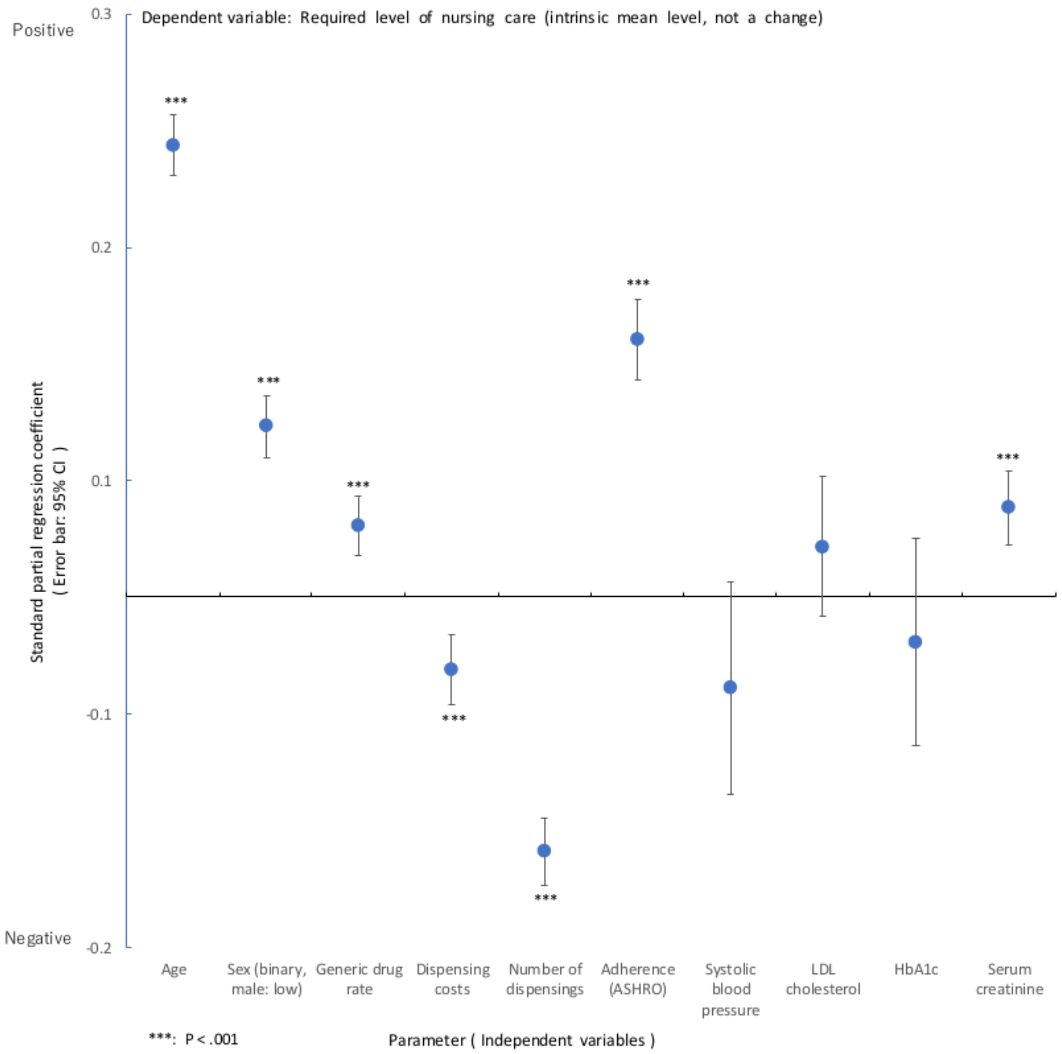
[a] Sex: binary (male: 1, female: 2).

Supplementary Analysis: Analysis Focusing on the Nursing Care Level Required, Which is a Phenomenon of Aging

In the logistic regression analysis mentioned above, no statistically significant relationship was found between the displacement in the required nursing care level and switch to generic drugs for the study population, the majority of which were older adults. This finding is noteworthy as the level of nursing care is often associated with aging, thus indicating the need to explore whether declining daily functioning owing to aging influences pharmacotherapy choices and their socioeconomic implications.

In a multiple regression analysis using the intrinsic level of nursing care (as an aging phenomenon) as the dependent variable, the rate of generic drug use among older adults requiring nursing care was found to increase (standard partial regression coefficient, 0.051, 95% CI 0.043-0.059; Figure 8). While nursing care assessments focus on daily living functions and generally show little correlation with medical severity, cognitive function was included but did not reveal significant risk factors (eg, systolic blood pressure, –0.039, *P*=.09).

Figure 8. Analysis using the required level of nursing care (intrinsic mean level, not a change), which is a phenomenon of aging, as the dependent variable: multiple regression analysis. LDL: low-density lipoprotein; HbA$_{1c}$, hemoglobin A$_{1c}$.



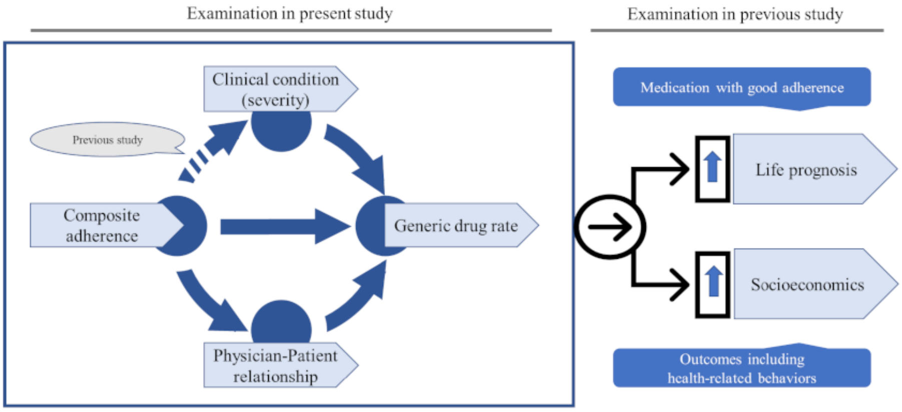
Furthermore, exploring the clinical and economic relationship between drug therapy and nursing care level, we observed that average nursing care levels tended to increase with a decrease in the dispensing frequency (standard partial regression coefficient, –0.109, 95% CI –0.123 to –0.094) and drug costs (standard partial regression coefficient, –0.031, 95% CI –0.045 to –0.016; Figure 8). Conversely, poor adherence (ASHRO) was associated with an increased nursing care level (standard partial regression coefficient, 0.110, 95% CI 0.093-0.127).

Discussion

Principal Findings

The results of this study demonstrated that improvements in the patient condition (severity) and intrinsic composite adherence were generally associated with increased generic drug switching. Furthermore, the rate of generic drug use tended to increase with improvement in the physician-patient relationship. The results also suggest that a better physician-patient relationship positively affects the PDC rate. Thus, enhancing comprehensive medical management and improving the medical environment is essential for further promotion of the appropriate selection of generic drugs. This includes fostering better relationships among stakeholders and increasing awareness among health care providers. Based on the above results and considerations, we organized the following mechanisms regarding the significance and social background of promoting generic drugs. Improvements in composite adherence improved the severity of patient illness and physician-patient relationships. Consequently, the number of prescriptions for generic drugs increased. Our previous study indicated that enhanced adherence positively impacts clinical outcomes and economic factors, such as life prognosis and medical costs [26]. Based on these conditions, it was speculated that generic drug selection would contribute to long-term clinical benefits and good socioeconomic impact (Figure 9). In addition, we speculate that the findings obtained in this study will contribute to the discussion on the prescription of brand-name drugs. However, future large-scale prospective studies are warranted to test this hypothesis.

Figure 9. Summary of the findings and interrelationships of this study.



As this study included patients with CVD who were hospitalized at least once, the cohort had a wide range of patient backgrounds. Therefore, the compositions of the prescribed medications were also widely distributed, not only for heart failure (CVD) but also for renal failure (chronic kidney disease [CKD]), endocrinology, and metabolism. For disease characteristics that repeat between the acute and chronic phases, we hypothesized that the sensitivity of health care providers to the severity (or complexity) of a patient's condition would be high. The results of this study support this hypothesis. The presence of physician distrust and patient anxiety about generics was also considered terms of the diversity of diseases and drugs addressed in the study. In previous studies, there have been many reports investigating the confidence in or validation of clinical outcomes for generic drugs [16-25]. Scattered reports involving statins and warfarin showed no difference in the clinical outcomes and PDC between brand-name and generic drugs [18-21]. On the contrary, although only as a reference, the validation of generic drugs against pregabalin and gabapentin in the pain management of neuropathic pain showed that brand-name drugs were superior in improving PDC and reducing pain [23-25]. As described above, the evaluation of generic drugs varies according to the disease mechanism and drug class. This study did not delve deeply into individual drug characteristics, as it focused on organizing the overall trends from a long-term longitudinal analysis of a large real-world sample. This is one of the limitations of this study. Future studies elaborating on the patient characteristics and drug effect categories are warranted.

Many studies on the risk factors for CVDs (angina pectoris and myocardial infarction) have been conducted in Japan. Epidemiological studies in Japan and overseas have reported that hypertension is an independent risk factor not only for stroke but also for CVDs. For example, a 10-mm Hg increase in systolic blood pressure was associated with a 1.16- to 1.40-fold increase in the risk of developing or dying from ischemic heart disease [37,38]. In this study, the switch to generic drugs tended to increase considerably with an improvement in the systolic blood pressure, despite the OR to be small. Numerous epidemiological studies have shown that hypercholesterolemia is a risk factor for CVD [39]. Hyperlipidemia is the most important risk factor for CVDs. Japanese medical insurance targets the use of relatively new PCSK9 inhibitors in patients with statin intolerance. According to the analysis in this study, the OR of the LDL-C level for switching to a generic drug was neutral. Recent reports indicate that elevated LDL-C levels do not significantly affect the risk of death or vascular events [40,41]. A similar trend was observed in this study (Multimedia Appendix 3). Given the limited information available for deeper interpretation, future studies should extensively examine marker characteristics (such as diurnal variation), pharmacotherapy control status, and the evolution of target values in clinical guidelines. In addition, diabetes mellitus, a significant risk factor for CVD, should be considered in this context [42]. In contrast, the OR of the period change of HbA_{1c} levels for switching to a generic drug was neutral in this study. However, when the generic drug rate was analyzed according to HbA_{1c} level bands, a significant decrease was observed in the abnormal values than in the normal values. The estimated glomerular filtration rate and albumin-creatinine ratio were reported to be independent predictors of future acute kidney injury, CVD, CKD, nonfatal cardiovascular accidents, and death [43,44]. In this study, an improvement in the serum creatinine levels was associated with a marked trend toward switching to generic drugs. Aspartate aminotransferase displacement was also associated with the generic drug rate. Considering these findings comprehensively, improvements in the clinical indicators may influence the decision to switch to generic drugs.

Although the OR results showed statistical significance, there were also some indicators with extremely small numerical values. Caution should be exercised when interpreting these indicators clinically. The OR represents the degree of change (risk) of the target variable relative to the change of one unit of the independent variable. Considering the blood pressure index as an example, a change of 1 mm Hg in clinical practice is considered to have minimal clinical significance for a single patient because it may be affected by measurement errors and diurnal fluctuations. Typically, a change of 10 mm Hg is considered the standard for clinical discussion. Previous research has shown that an increase of 10 mm Hg increases the risk by 1.16 to 1.40 times [37,38]. In this analysis, we did not adjust the levels of the independent variables (eg, by a factor of 10), which may explain why some indicators showed smaller results. Therefore, when interpreted in terms of actual clinical practice, results with small ORs (indicating statistical significance) can be inferred to be significant in clinical practice. Particularly when discussing the representativeness of long-term fluctuations in large groups, even small ORs can be considered meaningful in the real world. Further examination of the data processing method for each analysis and the clinical usefulness of the results is desired through the development of new research.

In this study, it was inferred that many drugs had a high percentage of effects on the treatment outcomes due to medication compliance among the drugs studied. Therefore, patient adherence is an important factor in defining treatment outcomes. Given the characteristics of the study cohort, it was desirable to consider PDC as well as other health-related behavioral factors with regard to adherence. Particularly, the contribution of disease prevention interventions to improving long-term outcomes tended to be higher in populations with CVD and CKD associated with lifestyle-related diseases. Considering these factors, this study used the composite (intrinsic) adherence (ASHRO score). The results showed that improvements in the adherence scores, along with improvements in the levels of key clinical indicators, had a remarkable effect on the rate of generic drug use. Previous reports have suggested that improved PDC contributes to improved clinical outcomes [45-47]. The results of the analysis in this study suggest that composite adherence contributes to clinical outcomes since improved adherence scores improve PDC rates. In a previous study, the group with better ASHRO scores had better long-term life expectancy [26]. Incidentally, as adherence is an integrated index that also includes a PDC component, caution should be exercised when interpreting multivariate analyses involving PDC due to multicollinearity. Considering these points, this study has certain limitations in discussing causal inferences. Therefore, further verification of the representativeness of the data sources and the accuracy of the study design is desired.

A trial analysis of the relationship between physicians and patients was conducted to consider factors other than clinical indicators and adherence when examining factors leading to generic drug switching. Due to the difficulty in developing quantitative indicators of relationships, no previous studies have been conducted. A few studies have examined the effects of the level of information provision and medical personnel’s attitudes on PDC, and no clear effects have been found [11,13,46]. According to the results of this study, improving physician-patient relationships promoted generic drug rates. Composite adherence is positively related to this relationship. Therefore, promoting a good physician-patient relationship is expected to have a clinical effect. The PDC and this relationship tended to increase as patients’ age increased, which may be due to an increase in morbidities and a learning effect on patients [10]. Because this study was a long-term longitudinal observation, the physician-patient relationship indicator, which consisted of the visit interval component, included a time effect. Therefore, we cannot rule out the possibility that this effect may have influenced the aging trends described above. In this study, the physician-patient relationship was derived vicariously from the prescription entity, with medical ethics (including medical treatment institutional contracts) as a background. Therefore, this proxy indicator has limitations in discussing the psychological “relationship of trust” as a human relationship. In addition, the influence of confounding factors on analysis is also expected. Therefore, we believe that these findings should be interpreted with caution, and further studies are warranted to verify these mechanisms.

This study also considered the influence of government health care policies that promote the use of generic drugs. However, even after adjusting for current policies, the effect of clinical parameters on the rate of generic drug use remained largely unchanged. These findings may further encourage appropriate pharmaceutical prescribing, especially if the policy diffusion of generic drugs starts to slow. Prescribing generic drugs when appropriate could yield significant long-term socioeconomic benefits in clinical settings. For example, the argument above not only highlights clinical and economic benefits but also expands health policy options, potentially reducing social risks [48]. The findings of this study are particularly relevant for older adults requiring nursing care or end-of-life care, where multifaceted decision-making (shared decision-making) by various medical professionals is essential. The results of this study provide valuable insights into the realization of this objective.

The analysis revealed that patients requiring higher levels of nursing care tended to have higher prescription rates of generic drugs. This trend may seem contradictory to the earlier discussion on the relationship between medical severity and generic drug rates. However, examining the issue from different perspectives provides clarity. Two primary hypotheses could explain this phenomenon. First, long-term care insurance often involves higher out-of-pocket costs and services not covered by insurance. This may financially constrain individuals, especially after retirement, leading them to prefer lower-cost generic drugs [49]. Second, in nursing care facilities, which typically lack pharmacists, the preference for generic drugs may be driven by their lower prices and easier handling, reflecting the practical and financial constraints of managing long-term care services.

The interpretation that higher levels of nursing care are associated with increased generic drug prescriptions was supported by the general lack of a relationship between the unchanging average nursing care level and clinical indicators. This suggests that the level of nursing care and its degree of displacement do not necessarily align. One hypothesis is that the transition from medical institutions, where new drug prescriptions are more common, to nursing care facilities, where generic drugs are preferred owing to lower costs and ease of handling, could explain this discrepancy. The finding that drug costs decrease as the required care level increases and that adherence (measured by ASHRO) is related to the nursing care level supports this hypothesis. Specifically, drugs like donepezil hydrochloride, which is used to manage cognitive function, show a relationship between adherence and the nursing care level [50]. Despite this, the population with worsening nursing care had poorer adherence, highlighting that the dimensions of care level and medical severity may differ. Adherence appears to be more sensitive to medical severity, reflecting the complex interplay between care needs and medical management.

To our knowledge, this study is the first to focus on the patient-side factors involved in switching to generic drugs, using a long-term longitudinal cohort study design. This approach offers a novel perspective on how patient characteristics, adherence, and physician-patient relationships impact generic drug use over time. However, as shown in this study, the causal relationships related to the theme were complex. In particular, there was significant variability in changes in physical function and facility type among older adults. Therefore, we believe that leveraging data science is crucial for developing research strategies tailored to drug therapy for populations with such pathological characteristics. Moving forward, it would be beneficial to expand the application of reinforcement learning, particularly using prioritized experience replay. It is known for its effectiveness in addressing diverse problems, such as game theory and resource optimization, which holds promise for advancements in preventive medicine and social medicine.

This study has the following limitations. First, it did not delve deeply into the characteristics of individual drugs and the specific backgrounds of patients. Second, careful adjustment was not made for bias among the independent variables. Third, the physician-patient relationship was analyzed using proxy indicators. Consequently, the study's design has limitations in terms of making causal inferences about this relationship.

Conclusions

The patient condition (severity) and composite adherence (intrinsic) influenced the choice of generic drugs. Adherence tended to improve, and generic rates increased as physician-patient relationships improved. To further promote the appropriate selection of generic drugs, relationships with stakeholders must be improved, and patient awareness must be raised. Further development of methods to accurately evaluate adherence and relationships would be beneficial. The findings of this study suggest a novel approach for effectively promoting the use of both generic and brand-name drugs. However, the study possesses limitations affecting its ability to draw causal inferences.

Acknowledgments

This study was partially linked to a project of the Ministry of Education, Science, Sports and Culture, Grant-in-Aid for Scientific Research(B), 2022-2024 (22H03307). The datasets generated and analyzed in the current study are not publicly available because of their high sensitivity and strict availability. However, if there is a socially and academically reasonable request, then it can be obtained from the project director. The project director is Dr. Takura, the final person in charge of this research (responsible for data management). This study was self-funded by the authors. Fujitsu Ltd provided indirect technical and professional support for the operational explanation and condition setting of the artificial intelligence tool provided by the company in a previous study related to this study.

Conflicts of Interest

TT reports grants from the Nihon Medi-Physics Co Ltd, Terumo Corporation, and Fujifilm Toyama Chemical Co, Ltd, outside the submitted work. The other authors have no conflicts of interest to declare.

Abstract

Background: Multidose drug dispensing (MDD) is an adherence aid where medicines are machine-dispensed in disposable unit bags, usually for a 14-day period. MDD replaces manually filled dosettes in many home care services in Norway. While evidence suggests that MDD can improve medication adherence and reduce errors, there are few studies on how patients manage MDD at home and how this affects their daily routines.

Objective: The aim of the study is to identify factors influencing medication self-management behavior among MDD users living at home and explore how MDD affects medication self-management.

Methods: We conducted semistructured interviews with 19 MDD users in Oslo between August 2019 and February 2020. The interviews were held at the participants' homes, and the interview transcripts were analyzed thematically.

Results: All participants in the study received some form of assistance with medication management from home care services. This assistance ranged from MDD delivery every other week to actual assistance with medication administration multiple times daily. However, regardless of the level of assistance received, participants primarily managed their MDD medications themselves. Daily medication routines and knowledge about medicines varied among the participants, with some taking an active role in their medication management, while others relied on others to take responsibility. The degree of involvement seemed determined by motivation rather than capability.

Conclusions: MDD can support medication self-management, but its effectiveness varies among patients. The level of medication management by MDD users is not solely determined by their actual capabilities. Factors such as interest in self-care and independence, available support, information, and cognitive capacity all play a role in determining the degree of autonomy.

Introduction

Medications play a crucial role in modern medicine. However, various studies have indicated that patients encounter drug-related problems and struggle with medication management [1-5]. Medication nonadherence, when medications are not taken as prescribed, has significant consequences, leading to poorer health outcomes and increased costs for society [5].

To adhere to a medication regimen, patients must undertake a series of actions that demand specific knowledge, skills, and behavior. According to the model developed by Bailey et al [6], medication self-management can be categorized into 6 phases: filling the prescription, understanding how to take the medications correctly, organizing the medication use, taking the medication, monitoring effects and side effects, and sustaining use. These phases necessitate various skills, and numerous factors can contribute to patients being unable to manage their medications correctly. For instance, the complexity of the medication regimen, impaired vision and manual dexterity, polypharmacy, medication knowledge, perceptions about the severity of one's illness, and experiences of side effects are among the contributing factors [7]. Additionally, there are medication-related risk factors, such as confusion between generic and brand names, lack of medication administration routines, hoarding, retaining discontinued medication, and involvement of multiple prescribers [8].

In Norway, as in several other countries, there is now a trend toward shorter hospital stays due to an increased focus on providing health and care services in patients' homes [9,10]. Consequently, more individuals with medication management problems are living at home with help from home care services. One of the main goals of the service is to enable individuals to live in their homes for as long as possible, both to improve the quality of life and to contain costs for the health system. One area of support often provided by home care nurses is to help with medication dispensing and administration. In Norway, about one-third of home care users get help administering their medications through multidose drug dispensing (MDD) [11].

MDD is a dispensing system where solid medications are machine-dispensed in unit-of-use disposable bags, 1 bag for each dose occasion [12]. The bags are labeled with patient information, name and strength of the medications, and date and time of day the medications should be taken. Only solid medications such as tablets and capsules can be dispensed as MDD. Although MDD systems are common in many hospitals across the world where the system has shown to reduce certain types of medication errors, only some countries use it in primary care [13]. The MDD system has the potential to reduce medication costs, improve medication adherence, and reduce medication errors also in a primary care setting [12,14]; however, like with other adherence aids, the scientific evidence to support these claims is limited [12,15-18]. In general, there are few studies on how patients manage MDD at home and how this affects their daily routines [12,17-19].

In this study, we aim to explore how MDD is used by patients living at home and how the service affects medication self-management and to identify factors influencing medication self-management behavior.

Methods

Study Design

A qualitative approach with face-to-face, semistructured, in-depth interviews was used. We used the 32-item checklist of COREQ (Consolidated Criteria for Reporting Qualitative Research) for the reporting of this study [20].

Setting

All residents in Norway have a legal right to home care services provided by municipalities [9]. In 2022, approximately 172,000 citizens in Norway received home nursing services, with about one-third receiving help with administering medications through MDD services [11].

Municipalities purchase the MDD service from 2 main suppliers in Norway. The packaging fee varies between municipalities due to tender prices, but each municipality can be reimbursed 500 NOK (US $47) per MDD user per year [21]. Home care services are responsible for selecting patients for the MDD service, although it is recommended that both the patient and their general practitioner (GP) are involved in the decision [22]. Once a patient starts MDD, the pharmacist creates an MDD “prescription card” that includes a complete list of prescribed medications, regular medications (both dispensed as MDD and in their original packaging), as-needed medications, medical devices, and dietary supplements. MDD bags are usually dispensed every 2 weeks, while other medications are dispensed in their original packaging from a local pharmacy.

MDD bags do not include package inserts, but the MDD supplier provides a copy of the prescription card, which includes dosing schedules and short descriptions of each medication’s indication for use. They also provide pictures and descriptions of the dispensed medications, including instructions on whether tablets should be swallowed whole, split, or crushed. Some MDD users have automated dispensers for their MDD bags, which can remind them when to take medications and notify home care services if medications are not taken. However, most users manage their medications directly from the MDD bags without dispensers.

Recruitment

Due to privacy reasons, recruitment had to be done via the home care service. The study recruited MDD users from 4 different home care districts in Oslo, targeting both high and low socioeconomic areas. A nurse from each district contacted users and asked if they could give their phone numbers to the first author (AVJ) for participation in this study. The nurses were asked to recruit users with varying levels of independence. The inclusion criteria were MDD use, being 18 years or older, and able to consent. Of 25 - 40 users per district, a total of 21 agreed to be contacted by the researcher (AVJ), 19 ultimately participated in the interview study. The researchers did not know the nurses or informants prior to the study.

Data Collection

An interview guide (Multimedia Appendix 1) was developed by both authors, guided by findings from previous research [23,24]. The 2 main topics of the interview guides were the use of medications and information about medications. Before the interview started, the users were also asked to put their medications in clear view, where appropriate. The interview guide was pilot-tested on 2 MDD users in November 2018, which led to minor changes in the guide. These pilot interviews were not included in the results of this study.

All interviews were completed by the first author (AVJ) in the user’s home. Two interviews had 2 participants (spouses, where both used MDD), the remaining were individual interviews. The interviews lasted from 26 to 86 minutes. Fifteen were recorded on tape and transcribed verbatim by one of the researchers (AVJ). In the remaining 2 interviews, the participants did not want to be audiotaped, and AVJ wrote down the dialogue by shorthand. Immediately after these interviews, AVJ repeated the interviews for herself based on the notes and memory. After completing approximately 15 interviews, no new data emerged; however, 2 additional interviews were made to ensure data saturation [25]. The study was conducted from October 2019 to February 2020.

Authors’ Preunderstanding

The 2 researchers (AVJ and TSB) had different backgrounds providing different perspectives. AVJ is a pharmacist, and at the time of the study, a PhD student in social pharmacy. She has worked at a community pharmacy, providing MDD to nursing home patients, and at an MDD manufacturer for many years prior to this study. TSB is a senior researcher in health service research, with previous 7 years of clinical experience as a registered nurse. Both authors have some experience (3 - 4 studies) with qualitative research.

Data Analyses

The transcripts were coded manually in Microsoft Word (Microsoft Corp). Both authors read, discussed, and structured the transcribed material and participated in the analysis of the data. To identify factors influencing medication self-management, we followed the 6 steps of thematic analysis as described by Braun and Clarke [26]. This resulted in the themes and subthemes shown in the Results section.

Ethical Considerations

This study was approved by the data protection officer at the University Hospital of North Norway (project 02003). Participants were recruited by a home care nurse due to privacy reasons. The participants received both written and oral information, including information about the length of the interviews, anonymity of responses, and data management, before signing an informed consent form. The interviews were labeled with a study identification number and not the informant’s name. During the transcribing, names of persons or places were deleted, and the recordings were deleted after all interviews were transcribed.

Results

Overview

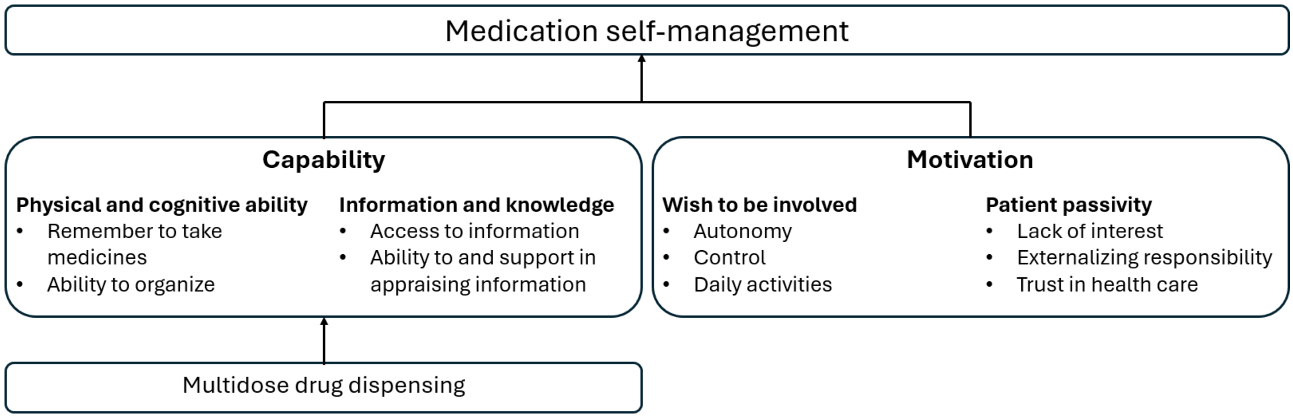
In total, 19 informants were interviewed. The majority (n=14) were female, the age range was from 59 to 92 years (Table 1). All the participants in this study had assistance with medication management from home care. For some, this only included getting the MDD delivered every other week and no other assistance, while for others this included help with both administering medications and other daily living activities several times a day. Two of the users got MDD dispensers.

Table . Characteristics of respondents.

ID	Age (years)	Sex	Home care visits
#1	76	Female	3 per day
#2	62	Female	1 per day
#3	88	Female	2 per month
#4	82	Female	3 per day
#5	71	Male	1 per week
#6	59	Female	2 per day
#7a	88	Male	1 per day
#7b	89	Female	1 per day
#8	87	Female	3 per day
#9	87	Female	1 per day
#10	92	Female	1 per day
#11	82	Male	2 per week
#12	66	Male	2 per month
#13	91	Female	1 per day
#14	72	Female	1 per day
#15	83	Female	2 per day
#16	62	Female	2 per day
#17a	82	Male	3 per day
#17b	82	Female	3 per day

There was a high degree of variation in the informants’ daily medication-taking routines as well as interest and knowledge about medications. We identified four main themes that influence the MDD user’s medication self-management at home: (1) physical and cognitive ability, (2) information and knowledge, (3) wish to be involved, and (4) patient passivity (Figure 1).

Figure 1. Main themes and subcategories of factors influencing medication self-management.



Physical and Cognitive Ability

Participants in the study highlighted the convenience of having MDDs delivered to their homes, eliminating the need to keep track of prescriptions. One participant cited this as the reason for starting MDD, as she was no longer able to walk to the pharmacy to collect her medications and had no other issues with managing them. While some participants faced challenges with opening the bags and experienced tablets falling out; overall, they expressed satisfaction with the MDD system, finding it easier to take medication correctly and appreciating the clear instructions provided.

> *Many old people have declining vision, and it's very easy to make mistakes, but when you have one of these [MDD bags] you cannot make mistakes. Everything is written here, the time to take them and everything [you need]. So, this is one of the best things they [home care] have ever started.* [Participant #15]

Mental capabilities were also discussed as a crucial factor in medication management. Organizing medication use was often cited as a challenge, leading participants or their families to request MDD services when they felt they could no longer safely keep track of their medications. Participants expressed relief in having one less thing to worry about in their daily lives when their medications were organized in the MDD bags.

> *I'm very happy with the MDD (...). Here it says the time and date and everything. Every day, so I don't have to think about it. And the dosing is correct too I assume because it's pharmacists who've done it.* [Participant #5]

While the MDD system did not provide reminders for medication intake, most participants had established routines that helped them remember to take their medications. They linked medication intake to daily activities, such as eating breakfast. Despite the assistance provided by the MDD system in organizing medication use, participants emphasized the importance of personal capacity and the potential for mistakes even with the use of adherence aids like MDD.

> *You know, when you read about things that has happened with medications. Maybe someone has got something they're not supposed to. Imagine that you've started forgetting, that can easily happen. If they have dosette boxes, that doesn't help. You can make mistakes with dosettes.* [Participant #13]

Information and Knowledge

The level of information and knowledge about medication use varied among the study participants. Some had a comprehensive understanding of their prescribed medications, including the reasons for taking them and the correct dosage. However, others had limited knowledge and were unsure why they were taking certain medications. The desire for more information did not necessarily correlate with the participant's level of knowledge. Even those with minimal knowledge expressed satisfaction with the information they received and did not express a desire to learn more.

> *I do get it [information] sometimes. A printed thing. But like I said, I'm not interested in it. I do have it around here somewhere, but I don't really know what's going on (...) I at least hope they [the medicines] don't harm me.* [Participant #4]

While most participants were aware of the prescription card that accompanied their MDD bags, many did not actively use it to keep track of their medications. Some participants found the MDD system helpful because it provided them with information about the names of their medications, which they struggled to remember before. However, there were also participants who felt that the MDD system made it harder for them to maintain an overview of their medications. One participant mentioned that they used to fill their own dosette boxes, which gave them a better understanding of their medications, but after transitioning to the MDD system, they felt they had lost control and struggled to keep track of what they were taking.

Participants expressed difficulties in obtaining the information they desired about their medications. Only a few participants actively used computers or the internet to access information. Some participants missed the information leaflets that were included with medications dispensed in their original packaging, while others desired more information on the prescription card provided with the MDD bags. Some participants felt that it was not just the lack of information itself that was challenging but also the lack of time to discuss their medications with their health care providers and receive help in understanding the information they had received.

> *I have asked [the home workers] many times. You can just read this, but that doesn't help me, I need help to understand it.* [Participant #16]

Wish to Be Involved

The patients who actively participated in the medication management process often expressed a wish or felt the need to be involved in the process. Organizing medication use and taking medications were the 2 steps they were mostly engaged in, but also to some extent seeking information about their medications. One informant phrased this as an active decision that one had to make:

> *You have to want to (...) people can't stand outside of your door telling you they will help you, you have to do something yourself as well. (...) Things don't come by itself. That's how it is with people, we tend to take the easiest way out.* [Participant #15]

Despite receiving medications in the form of MDD, participants still had to establish routines to integrate medication intake into their daily schedules. Many viewed this as the primary reason to engage in medication self-management. Several participants described how they adjusted their medication schedules based on their daily plans and activities, either by bringing the MDD bags with them or modifying the timing of medication intake. Some mentioned receiving assistance with afternoon medications only, as home care services were not available early enough for morning medication help.

Additionally, participants made adjustments to their medication routines based on their health-related needs. For instance, one participant described how she every evening opened the MDD bag for the next morning and took out the painkillers from the bag. She placed these on the nightstand so she could take them as she woke up, while the rest of the medications in the bag she left by the breakfast table to be taken a few hours later.

The desire to maintain independence and a sense of control over their situation motivated some participants to engage in self-management. For them, being able to perform tasks they were capable of themselves, rather than relying entirely on home care workers, was important for their independence and self-esteem.

> *They [home care workers] would prefer to apply the plaster (...) but I do not like being dependent on them doing it. I tell them that I manage it myself, and they have accepted that.* [Participant #10]

For users who had problems with organizing medications, the need to be involved manifested as routines to double-check the home care workers' work or the content of the MDD bags. This included actions such as sorting the tablets into egg glasses or visually inspecting and counting tablets before taking them.

Patient Passivity

All participants stated that they were capable of managing their MDD medications on their own, even those who required assistance with non-MDD medications such as inhalers, creams, or eye drops. However, not all participants took on this responsibility. One participant explained that while she was capable of taking her medications, she believed it was the home care worker's responsibility to provide them, and she only took the MDD bags herself if the home care workers had forgotten to give them to her during their visit. Another participant expressed a lack of interest in learning more about her medications, as she did not see medication management as her responsibility.

> *I take the medicines I am given. If anything goes wrong it is not my fault.* [Participant #4]

In many instances, the lack of engagement in medication self-management seemed to be related to a high level of trust in the GP or the MDD system. Participants expressed a significant amount of trust in their GPs, relying on their decisions and not questioning their prescribing practices. Most participants had been seeing the same GP for a long time and found it easy to contact them if they needed a new prescription or had questions. Given this trust in the GP and the MDD system, participants did not perceive a need to be actively involved in the medication management process.

> *No, I don't know. I take [the medicines] they tell me to take. As long as they're in the multidose bags I don't think more about it. And as you see here, there are pictures of all the tablets.* [Participant #2]

How the MDD System Affects Medication Self-Management

Many of the informants described how the MDD system helped them manage their medications, particularly with removing the need to keep track of prescriptions and help in organizing use. Based on the model of medication self-management by Bailey et al [6], the MDD system, however, affected all 5 initial phases of medication self-management:

- The first step in medication self-management—filling prescriptions and keeping track of prescriptions—was eliminated by the MDD system.
- In terms of understanding how to take medications, the MDD system appeared to reduce patients' ability to keep track of their medications, especially for those who desired and were capable of actively participating in their medication management. On the other hand, for patients who were less interested in self-care, the MDD system had either no impact or a positive one, as it reduced the amount of information they had to process.
- In terms of organizing medication use, the MDD system generally facilitated the organization of medication intake. However, participants still needed to adjust their timings and routines to accommodate their daily schedules.
- When it came to taking medications, the participants reported good overall adherence. However, there were instances of both intentional and unintentional medication nonadherence. The MDD bags provided clear instructions for the safe administration of medications, but they did not inherently help patients remember to take their medications.
- Finally, in terms of monitoring, the absence of information leaflets accompanying the MDD bags seemed to reduce users' knowledge and, consequently, their ability to monitor the effects of their medications. This lack of information

posed a potential drawback to the monitoring phase of medication self-management.

Discussion

Principal Findings

This study explored how MDD users living at home self-manage their medications. All the participants received assistance with medication management from home care. Some participants only got their MDD delivered every other week, while others received help multiple times a day. The level of engagement in medication management varied greatly among patients, primarily dependent on their motivation rather than their actual capabilities. The MDD service showed a positive impact on patient's ability to keep track of and filling prescriptions and on medication organization. However, the service could also adversely affect patient's ability to monitor their medications and decrease their knowledge about them.

Motivation to Participate

Perhaps one of the most obvious factors we found influencing medication self-management was the informants' preferences and motivation for involvement in the process. This came across as a choice informants made, which was not necessarily related to their capabilities of self-management. The reason for wanting to be involved could differ, and the users were thus not necessarily motivated and interested in being involved in all the steps. For instance, individuals who wanted to be involved for the purpose of fitting medication management into their daily schedules were not necessarily motivated to learn more about their medications or how to use them correctly.

In contrast, other participants clearly stated that they were not interested in participating and were happy with simply "following the doctor's orders." This type of "passive" medication user, who trusts their GP and with little interest of more information about their treatment, has also been described in previous studies [27-31]. There seems to be a correlation between increasing age and lower desire for participation [20,31], and in our study, most participants were older patients. The high degree of trust in the doctor's medical expertise is a predictor of medication adherence [21]. However, to accept information without question can also be a sign of inadequate health literacy, which again is associated with poorer medication adherence [22,32].

Patient preferences, while important, may not necessarily indicate how safely patients are managing their medications. Patients relying on their doctor's decisions can still make informed health choices, while those solely relying on their own judgment may make risky decisions [33]. The key lies in recognizing when to act autonomously and when to seek guidance from a physician [21].

Physical and Mental Capabilities

Poor cognition is associated with poor adherence and medication management capacity [7,34]. Informants in our study also stressed the importance of cognitive abilities in relation to medication self-management. Some had started the MDD service because of a decline in cognitive abilities and not being able to dose their medications safely anymore. However, even with adherence aids, such as MDD, informants described that cognitive abilities were still important to be able to manage these safely. This illustrates that even though MDD can support users in parts of medication management, it does not support all the phases of the process [6,35].

It is important to note that patients' capabilities and motivations to manage their medications are not always directly connected. Some capable patients choose not to manage their medications, while others who struggle still want to be involved and develop routines to maintain control, for example, sorting medications into other containers, inspecting or counting tablets, or intentionally adjusting their medication intake to fit their daily schedules. Although such alterations have previously been described as potentially reducing the safety of the MDD system and increasing the risk of medication errors [12,23,28], our participants described them as a way to regain control after transitioning to the MDD system, and in such a way, have a positive effect on their autonomy.

For some patients, MDD solved physical problems, such as difficulty walking to the pharmacy, but questions remain about whether MDD is the right tool for patients with such issues. A previous study from the Netherlands has shown that about 30% of patients with MDD, despite having some challenges, might not have lost their capacity to manage medications [36]. This raises concerns about the appropriateness of the MDD system, especially considering potential negative impacts on other phases of medication self-management.

Knowledge of Medications

Knowledge about medications is crucial for patients' ability to manage them [6,21,33]. However, studies have shown that MDD users often have less knowledge about their medications compared to those with regular prescriptions [37,38]. Many of our informants also described limited knowledge about their own medications, and more worrying some reported that the MDD service made it harder to track medications and reduced their sense of control. This is worrying, as initiation of the MDD service for patients who do not have problems with this part of medication management may lead to patients becoming more passive and less involved in their treatment, ultimately reducing their ability to self-manage medications [28,35,37,38].

However, not all users felt that MDD reduced their knowledge. One informant actually felt that their knowledge improved because the names of the medications were written on the MDD bags. This user was primarily interested in the names, and the MDD service made this information more accessible, empowering them to evaluate it. Our findings suggest that the lack of medication knowledge found in previous studies may be due to a decline in medication management capacity prior to MDD initiation. For patients with low interest or ability to evaluate information, MDD can provide much-needed support and relief, allowing them to feel more confident about correct dosing [28]. This can have a positive effect on autonomy and involvement. Therefore, a user's initial interest and capacity to evaluate medication information are crucial factors in determining whether the MDD service empowers or enables self-management.

Impact on the MDD Service and Policy

When MDD has been implemented in home care, it has been mostly seen as an aid to relieve the burden of dispensing and reduce medication errors [12]; however, this study shows that the service can affect all steps in medication management. It is thus important to consider the user's individual preferences and routines to ensure safe medication use:

- There should be a standardized assessment of the patient's medication management capabilities and motivation before starting MDD to help decide if MDD is the best solution for the patient or whether there are other forms of assistance that would be more beneficial. This assessment should identify which steps of medication management the patients have challenges with as well as to what degree they want to engage in the various steps.
- If MDD is deemed appropriate for the patient, the daily schedule of the patient should be noted so that the MDD bags can be adjusted accordingly (eg, making sure the time printed on the bags corresponds with the time the user gets up in the morning and have meals). This can help users making routines to remember to take medications.
- To ensure that patients have essential information about how to take their medications, the MDD service should make simplified medication information leaflets available to the patients. Patients should also be instructed to report to health care personnel if they experience side effects or other problems with their medication. In addition, home care workers should also have sufficient training to be able to educate and assist patients in understanding their medications better.
- For patients who have a low capacity to self-manage but still want to take an active part, the patients should be encouraged to make routines that provide a sense of control and flexibility (eg, routines for checking the contents of the MDD bags and allow for alterations of the bags under supervision).

Strength and Limitations

This study is one of the few to examine how patients use adherence aids at home [12,17-19]. We included users from diverse socioeconomic backgrounds and with varying levels of home care assistance. However, it is important to note that the participants were all from one municipality, so the findings may not be easily applicable to other municipalities with different organization of home care services. It is also important to consider that patients who were very unhappy with the MDD service may have stopped using it, and their perspectives are not included in this study. Additionally, the voluntary nature of participation and recruitment by home care nurses may introduce a bias toward more empowered patients. Although the researchers have different educational background and age, both are female and Norwegian, and we discussed our sociocultural positions and value systems during the research process to try to limit the effect of preunderstanding bias.

Conclusions

This study gives valuable insight into how the MDD service is used by home care users to support medication self-management. This study indicates that MDD can support users in their medication self-management and increase patient's autonomy. However, the service does not support all phases of the medication process or support self-management for all patients. The degree to which MDD users manage their medications is not necessarily related to their actual capabilities for medication self-management. The patients' own motivation for participating seems to be the most important factor affecting participation.

Acknowledgments

The authors would like to thank the health care workers for their help with recruiting patients for this study as well as the patients who participated for sharing their experiences.

Abstract

Background: Patients with knee osteoarthritis (KOA) often present lower extremity motor dysfunction. However, traditional radiography is a static assessment and cannot achieve long-term dynamic functional monitoring. Plantar pressure signals have demonstrated potential applications in the diagnosis and rehabilitation monitoring of KOA.

Objective: Through wearable gait analysis technology, we aim to obtain abundant gait information based on machine learning techniques to develop a simple, rapid, effective, and patient-friendly functional assessment model for the KOA rehabilitation process to provide long-term remote monitoring, which is conducive to reducing the burden of social health care system.

Methods: This cross-sectional study enrolled patients diagnosed with KOA who were able to walk independently for 2 minutes. Participants were given clinically recommended functional tests, including the 40-m fast-paced walk test (40mFPWT) and timed up-and-go test (TUGT). We used a smart shoe system to gather gait pressure data from patients with KOA. The multidimensional gait features extracted from the data and physical characteristics were used to establish the KOA functional feature database for the plantar pressure measurement system. 40mFPWT and TUGT regression prediction models were trained using a series of mature machine learning algorithms. Furthermore, model stacking and average ensemble learning methods were adopted to further improve the generalization performance of the model. Mean absolute error (MAE), mean absolute percentage error (MAPE), and root mean squared error (RMSE) were used as regression performance metrics to evaluate the results of different models.

Results: A total of 92 patients with KOA were included, exhibiting varying degrees of severity as evaluated by the Kellgren and Lawrence classification. A total of 380 gait features and 4 physical characteristics were extracted to form the feature database. Effective stepwise feature selection determined optimal feature subsets of 11 variables for the 40mFPWT and 10 variables for the TUGT. Among all models, the weighted average ensemble model using 4 tree-based models had the best generalization performance in the test set, with an MAE of 2.686 seconds, MAPE of 9.602%, and RMSE of 3.316 seconds for the prediction of the 40mFPWT and an MAE of 1.280 seconds, MAPE of 12.389%, and RMSE of 1.905 seconds for the prediction of the TUGT.

Conclusions: This wearable plantar pressure feature technique can objectively quantify indicators that reflect functional status and is promising as a new tool for long-term remote functional monitoring of patients with KOA. Future work is needed to further explore and investigate the relationship between gait characteristics and functional status with more functional tests and in larger sample cohorts.

Introduction

Knee osteoarthritis (KOA) is a degenerative and irreversible joint disease with typical symptoms including pain, stiffness, decreased joint mobility, and gait disturbance [1,2]. These symptoms worsen with the progression of the disease and may lead to serious treatment consequences, such as total knee replacement and the need for corresponding gait correction rehabilitation training. In recent years, the number of individuals diagnosed with KOA has rapidly increased owing to the aging of the global population and the rising prevalence of obesity. KOA is the primary cause of dysfunction among older adults, placing an extensive burden on both socioeconomic and medical systems [3]. Assessment of physical function in KOA is a crucial component of documenting and evaluating rehabilitation progress [4,5], which will accelerate the establishment of new diagnostic criteria and effective rehabilitation methods [6-8]. Traditional radiography presents limitations as a static assessment tool and cannot achieve long-term dynamic functional monitoring [9]. Both patient-reported outcomes (PROs) and performance-based measures (PBMs) have been used to assess physical function in KOA, but there is no universally recognized gold standard for evaluation [10]. Although PROs are convenient and cost-effective, their high subjectivity and susceptibility to patient's pain and emotions can lead to biased results. Moreover, they are not suitable for individuals with depression or cognitive impairment [5,11]. PBMs are objective and effective evaluation methods, considering factors such as time, cost, equipment, space, and management burden comprehensively. The OARSI (Osteoarthritis Research Society International) recommended a set of performance-based physical function tests, such as the 40-m fast-paced walk test (40mFPWT) and timed up-and-go test (TUGT) [12], whose validity and reliability have been validated by many research reports [13]. However, PBMs still need to be conducted in specific locations, such as hospitals or rehabilitation clinics, and under the supervision of well-trained medical practitioners. Therefore, developing a simple, fast, effective, and user-friendly method for functional assessment is beneficial to relieve the burden on the health care system in society.

Researchers are now able to easily acquire vast amounts of biomedical data through wearable sensors, including pressure sensors [14], inertial measurement units [15,16], and electromyography sensors [17]. The application of machine learning technology for the analyzing and processing of this data facilitates the identification and prediction of human physiological conditions and disease risks [18], thereby offering new opportunities for attaining personalized health care and health management [19]. Plantar pressure signal has shown potential applications in the diagnosis and rehabilitation evaluation of KOA. Studies [20-24] have shown that patients with KOA are prone to abnormal gait or gait dysfunction due to pain, stiffness, limited joint range of motion, and other symptoms, and their gait patterns are specifically characterized by unstable gait and high variability. Naili et al [1] found gait deviations between patients with KOA and healthy population through 3D gait analysis and suggested that PBMs may be more closely associated with overall gait pattern deviations in patients with KOA than PROs or perceived pain. In addition, statistical analysis of foot pressure parameters measured by the F-Scan (Tekscan, Inc) system showed that the pressure in the thumb and heel area of patients with KOA as a percentage of weight was significantly lower than that in healthy people, but the central region was higher [25,26]. Moreover, the center of pressure (COP) path range was smaller in the KOA group than in the healthy group, which may be due to incomplete gait in patients with KOA [27].

Unlike inertial measurement units, plantar pressure sensors provide stable and accurate plantar pressure distribution data, which is essential for accurate gait analysis, without being affected by changes in the wearing position or method. In contrast to force platforms, instrumented treadmills, and 3D gait analysis technologies [28], footwear systems with embedded foot pressure sensors can overcome the limitations of laboratory settings and enable long-term remote monitoring by inconspicuously integrating them into everyday footwear. Previous work on the functional evaluation of KOA using wearable pressure sensors has focused on PROs such as the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) [19,29] and Knee Osteoarthritis Outcome Score [8]. However, the connection between KOA gait characteristics and more objective PBMs has rarely been explored. Table 1 summarizes the differences between important relevant studies and ours per methods, gait features, and objectives.

Therefore, in this study, a wireless in-shoe system integrating a low-cost, high-durability foot pressure sensor was used to collect plantar pressure data during walking for patients with KOA. The performance of the shoe system used has been validated in previous research, demonstrating its ability to effectively monitor human gait dynamics information in real time for daily use, and has been applied to the detection of diabetic feet [30] and fall risk assessment studies in older adults [31,32]. We suggest that there is a mapping correlation between functional performance and gait features in patients with KOA. From the raw plantar pressure data, spatiotemporal parameters were extracted to construct a KOA gait feature database customized for wearable plantar pressure sensors. This construction involved expanding the dimensionality of gait features through mathematical methodologies. Effective feature selection and analysis were performed for the 40mFPWT and TUGT tasks, respectively. The objective of this study is to develop a functional evaluation model using multidimensional plantar pressure features to monitor and assess the functional performance of patients with KOA, potentially serving as a self-managed rehabilitation tool to provide long-term remote dynamic functional monitoring and progress recording for patients with KOA [33].

Methods

Recruitment and Data Collection

The research enlisted 92 adults diagnosed clinically as patients with KOA, exhibiting varying degrees of severity as evaluated by the Kellgren and Lawrence classification. These participants demonstrated independent walking capability for a duration of 2 minutes. All participants were sourced from Zhujiang Hospital of Southern Medical University, and the tests were administered under the guidance of proficiently trained medical personnel.

Participants were thoroughly briefed on the procedures and paradigm of the functional tests before they underwent the assessments. Adequate intervals were implemented between each test session to avoid the impact of fatigue. Successively, the participants underwent the TUGT and 40mFPWT to respectively evaluate the patients' overall functional mobility, balance capacity, short-distance walking performance, and gait speed. The TUGT and 40mFPWT scores indicate the time taken to complete the test, with higher scores representing worse patient function. Table 2 summarizes the participants' demographic characteristics and physical function tests. The results of the Mann-Whitney *U* tests revealed no statistical difference between male and female groups in the 40mFPWT and TUGT outcomes (*P*=.48 and *P*=.50, respectively).

The footwear system used for the collection of plantar pressure data has been detailed in prior studies [30]. Each shoe is equipped with eight integrated pressure sensors capable of detecting vertical ground reaction forces during walking. The sensor position distributions and corresponding pressure-sensing regions are illustrated in Figure 1A. Before formal data collection, participants were required to wear suitable socks and shoes. Ample time was provided for participants to adjust and ensure proper fitting of the shoes before engaging in natural walking. The participants were then asked to walk independently back and forth in a 20 m corridor at a freely walking speed for 2 minutes to simulate everyday locomotor activities. The shoe system collected plantar pressure signal data during walking at a frequency of 20 Hz and transmitted it to a mobile phone in real time via Bluetooth (Bluetooth Special Interest Group; Figure 1B).

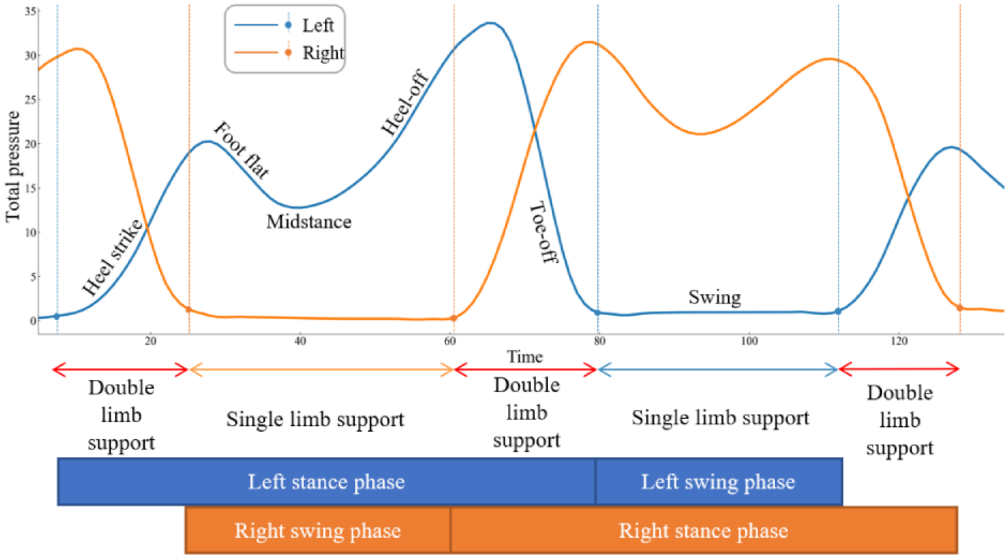
Feature Extraction

Overview

Feature extraction is a crucial step in gait data analysis and should adhere to the following principles. First, the features should have clear biomechanical meaning and be objectively observable. This ensures the physiological relevance of the extracted variables. Second, these features should exhibit generality across all participant types. The second principle is particularly pivotal because generalization directly affects the robustness of machine learning techniques [34]. Human gait is a periodic activity composed of the stance phase and the swing phase. In the stance phase, the pressure sensors in the corresponding regions of the heel, middle foot, and forefoot are activated successively as the gait advances. Before feature extraction, gait cycle segmentation is performed on the acquired temporal signal data of plantar pressure. A single gait cycle is divided by identifying the rise point of the total pressure curve from the 8 sensors when the heel strikes the ground, representing a gait cycle from heel strike to the end of the swing phase. When the toe is off the ground, the total pressure curve drops to its minimum value as the dividing point of the terminal stance and preswing phases, as shown in Figure 2. Excluding the starting step of the first 2 steps, the next 50 gait cycles with the left and right feet adjacent were selected as a sample for feature extraction and analysis.

Multidimensional features would be extracted based on the weight-normalized plantar pressure data obtained by the shoe system. The basic features include the single-foot feature extracted for each foot and the bipedal feature. Then the symmetry coefficient feature, SD feature, and the weak foot feature were calculated based on the single foot feature, which greatly enrich the plantar pressure feature database. We refer to some common plantar pressure feature extraction methods reported in previous studies [25,30,31] and perform corresponding feature extraction according to the sensor deployment position of our plantar pressure shoe measurement system. In addition, we not only focus on the extreme value features of a single sensing unit but also analyze the plantar pressure features corresponding to the transition of different stages in the gait cycle. The relevant features of the single sensing region and the combined sensing region corresponding to the subphases of the stance phase were extracted.

Figure 2. The total VGRF of the left and right feet in a gait cycle and the segmentation points of gait stages are shown. VGRF: vertical ground reaction forces.



Peak Plantar Pressure

Peak plantar pressure (PPP) represents the maximum load on the underfoot area during one step. Taking the left foot as an example, the calculation formula for each sensor's PPP is expressed as equation 1. The maximum pressure values for the eight regions of both the left and right feet are extracted respectively within one step. Here, s ∊ (1,8) denotes the sensor number, $P_s(n)$ represents the pressure data sequence of the corresponding sensor s, and n indicates the time sampling points. $L_{1\text{-}4}$PPP, $L_{5\text{-}6}$PPP, and $L_{7\text{-}8}$PPP represent the peak pressure combination of the sensors corresponding to the left forefoot, middle foot, and heel in one gait cycle, respectively. The total vertical ground reaction forces in a gait cycle exhibit a bimodal pattern, where the first vertical force peak (L_peak1) is caused by a heel strike, and the second peak (L_peak2) is attributed to the forward movement of the center of gravity during walking. The $L_{4/2}$PPP and $L_{8/7}$PPP represents the ratio of peak pressure in the lateral and medial regions of the left forefoot and heel, respectively. In this part, a total of 30 left and right foot features were extracted.

Pressure Gradient

Pressure gradient (PG) quantifies the rate of change of pressure over time, reflecting the rapidity of pressure curve fluctuations beneath the foot during locomotion. Positive PG indicates rapid pressure rises during foot-floor contact phases, while negative PG corresponds to swift pressure declines. The maximum and minimum PG of each sensing curve of both feet can be calculated by equations 2 and 3, where Δt is the sampling time interval. Partial region combination sensing can be used to describe the characteristics of state transition between substages of the gait cycle. For instance, $L_{1\text{-}4}$MaxPG represents the maximum gradient change upward when the center of gravity shifts to the forefoot of the left foot. On the other hand, $L_{1\text{-}4}$MinPG signifies the maximum negative gradient change when the toes lift off the ground, corresponding to the downward pressure curve. The $L_{5\text{-}6}$MaxPG and $L_{5\text{-}6}$MinPG in the midfoot region reflect the pressure change during the foot flat and heel-off phases, respectively. Similarly, $L_{7\text{-}8}$MaxPG and $L_{7\text{-}8}$MinPG in the heel region denote the changes during the heel strike and foot flat phases, respectively. The loading rate (L_loadr) is PG calculated by the first peak pressure and the initial contact pressure of the stance phase. The off-loading rate (L_unloadr) is PG calculated by the second peak pressure and the end pressure of the stance phase. The L_valleyPG represents the sum of the absolute values of the gradient at each sampling point between the 2 peaks for the total pressure curve, describing the degree of pressure variation of the 2 peaks. This section extracts a total of 50 features from both feet.

Temporal Features

As depicted in Figure 2, the gait cycle can be divided into the stance and swing phases. Taking the left foot as an example, the single-foot temporal features include the ratio of time between the stance and swing phases (L_tst/sw), the gait cycle time (L_tT), the ratio of stance phase to gait cycle time (L_tst/T), and the proportion of the time to reach the first ($L_t t_1$/T) and second peaks ($L_t t_2$/T) in the total gait cycle time. Bipedal temporal features include single-limb support time and double-limb support time [35]. This section extracts a total of 12 temporal features.

Pressure Time Integral

By quantifying the accumulated pressure over the duration of the stance phase beneath discrete foot regions, the pressure time integral (PTI) depicts the total mechanical dose imparted to soft tissues during one step. However, PTI shows a high concordance with PPP [36]. To avoid redundancy, only the PTI of the global region is extracted here. PTI from heel strike to the first peak pressure (LPTI_1) and PTI of the stance phase (LPTI_st) were extracted from equation 4. In this part, a total of 4 left and right foot features were extracted.

COP Features

COP is a commonly used dynamic parameter to track weight transfer. During the gait cycle from heel strike to toe-off, a series of coordinates for the COP trajectory can be obtained by calculating the weighted average of all pressure inputs acting on the foot, as defined by equation 5. Here x_s and y_s represent the sensor coordinates, which are converted into a unified coordinate system before computation, considering different shoe sizes [31]. Take the left foot during one step, for example, the mean and SD of COP trajectory in the medial-lateral direction (L_{xcop}mean, L_{xcop}std) and for anterior-posterior direction (L_{ycop}mean, L_{ycop}std) were calculated. Length of the COP trajectory (L_{cop}len) can be calculated by equation 6. The resultant distance (RD) is the Euclidean distance between 2 points in COP coordinates. The mean (L_{cop}MRD) and SD of RD (L_{cop}SRD) can be calculated by equations 7 and 8, respectively [31]. In this part, 14 features of the left and right feet were extracted.

So far, a total of 54 single-foot features and 2 bipedal temporal features during one step have been extracted, and these will be averaged over 50 gait cycles. The following feature construction is to further expand the dimension of gait features through mathematical methods.

Symmetry Index

Asymmetrical gait patterns may be present in patients with KOA with functional impairment [37]. The symmetry index (SI) for the mentioned 54 single-foot features can be calculated by equation 9, where L_f and R_f represent the corresponding left and right foot features, respectively. In this part, 54 corresponding SI features are extracted and named with SI prefixes.

SD Feature

Patients with KOA often exhibit an unstable and highly variable gait pattern. Therefore, it is essential to extract the variability of relevant features across consecutive gait cycles. In this session, the SDs of 108 single foot features on both sides during 50 gait cycles were calculated and named with the suffix STD.

Weak Foot Feature

In previous studies [38], values reflecting lower performance were chosen from the features calculated separately for each leg. To further enhance the value of the extracted data variables and reduce the dependence of predictive models on extraction sides, this study refers to previous research on fall risk prediction in older adults [31] and extracts the weak foot features, that is, the features of the foot with weaker functional performance between the 2 feet. Features derived from the weaker side are posited to perhaps carry more predictive value for functional estimations. Weak foot features can be identified by anterior-posterior direction variability:

In this part, 108 weak-foot features named with the W prefix are extracted from the mean and SD of both foot single-foot features.

Physical Characteristics

Physical characteristics correlate with functional performance, so age, height, weight, and BMI are also included in the feature database.

All extracted features contained in the feature database are listed in Table 3. The related features of the left foot are named with the prefix L and the right foot with the prefix R.

Table 3. List of features.

Kinds of features	Features	Number

[a] PPP: peak plantar pressure.

[b] L: left foot.

[c] $_s$: sensor.

[d] s: sensor.

[e] $_{1-4}$: forefoot.

[f] $_{5-6}$: middle foot.

[g] $_{7-8}$: heel.

[h] peak1: first vertical force peak.

[i] peak2: second vertical force peak.

[j] $_{4/2}$PPP represents the ratio of peak pressure in the lateral and medial regions of the forefoot.

[k] $_{8/7}$PPP represents the ratio of peak pressure in the lateral and medial regions of the heel.

[l] R: right foot.

[m] PG: pressure gradient.

[n] Min: minimum.

[o] Max: maximum.

[p] $_{1-4}$MaxPG represents the maximum gradient change upward when the center of gravity shifts to the forefoot.

[q] $_{1-4}$MinPG signifies the maximum negative gradient change when the toes lift off the ground, corresponding to the downward pressure curve.

[r] $_{5-6}$MaxPG in the midfoot region reflect the pressure change during the foot flat phase.

[s] $_{5-6}$MinPG in the midfoot region reflect the pressure change during the heel-off phase.

[t] $_{7-8}$MaxPG in the heel region denote the changes during the heel strike phase.

[u] $_{7-8}$MinPG: in the heel region denote the changes during the foot flat phase.

[v] loadr: loading rate.

[w] unloadr: off-loading rate.

[x] valleyPG: the sum of the absolute values of the gradient at each sampling point between the 2 peaks for the total pressure curve, describing the degree of pressure variation of the 2 peaks.

[y] $_t$: time.

[z] st: stance phase.

[aa] sw: swing phase.

[ab] T: gait cycle time.

[ac] t_1: first peak.

[ad] t_1: second peak.

[ae] PTI: pressure time integral.

[af] COP: center of pressure.

[ag] $_x$: medial-lateral direction.

[ah] std: SD.

[ai] $_y$: anterior-posterior direction.

[aj] len: length of the center of pressure trajectory.

[ak] MRD: mean of resultant distance.

[al] SRD: SD of resultant distance.

[am] SI_f: The corresponding symmetry index features of both feet.

[an] W_f: mean value of weak foot features.

[ao] W_f_STD: SD of weak foot features.

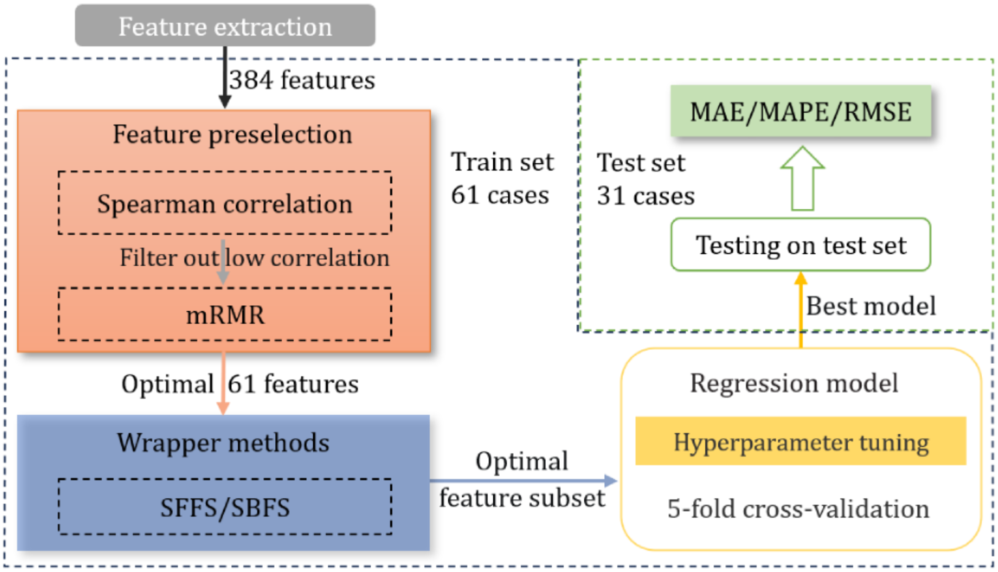
Feature Selection

Overview

In the feature extraction process, a total of 380 gait features and 4 physical characteristics were extracted to form the feature database. For machine learning model training, high-dimensional data not only increases computational workload but also results in severe overfitting, leading to poor generalization performance of the model. Therefore, before developing regression prediction models, it is necessary to undertake feature selection from the extensive feature database to alleviate the curse of dimensionality [39]. If the data of all participants is used during the feature selection process, it may lead to premature use of the testing set in feature selection, causing information leakage and inflating the model's performance. Therefore, before feature selection, we used a holdout method by randomly partitioning 33% (31 cases) of the data as an external testing set, while the remaining 67% (61 cases) of the data is designated as the training set for feature selection, model development, and performance comparison. The testing set is strictly excluded from both the feature selection and model development processes, ensuring that the model exhibits objective and genuine generalization performance when confronted with new participants. Figure 3 illustrates the pipeline of feature selection and model development.

There are various methods for feature selection, mainly categorized into filter, embedded, and wrapper methods. This study used correlation analysis and the filter method, specifically the Minimum Redundancy and Maximum Relevance (mRMR) [40], as a preliminary feature selection. Subsequently, the wrapper methods were used to further determine the optimal feature subset. The stepwise reduction of the feature space through the combination of multiple methods proved effective in identifying valuable features. Meanwhile, principal component analysis [41], a popular feature dimensionality reduction method, was used as a benchmark for comparison to evaluate the effectiveness of the stepwise feature selection approach. The same machine learning model was trained on the reduced datasets and cross-validation was used to evaluate the performance of different methods.

Figure 3. Pipeline of feature selection and model development. MAE: mean absolute error; MAPE: mean absolute percentage error; mRMR: Minimum Redundancy and Maximum Relevance; RMSE: root mean squared error; SBFS: Sequential Backward Floating Selection; SFFS: Sequential Forward Floating Selection.



Spearman Correlation Coefficient

Conducting Spearman correlation analysis between each feature and the corresponding task labels on the training set, features with low correlation ($|r|<0.2$) are eliminated to enhance computational efficiency.

About mRMR

Owing to the possible information redundancy between single-foot features and weak-foot features, it is not conducive to the speed, accuracy, and interpretability of the training results. The mRMR is a minimal-optimal feature selection algorithm that can find a subset of features in a machine learning task that has the greatest correlation with the target variables and the least redundancy between them [40]. Choose the optimal feature for the next feature selection, ensuring that its number does not exceed the number of samples in the training set.

Wrapper Methods

After feature preselection using statistical analysis methods, the wrapper methods based on the machine learning model are used for a more comprehensive feature selection. The wrapper methods determine the optimal feature subset through the average performance of cross-validation. This paper uses Sequential Feature Selection algorithms, including Sequential Forward Floating Selection and Sequential Backward Floating Selection, to automatically determine the optimal feature subset based on their impact on the performance of a user-defined model [42]. These 2 algorithms are implemented using *mlxtend* (version 0.20.0 for Python 3.7; Python Software Foundation) [43].

Regression Model Development and Evaluation

After stepwise feature selection, a subset of features most relevant to the current problem is identified for developing machine learning models. The models considered include linear regression (LR), support vector machine (SVM), random forest (RF), Adaptive Boosting (AdaBoost), Extreme Gradient Boosting (XGBoost), and Light Gradient Boosting Machine (LGBM). Hyperparametric tuning of each model was performed using Optuna (Preferred Networks, Inc) [44] and 5-fold cross-validation was used to evaluate the results.

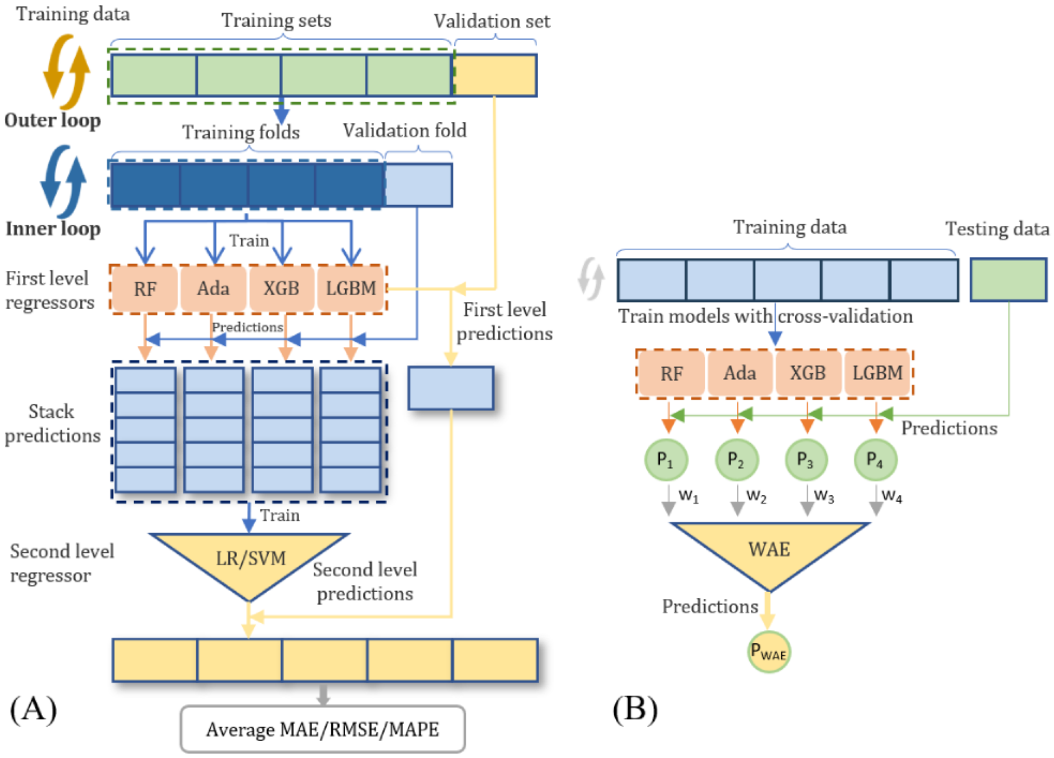
Based on the training results of each model and referring to previous studies [45], the 2-level ensemble learning model was constructed using the stacking regression method [46], as shown in Figure 4A. The training data were randomly partitioned into 5 mutually exclusive subsets, 4 of which were used as 5-fold cross-validation of the inner loop to train the models. At the first level, 4 decision-tree-based regressors including RF, AdaBoost, XGBoost, and LGBM were used to fit the training folds, respectively, and then predict the validation fold. The predictions from these 5 rounds were stacked to form the input features for the second-level regressor, which uses a simple model such as LR or SVM. The validation set of the external loop is used to evaluate the performance of the stacking model and hyperparameter tuning. Additionally, for comparison purposes, simple average ensemble (SAE) and weighted average ensemble (WAE) were also adopted to construct 2-level models for these 4 tree-based models. The final prediction of the SAE model is obtained by taking the average of the predictions from all individual models, while WAE assigns different weights to the predictions of each model according to their performance, allowing models with better performance to have a greater influence on the final prediction, as shown in Figure 4B. The ensemble model can reduce variance, enhance robustness, and improve generalizability by combining the prediction results from multiple models.

Mean absolute error (MAE), mean absolute percentage error (MAPE), and root mean squared error (RMSE) were used as regression performance metrics to evaluate the results of different models [47,48]. To avoid deceiving performance caused by data bias, the average of the known training set labels is used as the prediction of the unknown test set to calculate these metrics as the performance of the baseline model. The improvement of each metric for each model relative to the baseline model is calculated and normalized into a regress relative index (RI) to comprehensively evaluate the model performance [49,50], as shown in equation 11.

Where $model_i$ and $baseline_i$ represent the performance metrics corresponding to each model and the baseline model, respectively.

Models with high RI values will be considered as candidate regressors for 2-level ensemble learning models. The contribution of each model in WAE prediction was weighted according to the proportion of their RI value. The final predicted value $\hat{y}_{WAE}$ of the WAE model can be calculated by equation 12.

Figure 4. (A) Flowchart of stacking regressors with nested 5-fold cross-validation. (B) The prediction process of the WAE model. Ada: Adaptive Boosting; LGBM: Light Gradient Boosting Machine; LR: linear regression; MAE: mean absolute error; P: prediction; RF: random forest; RMSE: root mean squared error; MAPE: mean absolute percentage error; SVM: support vector machine; W: weight; WAE: weighted average ensemble; XGB: Extreme Gradient Boosting.



Ethical Considerations

All experimental procedures were approved by the institutional review board of Zhujiang Hospital of Southern Medical University (IRB 2019-KY-016-02). This study ensures informed consent with the right to withdraw. Participants' privacy is safeguarded through data anonymization. Compensation for human subjects involved a payment of CN ¥200 (CN ¥1=US $0.14) per individual.

Results

Feature Selection Results

Table 4 shows the benchmark experimental results of feature selection, comparing the performance of various algorithms using the RF regressor as the base model, and it can be seen that the method using stepwise feature selection performs better than the principal component analysis algorithm in both tasks.

After applying the Spearman correlation coefficient to filter out low-correlation noise features, the 40mFPWT task retained 161 features and the TUGT task retained 131 features. Then select an optimal subset of 61 features with mRMR, which was set to not exceed the number of training samples. For 40mFPWT, the subset of 11 features identified by the Sequential Backward Floating Selection method yields the best performance. For TUGT, the optimal feature subset determined by the Sequential Forward Floating Selection method consists of 10 features. The optimized feature subsets and Spearman correlation coefficients for both tasks are depicted in Figure 5.

Evaluation of Machine Learning Regression Model

After feature selection, six regression models were trained and their hyperparameters were tuned using Optuna with 5-fold cross-validation for both the 40mFPWT and TUGT tasks, respectively. RF, AdaBoost, XGBoost, and LGBM were used as first-level regressors for the stacked model, and the performance of LR and SVM as second-level regressors were compared, respectively. SAE combines the predictions from 4 trained tree-based models equally, while WAE weighs the contribution of each ensemble member proportionally based on RI value. The performance of each model compared with the baseline model is shown in Table 5 for 40mFPWT and Table 6 for TUGT. Among individual models, the LGBM model achieved the best predictive performance in the 40mFPWT task, while the XGBoost model performed best in the TUGT task.

The performance of the stacking model using SVM as the second-level regressor is better than that using LR in both tasks. The average integration model using the WAE strategy has better performance than that using SAE in both tasks.

Prediction Outcomes for Functional Tests

The best-performing trained models obtained from optimizing hyperparameters on the training set were used to generate predictions for the holdout test set, including the individual model, stacked model, and average ensemble model. The results in the holdout test set for the 40mFPWT are shown in Table 7 and for the TUGT are shown in Table 8. Among all models, the WAE model using 4 tree-based models has the best generalization performance in the test set, with MAE of 2.686 seconds, MAPE of 9.602%, and RMSE of 3.316 seconds for the prediction of 40mFPWT, and for TUGT with MAE of 1.280 seconds, MAPE of 12.389%, and RMSE of 1.905 seconds.

Discussion

Principal Findings

This study developed a functional evaluation model using multidimensional plantar pressure features to predict the functional performance of patients with KOA. The plantar pressure data collected by the shoe system were preprocessed through feature engineering. These features were then input into the trained model to enable prediction and thereby realize functional assessment and monitoring of patients with KOA.

The results of feature selection indicated that age was the most relevant predictor of functional performance on the 2 tasks. It is reasonable that higher age correlated with a longer duration to finish the function tests, and therefore poorer function (Figure 5). Notably, 4 features showed negative correlations with 40mFPWT outcomes (Figure 5A). Specifically, higher values of the $L_{7\text{-}8}$PPP feature were associated with better functionality, aligned with previous findings that individuals with KOA tend to exhibit diminished plantar pressure in the heel region [25,26]. Four SI features were selected for the TUGT task. This is likely because diseases or impairments that impact proprioception or postural stability could thereby influence balance performance on the TUGT by altering one's symmetry [51]. The results showed that plantar pressure–derived features in the forefoot and rearfoot regions, specifically PG and PPP values, exhibited relatively strong correlations with functional test outcomes. In addition, COP-derived features, SI features, and weak foot features were selected and exhibited relatively strong correlations with functional test outcomes. These observed relationships are biologically plausible and concordant with existing understandings of pathological gait patterns in populations with KOA.

The performance of the baseline model, which uses the mean of known labels in the training set as predictions for the test set, provides an unbiased evaluation metric without issues of overfitting or overoptimism. The model-free nature of this design ensures a fair assessment of predictive gains attributable to model architecture rather than data traits. The RI value of each model was obtained by calculating the sum of the improvement of each performance metric relative to the baseline. A higher RI value represents better overall model performance. The results demonstrate that tree-based models outperform LR and SVM models significantly (Tables 3 and 4). Using SVM as the second-level regressor in the stacked model yields better results than LR, primarily attributable to SVM's ability to handle nonlinear relationships and demonstrate robustness against outliers in the data. Within the averaged ensemble framework, the WAE model outperformed the SAE model, possibly due to its weighted aggregation mechanism. The WAE model produced superior outcomes by assigning higher weights to individual models with higher predictive power, thereby generating more refined ensemble predictions.

Due to feature selection being performed on the training set, the models may still overfit the training set even with the use of cross-validation techniques, resulting in overly optimistic performance estimates. Therefore, in general, the model performs better on a training set than on a holdout test set containing unknown samples. The performance on the test set provides a more robust evaluation of the models' generalization capability when encountering new data. The results indicate that the WAE model demonstrated the best generalization performance in both tasks, rather than the stacked model that used SVM as the second-level regressor (Tables 5 and 6). This aligns with the principle of Occam razor in model selection which is to prefer the more parsimonious model when performance is otherwise comparable [52].

Based on the prediction results from the 2 functional tests, the features we extracted appear to have a reasonably close correlation with functional performance. The models demonstrated good generalization for predicting traditional clinical function tests. In the future, the model could be integrated into a terminal application to longitudinally monitor patients' functional status. The identified plantar pressure features could serve as an evaluation tool to guide the rehabilitation and assessment of progress for patients with KOA, offering clear advantages per time efficiency, longitudinal documentation, and accuracy compared to conventional functional tests.

The findings of this study have significant clinical implications for the management and rehabilitation of patients with KOA. The proposed techniques enable continuous, real-time monitoring of patients' functional status beyond clinical settings. This capability facilitates more personalized and timely interventions. By accurately assessing functional performance, patients gain greater insight into their condition thereby improving overall management. Additionally, the system's ability to decrease the frequency of hospital visits and extensive clinical assessments contributes to cost-effectiveness, alleviating the burden on health care systems.

Limitations and Strengths

Several limitations of this study should be noted. First, this study's cohort consisted exclusively of patients diagnosed with KOA without the inclusion of data from healthy control participants for comparative analysis. The validity of the model prediction is limited to the patients' population with KOA. The participant data of this study are mostly female, and the validity of the model may be biased toward female patients. Second, this was a cross-sectional study without long-term longitudinal monitoring of patients in their daily living environments. Third, it only conducted a feasibility study on functional estimation based on wearable plantar pressure features for 2 clinical functional tests recommended by OARSI for KOA. Hence, the proposed techniques require further validation in larger prospective cohorts and preferably multicenter trials to corroborate generalizability.

Despite its limitations, we believe that this wearable plantar pressure technique captures objective quantitative indicators of functional status and has great application value. The preliminary findings indicate this methodology holds promise for enabling remote, quantitative monitoring of rehabilitation progress over time. Further work will refine the system for broader clinical application and validation.

Conclusions

This study aims to develop a lower extremity motor function evaluation model for patients with KOA based on multidimensional gait features, which was suitable for a wearable plantar pressure measurement system. The average performance and variability of left and right foot features were extracted from the raw plantar pressure data. An extensive feature database including 380 gait features and 4 physical characteristics was established by mathematical methodologies. Optimal feature subsets for both tasks are selected after stepwise feature selection including Spearman correlation coefficient, mRMR, and wrapper methods. Individual regression models and a 2-level ensemble learning model were trained for the 40mFPWT and TUGT tasks, respectively. The WAE model that weighs the contribution of each ensemble member proportionally based on RI value has the best performance in the testing set, with an MAE of 2.686 seconds, MAPE of 9.602%, and RMSE of 3.316 seconds for the 40mFPWT and an MAE of 1.280 seconds, MAPE of 12.389%, and RMSE of 1.905 seconds for the TUGT. The proposed technique has the potential to be a novel approach for objectively quantifying the functionally dependent gait features, which could be developed as a tool for the rehabilitation evaluation of motor function in individuals with KOA. This study fills the vacancy in dynamic functional assessment for patients with KOA based on wearable devices. In future work, a variety of sensing technologies will be integrated to evaluate and predict more functional tests, providing more accurate and scientific support in fields such as sports medicine and rehabilitation therapy.

Acknowledgments

Abstract

Background: Web-based advance care planning (ACP) interventions offer a promising solution to improve ACP engagement, but none are specifically designed to meet the needs of patients with heart failure and their caregivers.

Objective: We aimed to develop and assess the usability and acceptability of a web-based ACP decision aid called “My Voice,” which is tailored for patients with heart failure and their caregivers.

Methods: This study’s team and advisory board codeveloped the content for both patient and caregiver modules in “My Voice.” Using a mixed methods approach, we iteratively tested usability and acceptability, incorporating feedback from patients, caregivers, and health care professionals (HCPs).

Results: We interviewed 30 participants (11 patients, 9 caregivers, and 10 HCPs). Participants found the website easy to navigate, with simple and clear content facilitating communication of patients’ values and goals. They also appreciated that it allowed them to revisit their care goals periodically. The average System Usability Scale score was 74 (SD 14.8; range: 42.5-95), indicating good usability. Over 80% (8/11) of patients and 87% (7/8) of caregivers rated the website’s acceptability as good or excellent. Additionally, 70% (7/10) of HCPs strongly agreed or agreed with 11 of the 15 items testing the website’s acceptability.

Conclusions: “My Voice” shows promise as a tool for patients with heart failure to initiate and revisit ACP conversations with HCPs and caregivers. We will evaluate its efficacy in improving patient and caregiver outcomes in a randomized controlled trial.

Trial Registration: ClinicalTrials.gov NCT06090734; https://clinicaltrials.gov/study/NCT06090734

advance care planning; decision aid; heart; website; heart failure; care plan; caregiver; usability; acceptability

Introduction

Advance care planning (ACP) is a process to support individuals in understanding and sharing their values, goals, and preferences regarding medical care [1]. Systematic reviews by our team reveal that while ACP may not consistently result in goal-concordant care for patients [2], improve their quality of life, or reduce health care expenditures, it can enhance communication of patient values and goals with health care professionals (HCPs) and caregivers or surrogate decision makers [3,4]. This, in turn, equips patients, caregivers, and HCPs to be better prepared for making in-the-moment health care decisions, emphasizing “preparation” rather than “planning” as an objective for ACP [5]. This emphasis on preparation is crucial, considering that most patients and caregivers are often unprepared for making these decisions [6]. Effective preparation involves educating patients about their illness and enabling them to share their values and goals with their doctors and surrogate decision makers.

Despite these clear benefits, ACP completion rates remain low worldwide [7-12]. This is particularly concerning for patients with conditions such as heart failure, which have an unpredictable clinical trajectory that makes prognostication difficult. This uncertainty in prognosis often leads to delays or avoidance of ACP conversations [13,14]. Furthermore, ACP conversations and documentation require substantial time and effort, often dissuading clinicians from initiating them [15-17]. Patients themselves may lack the readiness, initiative, and knowledge to initiate these conversations [18-21]. Most notably, even when ACP conversations happen, they are conducted as a one-time occurrence rather than as part of an ongoing process [2]. Our previous research has revealed that patients’ care goals change over time, thus limiting the value of one-time ACP conversations, and requiring that ACP conversations be revisited periodically [22-25].

To enhance ACP completion rates among patients with heart failure and foster a truly patient-centered approach, it is crucial to empower patients to initiate ACP conversations with their caregivers and HCPs. ACP web-based decision aids offer a promising solution, preparing patients for these conversations while alleviating the time burden for clinicians. Yet, a scoping review of 11 web-based ACP decision aids for patients identified only two applicable for patients with heart failure, with only one specifically tailored for this group [26,27]. Furthermore, while these decision aids also hold promise for enabling periodic patient-driven revisions and providing access to the latest updates on patients’ evolving care goals, none of the existing decision aids incorporated mechanisms to promote a systematic reconsideration of patients’ care goals. With the exception of few web-based decision aids, most existing ACP decision aids also do not encourage the active involvement of caregivers in the ACP process, and simply coach patients to engage with them [28-33]. The latter is particularly pertinent given the crucial role caregivers play in the decision-making process in many settings including Singapore, where this study is based [34].

To address these gaps, we developed “My Voice,” a web-based ACP decision aid tailored for patients with heart failure and their caregivers. It educates users about their illness, enables sharing and systematic reconsideration of patients’ values and goals, and actively involves caregivers. This paper aims to present the development process, and usability and acceptability of “My Voice” among patients, caregivers, and HCPs. Given the extensive engagement with patient representatives and HCPs during its development, we hypothesize that “My Voice” will meet the standardized System Usability Scale (SUS) score cutoff of 68, as proposed by Lewis and Sauro [35].

Methods

Development of ”My Voice”

Between April 2022 and May 2023, we engaged in an extensive process involving literature reviews, examining existing ACP decision aids, and consultations with a study team comprising diverse experts including health services researchers, cardiologists, palliative care physicians, social workers, communication coaches, and information technology professionals. We also established a study advisory board consisting of patient representatives and HCPs trained to conduct ACP conversations and gathered their inputs regarding content and structure for the interactive web-based application “My Voice.” Guided by the COM-B model that focuses on capability (C), opportunity (O), motivation (M) to enhance behaviors (B) [36], “My Voice” aimed to improve patients’ capability for engaging in ACP conversations, creating opportunities for them to have these conversations and revisit them periodically, and motivating them to do so.

A professional production house produced narration-style videos featuring HCPs from this study’s team. The website content and videos were initially developed in English and subsequently professionally translated into two local languages (Mandarin and Malay) to ensure inclusivity and accessibility. Upon completion of the content development phase, we developed the initial prototype of “My Voice.” To ensure the security of participants’ identifiable information, we incorporated password protection and a two-factor authorization process. The research team obtained relevant institutional approvals at all stages of web application development.

Description of “My Voice”

“My Voice” includes patient and caregiver modules. The patient module consists of a series of educational videos lasting 1-2 minutes each, organized into five steps: (1) learn about heart failure, (2) think about what is important to you, (3) why and how to choose a spokesperson, (4) speak to your doctor about what is important to you, and (5) revisit “My Voice.”

In addition to the videos, step 1 includes a knowledge quiz. Step 2 incorporates questions to elicit patient values and goals (referred to as value clarification questions), which were based on the Serious Illness Conversation Guide [37]. Step 3 provides fields for nominating up to two surrogate decision makers, known locally as the nominated health care spokespersons. Upon completion of step 5, the patients’ responses to the value clarification questions and the details of their spokespersons are automatically populated into a summary document called the “My Voice” document. Patients can view and edit the document before it is saved on the website. The website then triggers automated emails and phone text messages containing the document to both patients and their designated surrogate decision makers. Patients and their designated surrogate decision makers can also view and print the document anytime through the website. The website also sends phone reminders to patients to revisit “My Voice.” Multimedia Appendix 1 highlights select pages from the “My Voice” website.

The caregiver module includes educational videos lasting 1-2 minutes structured into three steps: (1) learn about heart failure, (2) talk to your loved one, and (3) support your loved one. As with the patient module, step 1 incorporates a knowledge quiz. At the end of the module, caregivers have the option to view the patient's "My Voice" document.

Between May and August 2023, we recruited a convenience sample of patients with heart failure, their caregivers, and HCPs, from four public hospitals in Singapore. These groups of participants are the key stakeholders in ACP conversations, and hence best positioned to provide feedback on the website. We recruited patients from outpatient clinics and wards, based on the following inclusion criteria: (1) adults aged 21 years or older; (2) diagnosed with heart failure; (3) Singaporean or permanent resident; (4) able to understand either English, Mandarin, or Malay; and (5) willing to use a web-based intervention. Caregivers of the above eligible patients were approached independently and included if they consented. Caregivers were: (1) adults aged 21 years or older; (2) providing informal care or ensuring the provision of care, or serving as the main decision maker for the patients with heart failure with no expectation of financial compensation; (3) able to understand either English, Mandarin or Malay; and (4) willing to engage with a web-based intervention. HCPs from department of cardiology namely cardiologists, cardiology nurses, and medical social workers trained in having ACP conversations were included.

Testing Procedure

We used a mixed methods design incorporating both qualitative interviews that provided feedback to iteratively revise the website's content and design to improve the overall user experience, and quantitative surveys to estimate the website functionalities including its usability and acceptability. The results from qualitative and quantitative sections were integrated during interpretation as a narrative discussion.

Trained research staff (IC and SNK) conducted usability testing on a tablet device provided by the research team. Patients and caregivers viewed their respective modules while HCPs viewed both modules. On viewing the relevant modules, participants responded to open-ended questions during a qualitative interview and answered a brief questionnaire. Research staff facilitated navigation and ensured participants viewed all steps. All study procedures were completed in one sitting.

Qualitative Feedback

A topic guide developed by the research team based on concepts from the user-experience model [38]. The guide comprised of open-ended questions eliciting participants' perceptions and satisfaction with the design and content of the website, and feedback for enhancement. Questions were tailored for each participant group (Multimedia Appendix 2). Participants were given time to explore and navigate each page of the website. Subsequently, they were prompted to provide feedback on the website's navigational ease, and clarity of on-page explanations for each step. Research staff facilitated website navigation and ensured the participants completed all steps. Specifically, patients and HCPs were probed on the comprehensibility of the value-clarification questions and whether they could easily select their preferred answers from a potential list of response options. Their suggestions for refining the questions and the response options were elicited. Lastly, participants were asked about their overall impressions of the website, its perceived usefulness, aspects they liked most or least, and recommendations for improvement. Participant responses were audio-recorded and transcribed (to English if conducted in Mandarin or Malay) for analysis. The interviews were conducted in a private room within the health care facility and lasted between 30 - 80 minutes. We analyzed qualitative data concurrently with data collection. Data saturation was achieved by the 27th interview, when no new feedback about the website emerged.

Survey

After viewing the respective modules, participants answered a survey in the language participants viewed the website (English, Mandarin, or Malay). The survey collected demographic information, and questions assessing usability and acceptability. Usability was evaluated by the 10-item SUS; each item was rated on a 5-point Likert scale (strongly disagree to strongly agree) [39,40]. We assessed acceptability using the acceptability rating scale developed by the Ottawa Hospital Research Institute adapting it to specific decision-making aspects of our study [41]. Patients and caregivers, rated items on a 4-point Likert scale ranging from poor to excellent (score: 1 - 4), and for HCPs used a 5-point Likert scale ranging from strongly disagree to strongly agree (score: 1 - 5). Example items included, "it will be easy for me to use 'My Voice' for introducing ACP to my patients" and "this 'My Voice' website is better than how I usually go about conducting ACP" [41]. Lastly, patients and caregivers rated the length (too long, too short, or just right) and amount of information (too much, too little, or just right) for "My Voice."

The surveys were first developed in English and then translated by native speakers into Mandarin and Malay and verified by a second team member fluent in the language. Before fielding, the surveys were tested with volunteers from a nonclinical setting.

Sample Size

Previous literature suggests that a sample of 20 participants can identify 95% of usability problems [42]. Thus, a sample size of 30 was deemed to be sufficient for usability testing. Previous studies assessing usability of digital interventions also had similar sample sizes [43].

Data Analysis

Two authors CR and IC analyzed the open-ended interview transcripts using qualitative description methodology [44]. We categorized the interview feedback from participants into broad concepts (eg, language or layout) paying close attention to positive and negative views toward the website to derive themes and subthemes inductively. The two authors verified each other's coding carried out in Excel (Microsoft Corp), discussed and agreed upon the final themes derived. From the survey data we described participants' demographic and health status characteristics. We also calculated the total SUS score as a sum of each item score and rescaled it within the range of 0 to 100. A higher score signified greater usability, and a score greater than 68 indicated good usability [39,40]. We then present the total scores for each participant group and overall sample. For each item on the acceptability scale, we calculated the proportion of patients and caregivers responding as good or excellent and HCPs rating as agree or strongly agree.

Ethical Considerations

This study was approved by the SingHealth Centralized Institutional Review Board in Singapore (2022/2482) and was conducted in compliance to the institutional guidelines. Participants were briefed on this study's purpose and had the option to withdraw at any time. We obtained written informed consent and provided US $20 cash as compensation upon completion of usability testing procedures. All data was deidentified to protect participants' privacy and confidentiality.

Results

Participant Characteristics

A total of 30 participants out of 44 (response rate 68%) consented including 11 patients, 9 caregivers, and 10 HCPs. Among them 21 (10 HCPs, 6 patients, and 5 caregivers) reviewed the English version, 7 (4 patients and 3 carergivers) reviewed the Mandarin version, and 2 (1 patient and 1 caregvier) reviewed the Malay version of the website, respectively, and completed the surveys in the respective languages. Participants' mean age was 49 (SD 14.9) years and 60% (18/30) were females. Participant characteristics are described in Table 1.

Table . Participant characteristics (N=30).

Item	Patients (n=11)	Caregivers (n=9)	Health care professionals (n=10)
Age (years), mean (SD)	60.7 (13)	44.9 (15.4)	39.8 (6.1)

Qualitative Feedback and Iterative Redesign

Overview

The following three themes describe participants' feedback and suggestions, and highlight the revisions made by the research team.

Theme 1: User Experience of Navigating the Website

Many participants provided positive feedback about the ease of navigation and layout of the website. Patients, caregivers, and HCPs described the interactive features as easy to use and appreciated the simple layout of the website. However, two HCPs anticipated that older patients may have difficulty reading extensive text due to poor eyesight, scrolling down the web page, and navigating the site.

To address these concerns and enhance user experience and accessibility for older patients, we added a note on the expected time to complete the website and a progress bar to allow users to track their progress. We also increased the frequency of navigational buttons such as the "submit My Voice document," increased the font size and changed the font color to improve readability. Lastly, within the help section, in addition to allowing the participants to type their queries, we incorporated a drop-down list for them to select from. This enhanced the ease of reaching out to the research team in case of difficulties.

Theme 2: Acceptability of Website Content and Duration

Patients, caregivers, and HCPs found the language clear and straightforward with "no jargon." However, two HCPs suggested reducing the wordiness of the web page. Most participants also found the duration of the website to be suitable although one HCP recommended adding a pause button for patients who may need breaks or prefer to complete the website in smaller segments.

Some patients expressed that the quiz explanations were overly direct and demoralizing. Given the discomfort surrounding the topic of death and dying, they suggested incorporating elements of hope to make the website more comforting.

We received extensive feedback about the value-clarification questions and their response options. One HCP recommended adding details about caregiving arrangements and clarifying terms such as "physically comfortable" or "at peace." Another HCP highlighted that being dependent on others did not equate to being a burden on the family. Participants also had challenges understanding and responding to a question asking patients' willingness to trade-off between quality and length of life, despite multiple iterations and revisions. These revisions aimed to clarify the question, prompting patients to imagine a situation where such a trade-off would occur. We also changed the initial 3-point response to a 2-point response option, excluding the choice to prioritize both aspects simultaneously. Participants described this question as vague and difficult to relate to.

In response to these concerns, we shortened the introduction section of the website and reduced the wordiness of each web page. To enable participants to complete the website in multiple sessions, we implemented a feature that displays their previous responses if they have not submitted their "My Voice" document. We also simplified the phrasing of key terms and modified the explanations for the quiz responses to be more emphathic, acknowledging patients' desire for a cure and emphasizing that symptoms can be managed even though heart failure is incurable. We clarified the response options for the value-clarification questions by making them more specific and split up the initial option of "being dependent on others for their daily activities and being a burden on their family" into two separate response options. We removed the question assessing the trade-off on quality and length of life.

Theme 3: Usefulness in Understanding Patient's Values and Goals

Many HCPs noted that the website could complement and enhance existing ACP processes by helping patients reflect on their values and care goals, thereby preparing them for the challenging in-person ACP conversations ahead of time. This preparation could potentially save time during dedicated clinic appointments for ACP conversations. Patients and caregivers also found the website useful as it encouraged them to communicate with each other. Caregivers particularly appreciated that patients' "My Voice" document could be updated periodically to reflect their changing care goals.

Table 2 presents example quotes illustrating feedback obtained, and Table 3 outlines participants' suggestions for improvement alongside the corresponding revisions made.

Table . Participant feedback on “My Voice” website.

Subtheme		Patients	Caregivers	HCPs[a]	Selective positive quotes
Theme 1: user experience of navigating the website					
	Ease of navigation	✓✓×[b]	✓✓✓	✓✓×	• “Easy and straightforward. Quite nice to use” [UAT25, patient] • “Like most interfaces used in Singapore, it’s not particularly difficult…overall quite easy to use…I am quite sure that they (elderly) will need somebody to go through with them, for the elderly patients” [UAT05, cardiologist]
	Simple layout	✓✓✓	✓✓✓	✓✓✓	• “My favourite part is the document that is generated with the spokesperson. It’s written very clearly” [UAT24, caregiver] • “Not too cluttered, quite clearly delineated” [UAT05, cardiologist]
Theme 2: acceptability of website duration and content					
	Ease of understanding	✓✓✓	✓✓✓	✓✓✓	• “Very easy, very simple to understand” [UAT29, patient] • “I think the options listed inside are easy to understand…Questions quite straightforward” [UAT01, ACP[c] facilitator] • “Videos did not contain any jargon, so it’s quite clear” [UAT05, cardiologist]

Subtheme		Patients	Caregivers	HCPs[a]	Selective positive quotes
	Informative	✓✓	✓✓✓	✓✓✓	• "Very succinct, it tells me exactly what I need to do" [UAT25, patient] • "I think it's good that we have all this background learning, at least we know and can be more educated...it is important that we get the information directly from them (patient) [rather than making assumptions]" [UAT20, caregiver] • "They are very concise, not too long, not too short, but every point that is important I guess it's all mentioned" [UAT03, medical social worker]
	Suitable duration	✓✓✓	✓✓✓	✓✓	• "The length of My Voice is just right" [UAT13, patient]
Theme 3: usefulness in understanding the patient's values and goals					

Subtheme		Patients	Caregivers	HCPs[a]	Selective positive quotes
	Complementary to ACP	—[d]	—	✓✓	• "I think this website is in a way like helping the patient to do the first part [of ACP] to get them to think about it before they come and really start to think in detail what are the treatments they want" [UAT01, ACP facilitator] • "It's more effective to reach the mass rather than in every admission or outpatient when we refer to ACP coordinator" [UAT03, medical social worker]
	Understanding values and goals	✓✓✓	✓✓✓	✓	• "It addresses the issue (by allowing the patient to let their preferences be known) especially when my husband does not want to listen … if there is an additional step that can tell me what to do when my husband doesn't want to listen to me that will be great" [UAT25, patient] • "It is really true that based on their condition, they might change. It's not always that – and then human heart or mind may be a bit fickle, or they might change based on their condition. So, this (frequent updates) is quite a good way" [UAT20, caregiver]
	Saves time	—	—	✓	• "This will cut down a lot of professional's time and caregiver's time [during the ACP process]" [UAT03, medical social worker]

[a] HCP: health care professional.

[b] ✓ indicates a positive response and x indicates a negative response. Number of ✓ indicates strength of the responses (✓✓✓ strong, ✓✓ moderate, and ✓ mild), and likewise for x.

[c] ACP: advance care planning.

[d] Not applicable.

Table . Participant suggestions for improving "My Voice" website.

Suggestion		Changes made to "My Voice"
User experience of navigating the website		
	"I think the layout for most pages it's fine, except for those on the boxes right, with a solid background of blue or dark blue, the white fonts could be bolder, I think that would be more clear to the respondents" [UAT03, medical social worker]	• Replaced red text on blue background with yellow text on blue background for better readability.
	"A little bit lengthy, especially for the elderly patients whose eyesight is not so good … The shorter the better. Otherwise, they have a lot to scroll, and read, and their attention span is already so short" [UAT10, nurse]	• Added expected time to completion of the website - "This program will take approximately 30 min to complete." • Reduced the length of on-page explanation before the value-clarification questions. • Added a color coded progress bar on the pages to track completion.
Acceptability of website content and duration		
	"The options in the respective pages… can streamline them… can further divide them like personal, family, work, or finances" [UAT03, medical social worker]	• Merged similar terms to shorten the text in responses options for the value-clarification questions (eg including "pain" under "symptoms" instead of 2 separate fields). • Added explanations in brackets for terms that are not immediately understandable such as: "Make a legacy (something that is passed on, monetary or non-monetary)" and "Being cared for at home, rather than in an institution (eg, hospital)."
	"Don't just give the bitter truth, add some element of sweetness. Give some hope" [UAT26, patient]	• Rephrased explanations for answers to the knowledge quiz to be more empathetic (eg, "Heart failure is a serious condition that can shorten life. For some patients, heart failure is stable for a long time then gets worse. Others have a gradual decline over time." → "We wish heart failure got better over time. Unfortunately, heart failure is a serious condition. For some patients, heart failure is stable for a long time then gets worse. Others have a gradual decline over time."
	"Some thoughts about the Step 4 when it mentions about the medical records, patients may not know how to go about. They may have queries about this part, like how do I document, who do I approach" [UAT01, advance care planning facilitator]	• In the patient module, integrated the step for documenting patient preferences in medical records with the step to speak to your doctor (step 4).
	"You will need to use simple words because sometimes when they age, complicated words they won't understand" [UAT29, patient]	• Replaced wordy introduction with simple bullet points for describing the steps involved. • Used simpler terms (eg, "spokesperson 1" and "spokesperson 2" instead of "primary spokesperson" and "secondary spokesperson").

Survey Results

The overall mean SUS score of 74 (SD 14.8; range: 42.5 to 95), with mean scores in each of the three groups of participants exceeding the minimum cutoff score of 68, indicated good usability. Specifically, 70% of participants had scores above 68, which included 64% (7/11) of patients, 78% (7/9) of caregivers, and 70% (7/10) of HCPs (Table 4).

Table . System Usability Scale (SUS) scores by participant group.

	Patients (n=11)	Caregivers (n=9)	Health care professionals (n=10)	Overall (N=30)
SUS score				
Range (0 - 100)	47.5 - 92.5	50 - 95	42.5 - 95	42.5 - 95
Mean (SD)	72.3 (15.2)	76.4 (15.3)	73.8 (15.2)	74 (14.8)
SUS score category, n (%)				
>87	2 (18)	2 (22)	3 (30)	7 (23)
69 - 87	5 (46)	5 (56)	4 (40)	14 (47)
50 - 68	3 (27)	2 (22)	2 (20)	7 (23)
<50	1 (9)	0 (0)	1 (10)	2 (7)

Patients highly rated the way information was presented in the 5 steps, with over 80% of patients rating each of the 12 items on acceptability as good or excellent. Likewise, over 88% of caregivers rated each of the 3 items about acceptability as good or excellent (Table 5). Except for one patient who found the length of the website to be “too long,” 19 of 20 patients and caregivers (95%) rated the website length to be “just right,” and 18 of 20 patients and caregivers (90%) rated the amount of information presented to be “just right.” Seven of 10 HCPs (70%) rated 11 of the 15 items as strongly agree or agree. Items that received lowest levels of agreement (agree or strongly agree) included—“My Voice website is better than how I usually go about conducting ACP” (30%), “using My Voice website does not involve making major changes to the way I usually do things” (50%), “My Voice website is compatible with the way I think things should be done” (60%), and “the use of My Voice website is more cost-effective than my usual approach to conducting ACP” (60%; Table 5)

Table . Acceptability ratings by patients (n=11), caregivers (n=9), and health care professionals (n=10).

Item	Value, n (%)
Patients: good or excellent rating	
About heart failure (step 1)	10 (91)
Thinking about goals for end-of-life care (step 2)	10 (91)
Understanding what is important to you when it comes to your health	11 (100)
Questions on what makes life meaningful to you	11 (100)
Questions on when it gets to my health getting worse, what worries me most	9 (82)
Questions on choosing a preferred treatment	10 (91)
Questions on what matters most to you and choosing top 3 goals	9 (82)
Ranking the order of the top 3 goals	9 (82)
Choosing a healthcare spokesperson (step 3)	9 (82)
Document what is important to you in medical record	10 (91)
Discussing with the doctor about “My Voice” document (step 4)	9 (82)
Revisiting “My Voice” document periodically (step 5)	9 (82)
Caregivers: good or excellent rating	
About heart failure (step 1)	8 (89)
Talking to your loved ones about goals for end-of-life care (step 2)	9 (100)
Supporting your loved ones (step 3)	8 (89)
Healthcare professionals: agree or strongly agree	
It will be easy for me to use “My Voice” for introducing advance care planning (ACP[a]) to my patients.	8 (80)
It is easy for me to understand “My Voice.”	9 (90)
It will be easy for me to use “My Voice” website for advocating advance care planning.	8 (80)
The results of using “My Voice” website will be easy to see (increase in self-administered ACP-My Voice document)	8 (80)
This “My Voice” website is better than how I usually go about conducting ACP	3 (30)
This “My Voice” website is compatible with the way I think things should be done.	6 (60)
The use of “My Voice” website is more cost-effective than my usual approach to conducting ACP	6 (60)
Compared with my usual approach, “My Voice” website will result in my patients making more informed decisions.	8 (80)
Using “My Voice” website will save me time.	10 (100)
This “My Voice” website is a reliable method of helping patients do an ACP.	7 (70)
Pieces or components of the “My Voice” website can be used by themselves.	7 (70)
This type of “My Voice” website is suitable for helping patients make value laden choices.	9 (90)
This “My Voice” website complements my usual approach to conducting ACP.	8 (80)
Using this “My Voice” website does not involve making major changes to the way I usually do things.	5 (50)
There is a high probability that using this “My Voice” website may cause / result in more benefit than harm.	7 (70)

[a]ACP: advance care planning.

Discussion

Principal Findings

Study results show that “My Voice” ACP website was well received by patients with heart failure, their caregivers, and HCPs. Most participants provided positive feedback regarding their experience using “My Voice.” They found the website easy to navigate, its duration and content acceptable, and valuable in conveying and comprehending patient values and goals. The mean usability score of 74 (SD 14.8) exceeded the a priori threshold (68 and above) for both overall and within each participant group. Additionally, patients and caregivers’ acceptability ratings were high for all items, and 80% (8/11) of patients and 78% (7/9) of caregivers rated the website as good or excellent, while 70% (7/10) of HCPs rated 11 of the 15 items as strongly agree or agree. Most patients and caregivers (19/20, 95%) and 90% (18/20) of patients and caregivers found the length and amount of information in “My Voice” just right. These findings confirm the usability and acceptability of “My Voice.”

The findings on usability and acceptability are consistent with those of other web-based ACP decision aids [45-47]. Our findings regarding HCPs’ views of the decision aid as a tool for initiating ACP discussions also align with previous research [48]. However, in contrast to our findings, one study reported that participants had difficulty understanding and engaging with some website content [49].

Given that a significant proportion of patients with heart failure are older with lower literacy levels [50], feedback primarily focused on enhancing the website accessibility for this demographic. Suggestions included simplifying the login process, improving the layout, reducing wordiness, increasing font size, and simplifying terminology. Moreover, some patients expressed surprise upon learning about the incurable nature of their illness, indicating that they had not engaged in serious illness conversations with their HCPs. Our previous studies have also shown similar findings [51,52].

Patients and caregivers rated “My Voice” to be both acceptable and usable. However, while, HCPs rated its usability highly, they provided lower ratings to certain aspects of acceptability. These included suggestions that “My Voice” could potentially be more effective and replace the current ACP facilitation method. It is important to note that “My Voice” is primarily a patient preparation tool intended to complement, rather than replace, the patient-HCP conversations. Therefore, the concerns raised are not unexpected given its supplementary role in the process.

While web-based ACP interventions are increasingly prevalent in the literature, our intervention is innovative in several respects. First, it incorporates structured mechanisms to encourage frequent revisits to “My Voice,” through educating patients and caregivers about its importance and sending reminders to them via phone. Our previous research revealed that ACP conversations typically occur as one-time events despite evolving patient preferences [22-25]. “My Voice” thus addresses this current gap in ACP implementation by facilitating ongoing reflection on values and goals and fostering periodic ACP conversations with HCPs. Second, it is tailored specifically to patients with heart failure, featuring educational videos and a quiz regarding their illness. This targeted education not only imparts urgency but also provides the context for patients to reflect on their values and goals. Third, “My Voice” seamlessly integrates active caregiver involvement into the ACP process. Not only do we coach patients to choose a surrogate decision maker and engage with them, but our dedicated caregiver module educates the chosen surrogate about the patient’s illness and guides them on how to communicate with the patient and the HCPs. This caregiver module also facilitates the sharing of the patient’s “My Voice document” with the surrogate. This approach enhances the caregiver’s understanding of patient values and goals, preparing them to make end-of-life decisions for their loved ones. Importantly, caregivers in our usability study appreciated the “My Voice” website’s unique features, particularly its capability for patients to periodically update their goals and share them with their surrogates. Lastly, the inclusion of content in three different languages enhances the accessibility of “My Voice” to a broader range of ethnic and language groups, promoting inclusivity and ensuring that individuals from diverse backgrounds can effectively engage in the ACP process.

“My Voice” is one of the first web-based ACP interventions for patients with heart failure in the Asian context. This study’s strength lies in its use of a mixed methods design to gather participant feedback, agile methodology implementation to enhance user satisfaction, and inclusion of different ethnic and language groups across multiple sites. However, there are some limitations. The response rate from patients was low (46%), partly attributed to the older age of many participants approached and their reluctance to engage in web-interventions. Future studies could improve response rates by involving health and social care providers, community organizations, or adult children to facilitate initial contact with older individuals. Additionally, although the sample size was adequate to achieve thematic saturation, it was too small to discern variations across age, gender, and other sociodemographics.

Practice Implications

“My Voice” is a usable and acceptable tool for empowering patients to engage in ACP conversations with their caregivers and HCPs. The efficacy of the “My Voice” website in improving patient and caregiver outcomes is being assessed through a randomized controlled trial.

Conclusion

The findings support the usability and acceptability of the web-based ACP intervention, “My Voice,” among patients with heart failure and their caregivers. Participants largely endorsed the interactive website as a valuable tool for communication and understanding patients’ values and goals, offering constructive feedback to enhance its user-friendliness for older patients.

Acknowledgments

This work was supported by grants from the National Medical Research Council, Ministry of Health Singapore (MOH-001031). We are thankful to Mr Kalimuthu Kanchiyappan, MCA, Duke NUS Medical School, for providing the technical support for website development.

Abstract

Background: Despite positive results for the use of assistive technologies (ATs) in dementia, the uptake of ATs lags behind. It is considered important to assess determinants of successful or unsuccessful implementation of ATs.

Objective: We explored factors that influence the implementation of ATs for community-dwelling people with dementia, with the aim to better understand potentially effective implementation strategies.

Methods: A cross-sectional survey for researchers was developed and disseminated, exploring factors that influence either successful or unsuccessful implementation of ATs for dementia. The survey consisted of closed and open questions.

Results: The response rate was 10% (21/206); the 21 respondents who completed the survey were from 8 countries. Determinants of implementation were described for 21 ATs, of which 12 were successfully and 9 were unsuccessfully implemented. Various types of ATs were included, such as online platforms, sensors, or physical aids. The main determinants of implementation success were related to the AT itself, contextual factors, research activities, and implementation strategies. There was a lack of research data on some ethical issues and cost-effectiveness.

Conclusions: This study provided insight into some main barriers to and facilitators of implementation of ATs in dementia related to the AT itself, context, research-related activities, and applied implementation strategies. Lessons were formulated for various stakeholders to improve the implementation effectiveness of ATs in dementia.

KEYWORDS

assistive technology; dementia; implementation; caregiving; psychosocial research

Introduction

The importance of assistive technology (AT) in the delivery of health care and support is increasingly being recognized [1,2]. AT in dementia care has been defined as “any item, piece of equipment, product or system driven by electronics, whether acquired commercially, off-the-shelf, modified or customized, that is used to help persons with dementia in dealing with the consequences of dementia” [3,4]. A perceived advantage of AT is improved access to care, even for people in remote areas. AT can make it easier to provide customized care, can be more entertaining, and can save time and costs [5-10]. Specifically for people with dementia and their carers, positive effects have been reported from the use of AT. For people with dementia, AT has been found to positively affect, for example, cognition, task performance, participation in enjoyable and meaningful activities, social contacts, self-esteem and well-being, behavioral and psychological symptoms, and safety [4,11-13]. For family carers, the following benefits have been reported: feelings of reassurance, lessened burden, improved self-efficacy, more caregiving knowledge, and improved mental health [11,14,15]. Furthermore, systematic literature reviews on technology-based dementia education for professional carers showed positive effects on dementia knowledge, readiness to change, receptiveness to training, communication skills, and self-efficacy [13,16]. Finally, the potential of AT to improve access to dementia care is even more crucial given the context of the COVID-19 pandemic. During this period, AT provided an alternative means of support for closed day programs and services, as well as an alternative to the downscaled professional and social support for people with dementia and their caregivers. Recent articles have advised care professionals to use technology to organize support remotely [13,17].

Despite these positive results, the uptake of AT in dementia care has been disappointing. Various issues may account for this, such as relevant stakeholders and potential users not being included early on in the development of ATs, lack of high-quality effectiveness and cost-effectiveness studies, lack of easily accessible information about existing ATs, and negative attitudes toward technology among family and professional caregivers [4,18-20]. Numerous implementation models and theories have been developed to help identify and map factors that influence implementation, such as the nonadoption, abandonment, scale-up, spread, sustainability framework [21] and the Consolidated Framework for Implementation Research [22]. These factors include the characteristics of the innovation (eg, added value as compared to regular support, the development process, and reliability and ease of use), characteristics of the adopters (professionals) and the end users (people with dementia and family carers), characteristics of the context (organization, social setting, community, laws, and regulations), characteristics of the implementation process (implementation strategies used), and implementation outcomes. In a market study in the European Union, it was concluded that there are 7 potential categories of barriers to the uptake of AT: cultural, regulatory and policy, social security, industrial and technical, knowledge, financial, and market related. These types of barriers exist in all European countries but differ across countries in the extent to which they affect uptake [2]. This underscores the need to tailor AT implementation to specific contexts.

In this paper, we report on a study in which we explored factors that influence the implementation of AT for community-dwelling people with dementia, with the aim to better understand potentially effective implementation strategies. Implementation was defined as "the process of putting to use or integrating evidence-based interventions within a setting" [23]. We targeted community-based dementia care settings and focused on ATs that aim to promote social health in people with dementia, that is, technologies that intend to (1) help people living with dementia manage their everyday lives across the disease journey, such as electronic calendars and reminders for activities, medication reminders, aids to perform activities of daily life, robots, and navigation systems; (2) help people to engage in meaningful and pleasurable activities, such as cognitive stimulation and physical activities; and (3) improve participation in social and meaningful activities [24].

The objective of this exploratory study was to describe factors that determine (1) successful implementation of evidence-based ATs and (2) unsuccessful implementation of ATs. Based on understanding the determinants of successful or unsuccessful implementation, we made a set of recommendations for the benefit of various stakeholders, including researchers who wish to bring their ATs into practice, clinicians who wish to be informed about, and implement, best practices in AT, and policy makers who need to make decisions about effective ways to fund development, research, and implementation of ATs.

Methods

Design

A cross-sectional design was used in which data were collected digitally through a web-based survey accessible from October until December 2019. On the survey platform, all participants received an information letter explaining the aims of the study and guaranteeing the pseudonymous processing of their data and responses, as well as the option to discontinue participation in the study at any time. To ensure the anonymity of the participants, the studied interventions are not reported by name; only their characteristics are described.

The survey was sent out in October 2019 via email, and subsequently 2 reminders were sent after 2 and 4 weeks. Participants could decide for themselves whether they completed the survey on successful implementation of AT, unsuccessful implementation of AT, or both surveys.

Participants and Setting

Participants were recruited via the European Interdem network, which consists of psychosocial researchers from 19 countries in Europe and beyond, working together in the field of early, timely, and quality psychosocial interventions in dementia [25], as the objective of the survey was to map the determinants of the implementation of AT interventions for people with dementia that were developed in a research context. As such, researchers from this network are best placed to provide an overview of such interventions. The survey was sent out to all Interdem members (n=206). Those who were or have been working on projects on AT aiming to support people with dementia in the community were invited to participate. Members were also invited to forward the survey to colleagues known to work in this area (snowball sampling).

The Survey

The survey was developed based on the literature on implementation and on expert opinions. From the literature, we proposed 5 categories of influencing factors: characteristics of the innovation, the adopters and end users, contextual factors, implementation strategies, and outcomes of the implementation [26-28]. In addition, expert opinions about the content of the survey were collected during a symposium organized by the Interdem Taskforce Assistive Technologies at the Alzheimer Europe conference in 2018. The team of authors further finalized the survey with this input. Also, background characteristics of respondents were included, such as country of residence, type of work organization and area of work, job description, gender, and age. As this was a new survey designed for the purposes of this study, it has not been psychometrically validated as of yet.

The surveys for both successfully and unsuccessfully implemented ATs contained 67 identical structured and open-ended items regarding factors that potentially influence the implementation of ATs as described by respondents (Table 1).

Both surveys were programmed in dedicated survey software (QDNA version 1.1.4; ZorgDNA BV).

Table . Survey themes and subthemes.

Themes	Subthemes
Characteristics of the AT[a]	• The aim of the AT with respect to the 3 areas of promoting social health • Type of device • Dementia-specific development • Pricing • Training requirements • User-friendliness (personalization options, required support)
Characteristics of adopters and end users	• End user of the AT • Ownership of the AT • Main beneficiary • Required training or user criteria
Contextual factors	• Care setting • Policies and legislation • Ethical issues
Implementation strategies	• Stakeholder involvement • Conducted studies on usefulness, effectiveness, cost-effectiveness, and implementation • Presence of business plan; financing
Outcomes of the implementation	• Scale of uptake of the AT; facilitators and barriers for implementation

[a] AT: assistive technology.

Analyses

Descriptive statistics were used to describe the results of the survey and to explore differences between successful and unsuccessful implementations. Due to the small sample size and relatively large number of parameters, statistical tests could not be executed. The qualitative responses to the survey's open-ended items provided only additional information to the quantitative data, such as to clarify a type of device used in the AT, and these responses were not analyzed separately.

Ethical Considerations

This study did not fall under the scope of the Medical Research Involving Human Subjects Act. Therefore, ethical approval by an institutional review board was not obtained. The respondents were informed of the purpose of the study before the survey and gave their consent to the survey data being collected and analyzed pseudonymously (it was not possible to guarantee full anonymity during analyses because the AT was discussed by name by study participants—for many ATs, it is possible to ascertain which researchers or technological developers were behind their development). All AT names were removed from the final data, allowing for pseudonymous reporting of the results. The respondents did not receive any compensation.

Results

Respondents

Thirty-two of the 206 invitees declined to participate as they were not active in the field of AT; the survey was forwarded to at least 13 other researchers. The response rate was 10%; 21 of 206 respondents completed the web-based survey. The participants were employed in a variety of settings: 17 respondents indicated that they were employed in a university setting, 4 in a hospital setting, 4 in care organizations, and 1 in a research organization (nonacademic). Fifteen of the respondents described their main area of work as research, 5 as clinical (1 with inpatients and 4 with outpatients), and 1 as policy. The mean age of the respondents was 49 (SD 12) years, and 71% (15/21) were female. Respondents were from the Netherlands (n=9), the United Kingdom (n=4), Germany (n=2), the Czech Republic (n=1), Denmark (n=1), France (n=1), Hong Kong (n=1), and Italy (n=1). One response was missing.

Included ATs

All 21 respondents filled in the survey for a single AT. However, 2 respondents independently filled in the survey for the same AT, so the total of number of ATs included in this study was 20. Table 2 is an overview of the types of ATs included.

The respondents described the implementation of 12 of these ATs as successful, while 9 were described as unsuccessful. Successfully implemented ATs were associated with national uptake (7/12, 58%), as opposed to international (1/12, 8%) or regional (3/12, 25%) uptake. Only 2 of the 9 unsuccessfully implemented ATs were deployed on a national level (22%).

Table . Types of assistive technology (AT) included.

Type of AT	Responses (n=21), n	
	Successful (n=12)	Unsuccessful (n=9)
Online platform	6	4
Robot	0	1
Monitoring, sensors, or GPS	3	1
Physical aids	2	2
Virtual reality	1	1

Characteristics of the ATs

The survey responses showed that the majority of ATs were aimed at the management of everyday life (15/21, 71%). ATs that were available through multiple devices were more often implemented successfully. The devices most often used in successfully implemented ATs were personal computers (9/12, 75%), smartphones (7/12, 58%), and tablets (5/12, 42%). The range of devices used in unsuccessfully implemented ATs was less diverse, with tablets being reported most frequently (5/9, 56%). Moreover, mobile devices were more often implemented unsuccessfully, while apps were more often implemented successfully. The AT was not specifically developed for people with dementia in all cases; one-third to a quarter were described as “mainstream technology.”

Successfully implemented ATs tended to be more often developed specifically for people with dementia. An association between implementation success and personalization options of the AT was not clear. The design of almost all successfully implemented ATs was considered good or very good; the design of unsuccessfully implemented ATs was considered good by 56% (5/9) of the respondents and bad or very bad by 33% (3/9; the remainder were missing).

Successfully implemented ATs were more often freely available or considered as value for money and deemed affordable for everybody, while unsuccessfully implemented ATs were considered expensive or very expensive by one-third of the respondents. In contrast to the majority of the successfully implemented ATs, none of the unsuccessfully implemented ATs were described as functioning stably. Table 3 provides an overview of how the various device characteristics related to AT implementation success.

Table . Characteristics of the assistive technologies (ATs) and their contributions to implementation success. Note: missing answers are not reported but are taken into account in the calculation of the overall percentages per category (successful ATs and unsuccessful ATs).

AT characteristics		Successfully implemented ATs (n=12), n (%)	Unsuccessfully implemented ATs (n=9), n (%)

Characteristics of the Adopters and End Users

Approximately half of all ATs were owned by the person with dementia or informal caregiver. This was not clearly associated with implementation success. However, successfully implemented ATs were slightly more often owned by a care organization. Successfully implemented ATs were more often deemed affordable to everybody than unsuccessfully implemented ATs. ATs mainly benefiting the person with dementia were more often successfully implemented. If criteria were defined for users, this was associated with successful implementation of ATs. Relatively more unsuccessfully implemented ATs required a preassessment to advise on or tailor the AT to the user. Most of the ATs required training to be used well. Unsuccessfully implemented ATs slightly more often required training of informal and professional carers. Few ATs could be managed independently by the person with dementia, and support by an informal carer was more often associated with successfully implemented ATs (Table 4).

Table . Characteristics of adopters and end users. Note: missing answers are not reported but are taken into account in the calculation of the overall percentages per category (successful assistive technologies [ATs] and unsuccessful ATs).

Characteristics of adopters and end users		Successfully implemented ATs (n=12), n (%)	Unsuccessfully implemented ATs (n=9), n (%)

Contextual Factors

Most of the ATs were used in the home environment, without clear differences between successfully and unsuccessfully implemented ATs. Furthermore, interventions that were described as nonintrusive home ATs were more often seen as successfully implemented. Stable, continuous Wi-Fi was associated with successful implementation. Finally, while the majority of ATs were used within the home context, this was not associated with successful implementation. In contrast, ATs used outdoors were more often associated with successful implementation. When alternative products were available that addressed similar needs as the new AT, the AT was slightly more associated with successful implementation. Successfully implemented ATs were more often reimbursed by insurance or benefits or were paid by a care organization (Table 5).

Table . Contextual factors. Note: missing answers are not reported but are taken into account in the calculation of the overall percentages per category (successful assistive technologies [ATs] and unsuccessful ATs).

Contextual factors		Successfully implemented ATs (n=12), n (%)	Unsuccessfully implemented ATs (n=9), n (%)

Implementation Strategies

Stakeholder Involvement

The findings on the ATs' stakeholder involvement indicate that, in general, the involvement of people with dementia, informal caregivers, commercial parties, researchers, and care organizations was associated with successful implementation. Only the involvement of governments did not seem to affect implementation success (Table 6).

Table . Stakeholder involvement and assistive technology (AT) implementation success.

Stakeholder group involvement	Successfully implemented ATs (n=12), n (%)	Unsuccessfully implemented ATs (n=9), n (%)
Person with dementia	6 (50)	2 (22)
Informal caregiver	7 (58)	2 (22)
Commercial party	7 (58)	4 (44)
Government	3 (25)	2 (22)
Research	9 (75)	5 (55)
Care organization	7 (58)	2 (22)

Research Activities

It appears that ATs whose user friendliness has been studied are more often successfully implemented (10/12, 83% vs 4/9, 44%), independent of the outcome of the study. Also, effectiveness studies were more often part of the development process in successfully implemented ATs (7/12, 58%) than in unsuccessful trajectories (2/9, 22%). Few cost-effectiveness studies were performed—for just 4 ATs in total—and this was not associated with implementation success. Ethical issues were considered for 57% (12/21) of all included ATs. This happened equally often for successfully and unsuccessfully implemented ATs. Most respondents referred to the obtainment of medical ethical approval; for one study, AT ethical issues were registered, while another study addressed potential ethical issues in an intervention protocol. Ethics were considered most often in the development phase of ATs and least often during the implementation phase, in 25% (3/12) and 11% (1/9), respectively, of successfully and unsuccessfully implemented ATs. Regarding privacy and data security, these were taken into account for most ATs (16/21, 76% in total) and were not associated with implementation success. However, studies on barriers to and facilitators of implementation and the presence of a business plan were associated with successfully implemented ATs (6/12, 50% and 5/12, 42% for successfully implemented ATs, respectively, vs 2/9, 22% and 1/9, 11% for unsuccessfully implemented ATs).

Main Facilitators and Barriers

The respondents were also asked to select a maximum of 5 facilitators considered as most important and a maximum of 5 most relevant barriers out of 30 factors that applied to the implementation of their ATs.

Facilitators that were most often mentioned were associated with the AT itself, including user-friendliness, the type of device (ie, personal computers, smartphones, and tablets were more often successfully implemented), and the availability of the AT on multiple devices. For successfully implemented ATs, personalization options were also considered to facilitate implementation. Contextual factors were only considered relevant for successful implementation; availability of a continuous internet or Wi-Fi connection in particular appeared to be the major facilitator.

In general, barriers were mentioned more often in unsuccessfully implemented ATs. The main barriers were, foremost, the opposite of the facilitators: a lack of user-friendliness and the unavailability of the AT on multiple devices. Next, contextual factors, such as an internet connection, available alternatives, ethics, privacy and data security, intrusiveness of the AT, and policy and laws, were mentioned as factors impeding the implementation. No main barrier could be identified.

Also, for successfully implemented ATs, respondents reported that the lack of financing and business plans for the AT was a major barrier that needed to be addressed in the implementation strategy. On the other hand, barriers for unsuccessfully implemented ATs were related to not being effective or cost-effective and lacking a marketing strategy and business plan (Table 7).

Table . Frequency of mentioned main facilitators of and barriers to implementation of assistive technologies (ATs) per category.

	Facilitators		Barriers	
	Successfully implemented ATs (n=12), n (%)	Unsuccessfully implemented ATs (n=9), n (%)	Successfully implemented ATs (n=12), n (%)	Unsuccessfully implemented ATs (n=9), n (%)
Adopters	3 (25)	2 (22)	1 (8)	3 (33)
Technology	7 (58)	5 (56)	3 (25)	7 (78)
Contextual	4 (33)	0 (0)	3 (25)	5 (56)
End user	2 (17)	2 (22)	1 (8)	4 (44)
Implementation strategy	2 (17)	2 (22)	3 (25)	3 (33)

Discussion

Main Findings

This study used a cross-sectional design to survey Interdem researchers with experience in AT projects for people with dementia on factors that influence the implementation of AT. This resulted in 21 survey responses, describing 12 successfully and 9 unsuccessfully implemented ATs. The main finding was that certain characteristics of the AT itself, such as the type of device used and the user-friendliness of the AT, seemed to be the most important for implementation success. Usability is one of the most relevant issues for successful implementation of technology [29]. The results also showed that contextual factors, although they can contribute to an AT's successful implementation, were mostly considered as barriers. Furthermore, research activities carried out during the development process of an AT, such as studies on the user-friendliness and effectiveness of the AT, were more often related to successful implementation. The findings add value to the existing literature by helping fill the identified gap in knowledge [29,30] on implementation determinants in AT for dementia. This study on AT implementation has resulted in several important lessons for researchers, clinicians, and policy makers that can be considered as guidelines for successful implementation of AT in dementia.

Lesson 1: Enhancing Value

The first lesson concerns how specific characteristics of the AT device are associated with implementation success. First, the ability to use the AT on multiple devices proved to be an important facilitator. This enables users to select a device matching their preferences and their capability to operate it. The possibility of multiple devices could also be related to another finding, namely the benefit of the availability of multiple delivery options for implementation success, such as the possibility of using a device not only indoors but also outdoors. The finding that an AT's flexible delivery on multiple devices was an implementation determinant is consistent with previous research that identified a lack of interoperability as the biggest barrier to innovation, as it is often very hard to integrate new ATs into existing systems and devices [31]. Second, the finding that an AT's user-friendliness played a considerable role in implementation success is in line with the outcomes of a previous systematic review on the implementation determinants of ATs for dementia [29]. However, as previously advocated by Bennett et al [32], it is important to find a balance between ease of use (for example, few or only simple actions required by the user) and proper diligence in terms of privacy and data security. This involves a thorough analysis of the implications of an AT for human rights laws, such as impacts on freedom of movement or privacy. Services such as surveillance technology should be refined to find the best balance between privacy and usefulness [33]. In sum, it is recommended to enhance an AT's value through specific device characteristics, such as interoperability, user-friendliness, and an ethical approach to data security.

Lesson 2: Optimizing Fit

The survey showed the importance of involving different stakeholders to facilitate implementation success. Previous research has emphasized the need to involve people with dementia throughout the development, evaluation, and implementation of ATs for dementia [34]. However, this study also makes clear that successful implementation depends on a wide involvement of actors in the dementia care network. Rigorously mapping stakeholder needs for a particular AT not only contributes to a more appropriate business model and sustainability, it also facilitates person-centered care [35] by taking into account the needs of all persons involved in the dementia care network. Potential barriers and facilitators such as workload and lack of resources in formal care, as well as easy access to and affordability of the AT for informal carers can be considered timely [36]. Moreover, the study findings indicate that the same feature can both hinder or facilitate implementation, depending on the context. This implies that there is no universal rule for implementing ATs successfully, and it remains necessary to adapt each AT to its implementation context, resulting in a better fit [36,37]. The findings of this study thus suggest that people with dementia as well as other stakeholders should be engaged in the cocreation of new technologies for dementia and that new ways and methodologies should be developed to promote this cooperation [38]. In sum, it is recommended to optimize the fit to the target group or groups by involving a wide range of stakeholders, in addition to people with dementia, at every stage of AT development and evaluation.

Lesson 3: Ensuring Equity and Sustainability

A third lesson is that the affordability of ATs in dementia care is important for equal access to care and, in turn, for sustainable implementation. This has also been stressed by Moyle [39], who pointed out that ATs can be quite expensive, as personalized solutions are preferred. A recurring criticism of ATs such as eHealth has been that they can foster exclusion, as users must have a high level of digital and mental health skills to engage with some ATs, as well as sufficient resources to purchase the required devices [40]. Moreover, the COVID-19 pandemic has exacerbated health inequalities around the world [41]. Not only did the disease itself lead to worse health outcomes in vulnerable populations, the limitations on human contact disproportionately affected older people, accelerated cognitive decline in people with dementia, and increased social isolation of informal carers [42,43]. ATs could prevent understimulation and support social contact at a distance. Thus, successful implementation of ATs is important.

A first way AT developers can mitigate these inequities in AT implementation for dementia is by ensuring affordability through business modeling [44]. Previous research has emphasized the benefits of preliminary business models for new ATs. A study of AT applications in dementia not only helped to determine (affordable) costs and revenues, but also showed that establishing a business model facilitates decision-making by potential implementers, as there is an indication that the AT will be available beyond the study period and that efforts to apply the AT will not be wasted [45]. A second way is for AT developers to emphasize the importance of rigorous research regarding evaluation and implementation that takes the diverse characteristics of potential target users into account. This study confirmed that the execution of certain research activities, such as research into user-friendliness and effectiveness, was in itself a success factor in AT implementation. An intersectional research approach would strongly contribute to better implementation of ATs in dementia. Intersectionality is centered around "a variety of multi-level interacting social locations, forces, factors and power structures that shape and influence human life," which goes beyond gender-specific and social-determinant frameworks [46]. An intersectional approach can help broaden the impact of ATs intended for dementia care to a more diverse group by taking a wider range of needs into account and not reducing individuals to one defining characteristic, such as age, gender, migration status, education, sexuality, or ethnicity. It can also reduce implementation barriers by avoiding an unpersonalized, one-size-fits-all approach [47]. In sum, it is recommended to ensure equity and sustainability in AT implementation through an intersectional approach and business modeling.

General Recommendations

The findings from this study have produced a number of useful lessons for a variety of stakeholders, including researchers who wish to bring their ATs into practice, clinicians who want to provide the most suitable AT to their clients, and policy makers who wish to know the most effective ways to fund AT development, research, and implementation. In general, based on these findings, we recommend considering alternative study designs that are flexible and suit the fast-paced, changing, and innovative nature of technology, as well as the progressive disease trajectory of dementia, to complement more rigid and resource-intensive designs, such as randomized controlled trials. These alternative study designs can iteratively and responsively examine the user-friendliness, effectiveness, cost-effectiveness, and sustainability of the implementation of ATs, with varying relevant outcome measures depending on the studied stakeholder group.

These recommendations for improving successful implementation of ATs in dementia care are in line with previous implementation research findings [48-50]. For example, Ienca et al [51] proposed a proactive approach, taking into account four normative principles that may help successful implementation: (1) minimization of power imbalances in decision-making, which could be achieved through cooperation among different stakeholders, including end users; (2) compliance with biomedical ethics, such as beneficence, nonmaleficence, autonomy, and justice; (3) translation of research into practice; and (4) raising social awareness and sharing knowledge across society. They additionally complement the recent recommendations made in the *INDUCT/DISTINCT Best Practice Guidance on Human Interaction with Technology in Dementia*, including its recommendations around business modeling and optimizing AT fit to the implementation context [30].

Strengths and Limitations

A first major strength of this study is the multidisciplinary range of respondents' professional backgrounds. Although it is not clear how representative the Interdem Network is of researchers in the field of psychosocial dementia care in Europe, the multidisciplinarity of the network, ranging from physicians (psychiatrists, geriatric care physicians, and neurologists); clinical, social, and neuropsychologists; social scientists; paramedics; palliative care specialists; and movement scientists, allowed us to potentially involve a broad group of participants from diverse backgrounds in this survey. A second major strength of this study is the combined use of qualitative and quantitative research methods to paint a rich and detailed picture of the current field of implementation of ATs for dementia. This richness of data also sheds light on what happens after the end of the research phase, during which the interventions are well controlled and care professionals are motivated to participate. Hence, the added value of this research to the existing literature is its assessment of implementation results in real environments, in addition to quantitative data.

This study also had some important limitations, which need to be mentioned. First, the study had a cross-sectional design, which does not allow for any causal interpretations of the associations found between the studied implementation determinants. Furthermore, the survey questionnaire is in its first iteration and not psychometrically tested. Nonetheless, this study constitutes a first, important step toward identifying relevant determinants of successful implementation of ATs in dementia care for future study. Second, this study had a rather limited sample size and large variety of ATs and surveyed countries, making it difficult to generalize the findings. Also, we do not know the exact response rate as we do not know how many Interdem members had done research with AT at the time the survey was conducted. Also, the small sample size may have resulted in a biased sample. As a result, the analysis of this exploratory study was limited to a descriptive approach. Altogether, 20 different ATs were considered by the respondents, with specific issues addressed. Given the involvement of the respondents in the different ATs, despite the small sample size, valuable information has been obtained in this study. Third, the terminology used in the survey in this study regarding "free-to-use" interventions may have led to different interpretations, making it hard to draw definitive conclusions on this. It is possible that this was interpreted as "without costs for the end user," even though there are still costs for other parties, such as the implementing organizations or health insurers. Finally, this study focused only on a limited number of high-income implementation contexts. Therefore, the study's insights may not all apply to a wider variety of contexts, such as low- and middle-income countries.

Directions for Future Research

This study highlights several important areas for future research. First, while a number of implementation determinants were associated with successful implementation, future research could attempt to infer which strategies are the most effective in facilitating AT implementation by differentially evaluating these strategies in experimental designs tailored to specific types of AT and implementation contexts. Second, it would be useful to explore AT implementation in different contexts, including low- and middle-income countries. Finally, this study should be followed up, and participants should be asked to provide more qualitative first-hand data on their implementation experiences. In doing so, it will be important to ask people with dementia, informal carers, and care professionals about why they want or do not want to use these interventions.

Conclusions

This study provides insight into some main facilitators of and barriers to successful implementation of ATs in dementia care, such as factors related to the AT itself, contextual factors, if accompanying research activities were done into the AT, and applied implementation strategies. Based on this, lessons and recommendations were formulated to improve the implementation of AT in dementia care.

Acknowledgments

We would like to thank all Interdem members involved in disseminating and completing the survey for their time and support.

Abstract

Background: Considering the growing population of older adults, addressing the influence of loneliness among this demographic group has become imperative, especially due to the link between social isolation and deterioration of mental and physical well-being. Technology has the potential to be used to create innovative solutions to increase socialization and potentially promote healthy aging.

Objective: This 6-month study examined the usability and acceptability of a technology-based socialization service and explored how stress and living situation affect older adults' and their ecosystem's perceptions of technology, investigating cross-sectional and longitudinal differences among and across user groups.

Methods: Participants were recruited in Tuscany and Apulia (Italy) through a network of social cooperatives and a research hospital, respectively. A total of 20 older adults were provided with the same technology installed on a tablet and on a smart television. The technology has three functionalities: video calling, playing games, and sharing news. Additionally, 20 informal caregivers (IC) and 13 formal caregivers (FC) connected to the older adults were included in the study. After both initial training in the use of the system (T0) and 6 months of using the system (T6), questionnaires on usability, acceptability, and technostress were filled in by older adults, IC, and FC. Nonparametric or parametric tests were conducted to investigate group differences at both time points and changes over time. Additional analyses on older adults were done to assess whether differences in usability and acceptability were related to living situation (ie, alone or with someone). Furthermore, correlation analyses were performed between usability, acceptability, and stress toward technology at T0 and T6.

Results: At both T0 and T6, older adults had lower usability scores than IC and FC and higher anxiety than IC. Over time, there was a significant decrease in older adults' attitudes toward technology score, depicting a negative attitude over time (T0 median 4.2, IQR 0.5; T6 median 3.7, IQR 0.8; Cohen *d*=0.7), while there was no change for IC and FC. At T0, those living alone had lower acceptability than those living with someone but this difference disappeared at T6. People or participants living with someone had a decline in anxiety, attitudes toward technology, enjoyment, and perceived usefulness. Stress toward technology affected usability and acceptability in the older adult group entering the study ($\rho=-.85$) but this was not observed after 6 months. In the IC group, stress affected trust at T0 ($\rho=-.23$) but not at T6.

Conclusions: At the start of the study, older adults judged the system to be less usable and more stressful than did the caregivers. Indeed, at first, technostress was correlated with usability and acceptability; however, with repeated use, technostress did not influence the perception of technology. Overall, getting accustomed to technology decreased anxiety and stress toward technology.

active aging; longitudinal study; technostress; technology usability and acceptance; scaling up

Introduction

Technological advances in health care research have extended the longevity of the population. However, solely increasing lifespan does not assure healthy aging or prevent age-related diseases. Older adults commonly report feeling lonely and socially isolated, feelings which are linked to decreased mental and physical health [1,2]. In Italy, 31.5% of people aged 65 years and older have limited autonomy due to health problems [3]. In 2019, it was estimated that 11.3% of older adults had depression, with the presence of comorbidity (ie, of other chronic conditions). Currently, about 65% of older adults with limited autonomy are helped by relatives, paid services, or others [3].

In this context, technological devices may play a pivotal role in supporting activities of daily living and promoting independent living. Technological devices are products that can be used to assist by increasing, maintaining, or improving functional capabilities of people with disabilities or difficulties [4]. These can range from communication devices to wheelchairs to visual or hearing aids. In recent years, there have been several research projects that have tried to develop technological devices to promote independent living and active aging [5,6]. Additionally, older adults are more likely to be experiencing or using new internet-driven personal devices such as smartphones and computers in their daily lives than before, boosted by the effects of the COVID-19 pandemic [7]. In that regard, formal caregivers (FC) and informal caregivers (IC) can play a crucial role in fostering the adoption of these technologies by older adults [8].

Contrary to stereotypes, many older adults show positive attitudes and expectations toward technological devices [9,10]. For instance, several studies have highlighted an association between social interaction through internet use and the quality of life of older adults [11]. Internet communication provides an inexpensive tool to stay connected with friends, family, and society. However, currently, the older population for the most part is not digitally experienced and decreased cognitive and physical abilities could be barriers to learning how to use technology [12,13]. Furthermore, personal susceptibility to stress could influence performance by increasing cognitive load [14].

The settings and environments in which technological devices, products, and services may be used are numerous and extend from older adults' homes to nursing homes and hospitals. In an independent living situation, technology can be used to monitor older adults by constantly monitoring their living environment, physical activity/exercise, medicine uptake, blood pressure, and heart rate, and it can also support caregivers in their daily tasks [15-17]. In a survey conducted during the COVID-19 pandemic, more than half of older adults reported that they used technology to connect with others and that they adopted new technologies since the start of the pandemic. The study also indicated that one of the main factors that supported older adults' willingness to learn was keeping in touch with family members, especially grandchildren [18]. The same study also highlighted that older adults living in rural areas experienced greater technological barriers to technology use. Moreover, since social isolation and loneliness are associated with higher mortality risk [19], it is important to investigate ways to increase socialization and promote social connectedness; technology could help in this matter. Indeed, although living alone has been suggested to be a risk factor for poor health, studies showed that it was a lack of social connectedness (measured by social network size), rather than the condition of living alone, that was associated with adverse health outcomes [20-22]. Furthermore, results from a systematic review and meta-analysis showed that technological interventions to support older adults in long-term care have one of the largest effect sizes in reducing social isolation and loneliness [23]. Regarding technology-supported interventions to improve well-being and socialization, from a recent systematic review [24], it was evident that the available studies had a short time span and less than half employed tailored solutions. The short time span between baseline and follow-up found in previous studies does not allow for an in-depth investigation of the effects of the use of different technological devices among older adults. Furthermore, as noted by an embedded case study [25] and reviews [26,27], adoption and acceptance are influenced by social influence from family, friends, and caregivers. It is therefore important to explore the whole ecosystem that revolves around older adults to understand the reasons behind low usage of a device or user acceptance. Additionally, soliciting a multistakeholder perspective by engaging both older adults and their caregivers in a study would be advantageous and provide further support for research outcomes.

In this context, this paper presents a service designed to increase socialization in older adults through a technological device. The study is part of the Pharaon project [28], which is a large-scale pilot under the "Digitising European Industry" strategy. The project aims to promote active aging using already available and mature platforms and technologies. The Pharaon project uses the action research method, which entails 4 cyclical actions: reflect, plan, act, observe, and then reflect again to continue through the cycle. Specifically, after deployment and data collection, reflection meetings were organized to assess how the deployment was proceeding and to better plan next actions.

For this particular socialization service, the same technology was installed on two different user interfaces (UIs): a smart television or a tablet. This technology allowed video calling between older adults (n=20) and their IC (n=20) and FC (n=13), and it offered the ability to share news/pictures and play games. The service was implemented for 6 months in the home of the older adult. The 3 cohorts were compared with each other and over time in terms of usability and acceptability in a cross-sectional and longitudinal design. Furthermore, we explored whether stress or living alone/with someone affected user perception of the older adult. Specifically, we aimed to answer the following research questions (RQ):

- RQ1: Are there any differences in acceptability and usability intergroup and between cohorts (ie, older adults, IC, FC) over time? For the older adults, are differences related to different devices?
- RQ2: Can living situation represent a discriminant factor for acceptance and usability of technology by older adults?
- RQ3: Will stress related to technology usage affect usability and acceptability as reported by older adults?

Methods

System Service Description

The types of technologies were selected based on feedback received from older adults and their caregivers during the needs analysis phase of the project. In the Italian pilot, the needs analysis led to the identification and deployment of two services: monitoring and socialization [29]. In this paper, we focus only on the socialization service.

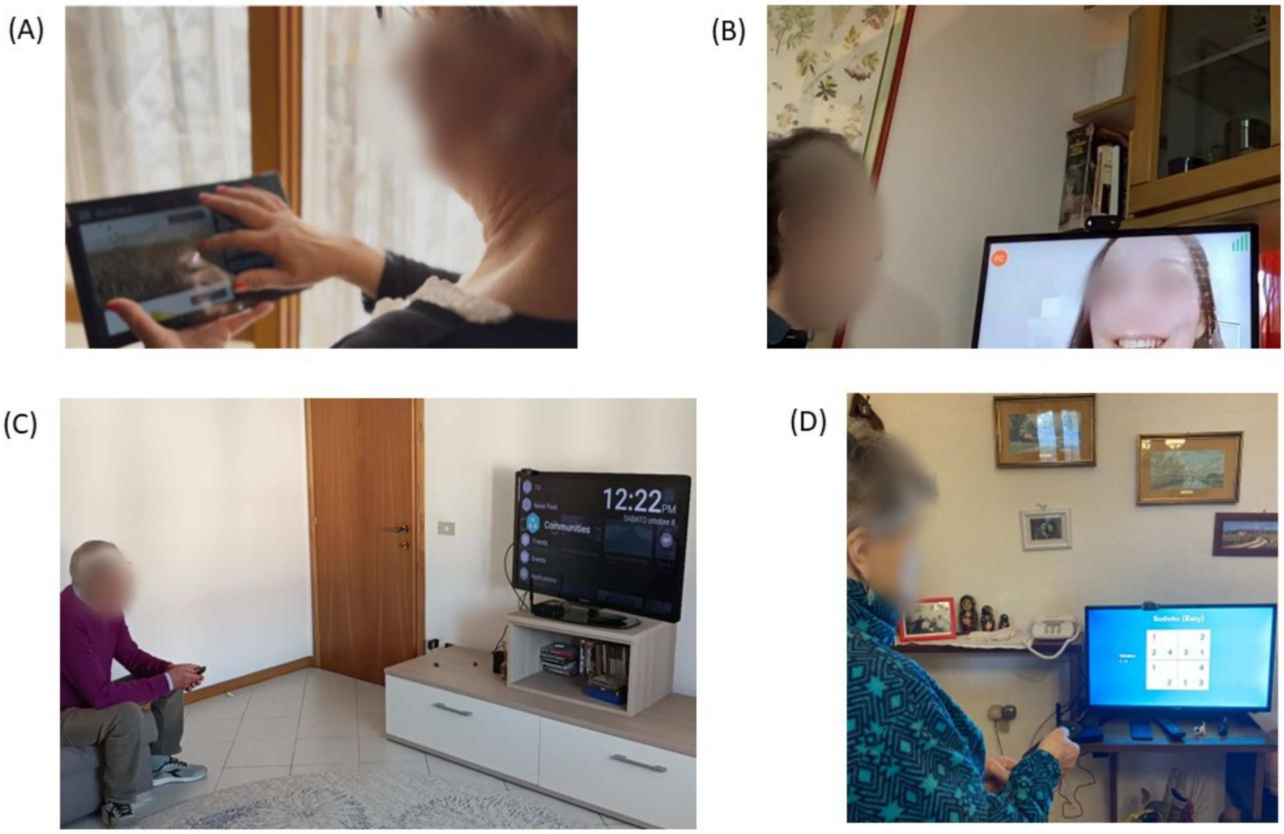
The socialization service is based on Sentab technology (Sentab Estonia OÜ). The system was developed around a UI working on the web, Android, iOS, and Android TV. From a technical perspective, the Sentab backend solution was based on Enterprise Java on Jetty, open source RabbitMQ, and Redis dockers. Information was stored in a MySQL database on Ubuntu servers. The content delivery network was built on Amazon CloudFront and S3.

In the project, two UIs were used: an Android application installed on tablets (Apulia) and televisions (Tuscany) and an Android app for caregivers installed on their mobile phone. This final choice was made based on the feedback received from pilot managers as an outcome of the needs assessment. It is worth underscoring that the service was the same for both technologies—only the devices changed.

The older adults could interact with the tablet using the touch screen, whereas for the television, a separate remote control was provided and Sentab was accessed using the arrows and an “OK” button (Figure 1). For both technologies (ie, tablet and television), the Sentab technology has the following functionalities: (1) a video calling function, where older adults and their caregivers could video call through the UIs; (2) a stimulating game function, where older adults can access some cognitive games (eg, sudoku, picture memory) and monitor their improvement by checking the cognitive index calculated by Sentab; and (3) a stay-informed function, where older adults and IC can access news and information shared by hospital clinicians regarding best practices for maintaining a healthy and active lifestyle.

An overview of the socialization service can be found online [30]. By connecting to their UIs, caregivers could communicate with their relative (or “assigned” older adult) and share photos or news.

Figure 1. Photographs illustrating participants enrolled in the study. All participants agreed and consented to have their picture taken and used in publications. (A) Older adult checking the “stay informed” function on the tablet. (B) Older adult video calling their formal caregiver on a smart television. (C) Older adult using the smart television. (D) Older adult participant using the television game app.



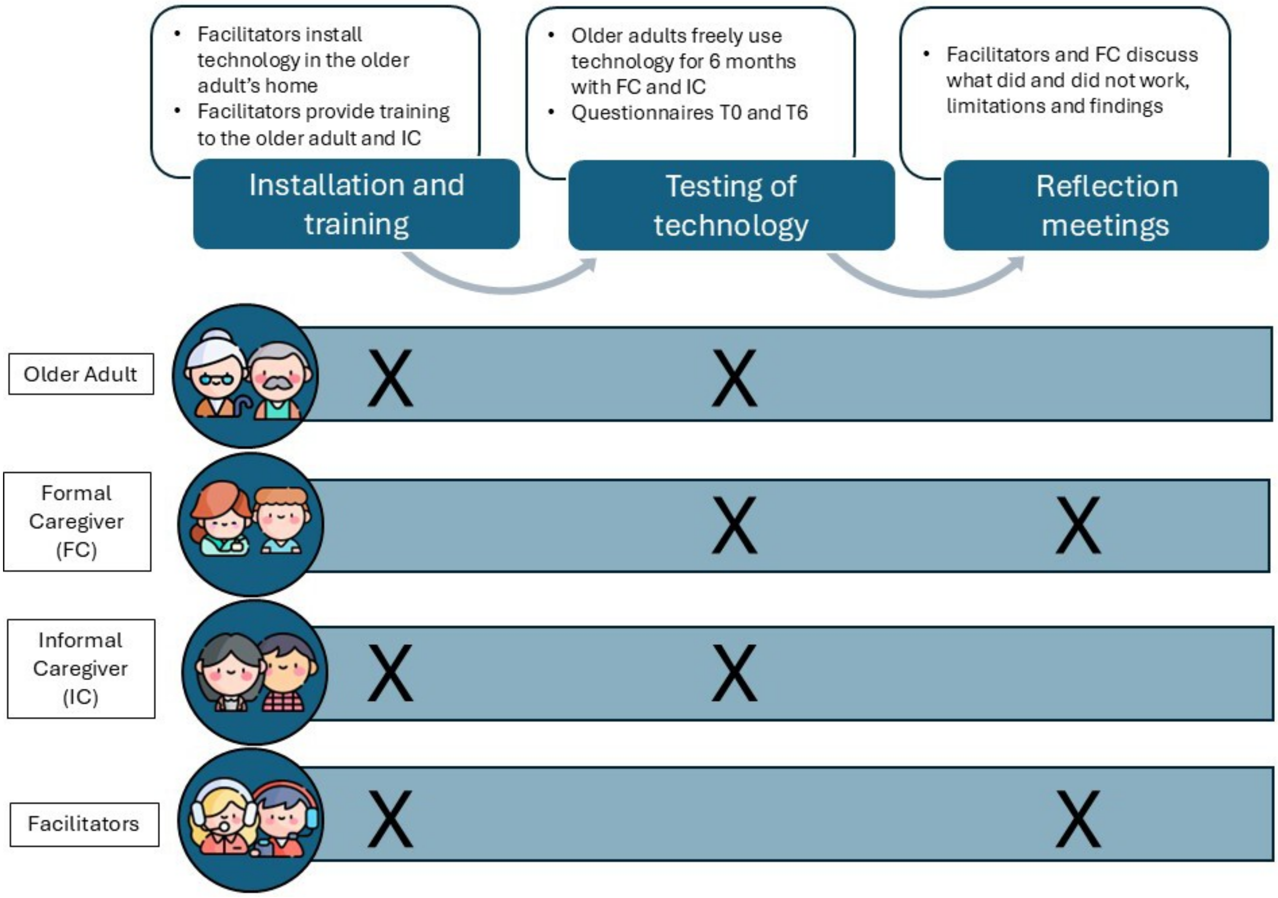
Experimental Protocol

The experimental protocol was composed of the following phases: installation and training, testing of technology, and a reflection meeting. An overview of these phases is presented in Figure 2.

As mentioned in the System Service Description section, Tuscany and Apulia tested different devices. In Tuscany, the smart television was installed in the older adult’s home and then facilitators trained them in the use of the technology. On the other hand, in the Apulian pilot, facilitators trained the IC together with the older adult and the tablet was subsequently given to the older adult to take home and use freely. The participants could ask questions for clarification. At the end of the training, facilitators gave the participants the user manual along with their contact details.

As soon as the participants felt confident with the technology, the facilitators administered the questionnaires, providing baseline data (T0). Participants were then requested to freely use the technology and the service functionalities in their daily life. After 6 months of use (T6), they were requested to fill in the same questionnaire that was administered at T0. A description of the questionnaires is provided in the Questionnaires section.

Figure 2. Graphical description of the experimental protocol of the 3 consecutive phases. The “X” represents when a certain cohort participated in a specific phase. Icons were downloaded from Flaticon [31]. FC: formal caregiver; IC: informal caregiver; T0: start of study; T6: end of study (after 6 months of technology use).



To better understand the end users, we used an action research approach that suggests organizing reflection meetings to critically reflect on the “results of action” [32] and to underscore the lessons learned in terms of aspects that did or did not work well in the pilot. The reflection meeting was scheduled after the first 6 months of use to collect feedback and it involved meeting facilitators, facilitators, and FCs. The meeting facilitators were in charge of presenting the results, fostering discussion, and taking notes during the meeting.

The meeting was divided in three parts: presentation of the results following the first 6 months of use, discussion with the facilitators and FCs, and an online survey. After the initial presentation, the quantitative results were discussed to understand whether the facilitators and FCs expected or were surprised by these results and whether they could explain the results in a qualitative way. The discussion touched on the following: (1) the things that did and did not work properly; (2) the limitations of the technology; and (3) the findings of the study, including acceptance of the technology. After the plenary discussion, before closing the meeting, participants were asked to complete an online survey to give feedback on the main factors related to technology readiness and its acceptability; additionally, participants were asked to report what they considered to be a significant outcome from the perspective of the older adult, IC, and FC. The results of this meeting and survey were then aggregated to critically discuss the results of the questionnaires and to plan and suggest corrective actions for future tests.

Participants

In order to answer this study’s RQs, three cohorts of participants were recruited: older adults, IC, and FC (professionals in charge of their monitoring). A total of 105 people were recruited to be part of the study: 40 older adults, 40 IC, and 25 FC. The older adults were recruited and were randomized 1:1 into either the control or intervention group. The IC and FC were divided into control and intervention groups according to their older adult’s randomization.

The inclusion criteria for the older adults were aged ≥60 years, intact cognitive status (Mini-Mental State Examination score >24), and a frailty score from well to moderately frail; exclusion criteria were presence of severe cognitive impairment and other conditions that cause memory impairment or engagement difficulties. Participants in the control group were recruited with the same inclusion and exclusion criteria; this group did not interact with the technology and was only required to fill in the sociodemographic questionnaire. In this study, we will focus on the user experience of technology use, and thus only focus on the intervention group (older adults: n=20; IC: n=20; FC: n=13).

Participants were enrolled in two Italian regions (Apulia and Tuscany) that composed the Pharaon Italian Pilot. The recruitment strategies were different across the two pilots; in Apulia, the IC was recruited first, whereas in Tuscany, the older adult was recruited first. In Apulia, the participants were recruited at the Casa Sollievo della Sofferenza research hospital (San Giovanni Rotondo, Foggia, Italy) in different clinical units and at the University of the Third Age, and no participants were cognitively or medically compromised. In Tuscany, the participants were recruited among people that were already accessing home services provided by the Umana Persone S.r.l. (Grosseto, Italy) network of social cooperatives. The research was approved by the Comitato Etico Clinico, Azienda USL Toscana Sud Est on July 22, 2021 (Prot. 2021/000227), and by the Azienda USL Toscana Centro on October 18, 2022 (Prot. 2022/22131_spe). Furthermore, the two pilot sites used the technology either on a tablet or a smart television according to guidelines and feedback acquired in the needs analysis [29].

Ethical Considerations

The ethical committee of the Casa Sollievo della Sofferenza research hospital approved the research on June 14th, 2021, with protocol number 89/CE. All participants read and signed the informed consent form before entering the study. The collected data were anonymized and no compensation was provided to participants.

Facilitators

Following the action research framework and to better discuss and reflect on the RQs, we also involved the facilitators, who have different professional backgrounds ranging from engineers to cooperative managers to health professionals, and whose main task was to ease the use of technology in all 3 cohorts and solve any problems that arose during the experimentation. Additionally, facilitators installed the technology and delivered the training to the intervention group and administered the questionnaires.

A total of 20 participants joined the reflection meeting: 5 participants from the University of Florence, who acted as meeting facilitators; 3 participants from the Apulian pilot site (Casa Sollievo della Sofferenza Research Hospital); and the remaining 12 participants were from the Tuscan pilot site (Umana Persone network of social cooperatives). Only 8 facilitators (3 from the Apulian pilot and 5 from the Tuscan pilot) agreed to fill out the final survey.

Questionnaires

To gather information about the participants' characteristics, sex, age, education, and living situation/environment, a semistructured interview was conducted at the beginning of the study. The Mini-Mental State Examination [33] was administered to assess the older adults' cognitive status.

Usability was measured with the system usability scale (SUS) [34] (Italian version [35]), which is composed of 10 items on a 5-point Likert scale where 1 stands for "strongly disagree" and 5 stands for "strongly agree." Items 2, 4, 6, 8, and 10 need to be reversed. The total SUS score is obtained by adding all the score contributions and multiplying the sum by 2.5. The SUS ranges from 0 to 100; scores lower than 68 are considered below average.

Acceptance was evaluated through the Almere model questionnaire (AMQ) [36], which is composed of 41 items on a 5-point agreement Likert scale. The AMQ is composed of 12 constructs created by combining specific items: anxiety (ANX), attitude toward technology (ATT), facilitating conditions, intention to use (ITU), perceived adaptiveness, perceived enjoyment (ENJ), perceived ease of use, perceived sociability, perceived usefulness (PU), social influence, social presence, and trust (TRUST). We investigated 6 of these 12 constructs: ANX, ATT, ITU, ENJ, PU, and TRUST. Note that ANX is reversed, therefore a higher ANX score translates to lower levels of anxiety.

To measure the quantity of perceived stress related to technology use (technostress), the Perceived Stress Scale [37] (Italian version [38] adapted as in [39]) was administered. The test comprises 10 items with a 0 - 4 Likert scale with 0 meaning "never" and 4 being "very often." Items 4, 5, 7, and 8 have reverse scoring. The total score is calculated as the sum of the single item contributions. A total score from 0-13 is considered low stress, 14-26 is moderate stress, and ≥27 is high stress.

At T6, participants were also asked to estimate how frequently they used technology by asking how many times they used it per day and per month.

A schematic overview of when and to whom the questionnaires were administered is presented in Table 1.

Table . Overview of the interview topics and questionnaires including when they were conducted and with whom.

	T0[a]	T6[b]
Semistructured interview		
Age, sex, education, digital skills	OA[c], IC[d]	—[e]
Living situation (alone/not alone) and living environment (urban/rural)	OA	—
Technology usage question	—	OA
Questionnaires		
Mini-Mental State Examination [33]	OA	—
System usability scale [34], Almere model questionnaire [36], and technostress [39]	OA, IC, FC[f]	OA, IC, FC

[a] T0: start of the study.

[b] T6: following 6 months of technology use.

[c] OA: older adult.

[d] IC: informal caregiver.

[e] Not applicable.

[f] FC: formal caregiver.

Statistical Analysis

Overview

We performed statistical analyses to evaluate longitudinal intragroup and cohort differences in usability and acceptability among the older adults, IC, and FC. Moreover, we investigated the effect of the older adults' living situation (ie, living alone or with someone) and stress related to technology on usability and acceptability. Each analysis is described in detail in the following subparagraphs. For each questionnaire, we calculated reliability with Cronbach α. Given the low sample size, a value of ≥.6 was deemed acceptable [40,41]. Effect sizes of significant results were calculated with Cohen *d*. In the statistical tests performed, a *P* value <.05 was considered statistically significant. Statistical analyses and graphical illustrations were performed using RStudio [42] (version 4.2.3; Posit team).

Differences in Usability and Acceptability

Data for SUS and AMQ were checked for normality using the Shapiro test. For changes over time in each cohort (intragroup), we checked for normality the distribution of the differences between T0 and T6. If the data were normally distributed, we performed a two-tailed paired *t* test to examine differences over time, otherwise a paired Wilcoxon signed-rank test was preferred. For older adults, additional analyses were performed to investigate differences between pilot sites.

A two-way mixed ANOVA was used to compare the scores for older adults, IC, and FC at T0 and T6, as well as changes over time (cohort differences). For older adults and IC, the models were also repeated including age and sex in the model to account for demographic differences in the two cohorts. If there was a statistically significant effect, post hoc two-tailed pair-wise *t* tests were Bonferroni corrected.

Effects of Living Situation on Usability and Acceptability in Older Adults

For older adults, a two-tailed *t* test was performed to investigate the effects of living situation (ie, alone or with someone) at T0 and T6, and a two-tailed paired *t* test was used to assess change over time between T0 and T6.

Effects of Technostress on Usability and Acceptability

For the older adult, IC, and FC groups, correlations were performed between technostress, SUS, and AMQ results. Data for technostress, SUS, and AMQ were checked for normality using the Shapiro test. If data were normally distributed, the correlation was Pearson, otherwise it was Kendall.

Results

Participant Characteristics

The demographic and cognitive characteristics as well as technostress at T0 and T6 for older adults and IC are presented in Table 2.

Participants on average used the technology 4 times per week. Overall, 85% (17/20) of the older adults lived in an urban area, and 60% (12/20) of the older adults lived with someone, of which 42% (5/12) lived with their IC. The older adults' associated FC were predominantly women (69%, 9/13). The FC were of various professional backgrounds including psychologists, nurses, and care workers. No other demographic information was collected for FC.

Table . Demographic and cognitive characteristics and technostress in the older adult and informal caregiver groups.

Characteristics		Older adults (n=20)	Informal caregivers (n=20)
Age (years), mean (SD)		77.15 (7.07)	47.85 (13.10)
Sex (women), n (%)		14 (70)	9 (45)
Education, n (%)			
	Primary education	13 (65)	0 (0)
	Secondary education	5 (25)	10 (50)
	Tertiary education	2 (10)	10 (50)
Mini-Mental State Examination score, median (IQR)[a]		26.45 (6.55)	—[b]
Technostress, median (IQR)[a]			
	T0[c]	13 (11.50)	7.00 (9.25)
	T6[d]	10.50 (3.50)	5.50 (5.50)

[a] Median values and IQR are presented when the variables were not normally distributed.

[b] Not applicable.

[c] T0: start of the study.

[d] T6: following 6 months of technology use.

Differences in Usability

Intragroup and Pilot Site Differences in Usability

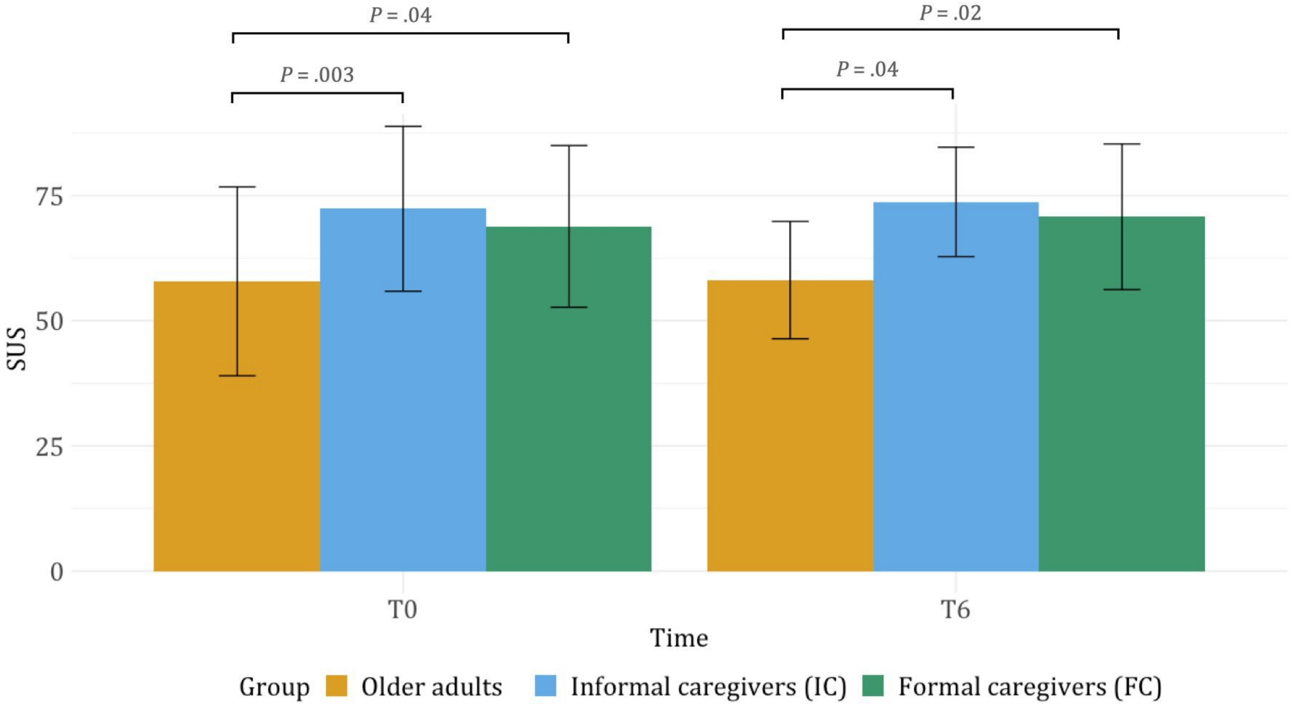
The Cronbach α for the SUS in all groups was higher than .6 at both T0 and T6.

In the older adults group, the distribution of the difference over time in the whole sample was not significantly different from a normal distribution, and normality was assumed. The mean SUS score increased slightly over time; however, this increase was not significant (Figure 3).

Both the Apulian and Tuscan pilot differences over time were distributed normally; still, there was no significant change over time. The mean of the Tuscan pilot increased and the standard deviation decreased, whereas in the Apulian pilot, mean SUS score decreased from T0 to T6 (Apulia T0: 70.8, SD 12.2 vs T6: 66.5, SD 4.7; Tuscany T0: 45.0, SD 15.3 vs T6: 49.8, SD 10.6).

In the IC group, the distribution of the differences over time in the whole sample was not significantly different from a normal distribution, whereas it was normally distributed for the FC group. The SUS score did not change over time in both groups (Figure 3).

Figure 3. SUS score in older adults, informal caregivers, and formal caregivers at T0 and T6. The error bars represent the standard deviation for each group. The brackets highlight statistical differences between groups. Note that the difference between older adults and FC at T0 and T6 was not significant after post hoc Bonferroni correction. SUS: system usability scale.



Cohort Differences in Usability

A 2-way mixed ANOVA with group (older adult, IC, and FC), time, and group × time interaction showed an effect of group on SUS score, but not of time or group × time interaction. Post hoc pair-wise *t* test showed a significant difference between older adults and IC at T0 (older adults: mean 57.9, SD 18.9; IC: mean 72.4, SD 16.5; *P*=.003; Cohen *d*=0.8) and T6 (older adults: mean 58.2, SD 11.7; IC: mean 73.8, SD 10.9; *P*=.001; Cohen *d*=1.4), and between older adults and FC both at T0 (FC: mean 68.8, SD 16.2; *P*=.04; Cohen *d*=0.6) and T6 (FC: mean 70.8, SD 14.6; *P*=.02; Cohen *d*=0.9) (Figure 3). At both time points, the older adults had significantly lower SUS scores than the IC and FC. The difference between older adults and IC was not statistically significant when considering age and sex in the model (group × time interaction *P*=.86). The difference between older adults and FC was not statistically significant after post hoc Bonferroni correction (T0: *P*=.13; T6: *P*=.06).

Differences in Acceptability

Intragroup and Pilot Site Differences in Acceptability

For the older adults and IC groups, Cronbach α for each construct of the AMQ was ≥.7 at T0 and T6. In the FC group, at T0, Cronbach α was greater than .6 for all constructs except PU, for which it was .2. At T6, reliability was greater than .7 for all AMQ constructs.

In the older adults group, for ITU and TRUST, the distribution of the difference over time was not different from a normal distribution. The distributions of the difference over time in the other constructs (ie, ANX, ATT, ENJ, TRUST) were not normal.

ATT significantly decreased (*P*=.01; Cohen *d*=0.7), whereas the other constructs did not significantly increase or decrease over time (Figure 4). In the Apulian pilot, there was a significant decrease in ANX over time (T0: 4.9 and T6: 4.3; *P*=.03; Cohen *d*=1.0) but no other significant changes in constructs were found. No changes in AMQ constructs over time were found in the Tuscan pilot (see Table S1 in Multimedia Appendix 1 for mean and median values).

In the IC group, the distribution of the differences was different from a normal distribution for ANX, but the distribution of the differences for other constructs could be assumed to be normal. In the FC group, the distribution of the differences in all constructs was not different from a normal distribution. There was no significant change over time in any construct in either the IC or FC group (Figure 4).

Figure 4. Mean values and standard deviations in parentheses for all acceptability constructs for older adults, informal caregivers, and formal caregivers at T0 (start of the study) and T6 (after 6 months of technology use). The green background highlights the higher value for each row, either at T0 or T6. Note that values are mean (SD) or median {IQR} according to the normality of the differences over time.

	Older adults		Informal caregivers		Formal caregivers	
	T0	T6	T0	T6	T0	T6
Anxiety	4.4 {2.6}	4.0 {1.1}	4.9 {0.6}	5.0 {0.5}	4.3 (0.5)	4.4 (0.6)
Attitude toward technology	4.2 {0.5}	3.7 {0.8}	3.9 (0.6)	3.8 (0.8)	3.8 (0.4)	3.7 (0.5)
Intention to use	3.9 (1.0)	3.5 (1.1)	4.1 (1.0)	3.6 (1.2)	4.0 (0.5)	3.7 (0.8)
Perceived enjoyment	3.5 {0.8}	3.3 {0.5}	3.5 (0.6)	3.8 (0.9)	3.7 (0.5)	3.4 (0.6)
Perceived usefulness	3.7 {0.8}	3.5 {1.0}	3.7 (0.7)	3.4 (1.0)	3.6 (0.4)	3.5 (0.6)
Trust	3.6 (0.7)	3.3 (1.0)	3.4 (1.0)	3.2 (1.1)	2.9 (0.9)	3.3 (0.7)

Cohort Differences in Acceptability

A 2-way mixed ANOVA with group (older adult, IC, and FC), time, and group × time interaction showed an effect of group on ANX, and time for ATT and ITU. No other group, time, or group × time interactions were found.

For ANX, post hoc pair-wise *t* test showed a significant difference between older adults and IC at T0 (*P*=.005; Cohen *d*=0.7) and T6 (*P*=.002; Cohen *d*=1.2), with older adults having higher anxiety than IC. The significant difference in ANX between older adults and IC remained after post hoc Bonferroni correction but disappeared when accounting for age and sex in the model (T0: *P*=.20; T6 *P*=.68). For ATT, there was a significant effect of time for only the older adults, as discussed in the Differences in Acceptability section (Figure 4). There was no effect of time on ITU for any group.

Effects of Living Situation on Usability and Acceptability in Older Adults

For usability, at T0 and T6, there was no difference between those living alone and those living with someone. There was no significant change over time in SUS score in either living situation.

For acceptability, at T0, those living alone had significantly lower AMQ constructs than those living with someone (ANX *P*=.02, Cohen *d*=1.1; ATT *P*=.04, Cohen *d*=0.9; ITU *P*=.01, Cohen *d*=1.3; ENJ *P*=.03, Cohen *d*=1.0; PU *P*=.01, Cohen *d*=1.4; TRUST *P*=.01, Cohen *d*=1.3). After 6 months, the difference disappeared (see Table S2 in Multimedia Appendix 1 for mean and median values).

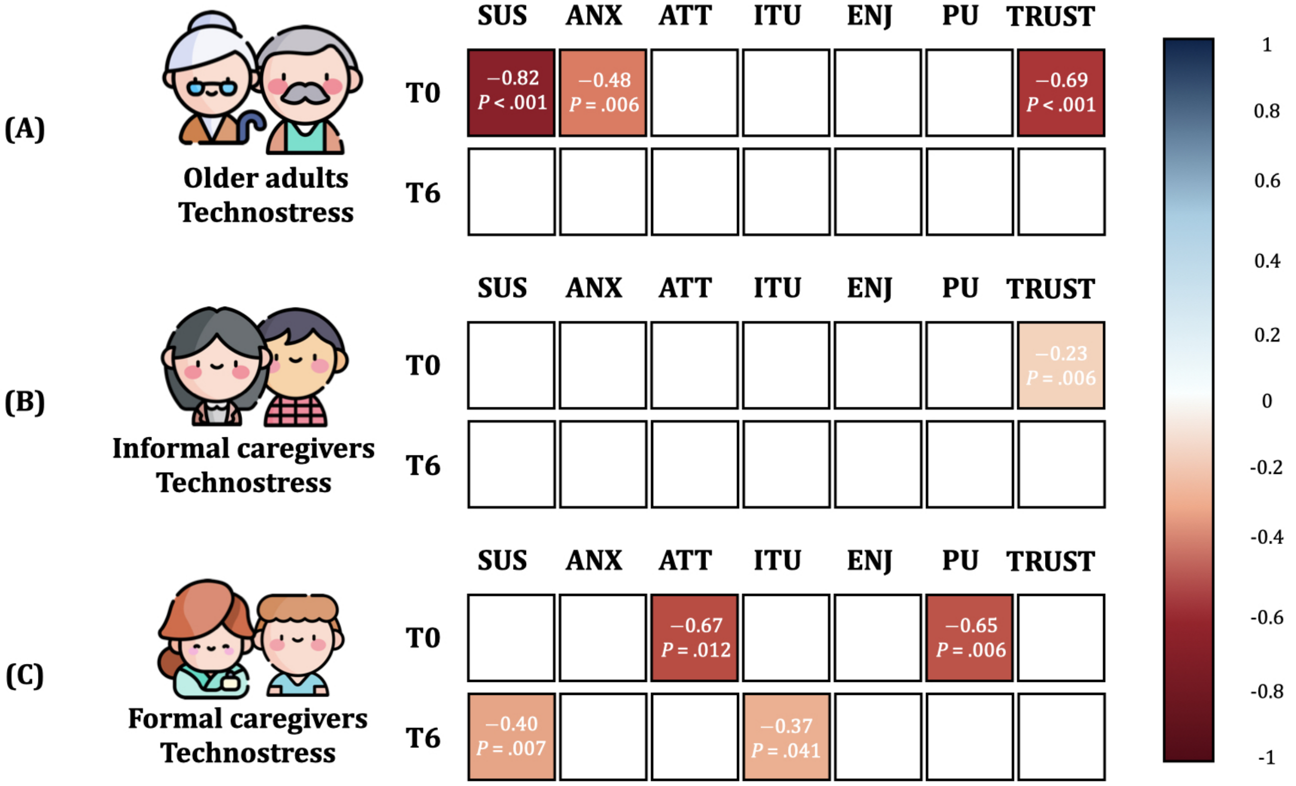
In older adults living alone, there was no change in AMQ constructs over time, whereas in those living with someone, ANX, ATT, ENJ, and PU declined over time (ANX *P*=.03, Cohen *d*=0.7; ATT *P*=.02, Cohen *d*=0.8; ENJ *P*=.03, Cohen *d*=0.7; PU *P*=.04, Cohen *d*=0.6; see Table S2 in Multimedia Appendix 1 for mean and median values).

Effects of Technostress on Usability and Acceptability

Older Adults

At T0, the ANX and ITU constructs of AMQ were not normally distributed, thus Kendall correlation was used; the same applied to technostress, ITU, and PU at T6. We found that technostress was highly negatively correlated with SUS score and TRUST and moderately negatively correlated with ANX (Figure 5A). After 6 months, technostress was not associated with SUS score or AMQ (Figure 5A).

Figure 5. Correlations between stress toward technology (technostress) and user experience (SUS and AMQ constructs) in (A) older adults, (B) informal caregivers, and (C) formal caregivers at T0 (start of study) and at T6 (following 6 months of technology use). Only statistically significant results are presented. AMQ: Almere model questionnaire; ANX: anxiety; ATT: attitude toward technology; ENJ: enjoyment; ITU: intention to use; PU: perceived usefulness; SUS: system usability scale; TRUST; trust.



Informal Caregivers

In the IC group, at T0, technostress, ANX, ITU, PU, and TRUST were not normally distributed; at T6, ANX, ITU, and PU were not normally distributed. At T0, technostress was significantly negatively correlated with TRUST, yet technostress was not associated with SUS score or other acceptability constructs (Figure 5B). After 6 months, the significant correlation between technostress and TRUST was no longer present (Figure 5B).

Formal Caregivers

ENJ and PU at T0 and technostress, SUS, ANX, and TRUST at T6 were not normally distributed. At T0, there was a significant moderate negative correlation between technostress and ATT and between technostress and PU (Figure 5C). At T6, technostress was moderately negatively correlated with SUS score and with ITU; there were no other significant correlations between technostress and AMQ constructs (Figure 5C).

Results of the Reflection Meeting With Facilitators

Overview

The reflection meeting lasted 2 hours and began with the presentation of the results, followed by a discussion. The discussion focused on the personal experiences and perceptions that facilitators and FC had, then touched upon aspects that did and did not work, technical limitations, and findings. The collected feedback was transcribed and combined with the responses collected by means of a questionnaire that dealt with similar topics. These arguments were aggregated and then summarized into concepts that could limit the use of technology. The identified barriers are summarized in the following sections and were used to discuss the quantitative results.

Digital Skills

All facilitators highlighted that in Italy, the educational level and digital skills of older adults are low, a finding confirmed by other studies [43]. These contextual factors could represent a barrier at the start of the study. Particularly, facilitators noticed differences in the ATT between older adults aged 65-70 years old and those aged ≥70 years. They also stated that the younger cohort of older adults was more skilled and "ready" to accept the technology compared to the older group. Indeed, the younger cohort was more likely to have a smartphone and use apps for SMS text messaging (eg, WhatsApp).

Recruitment

During the meeting, the facilitator highlighted some difficulties they had in recruiting the older adults and IC. As mentioned in the Methods section, the two pilots used two different strategies for recruiting participants. In Apulia, facilitators first recruited the IC by asking if they would like to participate in the study with her/his older relatives. Conversely, in Tuscany, the older adults were the first to be recruited. Facilitators also noticed that older adults were more likely to agree to be part of the study when they were part of domiciliary services (Tuscany pilot) or if they already had a relationship of trust with them. During the meeting, the facilitator exchanged ideas and strategies to optimize recruitment in the pilots.

Technology Reliability and Ease of Use

Technology reliability affects the user experience; indeed, facilitators indicated that when there were issues with the technology, such as "internet connection issues" or "other bugs," this had a negative influence on the experience, whereas ease of use was one of the key factors that positively influenced the overall user experience. During the meeting, the Tuscan facilitators reported some difficulties for older adults in accessing the service because the user must switch the "input" source on the television before using the Sentab technology, and the remote needed to be pointed directly at the Sentab box instead of the television. This procedure was considered confusing and complex. It was also noticed that after training, although the older adults were able to make the input switch and were able to use the technology, they tended not to use it independently. This feedback reflects the usability data; indeed, the older adults' usability was lower in the Tuscan pilot than in the Apulian one. However, older adults who were more motivated in using the technology used it without problem; this was the case for a 90 year old enrolled in Tuscany that loved the sudoku game. On the contrary, the Apulian facilitators did not experience any barriers related to technology use (ie, tablets). Indeed, they confirmed that it was the right technology for the older adult population enrolled in the study. Specifically, older adults in Apulia appreciated the size of the digital keyboard letters they were using.

Training

Facilitators observed and reported that older adults had some prejudice and mistrust of new technologies; therefore, we believe that the initial contact and explanation of the project must be effective. Facilitators noticed that older adults often forgot the instructions for the technology, therefore a more effective training process should be composed of multiple training sessions. Indeed, facilitators decided to call back the older adults after the initial training to refresh the instructions during the first weeks of testing.

Cognitive and Living Situation Profile

Facilitators highlighted that the older adults' cognitive profile may impact technology acceptance. Additionally, the older adults' cognitive profile may also impact their understanding of the questionnaire; indeed, the facilitators noticed that sometimes the older adults did not fully understand the questions. Facilitators also noticed some differences in technology perceptions linked to their living situation; namely, that the older adults living alone were overall more enthusiastic and perceived the technology as more useful than those living with someone, qualitatively confirming the research hypothesis.

Engagement

Facilitators highlighted that engagement and use of the technology were related to finding intrinsic motivation and perceiving the added value the technology may have on the older adult's life. Additionally, another suggestion from the facilitator was to foster interaction with other people using the same technology. As a matter of fact, older adults appreciated the presence of the operator and if and when they were unable to play a game, they called the facilitators. In Apulia, the facilitators re-explained the game to one older adult, and she really enjoyed the technology. Therefore, if the older adults are appropriately stimulated, they consequently use the technology. For instance, in the case of the "stay informed" function, the periodical publication of news acted as a "stimulus," so the older adults were more likely to read it. Additionally, facilitators were concerned that the technology could be used by the older adults not solely for the socialization service, but more as a means to foster the relationship with the caregiver. Indeed, in projects such as Pharaon, when the participant is recruited, he/she experiences more physical presence and connection with the operator compared to the usual home assistance service. Therefore, conceivably, the older adults tend to use the technology only with the operator and not independently because they do not know how to use it without assistance or do not have a real reason to use it.

Discussion

This paper aims to investigate the role of time spent using technologies, living situation, and technostress in older adults and their caregivers that were using a technological device aimed at increasing older adults' socialization.

Principal Results and Comparison With the Literature

The first research question aimed to investigate the role of time in technology perception intragroup and between cohorts of participants (RQ1). As for the acceptance evaluated intragroup, except for ATT, the differences reported in Figure 4 are just trends, as they are not statistically significant. It is worth mentioning that the older adult values for ITU (T0=3.88; T6=3.53) and ATT (T0=4.20; T6=3.65) were comparable to the intention to use and attitude measured in a related work (ITU=3.34; ATT=3.73) [44]. Moreover, values for ENJ, TRUST, and PU were similar to those of an older Chinese sample, demonstrating that the values we reported are aligned with the literature [45] even though the populations are geographically different. Note that we evaluated ITU and ATT with different models, but these constructs had comparable items. Additionally, in this study we observed a decrease of ATT for all 3 cohorts of participants over time. This result is aligned with the feedback collected during the reflection meeting; indeed, the facilitators emphasized how engagement is strongly interconnected with the personal intrinsic motivation that leads to long-term use of the technology. It was also noted that the FC or IC contacting the older adults through the technology (whether video calling or news sharing) helped in keeping the participant engaged. The higher value of ATT at T0 may be due to the older adults' initial high expectations. Nevertheless, despite the decrease in ATT, the participants stated they used the system on average 4 times per week.

It is also worth noting that we observed a higher TRUST value for the FC after use compared to the other two cohorts. Higher trust is important because trust is strictly linked with the use of technology. These results are aligned with the feedback collected during the reflection session that highlighted some participants' mistrust in technology use at the beginning of the study, during the training session.

Usability was rated differently between older adults and their caregivers, who on average rated the system higher through SUS. These results are aligned with a recent survey [10] that highlighted a different attitude and expectation toward technology according to age group. Indeed, the statistical difference between the older adults and IC group disappeared when including age and sex as controlling variables. Other than age and sex, there could be other factors that contributed to this result, such as the older adults' digital competence. Furthermore, as described in the Technology Reliability and Ease of Use section, it emerged that in Tuscany, the system was perceived as more difficult to use by older adults, and they needed the caregivers' support to use it. Nevertheless, despite the lower values, the usability for older adults increased over time, though not significantly. This suggests that older adults overcame their initial technical barrier and learned how to use the system, and this was independent of their living situation. Facilitators also noted that technical problems that occurred during the trial or problems surrounding the older adults' experience of using the technology negatively impacted technology acceptance, as also observed by Peek et al [27].

In the Apulian pilot, there was a decrease in ANX, which translated into an unexpectedly higher anxiety perception (see Table S1 in Multimedia Appendix 1 for mean and median values). On the other hand, in the Tuscan pilot, there was no significant decrease or increase in acceptability. However, it is also worth noting that the recruitment of the older adults in the Tuscan cohort was performed among those using domiciliary care services and thus included older adults with higher frailty and lower Mini-Mental State Examination score compared to the older adults in the Apulian pilot site, which might influence perception of the technology. This was also brought up in the reflection meeting. The difference in user experience between the 2 pilots could be related to the different types of technology (television and tablet) selected at the beginning of the study or to the slightly different profile of the 2 cohorts of older adults.

RQ2 aimed to investigate the role of living situation on acceptance; we found that those living alone had significantly lower AMQ constructs compared to those living with someone. However, this difference disappeared at T6. It should also be pointed out that those living with someone had decreased ANX, ATT, and PU over time, indicating that the anxiety toward the system increased, and the usefulness and attitude toward technology lowered, suggesting that having someone helping them use the system may remove the perceived usefulness of the technology. This finding could suggest that living situation may be a barrier at the beginning of the study: people that are living alone may be more skeptical at the beginning, whereas people who are living with someone may have had higher expectations, yet the reality after 6 months of use was disappointing, which lowered the acceptability of the system.

Finally, this paper aimed to investigate how stress related to technology may affect the acceptance and usability of a certain technology (RQ3). The results highlighted a strong correlation between technostress and usability, anxiety, and trust in the older adults at T0 (Figure 5A) but all the correlations disappeared at T6. The results obtained at T0 are aligned with our previous findings [39], where we highlighted a link between perceived stress and related acceptance. However, these results may suggest that technostress could be a barrier only at the beginning of the study; as soon as the older adult becomes familiar with the technology, the link between perceived stress and related acceptance disappears. To mitigate the effects of stress at the beginning of the study, proper training sessions should be organized. These sessions ought to be devoted to successfully teaching participants how to use the technology and recall the functionality of the system after the training session, adapting the training to the participant's cognitive and educational level. As remarked by facilitators, oftentimes older adults forgot how to use the devices and tended not to use them unless facilitators retaught them how to use the technologies. Indeed, well-conceived training is a key feature of success and critical for technology acceptance.

At T0, for the IC group, higher perceived stress was a barrier to trusting technology, and in the FC group, stress affected attitude and usefulness of technology, possibly because of fear of substitution or the worry that the technology may involve extra work for them [46-48]. Nevertheless, the correlations were not significant at T6 (Figure 5B,C). This highlights how technology-related stress for the proposed socialization service can be a barrier to technology acceptance; as caregivers can influence older adults' perception of technology, it is crucial to include them in the study to get a multistakeholder perspective to support and reassure their older adults and promote a positive attitude toward technology.

Limitations

The main limitations of this work are the sample sizes and the duration of the test phase (6 months), as well as the different recruitment strategies carried out at the 2 different sites. As for the sample size, we aim to increase the number of participants in the 2 pilots while tracking their cognitive abilities, thus evaluating the effect of this variable on the use of technology. Further studies should also be planned to extend the duration of the testing phase, given that our preliminary results at 6 months seemed to indicate that it was not long enough to get information regarding the impact of this service in real life. This is also of interest to policy makers who are coping with staff shortages and increasing health care expenses. Another encountered limitation was the different recruitment process between pilot sites and the lack of randomization for the technologies. These factors can all contribute to different results between samples; researchers should aim to standardize procedures as much as possible to obtain generalizable results. Future studies should also investigate the factors that may influence the low use of the technology and come up with countermeasures to encourage the use of technology, which can also have an impact on acceptability [27].

Conclusions

This paper investigates the role of time, living situation, and stress related to technology use on the usability and the acceptance of a socialization service. This paper presents the results collected after 6 months of use considering a multistakeholder perspective. In this study, we found that the older adults had higher stress and anxiety toward technology than the caregivers. Nevertheless, getting accustomed to technology over 6 months of use removed this initial barrier. It is also important to consider the living situation of the older adults as those living alone had lower acceptability than those living with someone, which could suggest an increased resistance to change. However, counterintuitively, the older adults living with someone had a decrease in enjoyment, usefulness, and attitudes toward technology, possibly because living with someone limits the need of the older adults to socialize with others. The reflection meeting with the facilitators qualitatively highlighted demographic barriers in the use of technology that should be further evaluated quantitatively.

Acknowledgments

The authors would like to thank all the older adults, informal caregivers, and formal caregivers that agreed to be part of this study. A special thanks also to Pharaon Italian facilitators for their key role during the tests. This work has been supported by the Pilots for Healthy and Active Ageing (PHARAON) project of the European Union’s Horizon 2020 research and innovation programme under grant agreement ID 857188.

Authors' Contributions

JP and LF wrote the original draft. JP performed all formal analyses and graphical visualization. Investigation, resources, and data collection were conducted by LL, F Ciccone, LT, SR, FG, and GV. LL and NC oversaw data curation and LL, DS, GD, F Ciccone, and NC oversaw data collection. TP was responsible for the software. ER and LF provided supervision. ER and F Cavallo were project administrators. LF and F Cavallo conceptualized the work and F Cavallo managed funding acquisition. All authors provided input to the draft, discussed the results, and reviewed the final manuscript.

Abstract

Background: Over the past decade, the adoption of virtual wards has surged. Virtual wards aim to prevent unnecessary hospital admissions, expedite home discharge, and enhance patient satisfaction, which are particularly beneficial for the older adult population who faces risks associated with hospitalization. Consequently, substantial investments are being made in virtual rehabilitation wards (VRWs), despite evidence of varying levels of success in their implementation. However, the facilitators and barriers experienced by virtual ward staff for the rapid implementation of these innovative care models remain poorly understood.

Objective: This paper presents insights from hospital staff working on an Australian VRW in response to the growing demand for programs aimed at preventing hospital admissions. We explore staff's perspectives on the facilitators and barriers of the VRW, shedding light on service setup and delivery.

Methods: Qualitative interviews were conducted with 21 VRW staff using the Nonadoption, Abandonment, Scale-up, Spread, and Sustainability (NASSS) framework. The analysis of data was performed using framework analysis and the 7 domains of the NASSS framework.

Results: The results were mapped onto the 7 domains of the NASSS framework. (1) Condition: Managing certain conditions, especially those involving comorbidities and sociocultural factors, can be challenging. (2) Technology: The VRW demonstrated suitability for technologically engaged patients without cognitive impairment, offering advantages in clinical decision-making through remote monitoring and video calls. However, interoperability issues and equipment malfunctions caused staff frustration, highlighting the importance of promptly addressing technical challenges. (3) Value proposition: The VRW empowered patients to choose their care location, extending access to care for rural communities and enabling home-based treatment for older adults. (4) Adopters and (5) organizations: Despite these benefits, the cultural shift from in-person to remote treatment introduced uncertainties in workflows, professional responsibilities, resource allocation, and intake processes. (6) Wider system and (7) embedding: As the service continues to develop to address gaps in hospital capacity, it is imperative to prioritize ongoing adaptation. This includes refining the process of smoothly transferring patients back to the hospital, addressing technical aspects, ensuring seamless continuity of care, and thoughtfully considering how the burden of care may shift to patients and their families.

Conclusions: In this qualitative study exploring health care staff's experience of an innovative VRW, we identified several drivers and challenges to implementation and acceptability. The findings have implications for future services considering implementing VRWs for older adults in terms of service setup and delivery. Future work will focus on assessing patient and carer experiences of the VRW.

Introduction

Implementation rates of virtual wards have increased over the last decade, mainly driven by technological advancements and the COVID-19 pandemic [1-5]. The UK National Health Service (NHS) report that virtual wards, including hospital-at-home services, are a safe and efficient substitute for inpatient care that is facilitated by technology [2,6,7]. Virtual wards offer at-home acute care in the form of monitoring and treatment to individuals who would otherwise require a hospital bed, using a flexible combination of remote and in-person services [2,6]. As virtual models of care are relatively novel, there can be ambiguity around terminology [2,8]. In the NHS model, virtual wards for older individuals function akin to hospital-at-home services, primarily delivering care through face-to-face interactions [8].

Virtual wards aim to prevent avoidable hospital admissions, facilitate early discharge home, and increase patient satisfaction [3,6,9]. For the older adult population, hospital admissions carry potential risks, including deconditioning, delirium, and hospital-acquired infections [10], so opting for home-based treatments may be beneficial [11]. Consequently, significant investments are being directed toward the expansion of virtual care models in health care systems, such as the UK NHS, encompassing patients with frailty [12,13]. However, economic assessments of virtual models often fail to meet quality criteria, leading to varying estimated cost savings [2].

The implementation of virtual care models has been hindered by issues such as nonadoption, abandonment, and difficulties with scaling up, particularly if the model requires significant changes to the broader care system [14-16]. There is a paucity of research investigating the sustainability of virtual models [15], particularly virtual wards [2]. Despite substantial policy-level discussions and modest proof-of-concept studies, virtual health care models are seldom mainstreamed [17-19]. The success or failure of implementing innovative virtual health care models is often attributed to a complex combination of facilitators and barriers, rather than individual factors alone, such as time pressures, infrastructure, unreliable equipment, and staff and service user preferences [20]. Understanding these issues is important as virtual care marks a monumental change in the delivery of health care for older individuals [2].

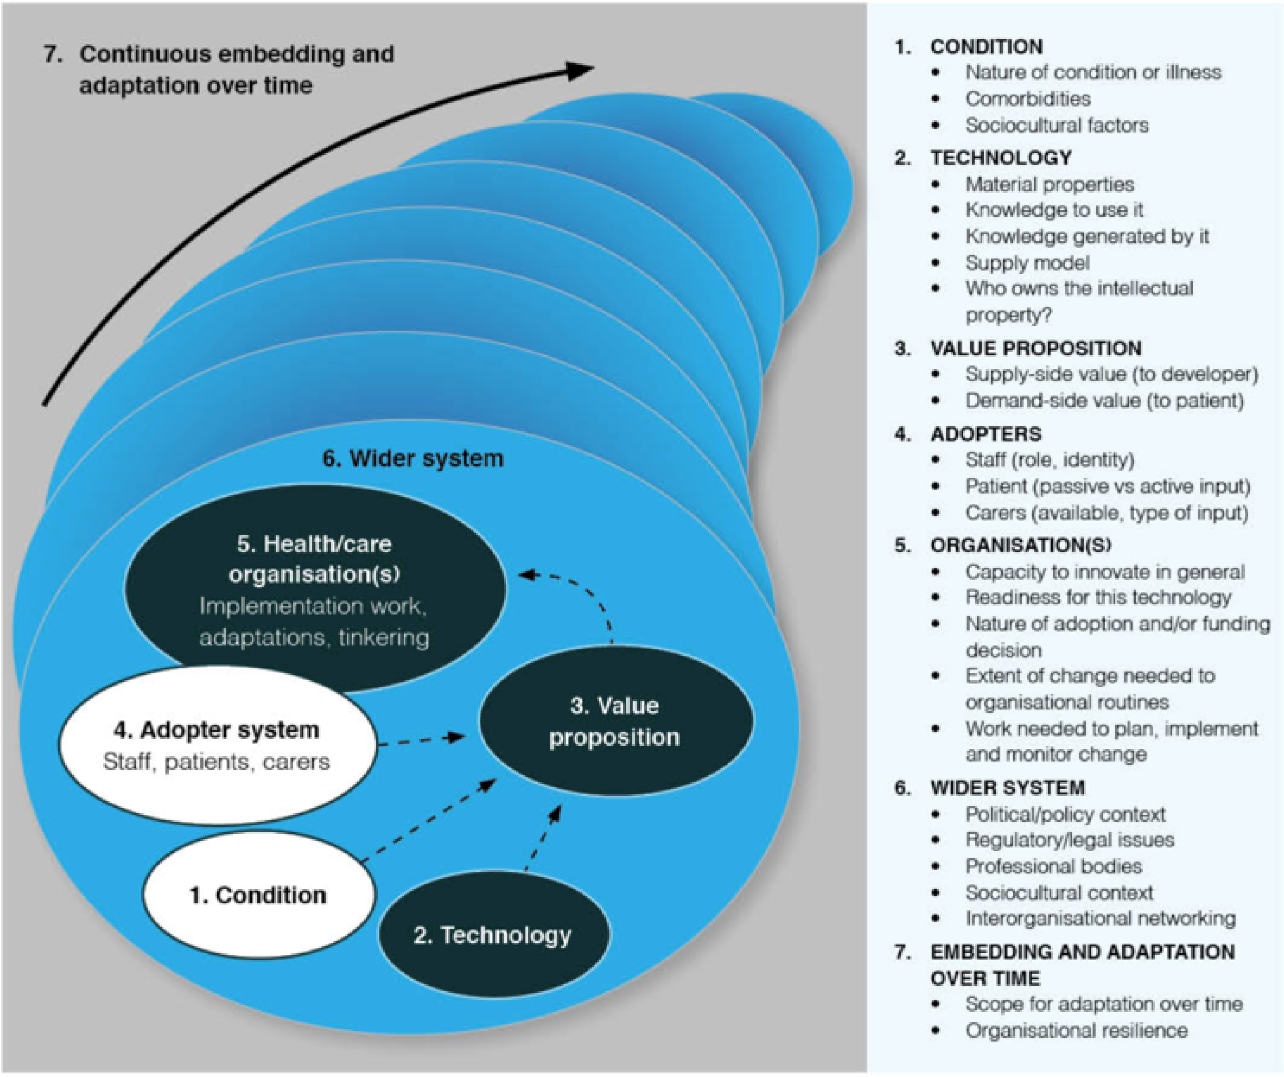
In practice, virtual wards are often added to existing hospital services as a solution to a bed capacity problem rather than being designed from the ground up as new freestanding services [21-23]. When hospital-based staff are asked to establish a virtual ward and commence providing services through videoconferencing and monitoring, significant shifts in practice are required. The facilitators and barriers experienced by hospital staff for the rapid implementation of these novel care models are not well understood, as evidenced by the paucity of literature in the area. There is also a lack of guidance for the provision of virtual wards, with calls for information on how these new models of care are being implemented [8]. This paper addresses a gap in the existing literature by offering insights into the experiences, perceptions, and attitudes of hospital staff working within a newly established Australian virtual rehabilitation ward (VRW). To our knowledge, no previous studies have delved into this specific research area. The implementation of the VRW was undertaken by the Flinders Medical Centre, part of the Southern Adelaide Local Health Network (SALHN) in South Australia, in response to the increasing demand for programs aimed at preventing hospital admissions. We explored the facilitators and barriers of the VRW from the view of staffs and present reflections for service setup and delivery.

Methods

Design

A multidisciplinary research team (clinicians and academic researchers) conducted this study under a constructivist paradigm [24]. Data were integrated and analyzed using the Nonadoption, Abandonment, Scale-up, Spread, and Sustainability (NASSS) framework [15] to understand staff experiences (Figure 1). Interview questions focused on the 7 domains of the NASSS framework including condition, technology, value proposition, adopters, organizations, wider system, and embedding and adaptation over time. These domains provided an analytical framework for organizing, classifying, and contrasting staff experiences into a rich narrative. The NASSS framework was chosen as it was designed to evaluate technology-supported change projects in health or social care [15] and, therefore, fitted with the aim of our research. Moreover, it has been previously used to evaluate technology-supported health care programs [25-27]. Other frameworks such as the Reach, Effectiveness, Adoption, Implementation, and Maintenance (RE-AIM) framework [28]; Precede-Proceed model; Dynamic Sustainability framework; or the Practical, Robust Implementation and Sustainability Model (PRISM) [29] were not chosen as they lacked the technology focus of the NASSS framework. We also report our study according to the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines [30] to improve the quality and transparency of our work.

Figure 1. The Nonadoption, Abandonment, Scale-up, Spread, and Sustainability (NASSS) framework, first published in 2017, provides a structured approach to examine the factors that impact the adoption, nonadoption, abandonment, spread, scale-up, and sustainability of health care technology (reproduced from Abimbola et al [27], which is published under Creative Commons Attribution 4.0 International License [31]).



Ethical Considerations

Ethics approval was received from the SALHN (Southern Adelaide Clinical Human Research Ethics Committee; 2022/HRE00107). Written informed consent was obtained from all participants, who were informed of their right to withdraw from the study at any time. The data presented in this article have been deidentified. Participants did not receive any compensation.

Setting

South Australia spans a geographical area of 983,482 km^2 with a population of 1.8 million [32]. SALHN services a community of approximately 400,000 people in the southern metropolitan area of Adelaide. The population in Southern Adelaide skews toward older age groups compared to other areas of Adelaide and the broader Australian population, with a projected accelerated aging rate [33]. The prevalence of lone-person households, concentrated among older age groups, is rising, and these demographic shifts will likely amplify the demand for health care services [33]. The Flinders Medical Centre is the second-largest tertiary hospital in Adelaide with nearly 600 beds, offering a wide range of medical, surgical, obstetric, and pediatric services.

Virtual Rehabilitation Service

The virtual rehabilitation ward (VRW) provides acute clinical care through rapid assessment and rehabilitation to patients with a range of diagnoses in their own homes. The service provides an alternative to hospital-based rehabilitation and allows patients to be discharged earlier from inpatient wards. A team of multidisciplinary staff (see Table 1), including doctors, nurses, and allied health professionals, work with the individual to achieve rehabilitation goals via a mix of tailored video calls and home visits over a 2-week period with daily clinical reviews. The patient’s medical status is also monitored remotely, for instance, blood pressure, oxygen saturation, temperature, and weight. All equipment is loaned to the patient (eg, iPad with cellular connection via SIM card and monitoring equipment), and training on how to use the equipment is provided by care staff. Home visits can occur as required, and an initial visit is made to set up equipment and provide training.

Table . Virtual rehabilitation ward workforce structure.

Profession	Full-time equivalent (hours)
Medical consultant, registrar, and resident medical officer	2.8
Nursing (clinical and enrolled)	10.5
Allied health professionals (physiotherapist, occupational therapist, pharmacy, psychology, exercise physiologist, social worker, speech pathologist, dietetics, and allied health assistants)	16

The service is available to individuals over the age of 18 years, but most patients are older adults. Between the commencement of the service in January 2022 and August 2022, a total of 181 (79%) out of 229 patients were aged 65 years or older, with an average age of 73.9 years and a median age of 75.0 years. Local hospital ward staff refer patients to the VRW, and a VRW coordinator assesses the individual's suitability for the program, usually in person while they are still an inpatient. The VRW accepts a wide range of patients with complex care needs, including individuals recovering from trauma, patients undergoing cancer rehabilitation, or those who require postsurgery care. The service delivers time-limited interventions and monitoring (usually 2 weeks) based on clinical needs. The service runs 7 days a week 24 hours a day, with full staffing between 8 AM and 8 PM and access to an on-call doctor available outside these hours. Patients are provided with a telephone number to contact if their symptoms worsen. The VRW is supported by a contracted external telecommunication provider, which supplements internal SALHN digital health support.

Participant Recruitment

Between July and September 2023, staff previously (ie, rotational junior doctors) or presently employed by the VRW were invited to participate in a semistructured interview exploring the implementation of the VRW. In phenomenological studies, a purposive sampling strategy—in this research, maximum variation sampling—is supported to recruit participants who have experienced the phenomenon under study. We aimed to recruit a diverse range of health care staff (ie, clinical, administration, and information technology) to capture various perspectives on the topic of interest, thereby illuminating diversity and revealing patterns or commonalities in traits across the spectrum [34-38]. Recruitment occurred through the ward managers circulating research information via email and word of mouth. Overall, 21 interviews were conducted, and participant characteristics are presented in Table 2. Data collection was ceased when all the staff who wanted to take part in the study had been interviewed. The number of VRW staff was smaller compared to conventional inpatient rehabilitation wards (Table 1). A total of 9 staff members declined because they were not interested in taking part in research or because they did not have the time to take part in an interview. No participants withdrew from the research after consenting. Each participant was interviewed only once, and no relationship was established prior to study commencement.

Table . Participant demographics (N=21).

Demographics		Value
Occupation, n (%)		
	Doctor	6 (29)
	Nurse	3 (14)
	Physiotherapist	3 (14)
	Exercise physiologist	1 (5)
	Occupational therapist	1 (5)
	Information technology officer	2 (10)
	Administrative assistant	1 (5)
	Manager	2 (10)
	Social worker	1 (5)
	Pharmacist	1 (5)
Age (years), mean (range)		39.1 (25-62)
Sex, n (%)		
	Female	15 (71)
	Male	6 (29)

Qualitative Data Collection and Analysis

We used phenomenology to understand the meaning of the perspectives of staff who worked on the VRW [37]. A researcher independent of the health service conducted the semistructured, audio-recorded interviews (LG). Field notes were made during the interviews to aid reflexivity [39]. A total of 20 interviews were in person and 1 was conducted virtually via Microsoft Teams. To ensure convenience for the staff, in-person interviews were held in a meeting room on the same floor of the hospital as the VRW offices. For the virtual interview, both the researcher and the participant were in their respective homes. Interviews lasted between 45 - 60 minutes and no one else was present besides the participants and researcher. Interview questions and descriptions of the 7 NASSS domains are provided in Multimedia Appendix 1. Questions were tailored for each staff discipline, for example, doctors were asked about remote prescribing while allied health professionals were asked about remote therapy. We did not conduct a pilot test for this piece of research.

Deidentified, audio-recorded interviews were transcribed verbatim by a professional transcription service. One participant requested for their transcript to be returned to them for comment, but no amendments were made. The data were analyzed by 2 coders (LG and MR) using framework analysis [40] to identify the key themes and meanings that emerged from the participants' descriptions. This method was chosen as it provides a rigorous and transparent approach for researchers to analyze multidisciplinary health research [41]. Moreover, as framework analysis is not aligned with a specific epistemological, philosophical, or theoretical perspective, it adapted well to the use of a preexisting theoretical framework (deductive analysis) while allowing room for revisions with inductive aspects of analysis [40]. In brief, the process of framework analysis involves organizing significant themes and issues into 5 distinct stages: becoming familiar with the data; identifying a thematic framework; indexing; charting; and finally, mapping and interpretation. Multimedia Appendix 2 [15,41-46] provides a detailed description of the methodology. NVivo 12 (QSR International) was used for coding and indexing the data into the 7 NASSS domains. The information was subsequently condensed and organized into a matrix. Multimedia Appendix 3 provides a description of our coding tree.

Results

Overview

Due to the small size of the VRW staff, where sometimes only 1 member represented each discipline, to ensure anonymity within quoted content, we have grouped them. Physiotherapists, exercise physiologists, occupational therapists, and social workers are grouped under the collective name "Allied Health Professional" and managers and administrative staff are grouped under "Leadership/Admin Team." Two participants provided feedback on the findings via email and during an informal face-to-face meeting.

In summary, the VRW sought to serve patients with varied health conditions. Challenges arose in managing complex cases such as heart failure and cognitive impairments, impacting staff confidence in virtual care delivery. Despite technological benefits such as remote monitoring, interoperability issues persisted, hindering adoption. The service's value lay in offering choice and access to care, particularly benefiting rural communities. However, risks included communication challenges with community care teams and less intensive therapy compared to inpatient settings. The transition to virtual care posed workflow and responsibility challenges, highlighting the need for staff training and support. Ambiguity surrounding the service's identity and referral processes impacted resource allocation and patient expectations. Challenges in patient transfer and continuity of care were observed, along with resistance to hospital readmission and overcrowded emergency departments. Staff recognized the service's potential but emphasized the need for specialized planning and ongoing adaptation. Adaptive actions included refining technology and identifying areas for improvement in patient care and service delivery.

Domain 1: The Condition

The VRW services patients with several health conditions, including ones that require high-level care (Multimedia Appendix 4). Participants commented on how certain conditions, such as heart failure, fluid retention, and complex wounds, were more challenging to manage using a virtual ward approach in comparison to a traditional inpatient setting.

> *We'd have fluid overloaded patients, and you just don't know how much they're drinking, or you can't do the same monitoring as you can in hospital.* [Doctor]

Comorbidities (including cognitive impairments, polypharmacy, frailty, disability [eg, limb impairments and tremors], and sensory impairments) were also discussed by all participants as factors impacting how confident the staff felt in engaging patients in the virtual ward service. There was a sense that the service might be better suited for patients with minimal cognitive impairment who are willing to engage with technology.

> *In the right population, yes. I think again, if they're cognitively not good, or they're really not wanting to engage through technology, then it's very difficult. But yeah, I think if they're willing to engage in that, I think it's no different to being in the room with them.* [Allied Health Professional]

The service's suitability was also influenced by sociocultural factors such as living arrangements. For example, the staff reported relying on carers to assist with virtual sessions or remote monitoring. Therefore, living alone or residing in a care home could potentially pose challenges.

> *I think it depends on what support the person has…So if they've got someone else there with them who can use the technology that works really well, and there's definitely no issues there.* [Allied Health Professional]

Domain 2: The Technology

A lack of interoperability between hardware and software systems was discussed by all 21 participants. There was agreement that the integration between different health care systems, service providers, technology, and security was poor and impeded adoption (Multimedia Appendix 4). This complexity appeared to make it difficult to pinpoint the exact sources of problems when difficulties occurred. Additional challenges came from unforeseen software updates, with the equipment dispersed across patients' homes (Multimedia Appendix 4).

> *It's like, "Don't really care whose fault it is, can someone just fix it?"* [Allied Health Professional]

The remote monitoring equipment and the capability to make video calls was perceived as advantageous, since it has assisted staff in monitoring patient conditions and facilitating the escalation of care or transferring to another health care service when necessary. This was particularly commented on by doctors, although other staff also made reference to the equipment's benefits in escalation. Despite staff's efforts to streamline the process for simplicity, there were reliability and usability concerns, occasionally affecting rapport (Multimedia Appendix 4).

> *...it's not 100% reliable for us, and for us to escalate care of patients based on an unreliable system is difficult to do…We need to have technology that we can rely on, that is safe.* [Leadership/Admin Team]

There was, however, recognition that some of these technology failures could stem from a lack of knowledge and education among both staff and patients (Multimedia Appendix 4).

> *...maybe we don't facilitate the education as good as we should. We are out there for what, maybe half an hour. And then, "Here's your kit, off you go."* [Leadership/Admin Team]

Medtasker, a mobile communication and task management platform, was widely used and commended for its ability to minimize work duplication and reduce the need for excessive phone calls and emails.

> *Because the virtual team is sort of here mornings, evenings, there might be people that might have seen the patient a few days and then they're not the next and so forth. We're trying to work out the best ways of managing communication. And I think a program like Medtasker helps.* [Doctor]

Domain 3: Value Proposition

The value of the service was the choice it provided patients on where they received their care (Multimedia Appendix 4). The staff felt that home-based treatment, especially for older individuals, would be a preferred and more comfortable option than staying in hospital. The service was considered empowering and enabled access to care for rural communities who might not be able to access rehabilitation services otherwise (Multimedia Appendix 4).

> *I think the gaps that it bridges is amazing and huge, because our country patients, who aren't able to travel…I see cancer patients who are palliative who really benefit from that ability to be able to connect via video link.* [Doctor]

The value of the VRW for patients was also discussed by identifying risks. The opinions about this varied, but in general, there was a sense that the VRW did not pose more risks, just different risks. One concern, particularly with doctors, was that patients often resumed contact with their community care teams (general practitioners [GPs] and community-based medical specialists).

> *…managing patients who are still attending their GPs, their specialists in other hospitals in the background, and if you do not have an understanding of what there is happening there and you are involved, I think that is somewhere where some confusion can happen.* [Doctor]

Additionally, there were fewer opportunities for physical evaluation, monitoring, and therapy, leading to concerns that clinicians might miss early signs of deterioration. This concern was elaborated upon by 4 of the interviewed doctors, while nurses and allied health professionals also indicated unease about not being able to examine severely ill patients as thoroughly as they typically would on a ward. Allied health professionals discussed patients having less-intense therapy compared to inpatient wards (Multimedia Appendix 4).

> *...a lot of clinical signs we aren't able to pick up by a video link, so we'll assess them a particular way, but then when the registrar's gone and done a home visit just because we were worried for whatever reason, we've actually found other signs which have triggered escalation of care later, which we weren't able to identify through video links.* [Doctor]

Domain 4: The Adopters

The commencement of the VRW has imposed many changes to staff practices. The interviews delved into the need for a cultural shift and how some participants (and their colleagues) were resistant to adopting the virtual approach. Face-to-face patient interactions were preferred by many, either because they were accustomed to it or because they perceived clinical advantages in such treatments. There was a tendency for conducting initial meetings in person, followed by remote reviews, whenever feasible.

> *That's just the way that I've nursed for 30 years…I'm not used to trying to do that over a screen.* [Nurse]

There appeared to be some uncertainty surrounding workflows and professional responsibilities, leading to concerns that clinical staff might be required to assume technology or administrative duties (Multimedia Appendix 4).

> *We're clinical, we're not IT.* [Leadership/Admin Team]

As the service developed, the participants described how they have acquired valuable knowledge about the essential support, training, and resources needed. For instance, the team has recently gained a pharmacist, and this addition has helped alleviate previous prescription medication challenges. Furthermore, due to the unanticipated complex care needs of the referred patients, it has been crucial to have experienced staff to handle the workload effectively. As such, the clinical team has made staffing adjustments to accommodate for the large number of junior staff working within the service

(Multimedia Appendix 4). It was highlighted that for a virtual ward service to succeed, the staff should possess strong clinical skills to ensure adaptability and flexibility in care delivery (Multimedia Appendix 4).

> *…just the more experience and the more training and the more feeding off each other and learning of each other, the more we're adapting the telehealth. There is a huge education component that's needed for junior staff and a lot of support for people that aren't experienced.* [Allied Health Professional]

A shift in the burden of care to the patient and their family was also discussed. Staff particularly recognized the essential role that carers play in the patients' journey during virtual care.

> *...we heavily use carers and family in this model because not only can they help a lot of the time with setting up the technology and working it out and things like that, they're quite often present during the reviews and we quite often use them to just be our hands.* [Allied Health Professional]

Domain 5: The Organization

There was a sense of ambiguity surrounding the identity of the service both for the staff and patients. The service was set up to provide rehabilitation with a primary focus on functional recovery, but hospital pressures resulted in large numbers of referrals from acute wards, leading to more medically complex referrals than the team had anticipated. This presented a particular challenge for allied health professionals who felt that their roles became almost redundant for certain patients, such as those from oncology wards with newly diagnosed conditions that they were struggling to come to terms with.

> *We have a lot of pal[liative] care patients coming through lately. And just the questions that they ask, and the difficult conversations, and where to go with rehab. Because it's not really restorative, it's more maintenance and optimizing.* [Allied Health Professional]

Participants expressed frustration with the intake process, as they believed that referrals should involve patients who are willing and able to use technology as part of their rehabilitation journey.

> *There needs to be more done in the triage of people's capacity to use technology…we've been getting people who've just said to us, "I'm not using the iPad."* [Allied Health Professional]

There was a perception that patients were not accurately informed about the service or that some patients did not fully understand the implications of the term "Virtual Rehabilitation Ward." Patients often had unrealistic expectations, assuming that rehabilitation at home would be less intensive than in a traditional ward setting (Multimedia Appendix 4).

> *...they would think that it's a ward, but then the virtual part of it, sometimes, well some people don't know what that means. Some people think it's purely virtual so that there's no home visiting service.* [Leadership/Admin Team]

The importance of resource allocation and the environmental setup was also discussed. Given the rise in the complex patient population requiring more in-person care, vehicle access was often an issue, particularly for nursing and allied health care staff (Multimedia Appendix 4). Open-plan offices and a lack of private spaces for confidential calls were among the challenges discussed (Multimedia Appendix 4). Staff emphasized that the organization and setup of the service were crucial factors in its successful adoption, stressing the need for a balanced approach that offers a supportive office environment and has enough room and resources to deliver care flexibly.

> *Because you want to have the team together and interacting like they would on ward in a way because they have that, there's then that team camaraderie but also that informal sharing of knowledge and teaching each other…but you also need space to be able to operate and talk to patients and hear them.* [Doctor]

Domain 6: The Wider Context

Staff felt that the new service aimed to fill gaps in the existing health care system, but it lacked a clear pathway structure and well-defined boundaries.

> *...a lot of people are starting to get frustrated because there's just no clear pathway structure, anything of what we are and what we're meant to be doing and where we can set those boundaries of that's not our role. It just seems to be like take everything, deal with it when it's there.*
>
> *[Allied Health Professional]*

All staff members were mindful that patients are eager to leave the hospital and might be willing to accept any form of home service. They were also aware of the hospital's pressure to discharge patients promptly due to the scarcity of available beds.

> *I think so many of them are just so desperate to get out of hospital they'll agree to anything. And I think that the hospital is so desperate to get them out of hospital as well that they will sign them up to whatever program will take them.* [Leadership/Admin Team]

The wider context, especially in terms of the continuity of care, was discussed from service and interorganizational perspectives. Staff emphasized the importance of connecting with GPs before a patient's discharge to ensure the continuity of care; however, this was rarely done in practice.

> *Especially with our frailty pathway, we're meant to call the GP and talk about our frailty management plan once they're discharged from our service, but that's just been really difficult. Haven't been able to get through to the GP.* [Allied Health Professional]

Support and knowing how to connect patients with services following discharge were also discussed as a matter of importance.

> *…discharging patients from inpatient rehab, there's only a couple of go-to places, but then it's very different if patients are already out in the community.*

> *Because there's a lot of options for further support that you can link them with.* [Doctor]

Transferring patients back to the hospital when their health deteriorated presented challenges. Staff encountered resistance from patients who were reluctant to return to the hospital setting. Moreover, escalation pathways were impeded by overcrowded emergency departments and a shortage of available beds in the hospital. These issues were encountered by all clinical staff.

> *The difficulty has been once we identify they need to come in, what pathway they go towards. ED'S ramping, there's no beds in [local hospital], and then you've got to take those measured risks.* [Doctor]

Domain 7: Embedding and Adaptation Over Time

In general, all of the staff recognized the advantages that the service could provide to clinicians, patients, and the broader health care system (Multimedia Appendix 4). Nevertheless, they emphasized the need for planning that considered the distinctive and specialized requirements of virtual wards.

> *We try and introduce new models like technology and you're trying to just do it on the edge of everything else that is happening but really it needs its own setup…that's one of the challenges really, is trying to introduce a new model of care into an old system.* [Leadership/Admin Team]

Staff were engaged with adapting and embedding the technology within the service in response to their patient's needs. There was recognition that the service is in its early stages of development (Multimedia Appendix 4), and as a result, certain aspects are not yet finely tuned. While some staff regarded glitches as failures, many understood that creating a new service is a gradual process that demands refinement over time.

> *It's changing that mindset, not seeing it as a failure. It's just seeing it as a sidestep again for now…They see that as a failure, which it isn't. Sometimes we've just got to fine tune things a little bit to be able to safely manage you at home.* [Nurse]

Sensemaking and collective reflection were evident throughout the interviews, with strengths of the service being the implementation of Medtasker as a platform for team communication and accountability, and remote health monitoring to help clinicians escalate care. Adaptive action is ongoing to ensure that the technology is more dependable and the service is reaching its target patient cohort. The team is continually learning and identifying areas for adaption: for example, having a stock of common medications to trial patients on them, and having more technology applicable to an older cohort with frailty such as fall devices, echocardiograms, and telemetry.

Discussion

This paper addresses the knowledge gap related to the facilitators and barriers experienced by hospital staff during the implementation of a new VRW [2]. The service aimed to provide early discharge with a functional and medical care program for adults who are able to rehabilitate at home. The perspectives of staff are pivotal as previous research has suggested that clinician endorsement can account for a significant portion of the variability in the adoption, growth, and continuity of telehealth services [47-49].

The VRW team successfully managed complex patients in the community but highlighted how some conditions were more challenging than others, such as individuals with fluid retention or severe wounds. This was particularly pertinent for older individuals, especially those with comorbidities and those who reside alone or in care homes, where they might lack the capacity to manage monitoring and communication equipment. Older people who were not proficient with digital technology were not disadvantaged in terms of quality of care or through digital exclusion [2], as the team was flexible in providing tailored care and would provide in-person services. Yet, it appears that for a virtual ward to achieve success, the service must possess a clear identity that is supported by its triage and intake process. A mismatch was described between staff expectations of medically stable patients focused on rehabilitation and the actual referrals of frail patients of varied case mix who were discharged early in response to hospital pressures. These findings underscore the importance of the consideration of patient characteristics prior to enrollment and the necessity of tailored care.

Regarding technology, interoperability was poor, a common issue in virtual care [50,51], and there were delays in pinpointing problems that impeded adoption. Nevertheless, some of these challenges appeared to be rooted in a lack of staff and patient training on correct technology use, an issue that appears common in new technology-supported health care models [15,16]. The brevity of the VRW program (typically 2 weeks) posed challenges, as there is limited time available for staff to adequately train patients, particularly older individuals who may need more support [52]. The substantial effort required may also seem disproportionate to the program's short duration. The attitudes around technology were multifaceted. While there was a consensus that the technology was useful, particularly in the escalation of care, promotion of self-management, and team communication and task management, there was recognition that it sometimes created burden for the patient and carers and that it was not always accurate in detecting health decline [53-55]. In line with recent reports, simplifying hardware and software use were deemed crucial for success [2].

The primary value proposition encompassed offering patients the option to select their care location and increasing access to rehabilitation without waiting in hospital for a bed. This was particularly pertinent for older individuals, considering the potential risks associated with hospital admissions [10], as well as for patients residing far from rehabilitation hospitals. Opinions on risk were varied; yet, overall, there was agreement that the VRW did not entail greater risks but rather presented different risks compared to inpatient rehabilitation. A notable concern was that patients reestablished contact with their community care teams, including GPs, a factor that could make cohesive care challenging. Additionally, fewer chances for in-person physical assessment, monitoring, and therapy raised concerns about clinicians possibly missing early signs of decline or patients receiving less intensive treatment compared to inpatient wards.

In terms of adopters, changing staff culture toward virtual care was recognized as an area for improvement. Many staff still preferred face-to-face visits due to familiarity or ease compared to dealing with technology. Uncertainty surrounding workflows and professional roles raised concerns that clinical staff were being asked to take on technology or administrative tasks. Furthermore, there were changes in staffing to align with the complexity of the patient cohort including the employment of a pharmacist and more experienced nurses. There was also a recognition of a shift in care responsibility to the patient and their family. Staff particularly acknowledged the crucial role that caregivers play in the patients' journey during virtual care. Little is known about carers roles in virtual models [2], and our ongoing work is exploring the experiences of patients and their family members who were referred to the VRW.

Clear pathways for early recognition of patient deterioration and appropriate escalation procedures were in place to ensure patient safety (eg, patients having a single phone number to call and the availability of remote monitoring equipment). However, challenges arose from wider pressures on public Australian hospitals, including overcrowded emergency departments and insufficient ward beds, which hindered patient transfers. Patients were reluctant to return to the hospital for these reasons. This holds significance because prior research has indicated that a major concern among staff regarding virtual care is the ability to swiftly admit patients to the hospital if their condition deteriorates [56]. Interorganizational collaboration, particularly handovers with GPs, occurred infrequently, leading to difficulties in seamless patient care transitions.

To our knowledge, this study addresses a significant gap in understanding by delving into the perspectives of hospital staff regarding the facilitators and obstacles in implementing a VRW. A key strength of this research lies in its qualitative methodology, allowing for a deep exploration of the topic within its natural context and enabling a nuanced examination of the multifaceted social, cultural, and environmental factors at play. Moreover, by centering the voices and experiences of hospital staff, an often-marginalized group in research as evidenced by the paucity of published literature, we aim to provide a platform for their narratives to be heard and valued.

Virtual wards represent a relatively novel concept, and there exists some ambiguity regarding their terminology [2]. Subsequent studies might prioritize the global standardization of the model, recognizing the importance of precise terminology in ensuring the generalizability of insights within the literature. Despite these variations, our research findings retain applicability to services that use monitoring and virtual technologies for postdischarge patient care.

To summarize, most staff acknowledged the benefits of the VRW service but emphasized the need for sufficient resource allocation and additional time to plan and implement the service and address early hurdles. In terms of health care access and equity, it appears that in a rehabilitation setting with a primarily older cohort, technology complements physical consultations but does not replace them and this must be factored into service design and delivery. We underscore that new health care models cannot exist on the fringes of traditional frameworks, as they require their own well-defined structure and setup with clear workflow and professional responsibilities.

Abstract

Background: Older adults experience a significant decline in muscle integrity and function with aging. Early detection of decreased muscle quality can pave the way for interventions to mitigate the progression of age-related physical declines. Phase angle (PhA) and impedance ratio (IR) are measures of muscle integrity, which can be assessed quickly via bioelectrical impedance analysis (BIA) and may be indicative of physical function.

Objective: This study aimed to characterize the relationships among handgrip strength (HGS), sit-to-stand (STS), BTrackS balance scores, fear of falling (evaluated using the Short Falls Efficacy Scale–International [Short FES-I]), and IR among community-dwelling older adult women classified as having a low or high PhA.

Methods: A cross-sectional analysis was conducted with 85 older women (mean age 75.0, SD 7.2 years; mean weight 71.0, SD 15.0 kg; mean height 162.6, SD 6.1 cm). To examine the influence of PhA on performance measures, participants were divided into 2 PhA groups: high (>4.1°; n=56) and low (≤4.1°; n=29). Data were nonnormative; hence, the Mann-Whitney *U* test was used to evaluate between-group differences, and Kendall τ coefficients were used to determine the partial correlations.

Results: The low PhA group had a significantly higher IR (mean 0.85, SD 0.03) than the high PhA group (mean 0.81, SD 0.03; *r*=.92; *P*<.001). The high PhA group had superior HGS (mean 21.4, SD 6.2 kg; *P*=.007; *r*=0.36), BTrackS balance scores (mean 26.6, SD 9.5 cm; *P*=.03; *r*=0.30), and STS scores (mean 16.0, SD 5.5; *P*<.001; *r*=0.49) than the low PhA group (mean HGS 17.6, SD 4.7 kg; mean BTrackS balance score 37.1, SD 21.1 cm; mean STS score 10.7, SD 6.2). Both PhA and IR were significantly correlated with HGS and BTrackS balance, STS, and Short FES-I scores (*P*<.05). However, on adjusting for the whole sample's age, only PhA was strongly correlated with HGS (τb=0.75; *P*=.003) and STS scores (τb=0.76; *P*=.002). Short FES-I scores were moderately correlated with IR (τb=0.46; *P*=.07) after controlling for age. No significant between-group differences were observed for height, weight, or BMI.

Conclusions: PhA and IR are associated with physical function and the fear of falling in older women. However, only PhA was significantly associated with physical function (HGS and STS) independent of age. Conversely, only IR was significantly associated with the fear of falling. Diminished physical function and increased IR appear to be characteristics of older women with a PhA of ≤4.1°. These findings suggest that PhA and IR measured through BIA together may serve as a valuable tool for early identification of older women at the risk of functional decline and a heightened fear of falling.

Introduction

By 2060, the population of American adults older than 65 years is projected to surge, doubling from 52 million in 2018 to 95 million [1]. Muscle weakness and functional loss contribute to falls; in 2020, approximately 3 million adults older than 65 years were treated in emergency rooms as a result of falling, with 800,000 of them having been hospitalized [2]. The annual cost of falls has exceeded US $50 billion, with Medicare and Medicaid covering 75% of these costs [2]. These older adults often experience a significant decline in muscle quality, quantity, and function [3]. Such age-related functional limitations can make everyday tasks, such as cooking, cleaning, and interacting with grandchildren, increasingly challenging [3]. The natural aging process brings about changes in body composition, often directly affecting physical function, as seen in sarcopenia [4]. Sarcopenia is characterized by a rapid loss of muscle strength with aging and is significantly associated with physical disability, decreased quality of life, and increased mortality [5,6]. Moreover, aging exacerbates traits of frailty, a syndrome characterized by a decrease in reserve capacity across various physiological systems, reducing their ability to withstand minor stressors [7,8]. This can result in an increased risk of falls, fractures, and disabilities [9,10], as well as higher mortality rates [7,8].

Aging also affects the musculoskeletal system, causing a decrease in skeletal muscle integrity, mass, strength, and function, along with an increase in the accumulation of noncontractile and adipose tissue [11,12]. Decreases in skeletal muscle integrity can result from a diminished cross-sectional area of muscle fibers, a transition from type II to type I fibers, and a loss of innervation [13]. A loss of skeletal muscle integrity can manifest through impaired balance and subsequently decreased physical function [13]. While not a physical characteristic, a fear of falling can also impose a restriction on physical activity and exacerbate functional loss [14]. Brouwer et al [15] assessed the fear of falling in healthy older adults and concluded that fear of falling was associated with poorer physical function characterized by a lower walking speed and lower limb weakness. Commonly assessed through questionnaires, early detection of the fear of falling can lead to interventions designed to increase physical activity in older adults and mitigate functional loss [16]. Likewise, early detection of decreased muscle quality can pave the way for interventions that may mitigate the clinical progression of sarcopenia and frailty [17].

Bioelectrical impedance analysis (BIA) is a quick, noninvasive, cost-effective method for assessing body composition within the Two-Compartment Model. It has also gained popularity, especially among older populations, as an assessment for skeletal muscle integrity and cellular health [10]. The BIA involves directing a constant low-level electrical current through the body [18]. This system has 3 main components: reactance (X_c), which measures the ability of cell membranes to store electrical charge (capacitance); resistance (R), which represents the resistive properties of cells due to intracellular water (ICW) and extracellular water (ECW) [19]; and impedance (Z), which represents the overall opposition to the electrical current [20]. Impedance provides another opportunity to examine cellular integrity with body cell mass [21]. Impedance ratio (IR) measures Z at high and low frequencies (in kHz) and can be indicative of possible cell membrane dysfunction based on body cell mass [22]. The IR for the whole body, upper limbs, and lower limbs is commonly calculated at 250 kHz or 5 kHz [21,23]. At higher frequencies, Z can penetrate cell membranes, therefore allowing for total body water (ECW + ICW) to be measured; however, at lower frequencies, Z can only measure ECW [24]. An IR ratio closer to 1 is indicative of cell membrane disruption, allowing more fluids, proteins, and electrolytes to shift into the extracellular space [22]. A strong inverse correlation has been reported between the phase angle (PhA) and IR in different clinical populations [22]. PhA is defined as the delay in current flow caused by a reduction in cell membrane capacitance [25].

PhA is calculated as the ratio of R to X_c at a frequency of 50 kHz, as measured through BIA [26]. Furthermore, PhA is influenced by hydration status and lean body mass [27]. Therefore, it directly relates to the electrical functioning of cell membranes, skeletal muscle integrity, and PhA itself [12,27]. Higher PhA values are indicative of superior cell membrane integrity and cellular health [10]. Disease, dehydration, inflammation, malnutrition, and functional disabilities can cause disturbances in electrical tissue properties, reflected by a lower PhA [28-30]. A low PhA increases the risks for disability, falls, sarcopenia, frailty, and mortality among older populations [29]. PhA can be used as a proactive measure against physical weakening by identifying older individuals at the risk of muscle loss and mortality [10,17,19].

Previous research has established relationships between PhA and handgrip strength (HGS) [31], balance [13], gait speed [32], age [10], sex [30], sarcopenia [33], and BMI [34]. However, previously reported regression models have only been able to account for approximately ≤30% of the variance in PhA [31,35] and have largely left the fear of falling unaccounted for. Therefore, the primary objective of this study was to compare HGS, sit-to-stand (STS) scores, BTrackS balance scores, and fear of falling between groups of older women categorized as having high or low PhA. Additionally, we aimed to assess the relationships among PhA, IR, and physical function metrics while controlling for age, and determine which variables are most strongly associated with PhA and IR in this population. We hypothesized that those with a high PhA would perform better on functional assessments and have a lower fear of falling, and that HGS would have the strongest association with PhA and IR when controlling for age.

Methods

Ethical Considerations

All study procedures were conducted in accordance with the tenets of the Declaration of Helsinki, approved by the University of Central Florida’s institutional review board (ID: STUDY00002473), and preregistered on ClinicalTrials.gov (NCT06063187).

Recruitment

The 85 female participants (n=64, 75% White; n=15, 17% Hispanic; n=4, 5% African American; n=2, 2% Asian) included in this analysis were part of a larger study funded by the National Institutes on Aging (R03AG069799) [36]. This analysis used data from female participants only to specifically characterize the relationships between bioelectrical impedance parameters and physical function metrics in older women. This study used a cross-sectional design to determine whether there were differences in HGS, STS, BTrackS balance scores, fear of falling, and IR based on a low or high PhA among older adult women. The sample of 85 older adult women had a mean age of 75.0 (SD 7.2) years, mean weight of 71.0 (SD 15.0) kg, and mean height of 162.6 (SD 6.1) cm. The study was conducted in low-income communities around central Florida, United States. Recruitment was achieved through flyer distribution, face-to-face engagement, local newsletters, and word of mouth. Community partners and clinical sites facilitated our introduction to potential participants for informed consent, initial screening, and eligibility verification using a checklist. Upon completion of the study, the participants received a US $30 gift card.

Eligible participants met all of the following inclusion criteria: (1) being aged ≥60 years; (2) being of low income status, based on 2019 poverty thresholds relative to family size and the number of children aged ≤18 years [18]; (3) absence of marked cognitive impairment, defined by a memory impairment screen score of ≥5 [37]; and (4) living independently in their own homes or apartments. Exclusion criteria were (1) medical conditions that inhibit balance testing or physical activity, such as the inability to stand on the balance plate or experiencing shortness of breath during physical activity; (2) active treatment from a rehabilitation facility; or (3) the presence of medical implants, such as pacemakers.

Measurements

Grouping of Participants: Low and High PhA

To verify the influence of PhA on performance measures, participants were divided into 2 groups: low PhA (≤4.1°; n=56) and high PhA (>4.1°; n=29). This cutoff was based on previous research that observed a higher prevalence of physical dysfunction and sarcopenia among community-dwelling women aged ≥65 years with a PhA less than 4.1° [34,38].

BIA

Body composition was assessed using the InBody s10, a direct segmental multifrequency BIA device from InBody Co, located in Seoul, South Korea. This device is designed to measure Z at 6 different frequencies—1, 5, 50, 250, 500, and 1000 kHz—for both the entire body and individual body segments. All BIA assessments were conducted before performing all other assessments, and all assessments were completed between 9 AM and 12 PM. To ensure accuracy, participants were instructed to fast for a duration of 3-4 hours, abstain from caffeine or alcohol for 24 hours, and avoid exercising for a period of 6-12 hours before testing. Participants were asked to maintain their normal dietary habits and arrive for testing adequately hydrated. On the day of assessment, participants were asked to remove their shoes, socks, and any metallic items. Height and weight were assessed using a digital physician scale and stadiometer (Health-O-Meter, Model 402 KL). Participants were then seated as their skin was prepared with an InBody wipe (InBody Co), and touch-type electrodes were then positioned on their left and right ankles, middle fingers, and thumbs. Participants were required to remain still for 1 minute before the electrodes were removed. PhA was derived by calculating the ratio of R to X_c at 50 kHz using the following formula: arc tangent $(X_c/R) \times (180/\pi)$ [26]. Moreover, IR was determined by dividing Z at 250 kHz by Z at 5 kHz [22,23]. The InBody s10 has good test-retest reliability among adults aged 65 years and older, with an intraclass correlation coefficient (ICC) of 0.82 [39].

HGS

Following BIA assessments, HGS was measured using a JAMAR Plus digital handgrip dynamometer (JLW Instruments) to ascertain maximal isometric force in kilograms. Participants, seated with feet flat on the floor and elbow bent at 90°, held the dynamometer in their hand, which was adjusted to allow for a flat second metacarpal and 90° bend at the knuckles. Participants then squeezed the dynamometer as hard as possible for 3-5 seconds across 3 trials, with 30-second rest intervals between each trial. All 3 trials were completed for 1 hand before performing 3 trials with the opposite hand. The maximum value for each hand was recorded, averaged, and used for analysis. The JAMAR handgrip dynamometer is a sound method to test HGS in the clinical setting with good intra- and intertester reliability [36,40].

BTrackS Balance Scores

BTrackS balance scores were gauged using the BTrackS balance system (Balance Tracking Systems) following HGS assessments. The BTrackS balance plate and BTrackS Assess Balance software (version 5.5.9) were used to measure center-of-pressure sway during a static stance. The scores and percentile rankings (0-100) were determined in accordance with age group and sex. A score of ≤30 signifies normal balance, while a score of ≥31 indicates poor balance and a moderate to high fall risk [41]. For each trial, participants were instructed to place their hands on their hips, close their eyes, and maintain a static position on the BTrackS Balance Plate for 20 seconds. Participants first underwent a familiarization trial that did not count toward their average score, followed by 3 trials that were averaged into their final score. To mitigate the risk of falls, a piece of sturdy furniture or a walker was placed within the participants’ reach during the test. The BTrackS balance system has been validated and has excellent reliability, with a Pearson correlation coefficient (r) of >0.90 and high test-retest reliability with an ICC of 0.83 [41].

STS

After BTrackS balance assessments, participants completed the 30-second STS test. STS scores were evaluated by instructing participants to stand up from a chair as many times as possible within 30 seconds. During the test, participants sat in the middle of the chair with their wrists crossed and hands resting on opposite shoulders. The 30-second STS test is a well-validated functional function measure in clinical research and practice, with good test-retest and interrater reliability [42].

Short Falls Efficacy Scale–International

Participants were asked to fill out the Short Falls Efficacy Scale–International (Short FES-I) questionnaire, which includes answering 7 questions on a scale of 1-4 that indicates if the participant would be concerned about falling during different activities. In the Short FES-I, a 1 indicates no concern at all and a 4 indicates being very concerned. The Short FES-I has been validated as a predictor of future falls and declines in functional capacity with balance and gait, and it has excellent test-retest ability [16].

Statistical Analysis

All statistical analyses were conducted using SPSS (version 28; IBM Corp). Descriptive data are presented as mean (SD) values along with ranges where appropriate. The Mann-Whitney *U* test was used to evaluate between-group differences for all variables. A Kolmogorov-Smirnov test determined that the data were nonnormal, so Kendall τ coefficients were used to determine the partial correlations between variables controlled for age. The α value was set considering a *P* value of <.05.

Results

A total of 88 older women were screened for eligibility and 85 were included in the analysis, with 34% (29/85) of them in the low PhA group and 66% (56/85) of them in the high PhA group. As shown in Table 1, women in the low PhA group were significantly older than those in the high PhA group (*P*=.001). As anticipated, the group with a low PhA had a lower PhA (*P*<.001) and a higher IR (*P*<.001) than those in the high PhA group. In the high PhA group, PhA ranged from 4.2° to 7.0°, and IR ranged from 0.69 to 0.84. In the low PhA group, PhA ranged from 2.5° to 4.1°, and IR ranged from 0.83 to 0.89. No significant between-group differences in height, weight, or BMI were observed. Approximately 52% (44/85) of participants were considered overweight or obese with a BMI of ≥25.9 kg/m^2.

Table . Participants' characteristics and bioelectric impedance analysis (n=85).

Characteristics	Total (n=85), mean (SD)	Low phase angle (n=29), mean (SD)	High phase angle (n=56), mean (SD)	*P* value[a]	Effect size[b]
Age (years)	75.0 (7.2)	79.6 (8.2)	71.0 (5.6)	.001	0.43
Height (cm)	162.6 (6.1)	162.0 (6.0)	163.0 (6.2)	.52	0.09
Weight (kg)	71.0 (15.0)	71.9 (15.7)	71.8 (14.8)	.81	0.03
BMI (kg/m^2)	26.8 (5.0)	27.3 (5.2)	26.9 (4.9)	.48	0.09
Body fat (%)	33 (10)	38 (9)	31 (10)	.003	0.40
Phase angle (°)	4.4 (0.8)	3.6 (0.4)	4.8 (0.6)	<.001	1.00
Impedance ratio	0.82 (0.03)	0.85 (0.01)	0.81 (0.03)	<.001	0.92

[a] *P* values refer to the difference between the groups (Mann-Whitney *U* test).

[b] Effect sizes are provided as rank biserial correlation, whereby 0.10, 0.30, and 0.50 represent small, medium, or large effects, respectively.

Table 2 shows that women in the low PhA group demonstrated poorer physical function than those in the high PhA group. Specifically, the low PhA group had significantly lower average HGS (*P*=.007) and STS scores (*P*<.001). The low PhA group also showed significantly higher balance scores (*P*=.03) and Short FES-I scores (*P*=.001) than the high PhA group.

Table . Physical function parameters (n=85).

Variable	Low phase angle (n=29), mean (SD)	High phase angle (n=56), mean (SD)	*P* value[a]	Effect size[b]
Average handgrip strength (kg)	17.6 (4.7)	21.4 (6.2)	.007	0.36
Sit-to-stand score	10.7 (6.2)	16.0 (5.5)	<.001	0.49
BTrackS balance score	37.1 (21.1)	26.6 (9.5)	.03	0.30
Short FES-I[c] score	11.6 (4.2)	9.3 (3.3)	.001	0.42

[a] *P* values refer to the difference between the groups (Mann-Whitney *U* test).

[b] Effect sizes are provided as rank biserial correlation, whereby 0.10, 0.30, and 0.50 represent small, medium, or large effects, respectively.

[c] Short FES-I: Short Falls Efficacy Scale–International.

Kendall rank correlation analysis (Table 3) revealed significant inverse correlations between PhA and age (τb=–0.37; *P*<.001) and between PhA and IR (τb=−0.79; *P*<.001). Significant moderate direct correlations were observed between PhA and STS scores (τb=0.34; *P*<.001) and between PhA and average HGS (τb=0.22; *P*=.002). Small but significant correlations were found between PhA and balance scores (τb=−0.19; *P*=.01) and between PhA and Short FES-I scores (τb=−0.25; *P*=.001). IR had a significant and direct relationship with age (τb=0.37; *P*<.001) and Short FES-I scores (τb=0.26; *P*<.001). IR had a significant and inverse relationship with average HGS (τb=−0.21; *P*=.004) and STS scores (τb=−0.33; *P*<.001).

Table . Relationships of phase angle and impedance ratio with participant characteristics (n=85).

Variable	Phase angle		Impedance ratio	
	τb[a]	*P* value[b]	τb	*P* value
Age	−0.37	<.001	0.37	<.001
Height	0.09	.25	0.02	.81
Weight	0.06	.39	−0.03	.70
BMI	0.03	.64	−0.04	.60
Impedence ratio	−0.79	<.001	—[c]	—
Average handgrip strength	0.22	.002	−0.21	.004
Sit-to-stand score	0.34	<.001	−0.33	<.001
BTrackS balance score	−0.19	.01	0.18	.02
Short FES-I[d] score	−0.25	.001	0.26	<.001

[a] τb=Kendall τ b correlation coefficient.

[b] *P* values refer to the correlation between variables.

[c] Not available.

[d] Short FES-I: Short Falls Efficacy Scale–International.

After controlling for age (Table 4), strong direct correlations were observed between PhA and average HGS (τb=0.75; *P*=.003) and between PhA and STS scores (τb=0.76; *P*=.002). A large direct correlation was observed between IR and Short FES-I scores (τb=0.46; *P*=.07). A moderate inverse correlation was found between IR and STS scores (τb=−0.32; *P*=.20).

Table . Partial correlations between phase angle and impedance ratio (n=85).

Variable	Phase angle		Impedance ratio	
	τb[a]	*P* value[b]	τb	*P* value
Height	0.50	.04	−0.06	.81
Weight	0.21	.41	0.25	.31
BMI	0.10	.68	0.26	.29
Average handgrip strength	0.75	.003	−0.003	.99
Sit-to-stand score	0.76	.002	−0.32	.20
BTrackS balance score	−0.04	.87	0.11	.66
Short FES-I[c] score	−0.24	.33	0.46	.07

[a] τb=Kendall’s τ b partial correlation coefficient.

[b] *P* values refer to the correlation between variables, controlling for age.

Discussion

Principal Results

The purpose of this study was to examine the relationships among HGS, STS score, balance, fear of falling, PhA, and IR in older adult women classified as having low or high PhA. When comparing physical function between high and low PhA groups, our results demonstrate significant differences in physical function between the high and low PhA groups. We observed a significantly lower IR within the high PhA group (*P*<.001; r_{rb}=0.92) and a strong negative correlation between PhA and IR (τb=−0.79; *P*<.001). The low PhA group had a significantly higher IR (*P*<.001; r_{rb}=0.92) and lower PhA (*P*<.001; r_{rb}=1.0).

When comparing physical function between the high and low PhA groups, our results demonstrate significant differences in physical function between groups. The low PhA group showed significantly lower HGS (*P*=.007; r_{rb}=0.36), STS scores (*P*<.001; r_{rb}=0.49), and higher balance scores (*P*=.03; r_{rb}=0.30) than the high PhA group. Additionally, when examining relationships among PhA, IR, and physical function on controlling for age, moderate correlations were observed between PhA and HGS (τb=0.75; *P*=.003) and STS scores (τb=0.76; *P*=.002). However, balance scores (τb=−0.04; *P*=.87) and fear of falling (τb=−0.24; *P*=.33) showed only weak correlations with PhA when controlling for age. The low PhA group demonstrated a significantly higher Short FES-I score than the high PhA group (*P*=.001; r_{rb}=0.42).

Comparison With Previous Literature

Previous literature has demonstrated an increased prevalence of physical dysfunction corresponding with a PhA less than 4.1° in older community-dwelling women, which informed our cutoff value of 4.1° to classify participants as having a low or high PhA [34,38]. Beyond a difference in PhA, the low PhA group also had a significantly lower IR of 0.85 (SD 0.01). This supports previous literature indicating that an IR closer to 1 is indicative of poor cellular health [22]. We observed a significantly lower IR in the high PhA group (Table 1) and a strong negative correlation between PhA and IR (Table 3). This aligns with previous evidence associating both a higher PhA and a lower IR with improved cellular integrity and health [22].

Reduced muscular strength and physical function in older adults has been associated with a lower PhA and higher IR [12,30]. In our study, we did not observe a strong correlation between HGS and PhA (Table 3). This is contrary to previous research, where IR and HGS were significantly correlated (r=0.46; P<.001) when controlling for age [24]. This discrepancy may be due to differences in methodology; Ballarin et al [24] assessed IR among 19-35–year-olds using a 300 kHz/5 kHz frequency ratio, while our study used a 250 kHz/5 kHz frequency ratio and included participants no younger than 60 years. IR is understood to be lower in younger populations [27], and younger populations still experience increases in HGS. This is contrasted by the higher IR and declining HGS experienced by older individuals.

Few studies have examined the relationship between STS score and PhA. Previous studies have instead used the gait speed test to assess physical function [43]. While STS and gait speed tests are not synonymous, both are dynamic multijoint movements that require both muscular strength and balance. This may explain why STS and gait speed performance are consistently observed as strong predictors of PhA in healthy individuals. This aligns with previous studies showing associations between lower limb strength and PhA [44]. Retaining muscle mass and physical function in the lower legs would have a direct impact on the R, X_c, and Z measured by BIA via an increase in muscular tissue and intracellular hydration [45]. A recent systematic review and meta-analysis of randomized controlled trials supports this theory, reporting that resistance training of at least 8 weeks increases PhA in older adults [45]. Furthermore, 6 out of the 7 studies included only involved female participants, which aligns with our sample [45]. Within clinical settings where the risks of conducting an STS test or other physical assessments may outweigh the benefits, BIA may serve as a proxy for skeletal muscle quality and physical functioning. PhA has been shown to change with physical functioning longitudinally, as numerous studies have focused on sarcopenia and frailty regarding PhA [29].

The poorer physical function seen in the low PhA group suggests that a lower PhA reflects diminished skeletal muscle integrity and functionality in older adult women. Balance scores were significantly higher in the low PhA group, which are representative of poor balance and moderate to high fall risk (Table 1). A longitudinal study conducted by Asano et al [13] concluded that lower body strength diminishes with aging, and the observed poor balance score was associated with low PhA. We observed a greater fear of falling in the low PhA group (Table 2), and a moderate correlation between IR and fear of falling (Table 4). One study concluded that in women with osteoporosis, slower walking speed, decreased muscular strength, and greater postural sway were correlated with an increased fear of falling [46]. An increase in the fear of falling is associated with decreased muscular strength, which aligns with our findings [15].

Strengths and Limitations

One of the strengths of this study was the diverse population, including low-income female participants from 4 different racial and ethnic backgrounds. This study also intentionally used portable, accessible, and valid instruments to increase the applicability of the results to clinical practice. However, there are limitations to the study that should be considered. The main findings were raw BIA variables that are directly influenced by fluid distribution throughout the body, as the different frequencies used in calculated IR allow for the assessment of ECW and ICW. Hydration status may thus be a confounding variable as it was not assessed or controlled, although all testing occurred in the late morning for all participants after they were encouraged to void their bladders. In addition, the nonnormal data distribution was accounted for by using robust nonparametric tests during statistical analysis.

Implications and Future Directions

BIA is a brisk assessment that can be used in older adults to evaluate body composition and cellular health. This study concluded that PhA and IR are both linked to physical function and fear of falling in older women but associate differently when controlling for age. Although they are both measures of cellular health, our study demonstrates how PhA and IR differ in their relationship with physical function and fear of falling. As BIA continues to grow as a clinical assessment, there is a need to better understand how its measures relate to other assessments. A higher IR closer to 1 is indicative of poorer cellular health, which was observed in our low PhA group [22], and is also associated with diminished physical function and a heightened fear of falling in this study. Our study aligns with previous research reporting a strong inverse correlation between PhA and IR [21]; yet, there has been a lack of research investigating IR and its relationship with physical function. IR is a direct reflection of hydration status; therefore, we believe that IR is a helpful passive assessment to use, given the noninvasive and simple nature of the tool. More research on IR in older adults is needed to further examine its relationships with functional assessments.

Aging is associated with a change in body composition and decline in physical function. Therefore, PhA may reflect skeletal muscle health and can be assessed along with physical function. Based on this study, a PhA of ≤4.1° would be indicative of decreased physical function in older women, and an intervention can be implemented to help improve PhA. Additionally, in instances where physical function assessments cannot take place, measuring PhA and IR may be valuable as indicators of physical function for that period. Our results suggest that muscular strength assessments such as HGS and STS may be more closely related to PhA than balance in older adult women. STS scores are indicative of lower body strength, suggesting that lower body strength may be an important factor in PhA and IR. Balance scores can be indicative of muscle integrity, which is associated with frailty, sarcopenia, and malnutrition [29]. It is plausible that lower body strength may be particularly important when evaluating cellular health and physical function via bioimpedance parameters in older women, but more research is needed.

While physical function assessments are commonplace among older adults, psychological and physiological assessments should also be considered. Our results show that the fear of falling has an inverse relationship with physical function and PhA and a direct relationship with IR. Future research should further examine the relationships among fear of falling, physical function, PhA, and IR as they change over time. Understanding how these variables influence each other may aid in designing interventions to improve the health and quality of life of older adults.

Conclusions

Our results indicate that low PhA (≤4.1°) and high IR are linked with poorer physical function in older women, particularly for HGS and STS ability. PhA and IR are variables that can be assessed regularly during routine checkups and provide an indication of physical function and cellular health. Despite being indicative of cellular integrity and health, IR has not been widely studied in older adults. Assessing hydration status along with BIA measurements may help strengthen the design of future studies. Future research should also compare IR and physical function to our results and assess changes in IR longitudinally within older adults.

Abstract

Background: The 3-Minute Diagnostic Interview for Confusion Assessment Method–Defined Delirium (3D-CAM) is an instrument specially developed for the assessment of delirium in general wards, with high reported sensitivity and specificity. However, the use of the 3D-CAM by bedside nurses in routine practice showed relatively poor usability, with multiple human errors during assessment.

Objective: This study aimed to develop a mobile app–based delirium assessment tool based on the 3D-CAM and evaluate its usability among older patients by bedside nurses.

Methods: The Delirium Assessment Tool With Decision Support Based on the 3D-CAM (3D-DST) was developed to address existing issues of the 3D-CAM and optimize the assessment process. Following a randomized crossover design, questionnaires were used to evaluate the usability of the 3D-DST among older adults by bedside nurses. Meanwhile, the performances of both the 3D-DST and the 3D-CAM paper version, including the assessment completion rate, time required for completing the assessment, and the number of human errors made by nurses during assessment, were recorded, and their differences were compared.

Results: The 3D-DST included 3 assessment modules, 9 evaluation interfaces, and 16 results interfaces, with built-in reminders to guide nurses in completing the delirium assessment. In the usability testing, a total of 432 delirium assessments (216 pairs) on 148 older adults were performed by 72 bedside nurses with the 3D-CAM paper version and the 3D-DST. Compared to the 3D-CAM paper version, the mean usability score was significantly higher when using the 3D-DST (4.35 vs 3.40; *P*<.001). The median scores of the 6 domains of the satisfactory evaluation questionnaire for nurses using the 3D-CAM paper version and the 3D-DST were above 2.83 and 4.33 points, respectively (*P*<.001). The average time for completing the assessment reduced by 2.1 minutes (4.4 vs 2.3 min; *P*<.001) when the 3D-DST was used.

Conclusions: This study demonstrated that the 3D-DST significantly improved the efficiency of delirium assessment and was considered highly acceptable by bedside nurses.

KEYWORDS

delirium; 3D-CAM; older adults; clinical decision support system; nurse; 3-Minute Diagnostic Interview for Confusion Assessment Method-Defined Delirium

Introduction

Delirium is a common complication that is highly prevalent among hospitalized older adults; it can affect up to 40% of hospitalized older patients [1,2]. Delirium is associated with many adverse outcomes, including cognitive and functional impairment, increased hospital stay, care burden, and mortality, and therefore leads to increased care needs and poor prognosis [3,4]. The severity of the adverse consequences of delirium are positively correlated with the severity and duration of delirium [5]. Therefore, early recognition of delirium is essential for timely management of delirium to improve the patient's prognosis [6].

Although many clinical guidelines and representative societies have recommended the use of standardized assessment tools for daily delirium screening in clinical practice, delirium is still poorly recognized among hospitalized older adults [6,7]. A previous study has shown that up to 66% of older adults with delirium went unrecognized in routine practice [8]. The possible reasons for underdiagnoses of delirium include communication barrier, inadequate use of the screening tools, and a lack of education on and conceptual understanding of delirium [9].

The Confusion Assessment Method (CAM) has been used as the reference standard for delirium screening [10]. However, the use of the CAM to assess delirium requires a combination of cognitive testing and subjective judgment based on clinical experience. Lemiengre et al [11] found that the sensitivity on the daily use of the CAM by bedside nurses was only 30%. Therefore, to overcome the feasibility issues associated with the use of the CAM, Marcantonio et al [12] developed the 3-Minute Diagnostic Interview for CAM-Defined Delirium (3D-CAM) based on the key features of the CAM and simplified the evaluation process. The 3D-CAM was perceived as easy to use, and it had a sensitivity of 92% to 100% and a specificity of 88% to 94% among studies that were tested in different ethnic groups [12-15]. Kuczmarska et al [15] has identified that the 3D-CAM is appropriate for delirium assessment in general wards.

However, a previous study has shown that the use of the 3D-CAM by bedside nurses in routine practice demonstrated relatively poor usability, with multiple errors (such as human error, misunderstanding of item content, and incomplete or missing nursing records) during assessment [16]. The assessment of alteration on attention and thinking must be combined with cognitive assessment. During the process, nurses need to memorize, calculate, and make a judgment according to the patient’s response, which is prone to human errors. Meanwhile, the patient’s consciousness status needs to be compared with the assessment results at admission by reviewing the patient’s medical records. With these identified challenges, nurses often fail to complete the assessment successfully due to communication problems and difficulties in finding or loss of related materials. Moreover, due to the limited knowledge level on delirium among clinical nurses, adding prompts or cues to the items can effectively improve nurses’ identification of delirium, in addition to providing training on basic delirium knowledge before the use of the 3D-CAM [16]. Therefore, there is an urgent need to develop and adopt innovative ways to promote prompt delirium assessment in routine practice both effectively and accurately.

Several studies have reported that a clinical decision support system (CDSS) with some degree of autonomy may help solve this issue and improve the accuracy and adequacy of delirium assessment among bedside nurses [17,18]. Marcantonio et al [19] developed a brief app-based delirium identification tool, and it has shown good performance. Based on the Confusion Assessment Method for Intensive Care Unit (CAM-ICU), mobile apps have also been developed for delirium screening of patients in intensive care units (ICUs), and they showed acceptable usability and accuracy when used by bedside nurses [20-22]. Therefore, in this study, we aimed to develop the Delirium Assessment Tool With Decision Support Function Based on the 3D-CAM (3D-DST) and to evaluate its usability among older patients by bedside nurses.

Methods

Ethical Considerations

The research protocol and secondary data analysis were approved by the institutional review committee of Capital Medical University (2015SY49). This was a substudy under a clinical trial, which was registered at the Chinese Clinical Registry (ChiCTR-IOR-17,010,368). Verbal informed consent was obtained from each participant before the start of the program, and participants had the right to withdraw during the study. The data were anonymized. The study protocol was safe and reliable and did not provide any compensation to the participants.

Design and Development of the 3D-DST

Previous Work

The 3D-CAM was translated into Chinese in a previous study and validated by nurse researchers; it showed acceptable sensitivity and specificity among hospitalized Chinese older patients [23].

Phase 1: Analysis of Problems in the Use of the 3D-CAM Paper Version

The task walkthrough method was used to fully address the end users’ needs and achieve the overall goal of automatic delirium evaluation [16].

Phase 2: Design of the 3D-DST

In this phase, we first formed a multidisciplinary team that included experts with rich experience in delirium assessment. Bedside nurses, nursing researchers, software engineers, and user interface designers who were specialized in developing nursing information systems (NISs) were involved in the designing phase. The 3D-DST was designed and developed following the American Medical Informatics Association usability design principle [24]. Details of the design principle are shown in Multimedia Appendix 1.

Evaluation Process Analysis and Optimization of the 3D-DST

Based on the evaluation content and rules of the original 3D-CAM, this study scrutinized and analyzed the 3D-CAM evaluation process, identified the best path, and reoptimized and standardized the 3D-CAM evaluation process. By optimizing the 3D-CAM evaluation process, only the necessary paths to support the delirium evaluation were reserved, unnecessary links were eliminated, and the assessment was standardized to reduce intermediate errors; , thus, a clinical decision-making system for delirium screening was established. Automatic evaluation logic jumps were incorporated into the system design according to the evaluation rules. Based on the problems identified by bedside nurses and the overall goals of the system, the key functional modules of the 3D-DST were initially drafted in mind-mapping software (Xmind software, version: 3.7.4.0; XMIND LTD).

User Interface Design of the 3D-DST

Overview

The interface design was completed in several steps. First, we used AxureRP (Axure Rapid Prototyping) to draft the logical diagrams, workflow, functional components, and user interfaces of the 3D-DST. Second, we made a web page to facilitate communication with engineers and team members. This was achieved via WuliHub (a domestic data hosting and sharing platform), and the interface prototype diagram and interaction components drawn by AxureRP were uploaded into this web browser–based demonstration scheme. Via WuliHub, a set of HTML files were generated based on the interface prototypes and interaction schemes drawn by AxureRP; they were compressed and uploaded to the platform for easy sharing. Third, following the American Medical Informatics Association interface design principle, the order of the evaluation content of each interface was determined based on the evaluation content and the optimal evaluation process of the 3D-DST. Finally, the prototype design of the evaluation interface of the 3D-DST was completed with the identified functions, including evaluator registration, log-in authentication, and user log out. Corresponding functional assessment modules were also developed, along with the result-reporting interface. The 3D-DST was designed by following the existing delirium assessment system [23], with easy access and a friendly display; for example, the patient's identification was obtained by scanning their wristband, and different color selection, buttons, and information composition were used to increase its feasibility and usability.

Phase 3: Architecture and Development of the 3D-DST

In this phase, the system architecture, databases related to personal information and assessment data, and the user interfaces were identified. The 3D-DST was developed to fit on Android-compatible devices (Huawei nova 3), as the personal digital assistant used in clinical practice was largely based on the Android system rather than the iOS system in China.

We used Java, Spring Boot, and RouYi-Vue to program the backend framework and Vue for the front-end framework. Mysql was used to formulate the databases. GitLab and Docker were used to release the 3D-DST. To make the 3D-DST system more stable, the model-view-viewmodel (MVVM) was used as the architecture scheme. The synchronization between view and model was completely automatic without human interference, the data maintenance was completely managed by the MVVM, and the operating environments were Linux and Windows [25,26]. To maintain information security, the 3D-DST set a cookie scheme with a time limit. The users needed to log in and verify their identity again when the cookie expired.

Usability Evaluation of the 3D-DST

Overview

The usability of the 3D-DST was evaluated using the acceptance questionnaire, and the results were compared to the 3D-CAM paper version when it was used by bedside nurses. The questionnaire included 6 domains regarding usability: perceived usefulness, ease of use, ease of learning, trustworthiness, intention to use, and satisfaction. The performance of the app was evaluated on 4 domains and compared to that of the 3D-CAM paper version, which included the successful completion rate of delirium assessment (proportion of nurses who completed the assessment correctly when they used the 3D-CAM paper version and the 3D-DST), evaluation completion time (time used to complete the assessment), the number of mistakes made during assessment against the results from a researcher, and satisfactory evaluation using an acceptance questionnaire.

Design, Setting, and Participants

This study was conducted among 72 bedside nurses from 3 tertiary hospitals in Beijing, China. Eligible patients from 3 internal medical wards (neurology, respiratory, and cardiology) and 1 surgical ward (orthopedic) of the study hospitals were assessed by participating bedside nurses using both the 3D-DST and the original 3D-CAM paper version. All participating patients and bedside nurses provided informed consent before study initiation.

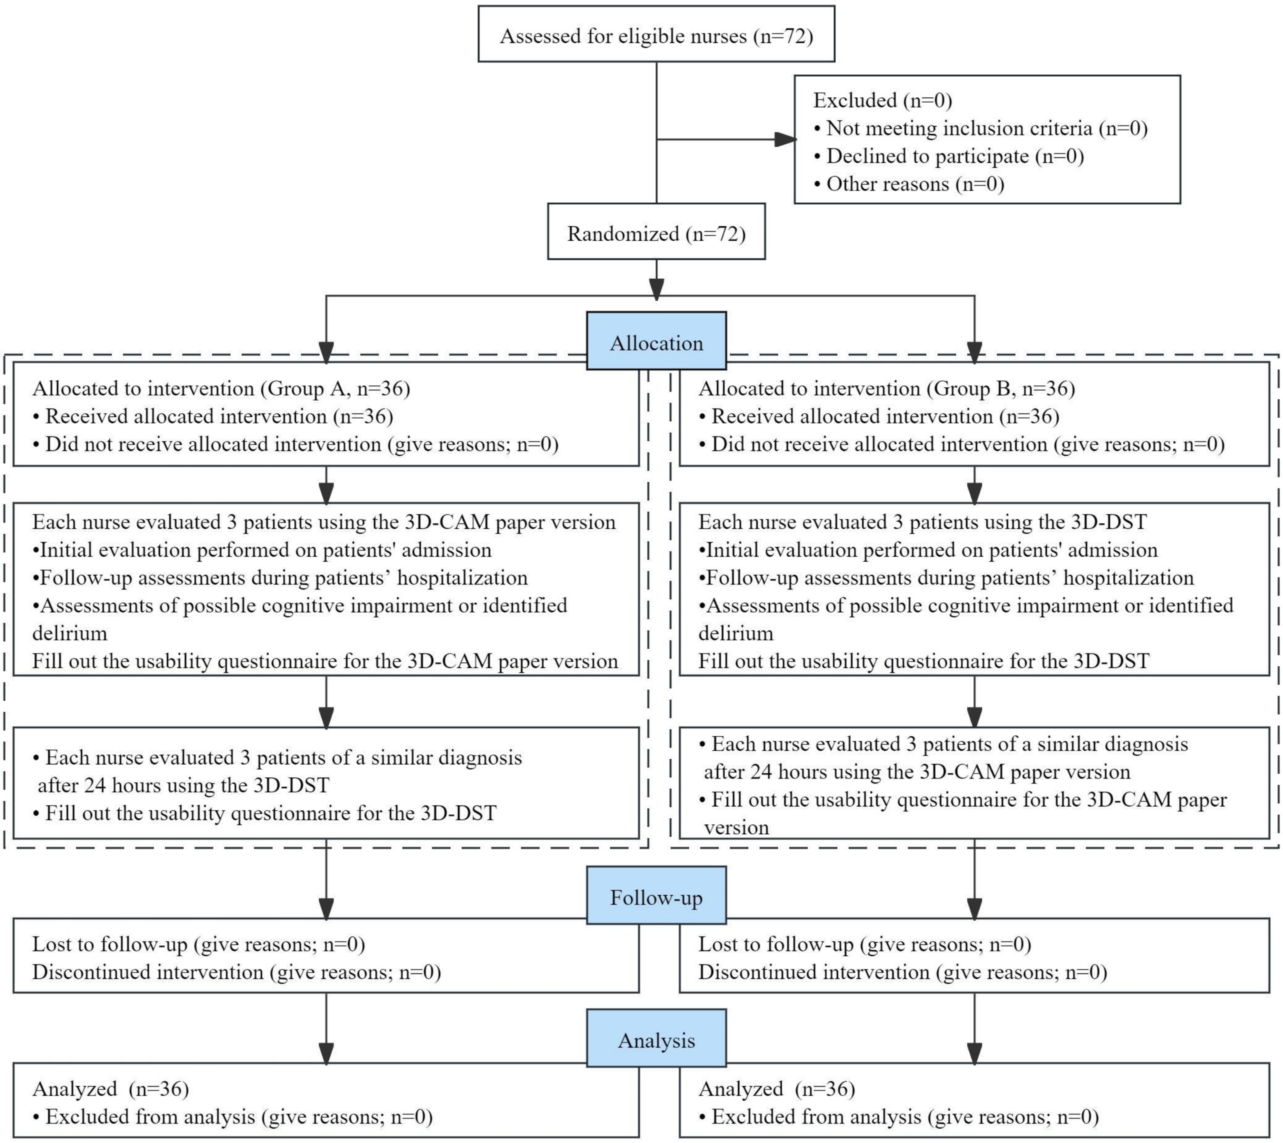
Following convenient sampling, bedside nurses who met the following criteria were included in the usability testing phase: (1) registered nurse with a valid license; (2) had more than 1 year of working experience and had been working continuously in their department for more than 3 months; and (3) willing to participate in this research. Hospitalized older adults who were aged 65 years or older and could communicate effectively in Mandarin were included in the study, and those with identified severe visual or hearing impairment were excluded from delirium assessment. Nurses who declined to participate during the study period were also excluded from the final analysis.

Usability Evaluation

The usability evaluation of both the 3D-CAM paper version and the 3D-DST was conducted using the usability testing questionnaire designed by Feng et al [27]. The content validity index scores for the 3 areas in the questionnaire (topic suitability, topic importance, and content clarity) were 1.00, 1.00 and 0.96, respectively. Since the dimensions for evaluating the usability of the CAM-ICU and 3D-CAM are similar, the questionnaire can also be used to evaluate the usability of the 3D-CAM. In this study, we revised several items of the questionnaire to make it suitable for the 3D-CAM paper version or the 3D-DST. For example, we changed the item "I think this tool meets the requirements of ICU nurses for a delirium assessment tool" to "I think this tool meets the requirements of nurses for a delirium assessment tool in general wards." In addition, the term "CAM-ICU" in the items evaluating the ease of use was replaced with "3D-CAM." The reliability of the revised questionnaire was tested for overall internal consistency, and the Cronbach α coefficient was 0.907. The questionnaire was rated on a 5-point Likert scale ranging from "1=strongly disagree" to "5=strongly agree." A higher score indicated better user acceptance. The usability evaluation was evaluated on 6 domains: perceived usefulness, ease of use, ease of learning, trustworthiness, intention to use, and user satisfaction. To evaluate the acceptability of the 3D-DST, items to evaluate the interfaces of the app were added to the questionnaire, so the usability questionnaire contained 26 and 43 items for the 3D-CAM paper version and the 3D-DST, respectively.

Before study initiation, researchers used a computer program to generate random numbers and made an assignment sequential table. Eligible bedside nurses were numbered according to the order they participated in. One group of nurses (Group A) used the 3D-CAM paper version first to evaluate 3 patients (initial evaluation at admission and follow-up assessments during the patients' hospitalization, including assessments of possible cognitive impairment or identified delirium). Subsequently, the same group of bedside nurses used the 3D-DST to evaluate patients with a similar admission diagnosis after 24 hours to avoid the impact of short-term memorization on the evaluation process. Conversely, nurses from the other group (Group B) used the 3D-DST first and then the 3D-CAM paper version second to evaluate 2 different sets of patients (3 patients per nurse). Nurses who participated in the study only assessed patients admitted in the wards where they worked. A nurse researcher conducted training sessions for all bedside nurses on the use of the 3D-CAM and the 3D-DST before their assessments; the nurse researcher also selected the eligible patients based on their admission diagnosis prior to being approached. Usability testing of both the 3D-CAM paper version and the 3D-DST was carried out when each set of assessment was completed (Figure 1).

Figure 1. Flowchart of participant recruitment and participation. 3D-CAM: 3-Minute Diagnostic Interview for Confusion Assessment Method–Defined Delirium; 3D-DST: Delirium Assessment Tool With Decision Support Function Based on the 3-Minute Diagnostic Interview for Confusion Assessment Method–Defined Delirium.



Performance of the 3D-DST

During each assessment, 1 experienced nurse researcher observed the performance of bedside nurses and completed the patients' delirium screening using the 3D-CAM paper version at the same time. The successful completion rate of delirium assessments in terms of the proportion of correctly identified delirium, whether using the 3D-CAM paper version or the 3D-DST by bedside nurses, was recorded. In addition, the number of mistakes made during the assessments (compared to the researcher's assessment results) and the evaluation completion time were also recorded for each nurse. Nurses were blinded to the researcher's assessment results.

Sample Size

The highest score for each item of the usability questionnaire was 5 points (the higher the score, the better the usability). We expected that an average score of 4 or more would be achieved when the 3D-DST was used by bedside nurses, which is 1 point higher than the average score of the 3D-CAM paper version. With the SD being 1.0 and α=.05, at least 54 bedside nurses were needed to achieve 90% power. Considering that a quarter of bedside nurses might not be able to complete the study, a final sample of 72 nurses was required for this study.

Data Analysis

SPSS software (version 21.0; IBM Corp) was used to perform the data analysis. Normally distributed variables were presented using the mean and SD, whereas nonnormally distributed variables were presented using the median and range. Categorical variables were presented with frequencies and proportions as appropriate. The χ^2 test or Fisher exact test was used to compare the differences between nurses' baseline data (different age groups, sex, etc) and the evaluation success rate. The comparison of evaluation completion time, the total usability score, and the impact of the sequential use of the 3D-CAM paper version and the 3D-DST between 2 groups were achieved using ANOVA. A nonparametric test was used to test the differences between the scores of each domain of the usability questionnaire and the order of using the 2 types of assessments. *P*<.05 was considered statistically significant.

Results

Design and Development of the 3D-DST

Phase 1: Analysis of Problems in the Use of the 3D-CAM Paper Version

Several problems were identified with the use of the 3D-CAM paper version by bedside nurses, including human errors, insufficient or incorrect understanding of the assessment contents, and incomplete or failed retrieval of the relevant information from the nursing record [16]. In developing the 3D-DST, the delirium evaluation process was simplified as unnecessary steps were automatically omitted after sorting out the procedural results related to specific features of the 3D-CAM. The evaluation processes of the 3D-CAM paper version and the 3D-DST are shown in Multimedia Appendices 2 and 3.

Phase 2: Design of the 3D-DST

The 3D-DST was installed on mobile phones with an Android (8.1.0) system, 128 GB, 8-core processor, and 1.8 GHz. Three evaluation modules were incorporated into the 3D-DST, reflecting the inquiry, observation, and selective evaluations. The evaluation interfaces (Figure 2) of the 3D-DST included 8 evaluation pages and 16 different evaluation result interfaces (3 delirium-positive interfaces and 13 delirium-negative interfaces).

Evaluation time: two minutes

Auxiliary reminders based on the common mistakes reported by nurses in phase 1 were added to the system. In overcoming these burdens, the 3D-DST was developed to include reminders on the correct answers regarding items 1, 2, and 5. Nurses only needed to check whether the patient's response was consistent with the reminder or not. As the 3D-DST can automatically record and retrieve previous evaluation results, item 22 was not displayed in the 3D-DST but was incorporated into the algorithm of the 3D-DST, and the result was generated automatically. To address issues associated with "incorrect understanding of item content," cues were incorporated into the 3D-DST to facilitate better understanding of the contents of related items (11 through 20) during assessment.

In the development of the 3D-DST, we also included functions to automatically retrieve necessary information from the record for comparison, which was incorporated to the 3D-DST. Nurses using the 3D-DST do not need to manually search and compare the previous evaluation results, which could increase the successful completion rate of the assessment.

Usability Evaluation of the 3D-DST

A total of 72 bedside nurses completed the usability testing of the 3D-DST. The demographic characteristics of participating bedside nurses are shown in Table 1. They were mainly female (n=67, 93%), with 44 (61%) nurses holding a bachelor's degree. A total of 148 patients were evaluated by nurses in this study, with 98 (66%) being female and a mean age of 76 (SD 7.18) years.

Table . Demographic characteristics of the participating bedside nurses.

Characteristics		Group A (n=36), n (%)	Group B (n=36), n (%)	*P* value
Age group (years)				.93
	20-30	20 (56)	20 (56)	
	31-47	16 (44)	16 (44)	
Sex				>.99
	Female	33 (92)	34 (9)	
	Male	3 (8)	2 (56)	
Education level				>.99
	Junior college	12 (33)	13 (36)	
	College and above	24 (67)	23 (64)	
Work experience (years)				.71
	<5	15 (42)	16 (44)	
	5-10	11 (31)	9 (25)	
	≥11	10 (28)	11 (31)	

A total of 432 delirium assessments (216 pairs) were performed by the bedside nurses on 148 older adults with the 3D-CAM paper version and the 3D-DST, of which 38 (26%) older adults were confirmed as delirium positive by a nurse researcher using the 3D-CAM paper version.

The mean usability scores of bedside nurses using the 3D-CAM paper version and the 3D-DST were 3.40 (SD 0.43) and 4.35 (SD 0.31), respectively, with the score of the 3D-DST being 0.95 points higher than that of the 3D-CAM paper version (*P*<.001). The median scores of the 6 domains of the satisfactory evaluation questionnaire for nurses using the 3D-CAM paper version and the 3D-DST were above 2.83 points and 4.33 point, respectively. As shown in Table 2, the median scores on the ease of use, ease of learning, and trustworthiness were 1 point higher than the other 3 domains (*P*<.001). The total satisfactory score of the 3D-DST was higher than that of the 3D-CAM paper version (*P*<.001), whereas the order of assessments, whether using the 3D-CAM paper version first or the 3D-DST first, had no effect on the results.

Table . Comparison of the effectiveness and efficiency of the 3D-CAM[a] paper version and the 3D-DST[b].

Discussion

Principal Findings

This study described the development process of a CDSS based on the 3D-CAM and evaluated its usability in delirium screening among older patients. Our results demonstrated that the 3D-DST was perceived as highly satisfactory with acceptable usability when used by bedside nurses, and it improved the completion rate and reduced the evaluation completion time when bedside nurses used the app among older patients.

CDSSs are tools incorporated with a significant clinical knowledge base and are designed to provide users (health care professionals, patients, and caregivers) with an intelligent way to assist in clinical decision-making [28]. Previous studies have found that well-designed CDSSs are effective and can improve clinical outcomes and health processes [29]. Therefore, it is very important to ensure the quality of CDSSs and avoid unpleasant situations when deploying unreliable systems.

Functional suitability is a very important feature when developing CDSSs; it refers to the extent to which a system meets the stated and implied requirements through its functional components under certain conditions [30-32]. In our study, the 3D-DST is aimed to connect with the hospital information system or NIS, so that it can automatically retrieve the patients' information via the hospital information system. The 3D-DST can obtain information by scanning the QR code on the patient's wristband, which allows the 3D-DST to be easily integrated into the portable NIS and facilitates efficient delirium assessment by bedside nurses.

As indicated by the study results, the median scores on the ease of use, ease of learning, and trustworthiness of the 3D-DST were over 1 point higher than those of the 3D-CAM paper version. It was demonstrated that the development of the 3D-DST met the requirements of bedside nurses, improving the acceptability and usefulness of the screening tool. There were several possible reasons. First, the 3D-DST was designed through process optimization, which incorporated strategies such as automatic evaluation logic jumps, embedded prompts, automatic comparison function, etc. The design process made full use of information technologies, such as automatic recording, calculation, and other intelligent functions, that could effectively solve the problems identified by nurses when they used the 3D-CAM paper version. The 3D-DST was well accepted by bedside nurses, the burden on the memorization of information was reduced, and the ease of use of the 3D-CAM was improved. Second, nurses only needed to complete the evaluation process by following the interfaces and the embedded prompts. Nurses did not need to learn the specific instructions, and the system could automatically record, calculate, and output the results, therefore improving this tool's learnability and scalability. Third, since the content of the 3D-CAM is mostly a routine assessment, nurses needed less training time to use the tool. Moreover, with reduced time to complete the delirium assessment, nurses perceived the 3D-DST as highly acceptable, which generated trustworthiness and solved the existing problems associated with the use of the 3D-CAM paper version.

The improvement of the perceived usefulness, intention to use, and satisfaction scores was less than 1 point when comparing the 3D-DST with the 3D-CAM paper version. This could be attributed to the following reasons. The scores on these 3 domains of the 3D-CAM paper version were considerably high. Perceived usefulness was mainly evaluated based on nurses' knowledge of delirium assessment, whereas intention to use mainly referred to whether nurses were willing to use the tool and whether the nurses could accept the method of using the tool or not, notwithstanding the evaluation completion time. Since this study was only conducted in a short period of time, nurses may not fully understand and appreciate that the 3D-DST can standardize the assessment process and improve the recognition rate and accuracy of the delirium assessment. In the future, the duration that the nurses use the 3D-DST should be extended before the acceptance evaluation. Furthermore, the intention to use the 3D-DST and satisfaction perceived by nurses may be affected by organizational factors.

Our study found that the 3D-DST had a slightly higher successful completion rate than the 3D-CAM paper version in assessing delirium among bedside nurses (212/216, 98.1% vs 203/216, 94%; P=.045). In the 3D-DST, reminders of the correct responses for items 1, 2 and 5 (objectively testing patients' cognition) were incorporated into the app, which can increase the accuracy of the delirium assessment, reduce the information processing time, and improve nurses' work efficiency. When nurses evaluate delirium using the 3D-DST, the system will automatically record and generate the evaluation results without manual input; this prevented possible human errors that are introduced by the nurses. The 3D-DST also added prompts that aimed to reduce the assessment failure rate caused by incorrect or inadequate understanding of the content of the items. By integrating prompts into the 3D-DST, it may have contributed to the reduced failure rate among bedside nurses by guiding and standardizing the assessment process; thus, insufficient knowledge and possible human errors are fully addressed during the assessment. Therefore, the 3D-DST improved the success rate of the delirium assessment. With assistance of CDSSs, decision-making can be incorporated into the routine assessment to guide nurses to complete the assessment successfully with standardized procedures [33-35].

The advantages of the study are multifactorial. The 3D-DST was developed to solve the problems associated with the use of 3D-CAM paper version in routine practice by nurses. The research team included multidisciplinary members such as delirium assessment experts and software development engineers, and we used a combination of multiple architectures to ensure the stability of the system during the development process. In addition, in evaluating the usability and performance (completion rate, time required for completing the assessment, and the number of human errors made by nurses during the assessment) of the 3D-DST, both subjective and objective approaches were used by comparing the 3D-CAM paper version with the 3D-DST among bedside nurses, which showed the promising results of the 3D-DST.

This study also has several limitations. First, each bedside nurse only used the 3D-CAM to evaluate 6 patients, which may have limited the nurses' possibility to evaluate all types of patients with different admission diagnoses in general wards. Therefore, our result may not be generalizable to other clinical settings. Second, this study only applied a quantitative approach to evaluate the usability of the 3D-DST; interviews can be added to explore the usability of the 3D-DST among bedside nurses in the future. Third, during the usability testing phase, some usability issues in our system may not be adequately reflected due to limitations in the patients' admission types and the limited number of assessments. Fourth, bedside nurses were not physically involved in the interface design process, which may have affected the usability of the interface. However, we have examined the problems and issues associated with the use of the 3D-CAM paper version among bedside nurses, and the 3D-DST was developed to address these problems by including experienced nursing researchers during the development process, so the results should not be affected. Finally, this study did not analyze the accuracy of the 3D-DST in assessing delirium, as this was not required for the study objectives at this stage, and it was completed as a separate study.

Conclusion

This study demonstrated that the 3D-DST was perceived as highly acceptable and useful in assisting bedside nurses to identify delirium among older adults in routine practice. The integration of this app with existing health systems could enhance its positive impact on the efficiency and accuracy of delirium screening in the future.

Abstract

Background: Community-based social participation has shown promise in delaying cognitive decline in older adults with mild cognitive impairment (MCI) who are at risk of developing dementia. Although group storytelling interventions have proven effective, the need for a skilled workforce to support people with MCI can limit broader community implementation. Technology-based interventions may offer a solution to this limitation by replicating the abilities of therapists.

Objective: This study aims to co-design a digital storytelling intervention and evaluate its usability.

Methods: This co-design process involved 3 stages, engaging people with MCI (n=12), their caregivers (n=4), and therapists (n=5) in Beijing, China. In the first stage, we used card sorting and voting methods to identify potential incentives for social participation and target the specific abilities that people with MCI wanted to enhance. In the second stage, we conducted brainstorming sessions with people with MCI and their caregivers to identify the potential features of a digital storytelling application named Huiyou (“meeting new friends” in Chinese). Finally, we assessed Huiyou’s usability with people with MCI and therapists, leading to iterative improvements based on the usability findings.

Results: We uncovered a crucial link between boosting the self-confidence of people with MCI and their ability to address social participation challenges. Notably, we identified memory improvement and enhanced language expression as key factors for effective communication with grandchildren. Subsequently, participants suggested features and interfaces to address these challenges, leading to the development of Huiyou, a group-based digital storytelling application featuring functions such as generating story materials, conducting memory retrieval activities, and sharing stories. It received an “excellent” rating in the User Experience Questionnaire benchmark, displaying high levels of attractiveness, dependability, stimulation, and novelty. People with MCI achieved an average task completion rate of 87% (n=19; SD 0.13) of the 22 tasks. However, feedback from people with MCI and therapists highlighted usability issues in navigation, activity management, user interface, and feature optimization, indicating a need for improved accessibility and efficiency.

Conclusions: The co-design approach contributed to developing the Huiyou prototype, supporting community-based social participation. User feedback highlighted the potential of Huiyou to enhance well-being and facilitate meaningful social interactions while maintaining crucial existing relationships.

Introduction

Background

Social participation has proven efficacious in decelerating the progression of dementia from mild cognitive impairment (MCI) [1], particularly in low- and middle-income countries [2]. To enhance social participation among older adults with MCI, researchers are engaged in reducing the obstructions to social participation [3] and creating and customizing a variety of constructive social activities [4]. To expand social participation, researchers have explored an assortment of interventions aimed at improving memory, communication, and familial relationships among older adults with MCI [5]. Social participation is considered at different levels: societal, community, relationship, and individual levels [6]. Community involvement is defined by its significance and the sense of satisfaction it generates in people's lives as well as its potential for creating social support [7]. Older adults reported that technology could assist them in maintaining social connections [8]. For example, researchers used cameras, enabling people with MCI to memorialize their daily lives [9]. Most interventions concentrate on enhancing cognitive abilities [10] or facilitating recreational and sports activities [11]. The former relies upon participants' strong motivation to participate in interventions, whereas the latter has less impact on cognitive ability. Storytelling tools can simultaneously enhance cognitive abilities and create a novel form of social interaction. Incorporating storytelling as a therapeutic intervention possesses enormous potential for improving health care outcomes and promoting well-being among people with MCI [12]. Studies have demonstrated that socially isolated people with MCI may experience lower psychological well-being and exhibit more negative states of mind than older adults considered to have cognitive normality [13]. Owing to cognitive impairments, people with MCI may encounter the following issues: (1) reduced interest in and initiation of social interactions, suggesting a lack of proactive engagement [14]; (2) difficulties in establishing and maintaining interpersonal relationships, implying an impaired sense of social synchrony; and (3) challenges in recognizing and adhering to social boundaries and norms [15]. It is imperative to explore behavior change strategies aimed at fostering a positive social health lifestyle among people with MCI. Technology could be a beneficial tool to maintain social connection [8]. For example, ElderConnect is a web-based app designed to assist senior citizens in recognizing, preventing, and easing feelings of loneliness. It offers information and tactics to help them establish new social connections and sustain existing ones [16]. Notably, storytelling serves as an essential activity for promoting positive social health [17,18]. Harnessing the power of storytelling, people with MCI can be encouraged to participate more proactively in their health care by identifying their unique needs and knowledge gaps while fostering strong connections and support networks with peers with similar disease-related experiences [19].

However, these storytelling interventions often lack a focus on community-based social activities, primarily being individual interventions without emphasis on interpersonal interactions. Furthermore, community-based programs depend on skilled facilitators, such as therapists or social workers, to maintain quality. For instance, providing training for facilitators before they lead a group reminiscence program ensures expertise in techniques and effective program management [20]. In integrative group storytelling therapy, participants exhibited strong social integration, supported one another, displayed valuable life skills, and fostered positive self-worth and institutional loyalty during reminiscing and feedback sharing [21]. Consequently, participants felt supported and experienced a sense of belonging when performing digital group activities [22]. Community-based social participation relies on facilitators who organize activities and provide support in securing spaces and promoting events. Therefore, using a technology-based storytelling intervention to boost community-based social engagement can enhance community belonging.

The 3 main features of a digital storytelling application are multimedia material editing, memory recall, and story sharing. Some memory retrieval interventions may combine multiple functions of the interventions, such as people with MCI simultaneously reminiscing and sharing their recollections [23]. Challenges in using technology remain an unsolved issue; people with MCI typically exhibit lower digital literacy [24]. Most storytelling programs include training sessions before the intervention, such as storytelling classes [25], as mostly commercial, off-the-shelf technology is used to support digital storytelling [12], and these programs require digital literacy for multimedia editing and digital storytelling. Some studies required trained volunteers [26] or caregivers [23,27] to support people with dementia in developing stories. However, these settings are intended to enable people with MCI to adapt to existing environments and interactive tools rather than customizing the software to their specific needs (thus enhancing the usability of the storytelling application while simultaneously reducing learning costs). The applicability of these methods for memory retrieval among adults with MCI is currently not fully understood [28]. Therefore, our aim was to co-design a technology-based group memory retrieval intervention, which is a key form of digital storytelling intervention, to support social participation. We also investigated how to design user-friendly storytelling applications to manage digital resources and reduce learning costs for people with MCI.

Theoretical Framework

Co-design pertains to the collaborative involvement of people (users and stakeholders) in the design of a product or service [29]. Co-design workshops for interventions for people with MCI involve people with MCI, caregivers, and therapists in designing the intervention programs, providing unique perspectives. Involving users in design sessions helps engineers and researchers better understand requirements. A co-design approach would be helpful in identifying the requirements for designing technology-based group memory retrieval interventions for people with MCI. In our study, the development of the storytelling prototype was guided by 2 behavioral and theoretical frameworks to raise participants' awareness about their social health behaviors and tailor adequate actions for behavior change, namely the Behavior Change Wheel [30] and Theoretical Domains Framework (TDF). Beginning with the Behavior Change Wheel, a behavioral analysis enables intervention designers to select particular areas for exploration, thereby guiding the development of the digital storytelling approach. TDF deepens the understanding of psychological and behavioral factors influencing effective interventions. This integration aligned our application's features with identified behavior change strategies, fostering a comprehensive approach to promoting social health. In addition, a communication strategy called MESSAGE (an acronym representing 7 key communication strategies, each encapsulated by its initial letter; within each strategy, specific suggestions are aimed at enhancing effective communication: maximizing attention [M], focusing on expression and body language [E], keeping it simple [S], providing support for their conversation [S], assisting with aids [A], getting their message [G], and encouraging and engaging in conversation [E]) [31] was used to support digital storytelling communication. Considering the critical importance of providing caregivers with effective tools to bolster memory and communication abilities in individuals with dementia [32], the implementation of specific communication strategies between people with MCI and the Huiyou application is paramount.

Methods

Ethical Considerations

The Swinburne University of Technology's Human Research and Ethics Committee provided ethics approval for this research (20226525-11105) on September 26, 2022. All workshop participants provided written informed consent to participate and gave permission for their audio recordings and sketches to be used in publications. All methods were performed in accordance with relevant guidelines and regulations. We collected no identifying information from the research participants, such as their names or email addresses. Each participant was assigned a unique ID number to ensure their anonymity. In addition, we provided informed consent forms, including a project information sheet, to uphold their privacy rights.

Research Team

The research team is a collaborative ensemble of specialists in human-computer interaction, user experience, and design, each contributing their distinct expertise to the success of the project. AAM has an extensive background in design research and human-computer interaction, and WL has engaged in and performed research on user experience extensively. DZ is a doctor of philosophy student specializing in design.

Sample

A social work organization named Jingshilaonian, located in Beijing, China, expressed willingness to participate in this research. Situated within the Tiantongyuan community in Beijing, this institution specializes in providing psychosocial support, mental health services, and daily activity assistance to older adults, including those with MCI. Jingshilaonian played a vital role by assisting us with the recruitment and screening of people with MCI by administering the Montreal Cognitive Assessment, as developed by Nasreddine [33]. The inclusion criteria for people with MCI encompassed independent community dwelling, age >65 years, no visual or hearing impairments, and adequate reading ability. The exclusion criteria for people with MCI included significant neurological conditions, such as stroke or brain injury, because of potential confounding effects. Caregivers had no specific inclusion criteria. For therapists, the inclusion criteria were postgraduate qualifications and >3 years of experience in social interventions. To engage participants, we collaborated with the organization's manager to distribute information sheets to people with MCI and their caregivers, inviting them to participate in the study. We co-designed a storytelling intervention with people with MCI (n=12), their caregivers (n=4), and therapists (n=5) in Beijing, China. The brainstorming stage and rough prototyping stage for the intervention were attended by people with MCI and caregivers in a group setting, and the user testing stage was attended by people with MCI and therapists. People with MCI (n=12) were aged 65 to 77 (mean 69.91, SD 4.20) years, and their average Montreal Cognitive Assessment-Chinese version score was 23.58 (SD 1.38). A total of 4 caregivers participated in the workshops. Table 1 summarizes the demographics of people with MCI.

Table 1. Demographics of participants with mild cognitive impairment (n=12).

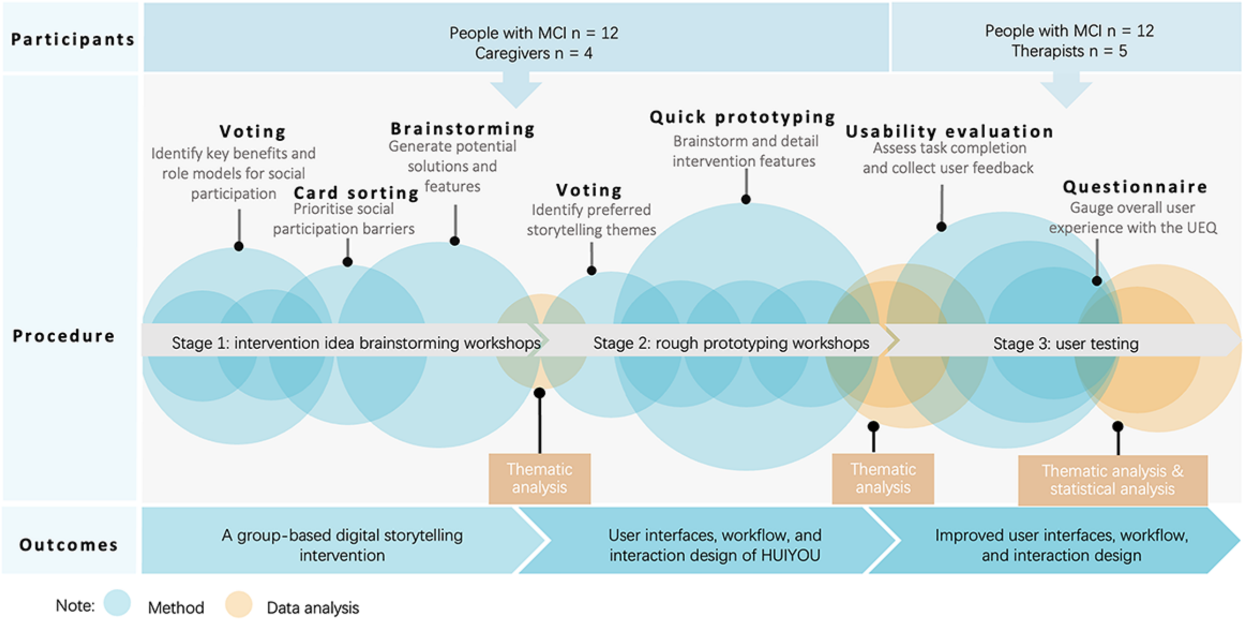
Characteristic	Values
Sex, n (%)	
Male	3 (25)
Female	9 (75)
Age (y), mean (SD)	69.92 (4.20)
Age (y), n (%)	
65-69	5 (42)
70-74	6 (50)
75-79	1 (8)
Educational background, n (%)	
Bachelor’s degree	2 (17)
High school	3 (25)
Junior high school	7 (58)

Procedure

Overview

We adopted the co-design stages proposed by Robinson et al [34], namely scoping (stage 1), participatory design workshops (stage 1), and prototype development (stage 2). After developing the prototype, we conducted a usability evaluation (stage 3; Figure 1). The specific tools and procedures used can be found in the protocol paper [14].

Figure 1. The process of data collection. MCI: mild cognitive impairment; UEQ: User Experience Questionnaire.



Stage 1: Intervention Idea Brainstorming Workshops

In this initial phase, it took 45 minutes to uncover the essential aspects of significant social participation for people with MCI and their caregivers. This stage involved a sequence of 4 workshops designed to identify the most compelling benefits, role models, and barriers related to social participation. By prioritizing these aspects, we sought to deepen our understanding of the significance of social participation for people with MCI and enhance the quality of data for the subsequent phase. During each workshop, people with MCI and caregivers voted on the most compelling benefits and role models, and people with MCI selected 2 abilities that they wished to improve. These insights were critical for informing the design of our digital storytelling intervention.

Stage 2: Prototyping Workshops

Building on the insights gained from stage 1, we focused on collaborative brainstorming sessions involving people with MCI and their caregivers in stage 2. The goal was to explore the design and interaction logic of the interface through 60-minute workshops. Digital storytelling interventions involve recalling past actions, events, and feelings using physical prompts. In addition to building on the insights gained from the literature review of digital storytelling interventions, we identified the main features of digital storytelling applications as story creation, memory retrieval, and story sharing [12]. Furthermore, we found that the themes of stories significantly impacted the storytelling experience [35]. Therefore, the research team proposed 4 primary properties for potential features of the digital storytelling intervention: identification of preferred storytelling themes, support for story material generation, memory retrieval, and story sharing. Participants were encouraged to describe, illustrate, or display sample interfaces on their mobile devices. Figures 2-6 were generated during the prototyping workshops by participants and facilitator DZ. The key objectives were to define the program's main goals; propose relevant features, interactions, workflow, and interface elements; and create rough prototypes to visualize the intervention's interfaces and interactions. The outcomes of this stage provided the foundation for designing the prototype of our digital storytelling application.

Figure 2. A sketch showing browsing and reminiscing topics and details.

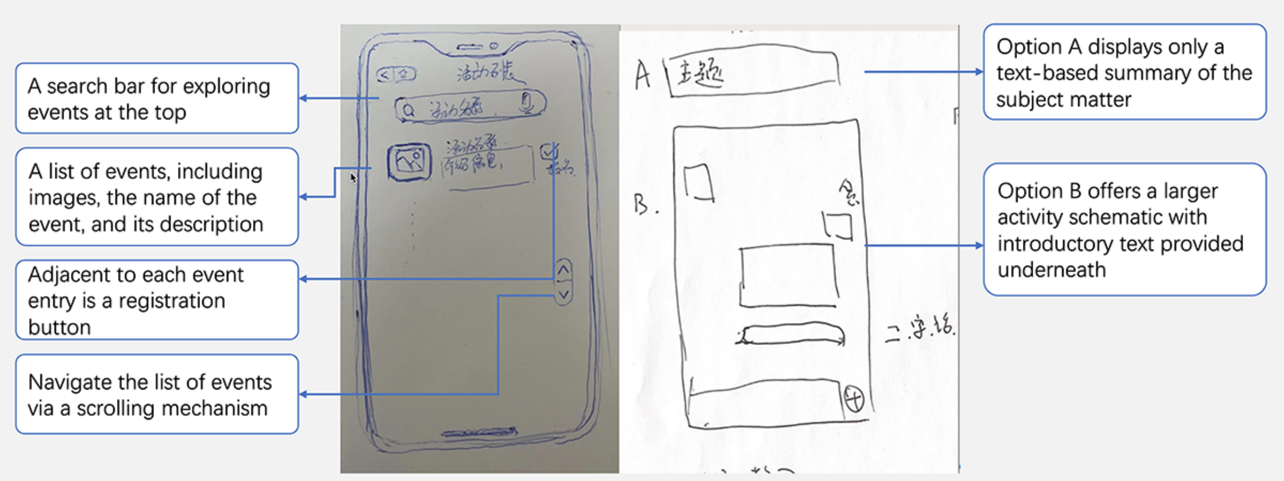


Figure 3. A sketch of (A) material addition entry point indicated by a "+" icon and (B) adding material description of story materials.

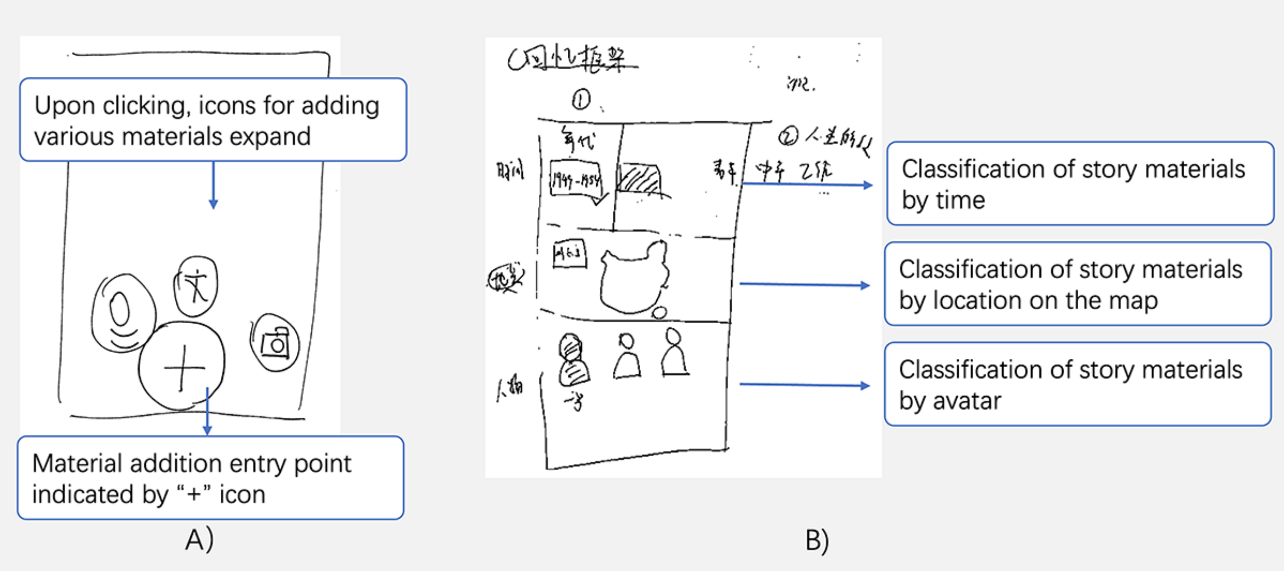

Figure 4. A sketch of changing the sequence of the content.

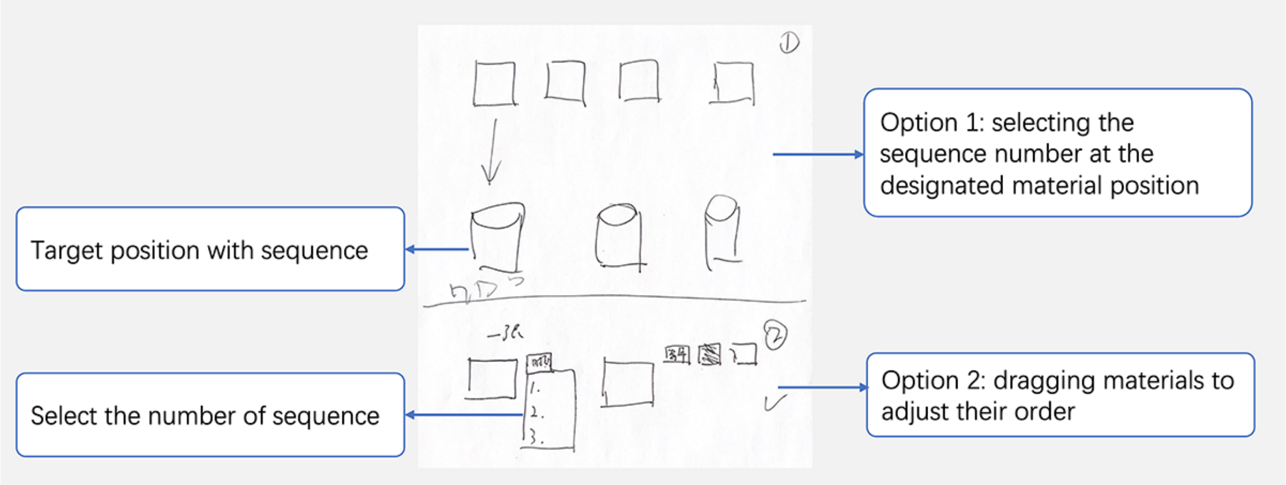

Figure 5. Cheat sheet example.

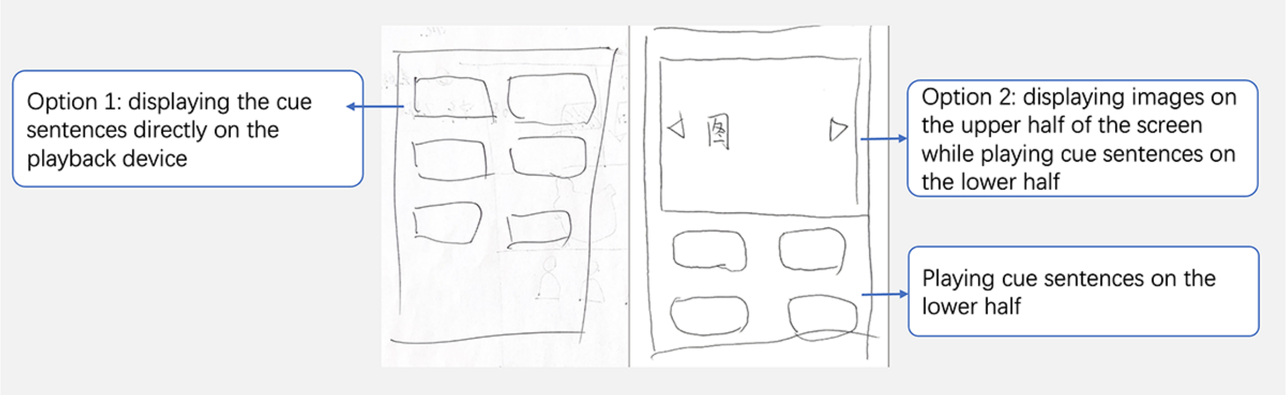

Figure 6. Participants can raise their hand with any question they wished to ask.

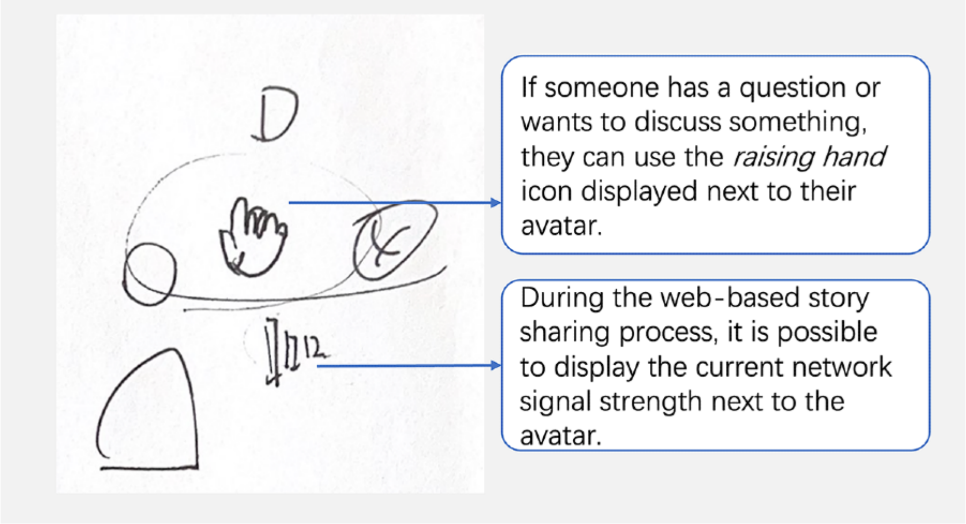


Stage 3: User Testing

We created the Huiyou prototype based on the insights and ideas gathered from stages 1 and 2. To evaluate the application's usability, we identified 22 specific tasks aligned with its features and interaction logic. These tasks were meticulously selected to ensure that the intervention's primary objectives, including enhancing social connection and community participation for people with MCI, could be effectively achieved. Participants, including people with MCI and therapists, engaged in usability testing sessions, where they completed these tasks and provided feedback on their experiences. The usability test session was 45 minutes long. Feedback gathered from these sessions included task success rates, concerns, and preferences. We also collected data on individual task completion rates and task completion with facilitator assistance. In our usability testing, we used a comprehensive approach to evaluate the features and subtasks of the Huiyou intervention. For instance, in testing the story sharing feature, participants were tasked with actions such as entering the speech mode, locating speech prompts, assessing speech length on the page, and identifying the screen projection button. If participants independently interacted with the interfaces successfully, the facilitator recorded it as task completion without assistance. However, if participants encountered difficulties in completing a task even after thoroughly examining the entire interface, the facilitator intervened by offering predefined tips, such as suggesting checking the bottom of the screen. In such cases where participants were able to successfully interact with the interfaces with the facilitator's assistance, the facilitator recorded it as completion with facilitator assistance. Following this, we initiated an iterative design process to refine and enhance the user interfaces (UIs) based on participant feedback, ensuring the application's usability and effectiveness.

Data Collection

Qualitative data were gathered through interviews, sketches, and focus group discussions at different stages of the research via audio recordings. In stage 1, focus group discussions were conducted to analyze the prioritized aspects of social participation. Stage 2 involved brainstorming activities during which participants generated sketches and discussed the potential features of Huiyou. In stage 3, participants' feedback was collected through self-reporting during usability testing and structured interviews. It is important to note that the Chinese version of the User Experience Questionnaire (UEQ) had previously undergone psychological validation [36]. A total of 22 usability tasks were used to evaluate task completion, providing a comprehensive approach to gaining valuable insights into the user experience of Huiyou and effectively assessing its usability.

Data Analysis

Qualitative data analysis followed a thematic analysis approach [37,38]. Two individual researchers reviewed and coded the interview transcripts and organized the codes into themes using NVivo (version 12.0; Lumivero) [39]. Labels, such as "Stage 1-group 2-people with MCI number 2," were used to distinguish different groups and participants.

In the design phase, the research team used the JiShiSheJi design to create the interface. After usability testing, a redesign phase was initiated, involving a detailed analysis of participant feedback and interview responses. These data were systematically summarized to identify improvement areas. An iterative design process was then used to enhance the UIs by incorporating participants' feedback. This approach ensured that the final version of Huiyou aligned better with the needs and preferences of people with MCI.

Quantitative data analysis involved calculating completion rates using Excel (Microsoft Corp) to determine the average completion rate and feature rankings. The UEQ results were assessed using the UEQ Handbook [40], whereas the UEQ Data Analysis Tool Version 12 was used to compute mean values, SD, and CI for various usability dimensions of attractiveness, ease of use, efficiency, dependability, stimulation, and novelty. We also used Excel to calculate the mean values of task completion rates with and without assistance.

Results

The key findings from each stage of this study are summarized as follows.

Stage 1 Findings: Intervention Idea Brainstorming Workshops

Overview

Our exploration unfolded into 3 distinctive themes, each shedding light on a crucial aspect of participants' experiences. We examined how social participation can be a powerful catalyst for enhancing physical health and fostering lifelong learning. Through the inspiring stories of confident older adults who wholeheartedly embraced challenges, our second theme showcased exemplars of unreserved social participation. Finally, we delved into the primary barriers people with MCI aimed to overcome, with a particular focus on memory, language expression, and the mastery of essential smartphone skills.

Enhancing Physical Health and Lifelong Learning Through Social Participation

Most participants with MCI (8/12, 67%) regarded social participation as an approach to maintaining physical health. They found that attending social activities can enhance their health status because they are less prone to catching colds when actively participating in social activities. People with MCI pay more attention to physical health; therefore, the benefits of physical health may attract people with MCI to participate in social activities.

Most participants with MCI (8/12, 67%) reported that engaging in activities with older adults positively impacted their physical well-being; these activities, such as exercise programs or outdoor group activities, helped improve their physical condition, increased their mobility, and supported their overall health. In addition, the social interaction involved in these activities afforded them a support system, along with accountability and the motivation to stay active and adopt a healthy lifestyle. In agreement with this, participants stated the following:

> *Engaging with others and staying socially active can help improve my physical health. It encourages me to stay active, spend time with people, and motivates me to maintain a healthy lifestyle.* [Stage 1, G2-P3]

Few participants with MCI (3/12, 25%) emphasized the value of lifelong learning and intellectual stimulation; participating in social activities provided these participants with a platform for communication, exploration, and the imparting of knowledge. By engaging in collaborative social activities and exchanging ideas with others, they were encouraged to continuously learn and discover new things. One of the participants commented the following:

> *Engaging in social activities can improve my mental health by allowing me to interact with others, receive emotional support, reduce feelings of loneliness, and*

> *enhance positive emotional experiences.* [Stage 1, G1-P2]

People With MCI Admire Peers Who Face Challenges Confidently

Most participants with MCI (9/12, 75%) admired older adults who displayed the confidence to attend various activities. Interacting with confident older adults allowed these participants to gain a new perspective on aging and life experiences; they were inspired to embrace challenges, overcome impediments, and approach life with a positive mindset:

> *They give me strength and inspiration, demonstrating passion and a positive attitude in caring for others, making me believe that I can still have a fulfilling and meaningful life even in challenging circumstances.* [Stage 1, G3-P3]

People With MCI Want to Improve Their Memory and Language Deficit and Smartphone Skills

Table 2 indicates that most people with MCI wish to improve their memory and expression of language, as participants mentioned that memory affects them frequently and that language expression can affect communication with their grandchildren. Of the 12 participants with MCI, 7 (58%) prioritized the improvement of memory, as this affected them the most:

> *I have poor memory; as I spoke, I forgot where I was talking. Therefore, I want to improve it first.* [Stage 1, G2-P2]

Table 2. The top 3 barriers identified (N=24).

Barriers to overcome	Votes[a], n (%)
Memory ability	7 (29)
Language expression	5 (21)
Smartphone use	4 (17)

[a] Each person with mild cognitive impairment had 2 votes; in total, there were 24 votes from the 12 participants.

Of the 12 participants with MCI, 5 (42%) mentioned that their storytelling ability also affected communication, mainly when talking with their grandchildren:

> *My education level is limited, and I hope I can improve my language skills so that I can tell my granddaughter vivid stories.* [Stage 1, G3-P1]

Among the 12 participants with MCI, 4 (33%) felt that using a smartphone was difficult, and some (3/12, 25%) people with MCI believed that the requirement for the ability to navigate a smartphone might prevent them from further social participation:

> *As I get older, I cannot use many functions of my phone. I always have to consult others, but it is more convenient to learn them myself.* [Stage 1, G2-P3]

All the participants with MCI (12/12, 100%) selected smartphones as the suitable device on which to install the application because they all had access to a smartphone, with only a few participants reporting that they owned an iPad (Apple Inc); smartphone was viewed as the more favorable option, being more portable than tablets or computers:

> *I have a smartphone; if the application could be installed on my phone, it would be more convenient since I carry the phone all the time.* [Stage 1, G2-P2]

In summary, the benefits of social participation for people with MCI included the improvement of physical health through engagement in activities, the fostering of a support network, and increased confidence among older adults. Memory and language expression were the primary barriers they wished to improve and were crucial for their communication with their grandchildren. Furthermore, their smartphone skills required enhancement to facilitate continued social participation.

Stage 2 Findings: Prototyping Workshops

Overview

Following the analysis of the findings from stage 1, the research team believed that the creation of a group-based digital storytelling intervention would be beneficial for improving memory, language expression, and smartphone use skills, and eventually, it could enhance social connection and participation. We have outlined the findings regarding the 4 primary features of the digital storytelling application as follows.

Preferred Storytelling Themes for Sharing With Others

All the participants with MCI (12/12, 100%) stated that they would like to share recent activities, including hobbies (as well as the changes they perceived around them), social activities, and current politics. Hobbies were most commonly cited because the participants were eager to share them with others and had invested much time and effort in them. The participants with MCI reported the following:

> *I enjoy content related to technology, as well as driving. I like observing different cars; whenever a related topic arises, I cannot stop talking about it.* [Stage 2, G2-P2]

Moreover, participants suggested receiving memory retrieval themes to ensure a well-defined topic to reminisce and allow them to gather relevant materials beforehand, expediting the process for smoother implementation.

Design of the Story Material Generation

After defining the storytelling themes, users could generate story materials by obtaining topics for memory retrieval, collecting materials, adding material descriptions, and integrating materials for further story sharing. The facilitator encouraged participants with MCI to create sketches; however, only 4 (33%) of the 12 participants with MCI were inclined to do so (Figures 5 and 6). Consequently, the facilitator assisted those who were unwilling to draw in visualizing their ideas.

Figure 2 presents a sketch for browsing a topic for memory retrieval; on the left side of the page, there are a search bar for exploring events at the top and a list of events, including images, the name of the event, and its description at the bottom. The user navigates the list of events via a scrolling mechanism. Adjacent to each event entry is a registration button. The page on the right offers 2 options for displaying the activity. Option A displays only a text-based summary of the subject matter. By contrast, option B displayed a more significant activity schematic with introductory text provided underneath:

> *For example, for my son's wedding, just get a few photos, just two or three.* [Stage 2, G2-P3]

The material collection feature enhances content by providing explanatory details and enriches the collection by sourcing pictures from various internet platforms. Recording snippets of information further aids by capturing valuable insights. In addition to collecting the target content, participants also suggested recording fragmented information informally. Figure 3 presents a sketch of an entry point for the supplementary material at the bottom of the page, indicated by a plus icon, which reveals 3 input methods when clicked. The input methods include voice input, text input, and video input:

> *The function of voice recognition is very convenient. With just a press of a button, recording starts, and in the end, it can be converted into text for preservation, making it easy to view later.* [Stage 2, G1-P2]

The adding material description feature aims to optimize the collection of data by associating individuals with each story (Figure 3); for instance, the developmental stages of the country, timeline, and the type of activities connecting people with MCI with the country's developmental stages and arranging them chronologically and by different activities for easy navigation. Participants recommended the provision of a framework of memories to aid them in refining the story; for example, participants could select the time stage, such as the founding of the People's Republic of China in 1949, and the stage of their life at the selected time, such as youth, middle-age, working, or retired. The choice of location is provided using a map. Finally, participants can apply labels for characters, including their avatars and names. One of the participants explained this as follows:

> *We can label the key characters that appear inside.* [Stage 2, G3-P2]
>
> *I like to categorize these [materials] by age and objectively exist since I am willing to use classification methods that are specific, not easily confused, preferably objectively present, and not prone to misunderstanding.* [Stage 2, G3-P3]

The integrating material feature aims to create a cohesive memory retrieval experience by uploading selected materials to the topic in question and adjusting sequences to promote a seamless and engaging narrative flow (Figure 4). The participants provided 2 options: option 1 displayed the candidate photos in the first row, and below, each theme was listed, with the corresponding material dragged and dropped into the theme; and option 2 allowed users to select the order of presentation after choosing the related theme. One of the participants with MCI commented the following:

> *After uploading these photos, we need to associate them with the story to be told based on different story themes. Before sharing, we could easily change the sequence of the materials.* [Stage 2, G2-P1]

Memory Retrieval Activity Design Through Facilitation Strategies

The digital storytelling application uses various strategies to enhance the experience in the memory retrieval function. It has 3 features: a story presentation, group discussion, and story summary.

During story presentation, the digital storytelling application has cheat sheets for recall, minimizing interruptions by using timers, promoting interactive discussions, and creating permanent records. Mobile technology facilitates the easy capture of memories, forming meaningful connections with cherished life events. Preparing a cheat sheet with helpful tips can provide valuable guidance to ensure a smooth and engaging memory retrieval experience (as shown in Figure 5). The cheat sheet might present either keyword prompts or corresponding content. A cue word switches to the content of the corresponding material, depending on the selected content format:

> *Sometimes [my] memory is poor, and this software can provide a cheat sheet to prevent me from forgetting what I need to share at the moment.* [Stage 2, G1-P2]

During the session, avoiding interruptions allowed participants to immerse themselves fully in their nostalgic journey, and a visual timer helped them manage their time effectively:

> *You can only limit the time. One is that most of the time, how many people cannot all stand on the same question, or you cannot all stand on your own time for a few minutes.* [Stage 2, G4-P2]

During a group discussion, the approach integrates memory retrieval with open discussion groups. Encouraging participants to pose questions by raising their hands fosters an interactive and dynamic environment (Figure 6). During the presentation, each participant has an avatar, and the Wi-Fi signal strength is displayed next to the avatar. If the participant has a question they wish to ask, they may raise their hand, and a small, raised hand icon is displayed next to their profile. These discussions can be informal, fostering a sense of engagement in shared experiences and collective memories:

> *Ask each other questions. This form is quite good. Ask each other because it is to discuss different opinions on a subject, and this is the best way. Yes, if there are no different opinions, this question may be a little biased.* [Stage 2, G3-P3]
>
> *I want to ask questions. If you want to ask questions that I am interested in, I can also raise my hand and answer them.* [Stage 2, G1-C1]

The story summary feature aims to make memory retrieval more tangible; facilitators can generate records or memories from the discussions, providing a lasting and meaningful resource for participants to cherish and revisit:

> *Currently, mobile phones are very convenient. When I take a group photo and see everyone's photos, I can recall what happened at that time. I also like to keep a diary and can simply remember one or two sentences.* [Stage 2, G4-C1]

Story Sharing to a Broader Audience

To share the records of their recollections with the desired person or group, participants suggested using WeChat (Tencent Holdings Limited), which allows for the convenient and efficient sharing of memories, ensuring that the memory retrieval experience can be cherished and enjoyed by those involved. Most participants with MCI (8/12, 67%) wished to share this experience with certain persons or groups, primarily through WeChat:

> *Based on different themes, [we can] send today's activities to corresponding people, such as those with common interests or children. Share with them through WeChat and let them know the latest situation as well.* [Stage 2, G2-P3]

However, one of the people with MCI showed no interest in sharing the content with others:

> *At this age, I'm not willing to share with more people; at least subjectively, I have no intention to please anyone.* [Stage 2, G1-P2]

In summary, Table 3 outlines the key functionalities and features of the memory log system, along with valuable suggestions for their implementation. To generate materials, the inclusion of memory topics aids in focused preparation. Collecting materials might include adding explanations to materials, collecting pictures from the internet, and the informal recording of fragments of discussions. While adding material description, users could add details such as time, location, and key characters to the material. Users could integrate materials into each presentation by changing the sequence of materials. During memory retrieval, facilitators can benefit from cheat sheets, minimize interruptions, and use visual timers in presentations. Open discussions, hand raising, and interactive dialogues further enrich the experience. Summarizing these records enhanced memory retention. Sharing options, such as WeChat, extend the impact beyond the scope of the audience.

Table 3. The main features of Huiyou identified from stage 2 (ie, prototyping workshops).

Functionalities and features	Suggestions to implement
Generating story materials	
Obtain a topic for memory retrieval	• Inform the topic and collect relevant materials in advance
Collect materials	• Add a description to each record • Collect pictures from others via the internet • Casually record fragmented information
Add material description	• Add essential character to each material • Link to the sequential steps of the country's development • Follow the timeline to show the content • Categorize by different activities
Integrate materials	• Upload selected materials to the target topic • Change the sequence of the materials
Memory retrieval activity	
Story presentation	• Prepare a cheat sheet to obtain tips • Avoid interruptions during the presentation • Set visual timer
Group discussion	• Combine memories and discuss • Raise hands to ask questions • Open discussion
Story summary	• Generate a record or memory
Sharing story	
Share storytelling records with certain a person or group	• Share the record via WeChat (Tencent Holdings Limited)

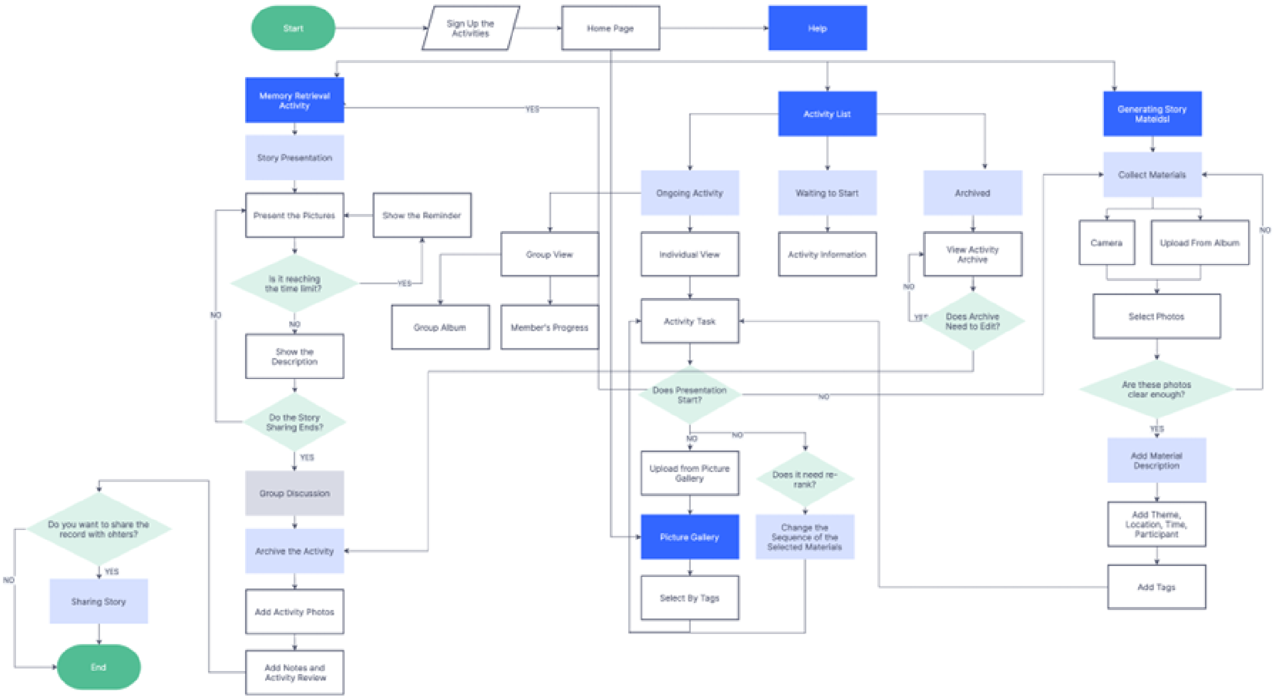
Developing the First Prototype of Huiyou

The first digital prototype of Huiyou (Figure 7) was produced in JiShiSheJi [41], a web-based free software prototype design and development tool, following an iterative process of co-design workshops and feedback collected from the meetings. The software name 会友, Huiyou, derived from the Pinyin pronunciation, means "meeting new friends" in Chinese. It is inspired by a classic quote from Confucius in the Analects: “A gentleman seeks friendship through literature and reinforces goodness through friendship.” This statement emphasizes the idea that individuals cultivate friendships through literary exchange and support virtue through companionship. The name reflects a positive vision of fostering social connections through literature, friendship, and benevolence. Users can leverage technological means through the software to expand their social circles, facilitating deeper communication and connections with others. The name embodies the social nature of the software and its goal of promoting friendship. Huiyou effectively stores memories from daily life and encourages people with MCI to reminisce and discuss favorable memories with new friends. Huiyou has 2 main features: supporting people with MCI to conduct self-reflection daily (preparing materials with cues) on certain topics and facilitating group memory retrieval (presenting a story and promoting a discussion with group members). Two innovative aspects of Huiyou are embedded memory retrieval for capturing daily life and its ability to collect recent, valuable memories. Another such feature is combined self-reflection and group reflection to enhance social interaction during the discussion, in addition to sharing and participating in social activities outside the home.

Figure 7. Huiyou prototype: home page.

As Figure 8 illustrates, the process of registering an activity on the Huiyou application begins with the user navigating from the home page to the activity page, where they can browse and select the activity they wish to register for; they then upload the material and edit it on the active page. When an event is about to commence, the user enters the event details page from the home screen. Next, they enter the activity and encounter a start screen for analyzing memories. The activity may be recorded and shared with others. If the user has any issues with the software, they can click the help button to discover operation guidelines.

Figure 8. Workflow of Huiyou. A higher resolution version of this figure can be found in Multimedia Appendix 1.



Stage 3 Findings: User Testing

Results From Task Analysis

Through this comprehensive usability testing stage, we identified minor areas of improvements in the interaction logic and interface layout to optimize user experience. In the 22 tasks, the participants scored an average success rate of 59% without assistance and 87% with assistance from the facilitator. Most challenges were identified to be associated with the direction of interaction; after knowing the direction, the success rate increased. Table 4 lists 5 tasks within the Huiyou digital storytelling application that demonstrated notably high usability, with completion rates exceeding 90% when performed individually. These tasks included “upload pictures” and “recording new materials,” both of which achieved perfect task completion rates of 100% with facilitator assistance. In addition, tasks such as “entering speech mode,” “find speech prompts,” and “insert a group photo after the event” also exhibited exceptional usability, with 92% individual task completion rates and 100% task completion rates with facilitator assistance.

This effectively communicates that within the Huiyou digital storytelling application, 5 tasks have a completion rate ≤75%, indicating the need for improvement. Tasks such as “add material description,” “browse registration activities,” and “switch the view of the activities” exhibited relatively lower individual task completion rates of 8%, whereas the presence of a facilitator notably enhanced completion rates to 58%. Similarly, the “judge whether the speech is too long on the page” and “enter the activity interface” tasks had initial completion rates of 25%, which significantly improved to 75% with facilitator assistance. These findings emphasize areas where the application’s UI and task guidance may benefit from refinement to ensure a more user-friendly and accessible experience, particularly for people with MCI.

Table 4. Task descriptions and completion rates of people with mild cognitive impairment (n=12).

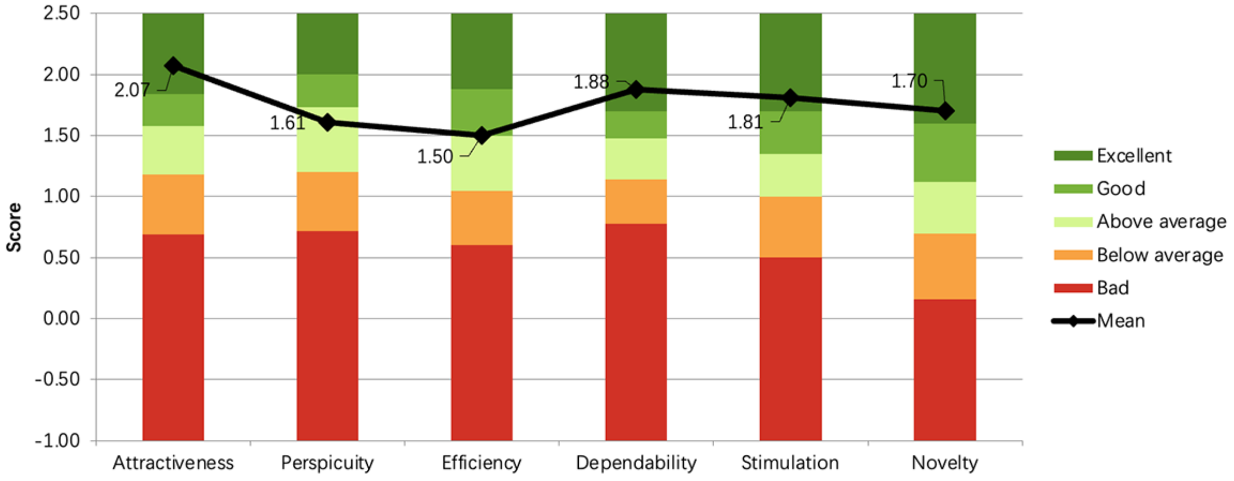
Features and task	Task completion without assistance, n (%)	Task completion with facilitator assistance, n (%)
Generating story materials		
Upload pictures	11 (92)	12 (100)
New materials for text input	6 (50)	10 (83)
New materials for voice input	7 (58)	10 (83)
Record new materials	12 (100)	12 (100)
Add material description	1 (8)	7 (58)
Add material tags	9 (75)	11 (92)
Edit material permissions	5 (42)	11 (92)
Enter my material	9 (75)	11 (92)
Change the sequence of materials	7 (58)	12 (100)
Browse registration activities	3 (25)	9 (75)
Enter the activity interface	6 (50)	9 (75)
Switch the view of the activities	1 (8)	7 (58)
Sign up for activities and add groups	5 (42)	9 (75)
View task progress	6 (50)	12 (100)
Enter task	10 (83)	11 (92)
Memory retrieval activity		
Enter speech mode	11 (92)	12 (100)
Find speech prompts	12 (100)	12 (100)
Judge whether the speech is too long on the page	3 (25)	9 (75)
Find the screen projection button	9 (75)	12 (100)
Sharing story		
Insert a group photo after the event	11 (92)	12 (100)
Use help features	4 (33)	10 (83)

Results From the UEQ

When comparing the ratings to the UEQ benchmark [36], it was noted that the application falls within the average and above range, suggesting that there is room for improvement. The combined ratings for all users, including both people with MCI and therapists organized by the value of each UEQ item can be seen in Figure 9, wherein the average score pertaining to attractiveness is 2.073 (SD 0.82), ease of use is 1.609 (SD 1.15), efficiency is 1.5 (SD 0.85), dependability is 1.875 (SD 0.76), stimulation is 1.813 (SD 0.96), and novelty is 1.703 (SD 1.33).

In the results obtained from the UEQ (7-point positive and negative scale; Figure 9), participants with MCI expressed favorable opinions about Huiyou, perceiving it as an enjoyable (mean 2.7, SD 0.6), supportive (mean 2.3, SD 0.7), clear (mean 2.5, SD 0.7), and friendly (mean 2.3, SD 0.8) application. However, they found learning challenging (mean 1.5, SD 1.9) and somewhat complex (mean 0.9, SD 2.1).

Figure 9. User Experience Questionnaire benchmark diagram for the Huiyou application.



Results From Usability Testing

On the basis of the interviews conducted and feedback collected during usability testing, we identified 15 usability issues to improve (Table 5). These issues were linked to the features of the application, including the home page and navigation, sign-up activities, adding material descriptions, changing the sequence of selected materials, sharing stories, uploading material, UI and design, and picture gallery. The main change was made to the home page (resolving the first usability issue in Table 5), addressing the user feedback that there was a lot of information on the home page and that the activity entrance was not clear, making it difficult to locate it quickly. One of the participants with MCI mentioned the following:

> *I'm not sure how to find the activities I want to participate in. The location of the activities should be more prominent. Those generated memories don't necessarily have to be on the first page.* [Stage 3, P3]

Therefore, notable enhancements included moving activity records to a separate tab, thereby streamlining the navigation and organization processes. In addition, more activity entries were added to the home page, providing users with a broader range of options. We followed all recommendations to redesign the Huiyou application.

Table 5. Usability issues and recommendations.

Features and issues	Recommendations
Home page and navigation	
There is a lot of information on the home page, and the activity entrance is not clear	• Show the activities list. Each activity may have a different status: ongoing activity (in a dark green rounded rectangle) and waiting to start (in a gray rounded rectangle) • Move the entrance of the "casually record fragmented information" feature from being suspended in the lower right corner to being fixed in the lower center
Category activity is hard to find	• Move activity records to a separate tab • Add more entries on the home page
Sign-up activities	
Activity registration setup issues	• Display activity registration first, followed by recent activities
Adding material description	
Unable to understand the edit permissions	• Change the heading to "invite others to edit"
Unable to find materials and view photos that have already been uploaded	• Integrate the image library and add tags • Allow easy switching and searching for images
Unable to understand content edit functions	• Change to content description, integrating the description on 1 page, including time, location, characters, events, and others • User should be able to add pictures' tags from material, including family, friend, sightseeing, group photo, and item
Changing the sequence of selected materials	
Unable to sort materials	• Provide operating instructions and make the font color of the instructions more eye-catching • Provide support for 2 sorting methods: drag and click
Sharing story	
The "share the screen" button is too small	• Make the screen projection button larger and highlight the color more prominently
Face-to-face discussions require no "raise hand" button	• Remove the "raise hand" button for inquiries in face-to-face discussions
Uploading material	
No need to find internet resources	• Delete the option of "upload material through internet"
User interface and design and picture gallery	
Need colorful and simple icons	• Update icons to be colorful, eye-catching, and more solid
The return icon is not prominent	• Increase the size of the return icon • Change the dark background of the "help" icon to a lighter background
Keyboard input and voice input	• Default voice input
The picture gallery contains too much information	• Reduce the number of images displayed in galleries and preset some images in advance

Discussion

Principal Findings

This study outlines the process and outcomes of co-designing and prototyping Huiyou, a digital storytelling application intended to facilitate social engagement and enhance the cognitive well-being of people with MCI in community-based settings. Insights collected from usability testing shed light on both strengths and areas for improvement in terms of user-friendliness and accessibility within the application's design and functionality. Furthermore, some functions have been simplified, including the path for uploading material without internet resources. People with MCI may take 15 minutes to collect the materials they want to present and 10 minutes to present their stories. Each story is original, proposed by people with MCI, and they may ask for the support of volunteers or caregivers. The storytelling process has 2 phases: preparation of materials and memory retrieval. Emphasizing the recollection of recent memories was found to encourage social engagement and foster a sense of belonging. Huiyou, the storytelling application used in this study, facilitated material generation by providing preset content prompts and allowing independent material collection, setting it apart from other interventions. During the memory retrieval activity, participants used personalized cues and multimedia elements, triggering meaningful conversations and connections. This study's findings suggested that storytelling themes for people with MCI should revolve around recent positive experiences and significant life periods. Notably, the application scored highly in attractiveness, dependability, stimulation, and novelty, although it required ease of use and efficiency enhancements. Recommendations for interface design included emphasizing crucial elements, minimizing cognitive complexity, and streamlining information presentation for improved user accessibility and experience.

Comparison With Prior Work

This research highlights the importance of selecting storytelling themes that evoke recent positive experiences for people with MCI in China. The emphasis on significant life stages and changes, excluding marital experiences, is supported by existing literature [37]. Surprisingly, the study observed a keen interest among older male adults in political subjects, deviating from expectations based on previous research on political engagement among older Chinese adults [42]. It is proposed that prioritizing recent positive memories through Huiyou can encourage social engagement, fostering a sense of belonging and participation among people with MCI. Huiyou facilitates the storytelling process for people with MCI through self-collected materials rather than preset content prompts [43,44], engaging them to share their stories. According to the Capability, Opportunity, and Motivation–Behavior (COM-B) system, Huiyou aims to enhance psychological capability, create social opportunities, organize social activities regularly, and reinforce reflective and automatic motivations. In addition, the following TDF components were embedded in the prototype: skills, social role and identity, beliefs about capabilities, goals, memory, attention and decision processes, and social influences. For example, Huiyou incorporates behavior change strategies in the TDF that involve social influence [45], such as group discussions that monitor group progress. As the therapists said, these design features can foster peer pressure, enhancing adherence to task completion and effectively facilitating the establishment of social connections. During group discussions, Huiyou implements the MESSAGE communication strategy to involve people with MCI actively. For instance, it allows users to add notes to materials, which are then displayed on the screen during memory retrieval. Unlike other interventions, Huiyou enables users to collect and arrange materials themselves, enhancing their sense of accomplishment and reducing the need for external support. The application's approach of facilitating material generation and arranging sequences aims to stimulate positive memories and encourage active engagement during the memory retrieval process. Therefore, Huiyou supports people with MCI in arranging the display sequences of materials, as OurStory does [23]. In memory retrieval activities, a substantial number of stimuli are prepared in advance and presented randomly to prompt older adults to narrate stories [46]. However, this approach relies on the divergent thinking abilities of older adults. Unfortunately, this method does not support the possibility of multiple stimuli coming together to form a more complete story. Unlike older adults with dementia, people with MCI possess the autonomy to select cues for their storytelling, fostering interpersonal connections and evoking positive emotions [47]. Personal topics serve as effective memory tests, enhancing storytelling and social memory [48]. Huiyou uses visual cues, music, and various technological platforms to stimulate memory retrieval and trigger discussions among older adults. By encouraging the recall of recent positive memories and promoting group discussions [49], Huiyou enhances the confidence of people with MCI, empowering them to actively participate in social interactions and community activities. Group discussions not only provide opportunities for self-expression but also foster reflection and inspiration from shared social experiences. Sharing recent memories via Huiyou fosters dialogue and active social engagement among individuals with MCI. They can either share their stories during group reminiscing sessions or record and distribute their memories to family and friends. Unlike some interventions that lack a structured approach to memory retrieval [50], Huiyou allows for the systematic recording and sharing of stories [51], primarily using WeChat as the chosen platform for its broad reach among friends and family.

Usability Issues of Huiyou

On the basis of the UEQ benchmark results diagram, Huiyou earned a place in the "excellent" category [36]. These insights serve as invaluable pointers for refining the user experience of the application. People with MCI typically adhere to a top-to-bottom, left-to-right reading pattern [52], emphasizing the importance of placing essential interactive elements at the center or the top of the screen. Furthermore, adopting a more noticeable design approach, such as incorporating colored buttons, may be beneficial. The cognitive complexity experienced by people is influenced by the quantity of content displayed on a single screen. Even subtle variations in interface design demand additional information processing time for people with MCI. To mitigate cognitive strain, it is advisable to minimize the amount of information displayed on each screen and segment tasks into more manageable steps.

Limitations

One limitation was the small number of participants with MCI throughout the study. To mitigate the impact of a small sample size, the research team invited the same participants to engage in multiple stages of the study, gathering diverse research data, including interview outcomes, hand-drawn interfaces, and usability task data, and introduced the perspective of caregivers of people with MCI. Reusing the participants was an efficient approach to prototype development and, to some extent, mitigated the impact on people with MCI as well as clinician time. Another limitation was that the Huiyou prototype was redesigned based on the participants' feedback; however, in this study, we did not evaluate the refined prototype. In the future, field testing with people with MCI will be used to measure the effectiveness of the tool in improving social participation.

Conclusions

We described the co-design processes of developing a digital storytelling intervention, Huiyou, in collaboration with people with MCI and caregivers. We then evaluated the user experience of the application based on the feedback of people with MCI, caregivers, and therapists. Huiyou incorporates story-sharing themes that align with the needs of people with MCI in China. These themes foster common topics and evoke positive emotions without delving into excessive privacy. Unlike traditional reminiscence therapy, it is confined to memory enhancement during intervention sessions, neglecting other potential intervention times. Huiyou transforms reminiscence into an everyday activity that individuals can engage in at their own convenience. This provides more opportunities to collect and cherish fond memories. Huiyou excelled in usability testing, earning an “excellent” rating in the UEQ benchmark for attractiveness, reliability, stimulation, and novelty. However, there is room for improvement in accessibility and efficiency. By combining social participation with the fostering of relationships and the stimulus to contact friends, the application not only promotes individual well-being but also meaningful social interactions and maintains vital relationships for people with MCI.

Acknowledgments

The authors would like to thank all the staff, people with MCI, and caregivers who were involved in this project.

Authors' Contributions

AAM and DZ conceptualized this study. DZ collected and analyzed the data. AAM directed several rounds of feedback and contributed significantly to the manuscript’s writing and revision. AAM and WL supervised the project. All the authors examined and approved the final manuscript.

Conflicts of Interest

Abstract

Background: Telehealth provides opportunities for older adults to access health care. However, limited research exists on the use of telehealth within aged care services, particularly regarding physiotherapy-led fall prevention and mobility programs. Understanding the experiences and interactions of older adults, physiotherapists, and aged care service providers is crucial for the scale-up and sustainability of such essential programs. The TOP UP study, a hybrid type 1 effectiveness-implementation randomized controlled trial in aged care, used a supported multidisciplinary telephysiotherapy model to motivate older adults to engage in exercises to improve mobility and reduce falls.

Objective: This qualitative substudy aims to achieve 2 primary objectives: to describe the experiences and acceptability of the TOP UP intervention for older people, physiotherapists, and aged care support workers and managers and to gain an in-depth understanding of program implementation.

Methods: A purposive recruitment strategy was used to select 18 older adults who participated in the TOP UP intervention, ensuring variation in age, gender, residential status (home or residential aged care), geographic location, and cognitive levels. In addition, 7 physiotherapists, 8 aged care support workers, and 6 managers from 7 different aged care provider partners participated in this study. Semistructured interviews were conducted to explore stakeholders’ experiences with the TOP UP program, gather suggestions for improvement, and obtain insights for the future implementation of similar telephysiotherapy programs. The interview framework and coding processes were informed by behavior changes and implementation frameworks. Data were analyzed using an abductive approach, informed by 2 behavioral change theories (Capability, Opportunity, Motivation, and Behavior Model and Self-Determination Theory) and the Nonadoption, Abandonment and Challenges to the Scale-Up, Spread and Sustainability of Health and Care Technologies framework.

Results: All participants (n=39) reported high levels of acceptability for the TOP UP program and cited multiple perceived benefits. The thematic analysis generated 6 main themes: telephysiotherapy expands opportunity; tailored physiotherapy care with local support enhances motivation; engaging, older adult–friendly educational resources build capability; flexible reablement approach fosters autonomy; telephysiotherapy is safe, effective, and acceptable for many; and organizational commitment is required to embed telehealth. The motivation to exercise was enhanced by Zoom’s convenience, use of tailored web-based exercise resources, and companionable local support.

Conclusions: This study highlights the inherent value of telephysiotherapy in aged care, emphasizing the need for investment in staff training, local support, and older adult–friendly resources in future telephysiotherapy iterations. TOP UP represents a convenient and flexible web-based care model that empowers many older adults to receive sustainable, high-quality care precisely when and where they need it.

Introduction

Background

The proportion of older people in the population is increasing worldwide. From 2020 to 2050, the number of older people aged ≥60 years will double to 2.1 billion, representing 22% of the world's population [1]. By 2050, the number of people aged ≥80 years is expected to triple to 426 million [1]. Older people experience poor mobility and higher rates of falls than younger people, leading to significant morbidity, mortality, and poor quality of life [2-4]. Poor mobility and falls are 2 of the biggest cost drivers in hospital and aged care services [2,5]. In 2021, a total of 10.7% of people aged ≥65 years living in the Organization for Economic Co-operation and Development countries received long-term care, either at home or in care facilities, costing these governments 1.5% of the gross domestic product [6,7]. Aged care spending has increased over the last 15 years in most Organization for Economic Co-operation and Development countries, and population aging will continue to increase the demand on stretched health care systems [7].

Strong evidence supports the effectiveness and cost-effectiveness of physiotherapy-led exercise programs for enhancing mobility and reducing falls in aged care settings [8]. However, the Australian Royal Commission into Aged Care highlighted significant barriers to accessing mobility-promoting and fall prevention interventions delivered by allied health professionals, such as physiotherapists [9]. Qualitative evidence suggests that (referred and defined in this manuscript as telephysiotherapy) could be a feasible, acceptable, and effective approach for delivering mobility and fall prevention programs to older adults living in the community [10]. Telephysiotherapy could be particularly advantageous in increasing access and convenience for people with travel constraints and mobility limitations or who live in regional and remote areas [11].

Telerehabilitation that has provided telephysiotherapy has been found to have similar effectiveness compared with in-person rehabilitation services for community-dwelling older people, and it shows no increased risk of adverse events [12]. However, there is no evidence supporting the effectiveness, cost-effectiveness, and implementation feasibility of telephysiotherapy for improving mobility, reducing falls, and enhancing the quality of life for older adults receiving aged care services in their homes or residential aged care.

Telehealth is currently being used in aged care, but there is limited guidance on how best to implement it [13]. Hybrid effectiveness and implementation research has been shown to accelerate research translation into clinical practice [14]. Implementation research explores the experience of a complex intervention such as telehealth and its relationship to other factors, such as intervention engagement and adherence, perceived effectiveness, acceptability, and self-efficacy, which can support implementation translation [15].

The TOP UP Trial

TOP UP is designed to provide a scalable solution for delivering physiotherapy exercise interventions via telehealth to improve mobility, reduce falls, and enhance the quality of life in aged care. The TOP UP program was developed in collaboration with our aged care partners, physiotherapists, and aged care service users and their caregivers. A series of workshops identified potential facilitators to improve older people's engagement with technology and motivation to exercise. The program's co-design was also influenced by behavior change models, such as Self-Determination Theory (SDT) [16] and the capability, opportunity, motivation, and behavior (COM-B) framework [17].

TOP UP is investigating synchronous and asynchronous care to optimize both personalized health care and self-directed exercise [18] in aged care settings. It involves the delivery of real-time physiotherapy assessments through videoconferencing (synchronous telehealth) using the Zoom app (Zoom Video Communications Inc) by older adults receiving aged care services at home or in residential care. These service users are given access to evidence-based exercise videos on the TOP UP website and the StandingTall app (asynchronous telehealth) to support their exercise program. Each participant has the weekly support of a trained aged care worker to help them access the Zoom app and follow the exercise program. The outcomes being measured include effectiveness (mobility, falls, and quality of life), cost-effectiveness, and implementation measures (acceptability, reach, fidelity, dose delivered, and adoption).

The program is being tested in a hybrid type 1 effectiveness-implementation randomized controlled trial. Older adults were screened by their aged care service providers. Eligibility criteria included the age of older people (≥65 years); possessing sufficient physical, sensory, cognitive, and English language skills to participate; and having individual consent or consent from the person responsible. Those with terminal or unstable illness, with severe dementia, having participated in a similar physiotherapy program in the previous year, or being unable to walk 10 m were excluded from the study. A total of 242 participants were recruited from a screening pool of 1348 aged care service users (older people).

A total of 242 participants (120 per group) will provide 80% power to detect a 0.9 point between-group difference in 12-point

Short Physical Performance Battery test scores at 6 months (assuming SD 2.8, *P*=.05, and 20% dropouts) [19]. A 0.5-point between-group difference in the Short Physical Performance Battery test was considered clinically significant. This sample size was expected to be sufficient to detect between-group differences of 10% to 15% for the secondary outcome measures. Quantitative data analysis is expected to be completed in 2024.

Participants randomized to the intervention group received 10 videoconference physiotherapy sessions over 6 months using the Zoom app and received an individualized balance and strength exercise program. These exercise programs are based on the World Health Organization 2020 guidelines on physical activity and sedentary behavior [20] and the Otago exercise programs [21]. Existing aged care support staff, called “coaches,” have been trained to supervise participants to access the technology and provide “hands-on” exercise support once per week with the assistance of exercise videos designed by the research team. The waitlist control group receives a 3-month version of the program once the intervention period at each site is completed.

To inform the successful development of programs such as TOP UP, it is essential to examine not just if but how and why TOP UP worked (or not) and what strategies could best improve it. The aim of this paper was to use interview data to provide detailed insights into the experiences of older people, physiotherapists, coaches, and aged care managers with the telephysiotherapy intervention. The objective was to understand how contextual factors mediate the delivery of the TOP UP program and to produce transferable lessons for the potential use of future telephysiotherapy in aged care [22].

Methods

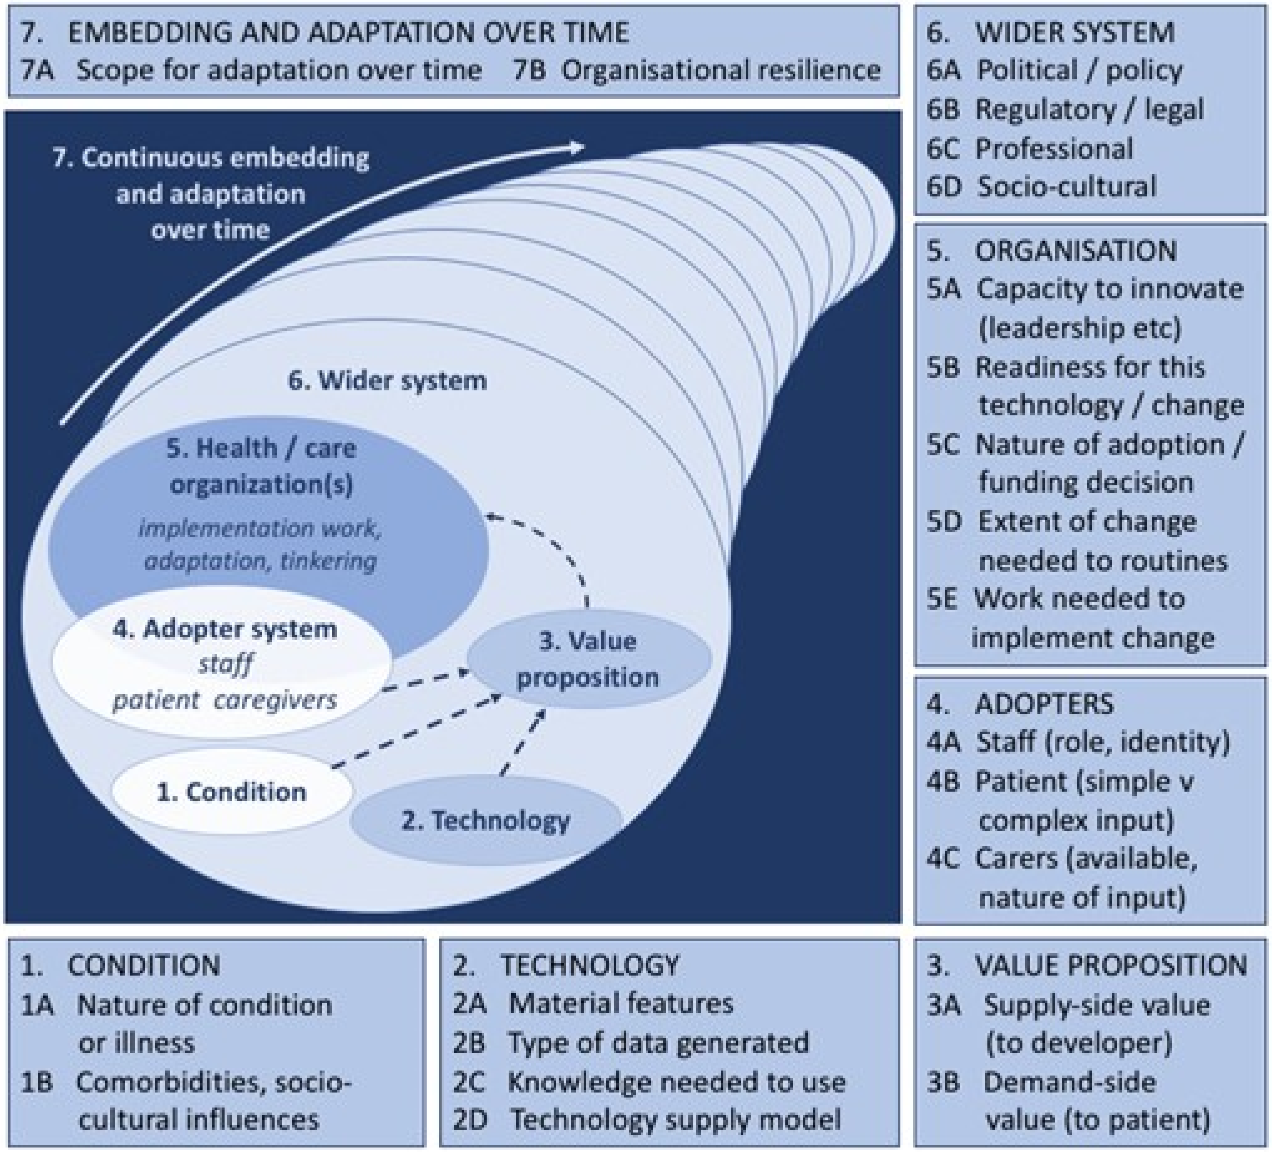
Study Design and Context

This study used a qualitative, descriptive approach through semistructured one-on-one interviews [23]. Qualitative description is increasingly used in conjunction with effectiveness and implementation trials and aims to present a straightforward description of participants’ experiences [24]. The analysis is grounded in the participants’ own words, making the results accessible to vulnerable groups, valid, highly translatable, and useful for refining interventions [25]. Qualitative description sits within a constructivist paradigm, considers multiple meanings, and recognizes that the research process is never neutral [26]. To strengthen the research rigor, we included triangulated data sources (by drawing on perspectives of different stakeholder groups) and a reflective discussion of emergent findings among the multidisciplinary research team [27].

Conceptual Framework

We used 2 behavior change theories, COM-B and SDT, and the Nonadoption, Abandonment and Challenges to the Scale-Up, Spread and Sustainability of Health and Care Technologies (NASSS) framework to provide a conceptual “lens” to inform data collection and analysis [28]. The COM-B model of behavior change proposes that to engage in a behavior such as exercise (B), a person must be physically and psychologically capable (C) and have the opportunity (O) to engage in the behavior, as well as the motivation to do so (M). COM-B simplifies complex factors and recognizes that to modify behavior, we need to address at least one of these components [17]. SDT focuses on the motivation underpinning behavior change, positing that effective programs must support autonomy, competency, and relatedness [16]. The NASSS framework is an evidence-based, theory-informed, and pragmatic framework that can help predict and evaluate the success of a technology-supported health program. It consolidates multiple implementation frameworks, targeting key issues relating to the implementation and uptake of telehealth at the microlevel of individual staff and consumers, the mesolevel challenges of organizational engagement and adoption, and macrolevel policy and regulatory factors (Figure 1) [28].

Figure 1. The Nonadoption, Abandonment and Challenges to the Scale-Up, Spread and Sustainability of Health and Care Technologies framework.



Recruitment and Data Collection

At the initial TOP UP recruitment, all aged care service users, coaches, physiotherapists, and aged care managers received an information sheet inviting them to participate in an interview for this qualitative study. After participants read the informational letter and confirmed their interest in participating in an interview, they received an informed consent letter to be signed by themselves or their person responsible before the interview appointment. A list of potential aged care service users and their coaches and physiotherapists was created in consultation with 3 of our aged care partners (Ashfield Baptist Homes, Whiddon, and Uniting AgeWell).

A purposive recruitment strategy was used to select 18 older adults who participated in the TOP UP intervention, ensuring variation in age, gender, residential status (home or residential aged care), geographic location, and cognitive levels. All 39 participants contacted agreed verbally and in writing before and on the day of the Zoom interview. None of the participants declined to participate in the interviews. The interviews were conducted 3 to 6 months after the interviewees commenced the program. Recruitment was stopped at the point when data adequacy had been reached, that is, when we judged that we had sufficient rich data across our purposive sample with which to answer our research questions [29].

The interview guide was created in consultation with the wider research team and representatives from our aged care partners (Multimedia Appendix 1). Interview questions targeted concepts from the COM-B model, SDT, and NASSS framework (described earlier). Specific questions explored the relative value of the different components of TOP UP (eg, Zoom, exercise videos, and the level of support provided). Questions regarding its implementation and effectiveness were also included. We also asked interviewees to identify local and potential system-wide barriers and facilitators to the successful adoption of telephysiotherapy, such as TOP UP and other programs aimed at delivering fall prevention and mobility programs in aged care. We used open-ended questions and active listening to confirm our understanding of the interviewees’ perspectives. RD and KN conducted the interviews individually on Zoom. They were involved in the delivery of the program, so to reduce sociability bias, interviewees were encouraged to critique the TOP UP program and its implementation to identify improvements [30].

Aged care participants had a family member or someone familiar to them from their aged care organization that was not their coach to assist them with connection to the Zoom app and to support them through the interview. The participants were reminded that they could stop the interview at any time. No repeat interviews were conducted. RD and KN completed memos after the interviews and met to discuss the data and the emerging thematic content. Interview audio recordings were automatically transcribed using Zoom's free transcription service, and transcripts were corrected by RD. Transcripts were not returned to the participants.

Data Analysis

The transcripts and interview field notes were uploaded to NVivo 12 (Lumivero) for data management and coding [31]. The transcripts were coded by one researcher (RD) using an abductive analytical approach. RD drafted an initial thematic framework drawing on emergent themes in the data and was informed by domains from the NASSS framework. In total, 2 researchers (RD and AH) tested and refined the coding framework on 2 manuscripts, adding codes and modifying existing codes from inductively identified concepts in the data. RD coded the remaining data. RD, CS, and AH met regularly to discuss emergent codes and themes.

Recurrent themes were generated from reading across the coded data and reviewed against concepts from SDT [16] and the COM-B framework [17,29] to understand how aspects of the TOP UP program influenced exercise engagement. An early overview of the findings was discussed with all coauthors and our consumer representative to explore a wider range of possible thematic interpretations and to help ensure that we had answered our research questions, including considering the implications of our findings. Disagreements were resolved through discussion. The criteria for reporting qualitative research was used as a reporting checklist (Multimedia Appendix 2) [32].

Ethical Considerations

Ethics approval for this qualitative substudy was included in the TOP UP study approval granted by the Ethics Review Committee at the Sydney Local Health District Research Ethics and Governance Office, Concord, Australia (approval number CH62/6/2021-009). The trial was registered with the Australian New Zealand Clinical Trials Registry (ACTRN 1261000734864).

Results

Participants

In total, 39 people participated in semistructured interviews: 18 (46%) aged care service users who completed the TOP UP program, 7 (18%) aged care physiotherapists, 8 (21%) coaches, and 6 (15%) aged care managers. Interviews took an average of 19 (range 8-53) minutes. These service users were aged from 70 to 93 (median 87.5) years at the start of the intervention; 11 (61%) were female and 7 (39%) were male; 11 (61%) used a 4-wheeled walking frame to walk and 7 (39%) did not need a walking aid to walk; 7 (39%) lived in metropolitan cities in New South Wales and 11 (61%) lived in rural or remote areas in New South Wales and Victoria; 6 (33%) had mild to moderate cognitive impairment and 12 (77%) had no cognitive impairment; all had multiple comorbidities (median 7, range 2-11); and 10 (56%; median 1, range 1-7) had one or more falls in the last 12 months. The median Technology Readiness Index score was 2 out of 5 (range 1-3.9), which classified aged care users as technology *avoiders*, people who tend to have a high degree of resistance and a low degree of motivation to use technology [33]. A total of 4 (22%) aged care service users had used phone-based telehealth before with their general practitioner, but none had used a videoconferencing app such as Zoom before the study or used telehealth to receive physiotherapy.

Of the 7 physiotherapists interviewed, 4 were based in metropolitan areas and 3 were based in rural areas. A total of 4 coaches supported aged care service users from residential aged care, and 4 coaches supported aged care service users from home aged care. In addition, 1 aged care manager worked at a remote residential aged care site, 1 managed a rural residential aged care site, and 4 were home care managers from rural areas.

Main Findings

Overview

Our qualitative analysis revealed that all interviewees found the TOP UP program to be acceptable and would recommend similar telephysiotherapy programs to other older people receiving aged care services. Thematic analysis generated 6 key themes related to the experiences of TOP UP. We also compiled evidence of these experiences to identify and manage emergent possibilities, uncertainties, and interdependence that could guide the adoption of telephysiotherapy in aged care using the NASSS framework. Quotations were used to illustrate each theme. We annotated the quotes for anonymity with aged care service users referred to as P1, P2, and so on, and other stakeholders are descriptively described.

Theme 1: Telephysiotherapy Expands Opportunity

Theme 1 highlights the expanded opportunities for accessing the physiotherapy that TOP UP provided. TOP UP minimized barriers to physiotherapy access related to travel and associated costs:

> *Travel in country areas is just too hard and having telehealth in the home makes it so easy to do. I can't do a 70 km round trip – it is too expensive.* [P10]

This was also echoed by service users whose significant disabilities created access barriers:

> *Because of my health, there's no way I can go out to see a physio. One, I've got to get someone to take me, like a relation, or pay someone to take you, it's not practical. It's hard to park anywhere near the physio, you've got to walk, so by the time you get to the physio you're exhausted.* [P1]

All the physiotherapists and aged care service managers indicated that telehealth could deliver physiotherapy care efficiently, improving opportunities for older adults receiving aged care services to receive physiotherapy where and when they need it:

> *Some people need to be able to see a physio quickly, and we can provide telehealth services quickly, it is so efficient.* [Home care physiotherapist, metro]

TOP UP had the greatest impact on rural and remote services, especially in areas where telehealth has the potential to address chronic health inequity issues related to workforce shortages:

> *Our town has a physio that visits once a month. Recently, one of our residents had a fall so I called the clinic and found out that we can't get an appointment to take our resident to see a physio for 6 weeks, if someone has a fall like this, we just can't wait six weeks. Telehealth really helps us.* [Residential manager, remote]

Theme 2: Tailored Physiotherapy With Local Support Enhances Motivation

Regular local support was identified by all interviewees as important for enhancing older people's confidence to try the exercise program and to support their motivation to "stick with" the program, including coping with TOP UP's increasing challenge over time. Many interviewees across the 4 stakeholder groups explained that it was not just physical and technological support that the coaches offered (eg, providing stand-by assistance while performing balance exercises and managing the Zoom app) but also companionship and emotional support:

> *I can't get out much and I began to look forward to the weekly session with my care worker as I really appreciated the support, she gave me to do something positive for my health. My coach understood what was going on in my life and she gave me the confidence to keep doing the exercises.* [P12]

All the physiotherapists interviewed indicated that the coaches' "hands-on" support was vital to the success of the program, as it helped to build capability and confidence. Importantly, TOP UP was a tailored program in which physiotherapists were able to modify exercises according to the individual needs of each service user, mirroring the person-centered approach typical in-person physiotherapy sessions. This tailored approach was particularly important to aged care service users whose health changes required program adaption:

> *My physio understood that I needed a break when I had some surgery, but was ready for me when I got back home and quickly helped me regain the fitness that I had lost in the hospital.* [P18]

The TOP UP program used technology and behavior change techniques to maximize program adherence. Zoom provided physiotherapists with a platform to deliver individualized real-time health coaching and goal setting, which has been shown in the literature to increase participant adherence [34]. Interview data indicated that these techniques were being used across program implementation, consistent with the behavior change theory:

> *Physiotherapists start with building external motivation by setting goals, by encouraging them, and highlighting their progress we help them develop internal motivation to keep going. If we can motivate them internally, half the job is done, and exercise will become a routine and a lifestyle habit.* [Home care physiotherapist, metro]

Further evidence emerged that these techniques were having the desired effect:

> *Their motivation seemed to improve when they reached their goals, and they wanted to keep on trying. Their motivation is the most important thing.* [Residential coach, metro]

However, it was the combination of live tailored physiotherapy with enthusiastic and companionable local support that seemed to both develop confidence and underpin motivation:

> *The individual sessions on Zoom were important, so I could ask some questions about how I was doing, and having my physio give me some individual feedback was important for my confidence to keep exercising. My coach has made it possible, and her support has been great, she is so lively, and she exercises with me which makes it fun, we had such a laugh, she keeps me motivated, and she takes the monotony out of it. If you are not having fun, it is not worth it.* [P10]

The previous quote also highlights the vital role of enjoyment in exercise and how this can be enhanced with a trained support worker acting as a coach. This may be especially important for engagement in the TOP UP program, given that many of the physiotherapists interviewed suggested that telehealth requires more time to develop a therapeutic alliance. Therapeutic alliance refers to how people experience the empathy of clinicians, and research shows that a strong therapeutic alliance is connected to positive treatment adherence and results in physical therapy [35]:

> *It's not until you get to the fourth or fifth telehealth session that people start getting to really know you and feel like you can be an advocate for them. I think that telehealth does allow for a personal connection which adds to exercise adherence.* [Physiotherapist, home care, rural]

TOP UP physiotherapists and coaches' person-centered approach to goal setting, highlighting progress during the program and celebrating any achievements, seemed to enhance the aged care service user's motivation to exercise:

> *TOP UP helped me care about my future before I just didn't care. I loved the way the physio explained things to me carefully, so I understood. I really appreciate having the support worker exercise with me and reinforce what to do, and how to do the exercises. All of this made me feel like I mattered and now I can walk further, do my shopping, which is a big improvement.* [P12]

Theme 3: Engaging, Older Adult–Friendly Educational Resources Build Capability

Interviewees expressed enthusiasm for the instructional videos that were designed to support high-quality independent exercises throughout the program. The videos incorporated exercises modeled by an older person, slow-paced dialog in a warm conversational style, natural lighting to maximize visibility, minimal visual distractions, and gentle humor, all of which seemed to increase exercise engagement by older people. In the following quotes, 2 participants describe the importance of “seeing” another older person in web-based videos:

> *It was great to see an older person do the exercises, really motivating to see someone my age doing the program. The videos were at the right pace, and I like how they got harder over time. It was fun.* [P17]
>
> *The exercise videos are motivating because I feel like I am doing it with someone – it’s interactive and fun. Following a book can be boring.* [P5]

Many stakeholders commented positively on the video design that incorporated slow demonstration and simple dialog that aimed to teach aged care service users how to perform safe and effective home exercise:

> *The physiotherapist in the videos demonstrated the exercises slowly and explained things easily. I was really surprised how the residents were able to follow everything without any help.* [Residential coach, metro]
>
> *Having online exercise resources really helps because people aren’t familiar with exercise techniques, they can follow their prescribed video and it helps keep their exercise dose up.* [Home care physiotherapist, regional]

Many of the physiotherapists interviewed commented that the TOP UP program was complex and challenged participants to navigate different apps and printed resources such as exercise diaries while using Zoom. They suggested that simpler telephysiotherapy programs (or simpler mechanisms for accessing program components) could be developed to enhance the user experience and minimize program dropout. One physiotherapist commented:

> *I think having an easy to navigate, no fuss system where our clients can look up an exercise, record their exercise program and any problems they may have had, a fall, etc. I think an app where physiotherapists could get access to this information easily during a session and to help prepare for another session would be useful.* [Home care physiotherapist, rural]

Theme 4: A Flexible Reablement Approach Fosters Autonomy

TOP UP is designed to encourage older adults to take a lead in their program planning; flexibility is emphasized, including choices about what resources to use (printed and web-based) and what skills they wish to develop that would enable them to engage in activities they found most important:

> *I liked how it started easily, and I moved my way up the program. There is structure to the program, and you commit to it. I often plan to do a session but if something comes up, I make an appointment with myself to make sure I do it another time.* [P16]
>
> *I liked that I could stop and start the videos according to my own needs on the day.* [P1]

This can be described as a reablement approach, and the physiotherapist and coaches were encouraged to build the aged care service users’ physical capability and support them in transferring their new skills to access other activities in their community independently:

> *Residents lack enough physical activity here, sometimes we are short staffed, and sometimes the staff don’t have time to help. It was great to see our residents on the TOP UP program improve their mobility and begin to walk to different activities on their own.* [Residential manager, rural]

All stakeholders valued the reablement approach, and it was reported that TOP UP seemed to be a catalyst for reablement, as many of their clients began to engage in more socialization with friends and families and embrace other physical activities as they became stronger and more mobile:

> *Physios and coaches can work together to ensure that the participant becomes independent and autonomous in their use of telehealth and do more exercise as the program progresses. As they improved, we had discussions with them and their coach about how they could do more outdoor walking.* [Home care physiotherapist, rural]
>
> *I was surprised about the other quality of life benefits of telehealth, talking to their physio on zoom, seeing their support workers in this new way, learning how to get out and about in the community, all seemed to reduce social isolation, which is so important for our customers.* [Home care manager, rural]

Theme 5: Telephysiotherapy Can Be Safe, Effective, and Acceptable for Many

Most interviewees regarded TOP UP as a safe, effective, and acceptable program. Interviewees reported positive physical and quality of life improvements:

> *I think it’s fabulous. I wouldn’t have imagined that I would be given the opportunity to get physio. Physically, I can walk further. My breathing is better. I’m stronger, it gives you more independence.* [P1]
>
> *Telehealth has not only helped my customer’s strength, mobility and coordination, but it seemed to help their overall quality of life, they seemed happier and more confident to walk.* [Residential care manager, rural]

Many interviewees reported that the combination of physiotherapist-led instructional exercise videos and supervision by trained support workers increased the safety of the TOP UP:

> *I think having a physio run exercises in the videos gives the intervention more authority, frees up my*

> *time to motivate the residents and keep them safe.* [Residential coach, remote]
>
> *I think having the care worker there with the client to help set up Zoom, hold the iPad, and angling the video so I can see them clearly makes the program safer and more successful.* [Home care physiotherapist, rural]

However, TOP UP was not considered to be suitable for all aged care service users. All stakeholders agreed that telehealth presents challenges for frail clients in residential aged care, who often have higher levels of mobility and sensory and cognitive disability. A total of 2 cognitive and sensory impaired aged care service users found using Zoom to "see" their physiotherapist frustrating and as a result, pulled out of the program:

> *First of all, not all dementia residents get used to it, and second, people with hearing and vision problems struggle to follow.* [Residential aged care manager, rural]

Some physiotherapists would hesitate to use telehealth without local support for those aged care service users with high fall risks:

> *For people who are mostly independent I wasn't worried, but if I did have someone who was who was frailer and there was no one there with them I was worried they might fall.* [Home care physiotherapist, regional]

Some aged care service users and managers suggested that although telephysiotherapy is a good secondary option, they would still prefer in-person physiotherapy, especially for older adults with more complex needs:

> *I prefer a blend of face-to-face physio and telehealth. I need some hands-on physio from time to time to manage the arthritis in my back, but I liked the telehealth program because I could follow the physio exercise videos at home, it was so convenient.* [P18]

It appears that a hybrid model that incorporates a blend of face-to-face physiotherapy and web-based exercise resources, such as exercise videos, was viewed as particularly acceptable for those with significant health challenges:

> *I don't know if someone with severe dementia or disabilities would be able to access telehealth. I also think a lot of clients would like a hybrid telehealth model starting with a face-to-face assessment.* [Home care physiotherapist, rural]

Finally, our screening process uncovered many technological hesitations and potential telehealth data concerns that prevented the recruitment of many potential aged care service users into the TOP UP trial:

> *There is some hesitancy around technology use due to recent cybersecurity anxiety in the community- for example the Optus and Medibank breaches.* [Home care manager, rural]

Theme 6: Organizational Commitment Is Required to Embed Telephysiotherapy

Interviewees explained that considerable organizational commitment is required to embed telehealth programs such as TOP UP in aged care. Sufficient investment is required to train staff, conduct more meetings with their physiotherapy service providers to plan for the development of a new service, such as telephysiotherapy, prioritize TOP UP sessions within busy service schedules, and, where necessary, direct funds toward supportive technology. Some coaches and physiotherapists commented that the use of devices such as large iPads and smart televisions enhanced telehealth engagement by improving the visibility and hearing experience of service users:

> *Zoom worked well when we connected the iPad to the TV, we were able to turn the volume of the TV up so the resident could hear better. It also gives a bigger picture as well, so they can see the physio better.* [Residential care coach, rural]

However, such equipment can be costly, and telehealth-specific funding was raised by physiotherapy, aged care managers, and coaches as a key condition for ongoing sustainability of telephysiotherapy in aged care:

> *I think that maybe there needs to be funding support. Telehealth is an important and easy way to increase access and uptake. One physio could service several homes in a full-time caseload.* [Residential care physiotherapist, rural]

TOP UP required 3 people to be available for appointments (the older person, their coach, and the physiotherapist on Zoom); thus, scheduling was more challenging than 2-person face-to-face health care interactions:

> *There are always challenges whenever it comes to scheduling, especially during COVID when we were short of staff. But if you have a good relationship with your physiotherapy provider, who is responsive to time slot suggestions, then our scheduling team could work their magic and get it all booked.* [Home care manager, rural]

Training was provided to older adults to increase their confidence using an iPad, our website, and relevant apps (Zoom and StandingTall). Coaches were trained to increase their level of comfort by navigating the TOP UP website and Zoom. Physiotherapists were trained to deliver effective telephysiotherapy assessments using Zoom and provided strategies to enhance relationship development with older adults and their coaches. All interviewees highlighted this training as an important factor in overcoming "telehealth hesitancy" both for service users and program providers:

> *There was a lot of telehealth hesitancy at the beginning, but with education they slowly got quite comfortable in doing it.* [Home care physiotherapist, metro]
>
> *There is a need to have some general training so we [physiotherapists] know how to use it [telehealth technology] effectively: make sure your voice is coming through, how to pace instruction so our clients*

> *understand us. The coaches and customers need training to know how to set up a shot, to make sure that they are visible to ensure that the client becomes independent and autonomous in their use of telehealth.* [Home care physiotherapist, rural]

The aged care service managers also noted the challenge of training adequate numbers of care workers to facilitate TOP UP and ensure that the coaches are safe and competent:

> *There is a need to train a large proportion of our support workforce so that we have more trained staff who know how the program works, how to use technology and how to supervise our customers safely.* [Home care manager, rural]

Some aged care service managers and physiotherapists indicated that more frequent and more detailed web-based exercise training programs would be useful to improve the skill level of a wider group of support staff:

> *It is very important to have lots of staff trained. For example, if the regular coach is sick, another staff member could take over and keep the program going.* [Home care manager, rural]

All stakeholders indicated the need for specific investment into better internet connectivity to ensure the sustainability of future telephysiotherapy programs:

> *I've found is there are still a lot of places in rural Australia where older people don't have fast Internet, they don't have smart TVs, or they don't have the technology that metro places have. People are ready to engage with telehealth, but there's no infrastructure in rural areas.* [Residential physiotherapist, metro]

Implementation Guidance Through the Lens of the NASSS Framework

TOP UP appears to be well positioned for sustainable adoption, and learnings from this study have informed the translation of telephysiotherapy services by our aged care partners into practice. Table 1 uses the NASSS framework to help explain TOP UP's successes and failures and explore the facilitators required to embed similar telephysiotherapy programs in aged care.

Table 1. An overview of TOP UP implementation guidance in relation to the Nonadoption, Abandonment and Challenges to the Scale-Up, Spread and Sustainability of Health and Care Technologies framework domains.

Domain	Definition of domain	Implementation guidance derived from study findings	Illustrative quotes from interviewees
The condition	The suitability of the participant's attributes/needs and their interaction with the intervention.	TOP UP is suitable for aged care service users with mobility challenges who can walk short distances. It is not suitable for those with significant sensory and cognitive disability	"Someone with severe dementia or severe disabilities would not be able to have that skill to access telehealth." [Residential coach, rural]
The technology	Technical features related to the usability of telehealth and its support requirements.	TOP UP requires access to the internet via an iPad or similar device. Aged care service users do not need technological skills due to the weekly support they received from trained care workers to help them use the iPad, navigate Zoom, and access exercise videos on a website. However, basic technological skills were often developed, which increased autonomy.	"One of my clients is really good with technology but other clients need my help to turn on the iPad and follow the program." [Residential coach, metro]
The value proposition	The value proposition of telehealth for upstream end users (aged care service providers) and downstream users (physiotherapists and their clients).	All stakeholders saw telephysiotherapy as a valuable addition because of its convenience and perceived effectiveness, especially for those with poor mobility or who are living in rural or remote areas. The value proposition for telehealth to treat musculoskeletal pain is less as stakeholders prefer a more "hands-on" experience. A hybrid model would add value for some.	"Telehealth would save us time and travel and help us to see more people." [Home care physiotherapist, regional]
The adopter system	The ongoing investment required to support the telehealth intervention and the ongoing acceptability of stakeholders.	TOP UP requires consistent investment in training, human (physio, coaches), and physical infrastructure (devices, fast internet, senior-friendly exercise resources) to create sustainable success. However, high levels of system support are likely to be reinforced as positive returns on investment due to their perceived positive impacts on mobility and well-being.	"TOP UP is more than just a fall prevention program, it offers a truly reablement focus where our clients can build their strength and balance and get out into the community again. I think many of our clients could benefit from telehealth." [Home care manager, rural]
The organization	An organization's capacity to embrace the telehealth intervention and the supports required to establish and maintain it as a viable service offering.	Not all aged care services chose to participate in TOP UP because of the perceived burden of working with technology. Providers who joined TOP UP wanted to investigate telehealth's impact on access to fall prevention and mobility programs, in areas where there are physiotherapy shortages. Providers offered considerable support via technology provision, extra administration support for scheduling of telephysiotherapy sessions, and enough care workers to support the program.	"I was surprised at how easy telehealth was to get started. We gave the clients an iPad and the assistance the care workers gave them was important to help them engage with telehealth. Our scheduling team are fantastic, and they managed to solve the scheduling challenges really well." [Home care manager, rural]
The wider context	The wider organizational and policy impacts on telehealth uptake and sustainability.	Stakeholders agreed that funders need to provide telehealth-specific funding and education for interventions such as TOP UP to reduce technology hesitation and improve telehealth systems that enhance its adoption and sustainability.	"I feel that people would be greatly advantaged if there was a separate pocket of funding for allied health so that we could afford to deliver ongoing telehealth" [Home care manager, rural]

Discussion

Principal Findings

This study, which included participants such as older adults, physiotherapists, aged care support workers, and managers in the TOP UP trial, offers valuable insights. Our thematic analysis identified key factors for the telephysiotherapy program's acceptability, including advice from physiotherapists, consistent support from trained care workers, older adult–friendly web-based exercise resources, and a flexible reablement approach. The interview data supported multiple themes, suggesting that the synergistic integration of these ingredients within the TOP UP contributed to its high acceptability. The discussion explores the impact of single components and emphasizes their combined contribution to TOP UP's acceptability.

TOP UP Study Is Acceptable

Acceptability is an important consideration in the design and implementation of complex health care interventions, such as TOP UP [36]. Our findings align with the increasing body of literature indicating acceptance of telehealth among older adults in community settings despite high levels of technology hesitation [37,38]. A cohort study of a telehealth program incorporating physiotherapy for rural older adults found that telehealth was safe (no adverse events) and feasible (average telehealth attendance 85%) [38]. A 2021 cross-sectional survey of health care providers further affirmed increasing telehealth acceptability over time among homebound older adults [39].

Barriers and Facilitators Related to Telehealth Adoption

TOP UP identified several barriers and facilitators that enabled aged care service users to overcome high levels of technology hesitation and, if appropriately addressed, could improve the translation of telehealth programs into aged care [40]. TOP UP's qualitative findings are reflected in the literature, which demonstrate that barriers related to this population's innate technology hesitation and greater sensory, physical, and cognitive impairments could be addressed by the provision of local support, internet-connected devices, fast internet, and appropriate telehealth training can mitigate these barriers [39,41,42].

A recent US survey of physician providers of homebound older adults during the COVID-19 pandemic revealed that a significant proportion of their patients were technology avoidant [39] (only a third of their patients had used video-based telehealth before, 310/873, 35.5%). Among patients who had not used telehealth before, providers deemed that one in 4 (153/563, 27.5%) of their patients would not be able "interact over video" due to cognitive or sensory impairments. This survey found other barriers: providers lacked knowledge of their patients' internet connectivity, and participants faced financial constraints in obtaining internet plans and were unable to pay for internet plans or video-capable devices. Similar findings emerged in the TOP UP, where most trial participants had limited access (10/18, 56%) to video-capable devices, limited telehealth experience (4/18, 22%), and low telehealth readiness (Technology Readiness Index 2 out of 5). Addressing barriers related to the purchase of telehealth infrastructure and providing local support can facilitate wider acceptance within aged care settings.

A recent qualitative exploration of factors influencing acceptability in dementia management revealed that videoconferencing had potential benefits over in-person appointments by improving access to care for those with mobility limitations and reducing the stress associated with clinic appointments [43]. A crucial insight from this study emphasized the necessity of technical support and telehealth training involving information on how to access and use different telehealth apps and tips for setting up the video camera for maximum visibility. Similarly, another study examining telehealth's role in enhancing oncology care for older adults emphasized that appropriate technology training integrated into the screening process and program delivery could enhance telehealth adoption [44]. These studies align with TOP UP's findings that emphasized the delivery of appropriate education at screening and recruitment to reduce technology avoidant behaviors, preprogram technology training to support adoption, and training to troubleshoot any emerging technology issues to enhance sustainability.

TOP UP demonstrated that behavior change training for physiotherapists and coaches in health coaching techniques, motivational interviewing, and collaborative goal setting can facilitate telehealth adoption. Behavior change training has been shown to increase therapeutic alliance and enhance exercise program outcomes in other studies [45]. A strong therapeutic alliance has been identified as a crucial facilitator in previous telehealth interventions [46]. In our study, physiotherapists, coaches, and aged care service users found telehealth suitable for effective behavioral change coaching and suggested that specific training on skills to enhance therapeutic alliance is important to augment telehealth acceptability. Specific examples included targeted training on using Zoom emojis to acknowledge client achievements and building a personal connection through virtual tours of the older person's home and garden. However, they noted that establishing a successful therapeutic alliance through telehealth demands more time compared with in-person sessions, potentially increasing program costs.

Telehealth Can Provide Key Ingredients for Behavior Change

TOP UP was co-designed to incorporate the COM-B model to create positive behavior changes related to exercise adherence [17]. Recent data from the Australian Institute for Health and Welfare have shown the critical significance of addressing insufficient physical activity in older individuals, given their 50% contribution to 2.5% of the overall disease burden in Australia [47]. Consequently, increasing motivation and opportunities for exercise in this demographic is crucial in mitigating the adverse health consequences stemming from sedentary behavior [19] and in supporting the efficiency of the health care system [48]. TOP UP's tailored approach and use of older adult–friendly resources appeared to increase the capability (C) of older adults to exercise. The program provided increased opportunities (O) for exercise by facilitating increased access to physiotherapists. Furthermore, TOP UP heightened motivation (M) through its reablement approach, goal-setting mechanisms, and cultivation of enjoyment via companionable coaching [16].

The TOP UP program strategically incorporated the principles of SDT to promote increased exercise adherence. According to SDT, intrinsic motivation thrives when individuals perceive a sense of autonomy and control over their activities [49]. Our study findings suggest that the aged care service users valued the opportunity to regain independence through self-directed exercise. The TOP UP program effectively nurtured feelings of competence through its personalized and progressive exercise routines program, fostering a sense of relatedness through local support and the rapport established during the telephysiotherapy sessions that actively promoted enjoyment. This observation aligns with the systematic review by Teixeira et al [50] on SDT and exercise adherence, affirming the positive correlation between intrinsic motivation, enjoyment, personal achievement, and heightened program acceptability.

Our study has provided insights into the potential explanatory effects of the social learning theory by Bandura [51] and Motivational Theory of Role Modeling in supporting the high acceptability of TOP UP. The social learning theory by Bandura [51] underscores the significance of observation and imitation in driving behavior change. When individuals perceive the modeled behavior as valuable, and the model possesses an admired status while being relatable, the likelihood of behavioral change increases. In this context, physiotherapists, esteemed as exercise professionals in the community [52], played a crucial role in enhancing the perceived value of the TOP UP program. Furthermore, the Motivational Theory of Role Modeling highlights another critical aspect of TOP UP's acceptability [53]. Many interviewees emphasized the importance of including older adults as role models in exercise videos. Both theories suggest that the inclusion of older role models was a pivotal factor inspiring behavioral change, explaining the positive reception of TOP UP exercise videos.

Scale-Up and Sustainability of Telephysiotherapy in Aged Care

Telehealth has emerged as a prominent method for implementing scalable health care interventions, a trend that has intensified during the COVID-19 pandemic [54]. However, the challenge of sustaining these programs is pressing, as is evident from reports of high participant attrition rates in telehealth-led exercise programs [55]. Successfully delivering cost-effective exercise programs to frail older adults with multiple comorbidities in the aged care environment is challenging and complex, demanding significant resourcing [8]. Insights gained from the NASSS framework [28] underscore the need for careful screening of older adults for telephysiotherapy participation and the provision of targeted training to all stakeholders to enhance its feasibility. Our analysis indicates that while TOP UP was acceptable, a hybrid model of virtual care that combines in-person initial assessments, subsequent synchronous telephysiotherapy sessions for program progression, and the integration of local support and older adult–friendly web-based exercise resources may further increase telephysiotherapy uptake and sustainability in aged care.

Although the cost-effectiveness analysis of TOP UP is pending, our qualitative observations indicate that establishing telephysiotherapy programs requires substantial investment in both physical and human infrastructure. The telehealth literature discusses the critical role governments play in developing policies and guidelines to foster telehealth adoption [56]. Our interviews revealed a consensus on the need for dedicated funding for telehealth to enhance adoption and sustainability.

Strengths, Limitations, and Future Studies

This qualitative study had several strengths. It triangulates empirical data relating to the uptake and sustainability of telephysiotherapy in aged care from 4 perspectives: older adults receiving physiotherapy within aged care services, physiotherapists, trained support workers who deliver the intervention, and aged care managers who are charged with case management and overseeing aged care service resource allocation and delivery. Our partnerships with aged care providers and their ongoing input in the research have enabled us to develop a deep understanding of how the TOP UP program was delivered in aged care and, if proven effective, this will speed up its translation into wider practice [14].

Qualitative research serves as a valuable tool for refining program design, deepening insights into the outcomes of quantitative research, and offering valuable guidance for enhancing the implementation of complex interventions such as telephysiotherapy in aged care [26]. In this study, we adopted a broad sampling strategy aimed at delivering a rich description of diverse intervention experiences, enlisting the perspectives of 18 older adults encompassing a range of sociodemographic characteristics distributed across 10 distinct sites. Moreover, the inclusion of independent physiotherapists, separate from both the aged care service partners and the research team, in our study design may have reduced potential social desirability bias, enhancing the credibility of our findings [30].

Several limitations of this study necessitate careful consideration. TOP UP excluded participants from culturally and linguistically diverse backgrounds and thus presented a notable gap in our understanding of their experiences. To address this gap, future trials that prioritize the inclusion of culturally and linguistically diverse communities are required. In addition, although the interviewee cohort was purposefully selected to encompass maximum variation, it is essential to acknowledge that this pool primarily consisted of individuals who voluntarily participated in the trial, potentially predisposing them to higher levels of exercise engagement and receptiveness to telehealth. Consequently, this may limit the generalizability of our findings.

Several aged care service users and coaches were interviewed by either a physiotherapist or aged care service provider who delivered the program. This can lead to social desirability biases, which may undermine the credibility of the study results [57]. Given this context, aged care service users and staff might hesitate to openly share negative experiences with their interviewers despite the research team’s assurances that their feedback would have no bearing on their ongoing care or employment status. To mitigate this bias, interviewers made concerted efforts to positioning themselves as eager learners, actively encouraging interviewees to share their “insider” perspectives on quality improvement and expressing genuine appreciation for any criticism offered. Future larger-scale mixed methods studies should be designed to enhance research quality and further explore the impact of telephysiotherapy uptake and sustainability in aged care while carefully addressing social desirability bias.

This study suggests a need for the development of simplified telephysiotherapy exercise programs to facilitate greater adoption in aged care. A recent scoping review conducted in 2021, examining the barriers and facilitators to the use of telehealth by older adults, found several impediments associated with current technology, including challenges related to small screens, text size, small icons, insufficient color contrast between text and background, and complex functionality [58]. The review also identified ease of use as a key facilitator of telehealth adoption. Some TOP UP stakeholders interviewed indicated a preference for simplified functionality tailored to this demographic. Respondents expressed a desire for telehealth programs that incorporated TOP UP program features such as Zoom, exercise diaries, and videos, into one user-friendly application. These findings advocate for further research aimed at enhancing the user experience.

Conclusions

This interview study explored the program experiences of aged care service users, physiotherapists, and aged care staff involved in the TOP UP trial, a telehealth-led exercise program designed to improve mobility, reduce falls, and enhance quality of life. All stakeholders indicated high program acceptability, underscored by its safety, and perceived effectiveness. The thematic analysis uncovered key insights: TOP UP’s provision of convenient access to physiotherapy services for aged care recipients, the positive impact of tailored physiotherapy coupled with local support on exercise motivation, the effectiveness of engaging older adult–friendly resources in fostering program adherence, and the facilitation of greater independence through a flexible reablement approach. This study emphasizes the importance of sustained organizational commitment for the successful implementation of telephysiotherapy programs, such as TOP UP, highlighting the need for training and external funding to ensure telephysiotherapy's adoption and sustainability.

Abstract

Background: There is a need to develop and coordinate dementia care plans that use assistive technology for vulnerable groups such as immigrant populations. However, immigrant populations are seldom included in various stages of the development and implementation of assistive technology, which does not optimize technology acceptance.

Objective: This study aims to gain an in-depth understanding of the acceptance of a digital personal assistant, called Anne4Care, by older adult immigrants living with dementia in their own homes.

Methods: This study used a qualitative descriptive research design with naturalistic inquiry. A total of 13 older adults participated in this study. The participants were invited for 2 interviews. After an introduction of Anne4Care, the first interview examined the lives and needs of participants, their expectations, and previous experiences with assistive technology in daily life. Four months later, the second interview sought to understand facilitators and barriers, suggestions for modifications, and the role of health care professionals. Three semistructured interviews were conducted with health care professionals to examine the roles and challenges they experienced in the use and implementation of Anne4Care. Content analysis, using NVivo11, was performed on all transcripts.

Results: All 13 participants had an immigration background. There were 10 male and 3 female participants, with ages ranging from 52 to 83 years. Participants were diagnosed with an early-stage form of dementia or acquired brain injury. None of the older adult participants knew or used digital assistive technology at the beginning. They obtained assistance from health care professionals and family caregivers who explained and set up the technology. Four themes were found to be critical aspects of the acceptance of the digital personal assistant Anne4Care: (1) use of Anne4Care, (2) positive aspects of Anne4Care, (3) challenges with Anne4Care, and (4) expectations. Assistance at first increased the burden on health care professionals and families. After the initial effort, most health care professionals and families experienced that Anne4Care reduced their tasks and stress. Contributions of Anne4Care included companionship, help with daily tasks, and opportunities to communicate in multiple languages. On the other hand, some participants expressed anxiety toward the use of Anne4Care. Furthermore, the platform required an internet connection at home and Anne4Care could not be used outside the home.

Conclusions: Although older adult immigrants living with dementia had no previous experience with digital assistive technology specifically, the acceptance of the digital personal assistant, called Anne4Care, by older adult immigrants living with dementia was rather high. The digital assistant can be further developed to allow for interactive conversations and for use outside of one's home. Participation of end users during various stages of the development, refinement, and implementation of health technology innovations is of utmost importance to maximize technology acceptance.

KEYWORDS

assistive technology; technology acceptance; immigrant; dementia; marginalized older adults

Introduction

Background

Dementia is a global health problem associated with emotional and financial challenges for people living with dementia, their relatives, health care professionals, and health organizations [1,2]. Worldwide, approximately 47 million people are diagnosed with dementia [3]. Around 280,000 persons are presently living with dementia in the Netherlands among a population of nearly 19 million [4]. The number of people living with dementia is expected to increase in the coming years. People with an immigration background are at an increased risk of developing dementia and are more likely to experience barriers in accessing dementia services and care, which may lead to health inequities and a reduction of quality of life [5-7]. Hence, there is a need to develop and coordinate dementia care plans, including the use of technology, for marginalized older adults living with dementia, such as those with an immigration background and low literacy levels [8].

Health Literacy and Health Technology

Health literacy has been defined as "the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions" [9]. Adequate health literacy and access to services among immigrant populations are important to empower, support or facilitate these persons to become active participants in their health [10]. Persons with limited health literacy have difficulty finding, understanding, and applying information about health and health care. Health technology–based solutions that support health promotion, for example, mental and physical health, offer opportunities to increase health literacy in vulnerable populations [11,12].

The World Health Organization reports that innovative health technologies are promising tools to enhance knowledge, skills, and coping mechanisms to improve the daily lives of people with dementia and their caregivers [13]. In recent years, a variety of technologies to support self-management have been developed for people with dementia and their caregivers. Studies have focused on the effect of these technologies on the physical, mental, and social well-being of people with dementia and their relatives and families [14,15]. Technology seems to stimulate cognitive function and communication skills and reduce loneliness among people with dementia, but these results are personal and context-dependent [14,15]. Acceptance of technology is a major challenge and prerequisite for the implementation of technology in practice. For successful technology implementation in the daily lives of people, it is important to have insight into the acceptance of technology among end users. Although studies have examined the acceptance of technology among people living with dementia and their caregivers [16-18], the number of studies that focus specifically on older adult immigrants living with dementia is minimal.

Citizen Science

Co-design and the involvement of people with dementia and their professional and family caregivers are crucial elements for the acceptance of technology [17]. However, immigrant populations are seldom included in stages of development, refinement, and implementation of assistive technology innovations [19]. This can be associated with low levels of acceptance of health technology innovations, which can contribute to health inequities among populations. One opportunity to increase the involvement of end users is through citizen science, which is an approach that engages end users to be partners in research so that their experiences and needs are considered [20]. Citizen science is a powerful approach to include public participation in research as well as optimize acceptance of technologies [20,21]. In citizen science, scientific principles and methods are used by nonprofessional "scientists" in close collaboration with scientific researchers [22]. The involvement of older adults in the development, refinement, and implementation of technology, acknowledging their expertise and needs, and working together in short iterations to adapt the technology for their specific needs are reported to be valuable elements by scientific researchers, older adults, and health care professionals [23].

Aim

This qualitative descriptive study aimed to provide an in-depth understanding of the acceptance of a digital personal assistant, called Anne4Care, among older adult immigrants living with dementia by using a citizen science approach.

Methods

Research Design

This study used a qualitative descriptive research design with a naturalistic inquiry [24] and citizen science principles [20]. In this study, Anne4Care was extended with the development of a Turkish version. All the involved older adults had the task of testing the device as well as communicating with each other, their care professionals, and the Anne4Care help desk. For example, there were workshop-like meetings in which all shared experiences, assisted each other with difficulties, and expressed the need to further develop the Turkish version of Anne4Care. Furthermore, participants actively collaborated with scientific researchers, for example, in discussing the topics for the interview guide and analyzing the data from the interviews.

Aligning with citizen science principles there was a close collaboration between older adults participating as co-researchers, health care professionals, and scientific researchers. A detailed description of how older adults with an immigration background were engaged in this study is described in a separate paper [23]. The team of researchers closely collaborated with a group of citizens representing the target group and health care professionals in their role as co-researcher, during all phases of this study: recruitment, obtaining informed consent, data collection, and analysis.

Setting

This research was part of the TOPFIT Citizenlab program, a research and innovation program in which citizens, health care professionals, and companies join forces with scientific researchers to develop and implement technology for health.

The Technology

Anne4Care is a digital personal assistant that includes video-calling, a personal agenda, medication reminders, reading the news, and games that can be used in one’s home. Anne4Care is a technological platform created to help people with dementia to continue living independently in their own homes and supporting caregivers in their tasks [25]. Anne4Care included hardware as well as a software platform. Anne4Care is available in Dutch, German, Italian, and English. The company was developing a Turkish version of Anne4Care and saw the embedding of Anne4Care in homes of older adults with an immigration background as an opportunity to test, improve, and implement the latest version.

Recruitment Strategy

The recruitment of participants was performed by 3 health care professionals from 2 health care organizations. These organizations provide care for clients with an immigration background with cognitive impairments.

Inclusion criteria were as follows:

- Diagnosed with an early-stage form of dementia or acquired brain injury;
- Having an immigrant background;
- Visiting the activity program of 1 of the 2 participating health care organizations

Exclusion criteria were as follows:

- Diagnosed with a severe stage form of dementia limiting their ability to participate

All clients of the 2 health care organizations (IMEAN Consultancy & Care and Alifa Wellbeing Older Adults) were invited by their health care professionals to participate in this study. All older adult participants had an immigration background, that is, 1 came from Britain and the other 12 came from Turkey (Table 1). They visited the activity program of 1 of the 2 health care organizations, which are situated in the Twente region of the Netherlands. In addition to an immigration background, all 13 older adult participants, or co-researchers, had an early-stage form of dementia or acquired brain injury. The sample included 10 male and 3 female participants, and their ages ranged from 52 to 83 years. There were no exclusion criteria based on digital literacy, that is, participants did not need any experience with technology. Internet access was provided to participants who did not have an internet connection at home.

Table 1. Demographic characteristics of the participants (N=13).

Variables	Values
Age (years)	
Mean (SD)	71 (9.8)
Range	52-83
Age group (years), n (%)	
45-54	1 (7.7)
55-64	1 (7.7)
65-74	6 (46.2)
75-84	5 (38.5)
Sex at birth, n (%)	
Female	3 (23.1)
Male	10 (76.9)
Nationality, n (%)	
Turkish	12 (92.3)
British	1 (7.7)

All 3 health care professionals involved in this study were female. They introduced Anne4Care to the older adults, assisted them, and were in close contact with the participants during all phases of this study. The health care professionals took care of the clients and spoke their native language, which created a safe and trustful environment. The health care professionals also served as a voice for the participants who could not communicate in the Dutch language.

Data Collection

Anne4Care was introduced to allow health care professionals to communicate with and monitor older adults. Data were collected between September 2020 and November 2021. Semistructured in-depth interviews took place at the care organization or at the home of the older adult immigrants. The location was chosen based on a participant's preference. During the interviews, a care professional was present and served as an interpreter. Participants were invited for 2 interviews. The first interview was planned shortly after the introduction of Anne4Care in their home, and a second interview 4 months later. Participants had the opportunity to continue using Anne4Care after the data collection period, funded through a stimulation subsidy for eHealth at home during the COVID-19 pandemic. Five researchers with mixed credentials, training, occupation, location, and gender conducted the interviews (MB, CMvL, TJJO, ES, and ZM). To secure interrater reliability, the researchers had biweekly meetings to discuss the procedure and previous interviews. Two researchers were present during each interview; the teams of 2 were different for each interview. One was the main interviewer and the other took notes and asked additional questions. The follow-up interviews were conducted by the same researchers to ensure the established relationship between researchers and older adults.

The topic guide was developed in collaboration with 1 participant from the daycare facility and 3 health care professionals. Thirteen first interviews were conducted focusing on understanding the lives and care needs of the participants, learning about their expectations regarding Anne4Care, and sharing previous experiences with care and technologies, what facilitators and barriers they encountered while using technology (Multimedia Appendix 1). The first interviews lasted between 30 and 60 minutes. A total of 8-second interviews were conducted with the same participants who participated in the first interview (5 of the participants were not able to participate in the second interview due to COVID-19 illness). The second interview focused on the facilitators and barriers participants experienced when using Anne4Care, suggestions for modifications of Anne4Care, and the role of health care professionals in using technology (Multimedia Appendix 1). The second interview lasted between 20 and 45 minutes.

Three semistructured interviews were conducted with the 3 health care professionals. These interviews took place at the care organization and lasted for 60 minutes. The aim of these interviews was to talk about their role and the challenges they experienced as professionals in the use and implementation of Anne4Care (Multimedia Appendix 2). Furthermore, the findings of the interviews with the older adults were shared with the care professionals.

Data Analysis

All interviews were audio recorded and transcribed verbatim. The transcripts were made in English and Dutch. All Turkish spoken words were translated by an interpreter during the interviews. Only these translations were part of the transcripts. Content analysis of transcripts used an inductive approach [26,27]. We used the software package NVivo11 to support data coding. Open coding was used to identify relevant themes, there were no themes in advance of the data analysis. Several steps were taken to develop a code book. First, 3 researchers (MB, CMvL, and TJJO) performed the analysis of 2 transcripts and compared codes. A preliminary codebook was developed comprising these themes. Second, the coding of one transcript was discussed together with one older adult. This participant was motivated and had some previous experience with research and data analysis. Together with the co-researcher, additional themes were added to the code book. Last, the other transcripts were analyzed by 1 researcher (CMvL). The data analysis and application of codes were discussed during biweekly meetings with the research team. Data saturation was reached after analyzing the data obtained with all involved older adults and care professionals. During the data analysis, similar and confirmation of all findings appeared when analyzing and coding the transcripts. In preparation for the paper, the quotes in the raw data were translated into English.

Ethical Considerations

Ethics approval was obtained from the ethical advice committee of the University of Applied Sciences Saxion (reference number SEAC-2020-005). The participants were informed about the study before the start of the research period with Anne4Care. Thirteen participants gave written consent and were informed about their right to withdraw at any time. Data were anonymized, confidentiality was maintained, and the data will be retained for a period of 10 years after which they will be destroyed.

Results

Overview

The analysis of data revealed that the personal situation and perceptions of participants regarding access to dementia services and care (in short: care) were 2 underlying themes that described the adopter system from the older adult immigrants living with dementia. The code tree is presented in Multimedia Appendix 3.

Personal Situation

Personal situation considers the perceptions of older adult immigrants regarding their health status (physically and mentally), level of spirituality, quality of life, social and societal participation, and daily functioning. The personal lives of participants were diverse, with their immigration background as a main commonality. They were all born in another country and moved to the Netherlands for their work. Most of the participants worked in the textile or metal industry. The participants were all retired and visited the facility for daytime activities once or twice a week. On other days, their daily activities consisted of grocery shopping, housekeeping, or just doing nothing. Spirituality (eg, religion) was an important part of the lives of most participants. The physical and mental health of all participants is deteriorating, with illnesses that range in severity. In addition to dementia or acquired brain injury, some have health conditions such as diabetes, high blood pressure, and cataracts. These deteriorating health conditions had a major impact on their daily functioning as well as their quality of life. In the earlier years of their lives, some participants experienced challenges in participating in Dutch society, but this became even more difficult during the COVID-19 pandemic. Social relations were mainly with family members, and some had close contact with their neighbors.

> *Since I came here in the Netherlands, in the year 1977, I bought a house and since then until now I live in the same street, the same neighborhood with the same neighbors and this was always a very good network. It is a community with the Turkish and Dutch neighbors, in which I am a beloved man, I go to the mosque a lot and had several board positions for a while, such as a board member of the mosque.* [Participant H]

Care

Care refers to the perceptions of participants regarding access to dementia services and care in including all assistive and care needs of the participants. All participants acknowledged the fact that they became older and had increasing trouble taking care of themselves. Some participants had troublesome experiences with care in the past or could not find suitable and personalized care. In most cases, family members, partners, children, or neighbors assisted and provided support and care. However, most participants perceived this as a burden for their relatives and, therefore, was not a desirable situation.

> *Now there is someone who assists in housekeeping, and our children assist with the more administrative tasks. Next-door there are some younger neighbors who offered to help for example with the garden. I have a lot of help from all of them. However, in the past I had a lot of frustrations with health care professionals. When we arranged a time, they did not show up and none made any record of my needs. Then the agency went bankrupt and the clients were left in the dark.* [Participant G]

Acceptance of Anne4Care

In addition to the 2 underlying themes, the analysis of the acceptance of Anne4Care by older adult immigrants revealed four themes: (1) use of Anne4Care, (2) positive aspects of Anne4Care, (3) challenges with Anne4Care, and (4) expectations. In this section, results are presented for each theme. The code tree is presented in Multimedia Appendix 3. Multimedia Appendix 4 provides visual information about Anne4Care.

Use of Anne4Care

This theme refers to the acceptance and actual use of the digital personal assistant Anne4Care by older adult immigrants living with dementia in their own homes. The use of Anne4Care applies to how someone uses Anne4Care, what someone does with Anne4Care, and how health care professionals or families are involved. None of the participants knew or used an assistive technology similar to Anne4Care. All were unfamiliar with the existence of these types of digital assistive technologies. One participant acknowledged that technology like Anne4Care could assist health care professionals. In addition, the health care professionals underlined the potential of Anne4Care for supporting clients at a distance. Although the participants were unfamiliar with technologies like Anne4Care, they were familiar with technologies such as a doorbell with a flashlight or a talking clock, and 1 participant owned a robot vacuum cleaner.

> *I was so pleased when I saw the result, this robot really cleans everything. You can just leave your home and it will clean everywhere.* [Participant L]

Anne4Care was mainly used as a memory assistive tool, for appointments and medication.

> *It is very useful. Anne4Care tells me when I must take my medication. She helps me to remembers, she is tough and fun. I am very happy with it.* [Participant M]

In addition to the agenda function and medication reminders, the game, radio, and newspaper functions of Anne4Care were used or requested by some participants. A health care professional would need to be aware of participants’ requests in order to activate the radio or newspaper functions.

> *He would like to receive more radio channels. He has a Turkish music channel, but would like to receive Dutch channels as well. We can add these channels easily to the list, I will ask him at a later moment which he would prefer.* [Health care professional B]

Thus, the health care professionals and sometimes family were responsible for adding new functions as well as appointments in the agenda, and changes in the medication list. In the beginning, this costed time and was a source of burden. Some assistance to understand Anne4Care was needed at the start. However, after this initial adjustment, most health care professionals and families experienced the tablet as a task relieving as well as stress relieving. Anne4Care gave the reminders so that care partners did not have to keep track of everything during the day. Some participants admitted that continuous reminders from their partners made them angry, but reminders from Anne4Care were received more positively, causing fewer troubling situations at home. Furthermore, some participants preferred to update the agenda themselves if they could learn to work with Anne4Care. This feature is currently not possible with the platform.

> *I just need a keyboard to add appointments in my agenda. It is important for me to do this myself without any assistance, just some explanation and exercises in the beginning. It would be great if that would work!* [Participant E]

After a few months, 3 participants decided to stop using Anne4Care. Two participants did not see the additional value, Anne4Care did not give them any new tools, and 1 participant stopped using them due to illness.

Positive Aspects of Anne4Care

This theme refers to participant experiences regarding the advantages and benefits of Anne4Care. During the interviews, participants were asked to share the positive aspects of Anne4Care. The avatar of Anne4Care was received positively by the participants. Coincidentally, “Anne” is also the Turkish word for mother. Although Anne does not look like a Turkish mom, she gave a feeling that there was someone in their homes because she talks, makes movements, and looks like a nurturing health care professional. Another positive aspect was the choice of language. Most participants chose their native language because Dutch was progressively more difficult to use with age and since the onset of dementia. However, some participants chose the Dutch language intentionally in order to develop and maintain their Dutch language skills.

With regard to positive aspects, the participants commented on the functionalities of Anne4Care: video calling, agenda, medication reminders, games, radio, and newspaper. The most positive aspect of the video calling was the quality and the size of the screen (respectively 10-12.3 inch diagonal). They could see the other person more clearly on the tablet than, for example, on their smartphone. The most positive aspect about Anne4Care was the agenda function with the reminders of appointments and the medication reminder function. These reminders were very essential for the participants’ personal life and health. One health care professional explained that any event or task could be added.

> *Take for example the timing for their regular prayers. These are essential for someone’s life, and we can easily add these into the agenda.* [Health care professional]

Another participant talked about the assistance of Anne4Care in the daily cooking routine.

> *There are reminders when I need to start cooking, but also already before which groceries I have to purchase. After a while Anne4Care asks: ‘did you turn off the stove?’ That is very helpful and important for me.* [Participant K]

The game function was experienced as a fun activity to do during the day. Furthermore, the radio and newspapers provided by Anne4Care were perceived to be valuable. For example, some radio channels with music from their past gave the participants an opportunity to escape from their current time and place. The newspapers were seen as essential to keep up to date with current events; the read-aloud option was an asset.

> *It is wonderful that the radio and newspapers can provide the news into my home. The news keeps me up to date, and I also know what happens in Turkey where my family is.* [Participant H]

Challenges With Anne4Care

After using Anne4Care, the participants were asked about any challenges they experienced. As mentioned, the agenda and medication reminder functions were experienced as positive. However, the video calling option presented challenges. The main challenge was in making a connection with others. A video call required both the caller and receiver to activate Anne4Care. Therefore, all participants had to first send an SMS text message with their mobile phone to request the recipient to activate Anne4Care in order to receive a video call. With this extra step, most participants decided to simply use their mobile device instead of Anne4Care to make a video call. In addition, the newspaper and radio functions do not allow participants to search for radio stations, other than the ones preprogrammed.

> *I cannot find that newspaper, also the radio channel is absent. When I try to search, I get the massage ‘no stations available’, so there is nothing programmed I think.* [Participant B]

Another challenge was real interactions with Anne4Care. The participants expected the possibility to have a conversation, but that was not possible. Furthermore, part of this interaction was the commands to which Anne4Care often does not react. For example, when a participant asked Anne4Care for the time, or to call someone, Anne4Care may not respond. This could have been caused by the fact that Anne4Care did not recognize all the verbal commands in the Turkish language.

> *We cannot talk together, because she does not respond. Every morning I hear ‘good morning’, but that is it.* [Participant B]

The Anne4Care device itself presented some challenges. One challenge was the anxiety among participants for the devices to overheat, which caused the participants to turn off Anne4Care. Another challenge was the requirement for an internet connection at home. Some of the participants did not have internet at the start of the study. Internet access was provided to participants who did not have an internet connection at home during the study period. However, internet access is not free. Some of the participants are strapped for cash. This makes it difficult for them to pay for Anne4Care and an internet connection when the study ends. They have to make difficult trade-offs.

> *Now we are using Anne4Care for free, but in a couple of weeks there are probably some costs involved. We do not have Internet connection. I only have a mobile phone subscription with which I am happy. But I am also happy with Anne4Care, so the costs make it quite difficult to make a trade-off.* [Participant N]

Because Anne4Care is now only available with an internet connection at home, another challenge is to receive messages from Anne4Care when someone is outside. It would be great, for example, to transfer this with the Anne4Care message app on their mobile phone in case they are not at home. According to some participants, Anne4Care is currently a device only for people who are at home most of the day.

Expectations

This theme represents the ideas, wishes, and future plans of the participants for Anne4Care. In the beginning, some of the participants expressed anxiety toward Anne. They turned the tablet off at night because they thought someone could see or listen to them through the device. One of the new plans most of the participants came up with during the use of Anne4Care was the addition of an option to connect quickly to emergency care services. This connection could be activated by the user, but it should also be activated automatically when older adult immigrants living with dementia do not respond to a call within a period of time. Although all participants expected that Anne4Care would improve the health care of people with deteriorating health or dementia, their expectations were higher at the start.

> *Anne4Care needs to be improved. At the moment, it is too basic and does not meet the needs of some people. We can do more by ourselves, it is a bit of a disappointment.* [Participant D]

As mentioned, it is a challenge to use Anne4Care outside the home because the platform requires the internet. Outside the home, it would be helpful if people could receive medication reminders, therefore, this platform should also be compatible with their mobile devices.

> *It would be great if I could just take Anne4Care outside. Then I have my medication reminders when I am outside, she will tell me to take the medication and I could take them at the right moment.* [Participant M]

There were different ideas for new functions on the current Anne4Care tablet. For example, the addition of short movies or documentaries would allow it to be used for entertainment. Additions to the game function and more options, such as multiplayer games allow an older adult to play with a partner. A range of memory or language-related games, and more challenging puzzles would help meet user preferences. The memory and language games were specifically mentioned by several participants and health care professionals, because of the perceived benefits of cognitive engagement for older adult immigrants living with dementia.

Discussion

Summary of Findings

This study aimed to understand the acceptance of Anne4Care as perceived by older adult immigrants living with dementia using a citizen science approach. This study showed that although older adult immigrants living with dementia had no previous experiences with digital assistive technology specifically, the acceptance of the digital personal assistant, called Anne4Care, by these participants was rather high. Anne4Care was mainly used as a memory assistive tool, for appointments and medication. The use of Anne4Care at first increased the burden of health care professionals and families because health care professionals and sometimes families were responsible for adding new functions as well as appointments in the agenda and changes in the medication list. After the initial effort, most health care professionals and families experienced that Anne4Care reduced their tasks and stress. Contributions of Anne4Care included companionship, help with daily tasks, and opportunities to communicate in multiple languages. On the other hand, some participants expressed anxiety toward the use of Anne4Care and experienced challenges in the use of functionalities, for example, video calling and having real interaction with the avatar. Furthermore, the platform required an internet connection at home and Anne4Care could not be used outside the home.

Reflection on the Literature

The personal digital assistant, Anne4Care, offered companionship for older adult immigrants living with dementia and helped them perform daily activities. Participants mentioned that Anne4Care was very useful as a remember assistive tool, especially for appointments and medications. This finding is consistent with the results of previous studies about technology acceptance in rehabilitation and assistive technologies, and in health care technologies in general [28-30]. Technology acceptance models, for example, the Unified Theory of Acceptance and Use of Technology suggest that if performance expectancy is high, that is, people believe that technologies can help them to achieve their therapeutic goals or achieve their health expectations, this increases the acceptability and actual use of health technologies [31].

A key finding in this study was that participants believed that they did not have all the conditions to use and adopt Anne4Care for a longer period. These conditions are also known as facilitating conditions in technology acceptance theories, for example, the Unified Theory of Acceptance and Use of Technology [31]. Facilitating conditions include, for example, internet connection, technical infrastructure, as well as other internal support such as health care professional involvement and supporting staff (eg, availability of engineers to support the system) [32,33]. In our study, participants reported a lack of internet connection as a main limitation for the acceptance of Anne4Care. There is an extensive body of literature in the field of technology acceptance and use that points toward facilitating conditions as an important determinant factor in technology use [34]. Our result shows that to take full advantage of the potential of digital technologies like Anne4Care, these digital technologies should be accessible also to people of lower socioeconomic status which may have an influence on a person's autonomy and independence [35].

In our study, health care professionals were involved in using Anne4Care. These health care professionals had close contact and a trustful and respectful relationship with the participants. They played an important role in giving participants information and instruction regarding Anne4Care, in which they can be supportive of the acceptance of technology. Some participants were concerned about their privacy when using Anne4Care. They turned the tablet off at night because they thought someone could see or listen to them through the device. The important role of the health care professionals in this study warrants discussion. The health care professionals, all with a Turkish background, had the expertise to provide access and involve the participants. They were an important frame of reference and guided the participants whenever they received questions, or observed discomfort or doubts. Furthermore, they were key users of health care technology and had a positive attitude toward implementing the new technology. Research suggests that creating a positive, supportive atmosphere is instrumental to the sustainability of technology use [36]. Other studies describe that caregiver engagement is important for the everyday use of technology among people with dementia [33,37].

Although in recent years several technologies have been developed for people with dementia and their caregivers to support self-management, in our study none of the participants knew or used an assistive technology comparable to Anne4Care. All were unfamiliar with the existence of these types of technologies. Globally, there is an increasing aging population and more people staying longer in their own homes which has an impact on society and health care [38]. Although evidence shows that technology for people with dementia seems to stimulate cognitive function and communication skills and reduce loneliness [14,15,39], the implementation of technology can also contribute to the burden of health care professionals and informal caregivers. In our study, participants needed the assistance of health care professionals or families, which increased the demand for health care professionals and families. However, after this initial effort, most health care professionals and families experienced that the tablet facilitated their caregiving roles.

Immigrant populations typically have limited involvement in the development, refinement, and implementation of health care technology. This may be reflected in lower levels of adoption of health care technology. The citizens' science approach within this study was important for this specific target group. A citizen science approach calls for the optimal involvement of the target group as co-researchers. This extra time and dedication was positively experienced by the older adult immigrant group. It was mentioned that it felt like having a real purpose and gave a sense of fulfillment. This collaboration resulted in an alignment of the technology with the needs and practices of the participants. In future studies, the citizen science approach could also be applied in the development of new technologies as this study focused on the refinement of a technology for a specific target population. Citizen science for health and well-being could provide an effective way to involve vulnerable groups within society to participate in research.

Recommendations for Future Research

Future research could examine ways to increase the implementation of technology among older adult immigrants living with dementia and how to develop the technology competencies of clients, caregivers, and health care professionals. Furthermore, for future research conducting mixed method research using both qualitative and quantitative research methods is recommended to provide more insight into the added value of these kinds of assistive technologies for end users and professionals or family members.

Strengths and Limitations

Although we included only 13 older adults, they were involved in the entire process and collaborated with the researchers as well as with the other participants and their health care professionals. All older adults of the 2 organizations with whom the company Anne4Care started collaboration in the Twente region were invited for this study. The 13 participants who were interested in collaborating were all involved in this study. Another strength of our study was the quadruple collaboration. In our citizen science approach, there was active collaboration between the researchers, older adults, health care professionals, and the company that developed Anne4Care. However, we only involved older adults with an early-stage form of dementia, and 5 older adults were not able to join the second interview, due to COVID-19 illness. In addition, assessing exact levels of health literacy would have provided additional information about the influence of these kinds of assistive technologies on health literacy levels. Finally, a care professional was present and served as an interpreter. This may have impacted the quality of the data collected and nuances in the conversations may have been missed. On the other hand, the presence of the care professional ensured a safe and trustworthy environment.

In this study, a qualitative descriptive research design with a naturalistic inquiry has been used. Four themes were found to be related to acceptance of Anne4Care: (1) use of Anne4Care, (2) positive aspects of Anne4Care, (3) challenges with Anne4Care, and (4) expectations. Data saturation regarding the acceptance of Anne4Care was reached. During the data analysis, similar and confirmation of all findings appeared when analyzing and coding the transcripts. However, besides these 4 themes, there might be other factors relevant to the acceptance of digital personal assistant technology for older persons to stay safe in their homes and be able to age in place.

Conclusions

Although older adult immigrants living with dementia had no experience with digital assistive technology specifically, the acceptance of the digital personal assistant, called Anne4Care, by older adult immigrants living with dementia was rather high. In our study, older adult immigrants living with dementia learned and used Anne4Care with the help of family caregivers. Most older adults accepted Anne4Care into their lives in which Anne4Care offered companionship and helped them to perform daily activities. Older adults provided suggestions for the continued development of Anne4Care.

Acknowledgments

The authors thank the company Anne4Care, which made the device available for the research, and the health care professionals and participants for collaborating with us in every research phase and giving valuable insight. This study was powered by the Twente Regional Deal and received financial support from the Central Government's Regional Budget, the Province of Overijssel, the Region of Twente, and the Twente Board. The funders had no role in study design, data collection and analysis, the decision to publish, or the preparation of the manuscript.

Authors' Contributions

MB, CMvL, TJJO, ES, and ZM conducted the interviews. MB, CMvL, and TJJO performed the analysis of 2 transcripts and compared codes. Peer debriefing took place at weekly meetings with the project team when scientific and organizational aspects were discussed. All authors contributed to writing the paper and have approved the latest version of the paper.

Abstract

Background: Usability is a key indicator of the quality of technology products. In tandem with technological advancements, potential use by individuals with dementia is increasing. However, defining the usability of technology for individuals with dementia remains an ongoing challenge. The diverse and progressive nature of dementia adds complexity to the creation of universal usability criteria, highlighting the need for focused deliberations. Technological interventions offer potential benefits for people living with dementia and caregivers. Amid COVID-19, technology's role in health care access is growing, especially among older adults. Enabling the diverse population of people living with dementia to enjoy the benefits of technologies requires particular attention to their needs, desires, capabilities, and vulnerabilities to potential harm from technologies. Successful technological interventions for dementia require meticulous consideration of technology usability.

Objective: This concept analysis aims to examine the usability of technology in the context of individuals living with dementia to establish a clear definition for usability within this specific demographic.

Methods: The framework by Walker and Avant was used to guide this concept analysis. We conducted a literature review spanning 1984 to 2024, exploring technology usability for people with dementia through the PubMed, Web of Science, and Google Scholar databases using the keywords "technology usability" and "dementia." We also incorporated clinical definitions and integrated interview data from 29 dyads comprising individuals with mild Alzheimer dementia and their respective care partners, resulting in a total of 58 older adults. This approach aimed to offer a more comprehensive portrayal of the usability needs of individuals living with dementia, emphasizing practical application.

Results: The evidence from the literature review unveiled that usability encompasses attributes such as acceptable learnability, efficiency, and satisfaction. The clinical perspective on dementia stages, subtypes, and symptoms underscores the importance of tailored technology usability assessment. Feedback from 29 dyads also emphasized the value of simplicity, clear navigation, age-sensitive design, personalized features, and audio support. Thus, design should prioritize personalized assistance for individuals living with dementia, moving away from standardized technological approaches. Synthesized from various sources, the defined usability attributes for individuals living with dementia not only encompass the general usability properties of effectiveness, efficiency, and satisfaction but also include other key factors: adaptability, personalization, intuitiveness, and simplicity, to ensure that technology is supportive and yields tangible benefits for this demographic.

Conclusions: Usability is crucial for people living with dementia when designing technological interventions. It necessitates an understanding of user characteristics, dementia stages, symptoms, needs, and tasks, as well as consideration of varied physical requirements, potential sensory loss, and age-related changes. Disease progression requires adapting to evolving symptoms. Recommendations include versatile, multifunctional technology designs; accommodating diverse needs; and adjusting software functionalities for personalization. Product feature classification can be flexible based on user conditions.

usability; dementia; older adults; technology; concept analysis; mobile phone

Introduction

Improving Technology Usability for Dementia

Usability, a critical determinant of technology's quality, influences user acceptance and overall experience, with its importance magnified for individuals with mild cognitive impairment or dementia [1-3]. The intricate nature of modern technologies necessitates designs that accommodate cognitive limitations, ensuring accessibility and ease of use for this demographic. However, the specific usability needs of those with dementia are often not adequately defined given the condition's variability and progression [4]. This underdefinition underscores the necessity for technology products to be designed with a deep understanding of the cognitive, memory, and learning challenges faced by individuals with dementia. It is critical to ensure that technology is designed not only to be convenient but also to address specific needs and enhance usability across the spectrum of dementia types, thereby facilitating its adoption and effective use.

Worldwide, >50 million people are living with dementia, a number projected to triple by 2050 [5,6]. Every 3 seconds, someone is diagnosed with dementia, posing significant challenges to health care, care provision, and social services worldwide [7]. Technological interventions, including digital tools such as calendars and talking watches, assistive devices, and telecare, offer potential benefits by aiding daily function, improving safety, and enhancing social connectedness, thereby improving life quality and mood [8-11]. Moreover, these interventions can alleviate caregiver burden by providing monitoring and reminders, with a potential to supplement human care [8,12]. The COVID-19 pandemic has further highlighted the crucial role of technology in health care, emphasizing its importance in maintaining quality care [13]. In alignment with the World Health Organization's "Dementia: a public health priority" report, advancements in communication and assistive technologies have provided a variety of intervention methods to improve the lives and health of people living with dementia, including maintaining independent living and enhancing safety and autonomy [14].

However, technological solutions must be designed with the specific needs and abilities of people living with dementia in mind to avoid confusion, frustration, and potential rejection due to complexity or unintuitive interfaces [15,16]. The World Health Organization's 2022 policy brief on agism in artificial intelligence (AI) technologies underscores the importance of addressing stereotypes, biases, or discrimination in AI, ensuring quality care for older adults [17]. Tailoring AI technology to the diverse needs, desires, capabilities, and vulnerabilities of people with dementia is essential for harnessing AI benefits while mitigating risks [18]. Thus, considering the usability of technology for dementia care is paramount for successful implementation.

Challenges and Considerations in Technology Usability for Dementia Care

Addressing technology usability for individuals with dementia and their caregivers is recognized worldwide as a priority in national and international funding programs. Despite an increase in information and communications technologies (ICTs) for dementia care, standardized methods for evaluating ICT acceptance and usability for this demographic are lacking [19]. The technology acceptance model (TAM) and its subsequent evolutions, including the TAM 2 and the senior TAM (STAM), highlight perceived ease of use and usefulness as critical to technology adoption [20-23]. These models account for personal factors, such as cognitive abilities, and system features, such as product design and instructional support, emphasizing the adaptability of the latter to enhance usability [24,25]. Therefore, to reduce the digital divide, one of the current promising strategies is to start with product design, adopt user-centered design, and use machine learning techniques to provide timely prompts or suggestions to support and help users [24-26].

The limited adoption of digital technologies by individuals with dementia suggests that usability aspects related to product requirements and design have not been sufficiently addressed [27]. While technology usability research is advancing, there is a notable gap in literature specifically addressing the unique needs of individuals living with dementia [28,29]. This gap in clarity and consistency hampers the advancement of nursing and health science knowledge and the development of theoretical models in technology research [30]. To bridge this knowledge gap and enhance technology usability for dementia care, a concerted effort focusing on clear, tailored design principles and user-centered approaches is crucial.

Aims

This concept analysis sought to examine the usability of technology in the context of individuals living with dementia to establish a clear definition for usability within this specific demographic.

Methods

Overview

Multiple sources were used to delineate the definitions and key attributes of usability specific to people living with dementia. Using the method by Walker and Avant [31], this paper offers a detailed analysis of the essential attributes of usability in the context of dementia. Their methodology uses a 7-step process that facilitates a comprehensive understanding of a concept. The process is structured as follows: (1) select a concept; (2) determine the aim of the analysis; (3) identify all uses of the concept; (4) determine the defining attributes; (5) construct model, borderline, related, and contrary cases; (6) identify antecedents and consequences of the concept; and (7) define the concept's empirical referents.

For the literature review on technology usability for people living with dementia, works from 1984 to 2024 were searched in the electronic databases PubMed, Web of Science, and Google Scholar. The keywords applied were "technology usability" and "dementia."

To illustrate the usability considerations of technology for individuals with mild dementia, we drew the interview data from a pilot study conducted by the third author (CB). This study involved the design and evaluation of a web-based interface tailored specifically for this population [32]. This study initially enrolled 33 dyads consisting of individuals living with dementia and their care partners. A total of 4 dyads did not complete the study for various reasons, including health-related issues and the difficulty presented by the standardized survey scales for those with dementia. Consequently, the pilot of the web application was conducted with 29 mild Alzheimer disease dementia dyads, totaling 58 older adults (29 with mild dementia and their respective care partners, with all but 1 pair being spousal dyads). Following the pilot, each dyad was interviewed regarding their experience with the web application. The participant characteristics were as follows. The average age among those living with dementia (n=29) was 70 (SD 7.06) years, ranging from 59 to 82 years, with a male majority (18/29, 62% of individuals). Most were White (28/29, 97%), and 1 participant was African American (3%). The care partners (n=29) had an average age of 68 (SD 6.73) years, ranging from 55 to 83 years, with 38% (n=11) identifying as male. Most were White (27/29, 93%), with 2 (7%) Asian American participants.

Ethical Considerations

The interview data were drawn from a pilot study designed and evaluated by the third author (CB), focusing on a web-based interface specifically for people living with dementia [33]. The study was approved by the University of Washington Division of Human Subjects (STUDY00014226). Informed consent was obtained from all participants. The data are anonymous and have been deidentified. Each individual participant received a Visa gift card for US $150 for their time upon completion of the 3 study components.

Results

Concept Definition

As of now, there has been no comprehensive conceptual analysis concerning the usability of technology for individuals living with dementia. Consequently, to elucidate the use and implications of related concepts, an examination of various sources defining usability, encompassing dictionaries, organizations, and academic studies, is imperative.

Dictionary Definitions

Usability is an abstract and interdisciplinary concept. Merriam-Webster's Online Dictionary [34] defines usability as "the quality or state of being usable: ease of use." In the Cambridge Dictionary [35], usability is "the fact of something being easy to use, or the degree to which it is easy to use." The Oxford English Dictionary [36] offers the following definition: "the degree to which something is able or fit to be used." These descriptions collectively converge on a comprehensive understanding of usability as a measure of a product's accessibility and ease of operation. Specifically, when considering individuals living with dementia, the concept of usability is tailored to the degree to which a product is easy to use or suitable for use by people living with dementia.

Definition From the International Organization for Standardization

The introduction section of the guidance on usability by the International Organization for Standardization [27,37] presents one of the most universally acknowledged definitions of usability. According to the International Organization for Standardization standard 9241-11, usability is defined as "the extent to which a system, product, or service can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use" (part 11, paragraph 2) [37]. This delineation emphasizes the importance of a user-centered approach in evaluating how well a product or service facilitates the attainment of goals by individuals. Therefore, in assessing usability for people with dementia, the focus is on determining the degree to which the product or service enables effective and efficient goal achievement for this specific user group, underlining the significance of tailoring technology to meet their unique needs and enhance their quality of life.

Literature Definitions

While the studies reviewed did not offer explicit definitions of "usability for individuals living with dementia," the prevailing focus within the literature revolves around the examination and assessment of technology interventions tailored for this demographic. These interventions encompass a spectrum of tools and methodologies designed to gauge acceptance, adoption, and usability among individuals living with dementia. Thus, by analyzing the content of these articles, we can derive insights into the underlying characteristics and properties associated with usability in this context. The concept of technology usability integrates essential characteristics, including ease of use, satisfaction, learnability, utility, effectiveness, efficiency, flexibility, familiarity, responsiveness, and the clarity and visibility of feedback mechanisms [38]. This comprehensive understanding of usability encompasses both objective and subjective elements, considering objective performance indicators such as actual use efficiency, effectiveness, and error rates alongside the subjective user experience and perceptions [4]. The seminal work by Meiland et al [39] classifies usability into dimensions of "user friendliness" (marked by gratification and manageability), "usefulness" (satisfying the requirements and aspirations of individuals living with dementia), and "effectiveness" (promoting independence, coping strategies, and overall well-being). These efforts to operationalize usability take into careful consideration the end users' goals, encountered obstacles during task execution, and the selection of assistive technologies [40].

Research indicates that 40% of individuals with dementia require additional assistance and time to understand and use technological tools, including navigation through certain icons and devices. This underscores the necessity for facilitators or supervisors to aid in explaining operational steps and the use of technological intervention tools [4]. The analysis by Shultz and Hand [30] enriches our understanding of usability as the degree to which technology is perceived by users as learnable, efficient, and satisfactory. In parallel, Gibson et al [41] defined usability as the degree to which the user perceives acceptable learnability, efficiency, and satisfaction when using the technology. Gibson et al [41] advocate for a design philosophy that emphasizes personalized and adaptable support for individuals living with dementia, advocating against the use of generic technological solutions.

Further elaborating on these insights, Asghar et al [42] articulate how assistive technologies enable social interaction, health monitoring, independent mobility, and punctual medication adherence, thereby supporting daily living activities and enhancing the quality of life of those living with dementia. This perspective reiterates usability's core definition as ease of use, efficiency, and the capacity to meet specific user needs.

The investigative effort by Miguel Cruz et al [19] into the assessment methods for the acceptance, adoption, and usability of ICTs by people living with dementia and their caregivers highlights the critical gap in standardized evaluation methodologies. This gap signals the need for further research and development to measure such technologies effectively. Hence, usability for people living with dementia hinges on the extent to which they can use specific technologies effectively, satisfactorily, and safely considering their unique requirements and cognitive limitations.

In the domain of mobile app development [43], the initiative to enhance the quality of life of those living with dementia and Alzheimer disease by creating older adult–friendly apps is paramount. This initiative directly addresses the cognitive and usability challenges faced by this demographic, aiming to make technology both accessible and beneficial.

The usability of mobile apps is fundamentally tied to 9 thematic areas: user interface design, physical considerations, screen size, interaction challenges, meeting user needs, addressing the lack of self-awareness regarding app necessities, mitigating the stigma associated with app use, overcoming technological inexperience, and emphasizing the importance of technical support [32]. These areas highlight the critical need for developing intuitive, user-friendly apps tailored to the unique challenges encountered by individuals with dementia, thereby significantly enhancing their autonomy and quality of life.

Considering the specific needs and limitations of individuals with dementia or mild cognitive impairments when designing and implementing technological interventions is critical. Through appropriate support and assistance, their user experience and the effectiveness of the intervention can be improved [4]. Usability is related to user friendliness and ease of use and learning, serving as a means for older adults and those with reduced capabilities to participate in activities and engage equally in society. Highlighting the value of involving users in technology development and clinical trials, the design of intervention studies should include people with dementia and their caregivers to understand the design features necessary to enhance usability and acceptance [9].

Kung and Chen [28] conducted a concept analysis on the usability of health promotion mobile apps, summarizing the characteristics of usability. The most common attributes of usability identified in their study included efficiency, user satisfaction, and learnability [28]. These attributes are crucial for health promotion apps, ensuring that user expectations are met, providing satisfaction, and facilitating ease of learning and use. Textbox 1 organizes the characteristics of usability for people living with dementia from the literature review. Notably, ease of use, effectiveness, efficiency, and satisfaction were frequently mentioned across various studies; these attributes are generally recognized as core characteristics of usability across various fields, not just in the context of designing for people living with dementia. Other significant attributes that repeatedly appear in the literature on usability for people living with dementia include adaptability, personalization, intuitiveness, and simplicity, suggesting a comprehensive approach to addressing the unique needs and challenges faced by people living with dementia.

Textbox 1. Summary of the characteristics of the definition of usability for people living with dementia.

Sources and attributes of usability for people living with dementia

- Boulay et al [44], 2011: effectiveness, efficiency, and satisfaction
- Lim et al [45], 2012: intuitive, engagement, and adaptability to users' needs
- Meiland et al [39], 2012: user friendliness, usefulness, and effectiveness
- González-Palau et al [46], 2013: effectiveness, efficiency, and satisfaction
- Yamagata et al [43], 2013: ease of use, personalization, accessibility, adaptability, and engagement
- Boger et al [47], 2015: intuitiveness, simplicity, customization, and adaptability
- Manera et al [48], 2015: effectiveness, efficiency, satisfaction, and engagement
- Martins et al [38], 2015: ease of use, satisfaction, learnability, efficacy, coherence, flexibility, and responsiveness
- Lindqvist et al [40], 2015: ease of use, effectiveness, and adaptability to users' needs
- Shultz and Hand [30], 2015: learnability, efficiency, and satisfaction
- Ben-Sadoun et al [49], 2016: effectiveness, efficiency, and satisfaction
- Garcia-Sanjuan et al [50], 2017: effectiveness, efficiency, satisfaction, and engagement
- Meiland et al [51], 2017: effectiveness, efficiency, simplicity, intuitiveness, personalization, and engagement
- Tziraki et al [52], 2017: engagement, acceptability, and accessibility
- Asghar et al [42], 2018: effectiveness, adaptability, and satisfaction
- Holthe et al [9], 2018: effectiveness, efficiency, and satisfaction
- Gibson et al [41], 2019: adaptability, accessibility, and effectiveness
- Tuena et al [53], 2020: ease of use, intuitiveness, effectiveness, engagement, personalization, and adaptability
- Contreras-Somoza et al [4], 2021: effectiveness, efficiency, and satisfaction
- Engelsma et al [54], 2021: personalization, simplicity, clarity, engagement, and adaptability
- Koh et al [55], 2022: ease of use and engagement, customizability, and adaptability
- Neubauer et al [56], 2022: effectiveness, efficiency, simplicity, and satisfaction
- Miguel Cruz et al [19], 2023: simplicity and adaptability
- Ye et al [32], 2023: ease of use, accessibility, personalization, and effectiveness
- Zheng et al [57], 2023: effectiveness, efficiency, satisfaction, simplicity and clarity, and engagement
- Zhu et al [58], 2024: ease of use, accessibility, personalization, and engagement

Potentially Related but Distinct Concept of Acceptability

Acceptability of technology is the extent of the primary users' predisposition to implement the technology in their daily activities as a result of their diverse perceptions of the product's characteristics [59]. The primary users of technologies for people living with dementia may include individuals living with dementia or their care partners. Some studies have reported the technology acceptability of people with mild to moderate dementia and their caregivers. For example, an inaesthetic device may be interpreted as unacceptable because of its unappealing appearance and, therefore, has lower acceptability.

Describing Usability for People Living With Dementia From the Clinical Standpoint

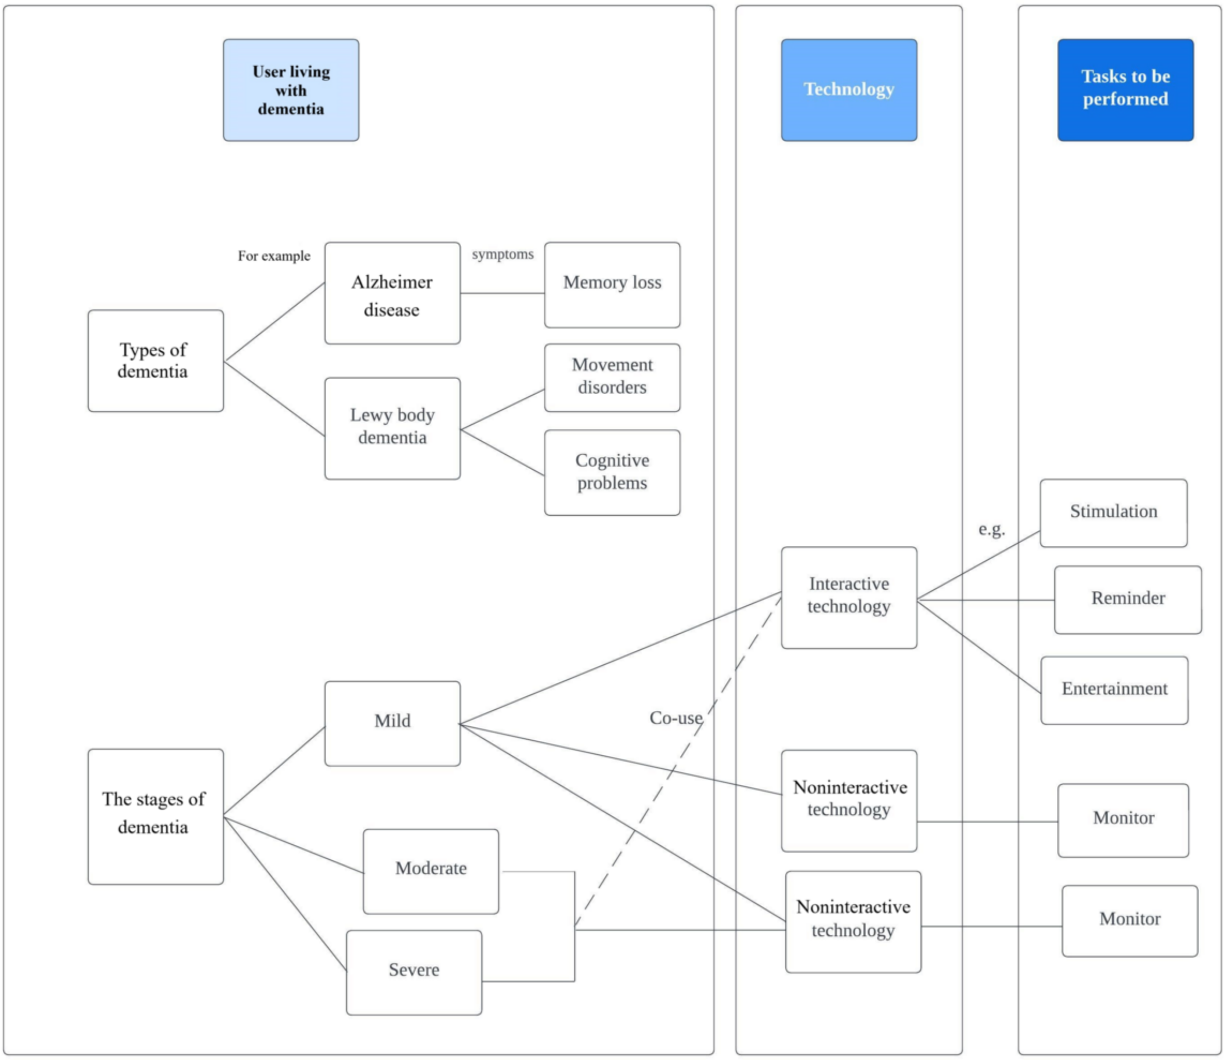
Dementia progresses slowly into 3 stages: mild, moderate, and severe, which can also be called early, middle, and late stages [60]. According to the Clinical Dementia Rating (CDR), there are different stages of dementia; based on an individual's cognitive functions, a 5-point system is used to describe each stage of dementia. A person in CDR-0 does not have dementia, and stage CDR-0.5 is considered very mild dementia or mild cognitive impairment, with slight but consistent memory problems. The expected duration of this stage is 3 to 7 years. Someone with CDR-1 has mild dementia. The average duration of this stage is 2 years, with memory loss, particularly recent events, and having trouble with the inability to perform daily tasks. In stage CDR-2, a person living with moderate dementia experiences more profound memory loss and is typically disoriented to time and place for the expected duration of 2 to 4 years. A person in stage CDR-3 is considered to have severe dementia. One might have multiple medical comorbidities, which often result in the end of functional independence. The average duration of stage CDR-3 is typically 1 to 2.5 years [60-63]. These stages help us understand how dementia may change over time and serve as a guide for the design of technology products at different stages, addressing different needs and usability.

Interactive technology refers to systems and devices that can respond to user inputs in real time, allowing for a dynamic exchange of information between the user and the technology. This domain of technology is characterized by the bidirectional provision and reception of information through actions such as language, text, movement, and touch. The key features of interactive technology include user input, real-time processing, and outputs that adjust based on user actions. Users communicate their requirements, and the technology delivers the results of their operations back to them through the interface [64,65]. Common forms of interactive technology, such as touch screens on smartphones, tablets, and information kiosks, as well as virtual reality, augmented reality, smart home devices, social media, and video games, enable users to directly interact with displayed content. Noninteractive technologies refer to products that do not require or allow for instant user input or feedback to operate. Unlike interactive technologies, which are designed to involve users in 2-way communication or interaction, noninteractive technologies, once activated or triggered, operate independently of user inputs. These technologies are often designed to perform specific tasks, display information, or execute commands without requiring ongoing user interaction. Television, smart speakers, sensors, static websites, and radio are typical examples of noninteractive technology. Operating interactive technology typically requires hand-eye coordination and precise control of the product, as well as reading or memorizing the steps or instructions on how to operate the technological product. It may even involve understanding complex user interfaces or executing multistep tasks to achieve the intended use of the product. Compared with the middle and late stages, people with mild dementia are still able to retain independence to complete many daily activities or do so with little assistance or guidance [60,66], and they are more likely to use interactive technology. For example, people living with mild dementia who attempt to have cognitive training using interactive tools to stimulate their cognitive functions might have one set of usability needs. The course of dementia is progressive, and when it enters the middle stage, people living with dementia have more profound memory loss. Their ability to cope with daily life becomes more complicated [60,66]. Due to the decline in memory functions and the ability to perform fine movements, the demand for technology products in the mid to late stages may be more often focused on noninteractive products due to usability issues.

In addition, different individuals may have different symptomology. There are different subtypes of dementia. Alzheimer disease and Lewy body dementia are the 2 most common progressive dementias. In addition to cognitive impairment, Lewy body dementia may be accompanied by muscle stiffness, hand tremors, and unsteady gait at an early stage [66]. A person with Lewy body dementia might have mobility issues that might imply the usability concern of motor activity, and someone with Alzheimer dementia might have issues with remembering instructions.

In short, from a clinical point of view, to look at the technology usability for people living with dementia, many factors require assessment, such as the stage, type, and symptoms of dementia. Furthermore, the categories of technology—interactive or noninteractive technology—should be considered based on the characteristics and needs of the disease, focusing precisely on the needs of tasks to be performed (Figure 1). In addition, people living with dementia retain certain relevant functions that are crucial for designers to consider. Despite the cognitive decline associated with dementia, individuals often maintain sensory and motor abilities provided they do not have other chronic conditions or age-related changes [67]. For designers, it is essential to recognize and leverage these retained functions when developing tools for this population. For instance, people living with dementia may be able to recall distant personal memories, which can be used in product design to evoke positive emotional and behavioral outcomes. By understanding and designing with knowledge of these maintained functions, digital tools can be better aligned with the abilities and needs of people living with dementia, thereby enhancing their engagement, enjoyment, and overall quality of life [67].

Figure 1. Factors affecting the use of technology for people living with dementia.



Definition From Interviews With People Living With Dementia

To illustrate technology usability considerations in people with mild dementia, we drew from a pilot study in which the third author designed and evaluated a web-based interface specifically for this population. In brief, the project aimed to investigate the experience of using a web application interface designed for people living with dementia and their care partners [33]. Its design complied with the criteria of the Web Content Accessibility Guidelines 2.1 at level AA, which is the standard for web accessibility developed by the World Wide Web Consortium. Components to enhance accessibility for people with sensory loss and with dementia included an audio option; screen reader compatibility; and clear, short sentences that avoided abstractions and multiple constructs. After conducting a pilot of the web application with 29 dyads of people with mild Alzheimer disease dementia and their care partners for a total of 58 older adults, each dyad was interviewed about their experience using it together. The interviewees indicated what they found positive about the web application that contributed to usability. They stated that they liked that the web application's interface was simple, clean, straightforward, and easy to use and that there were not too many options. The buttons were specific and clearly visible, and there were not too many distractions on the screen to create confusion. Participants appreciated how age-related vision changes were considered in the design. For example, the buttons on the web application were large enough, and the texts were of a size suitable for reading. Furthermore, because they could forget the operation steps or the functions of unmarked buttons, they found the clear and explicit wayfinding directions helpful and felt that they did not risk "getting lost" in the web application. Pilot participants further appreciated personalization options, such as open-text boxes to type in explanations so that the information could be entered in a familiar way. In addition, users said that they liked the app's summary feature, which reports the answers they chose for their future reference.

Many dyads of people with dementia and their care partners said that it was helpful to have an audio option, which read the text on the screen when selected while visually highlighting each sentence. It assisted people living with dementia in concentrating, and the care partners enjoyed not needing to read the text on the application aloud to their partners. Approximately

1 in 3 older adults experience age-related hearing loss, and their hearing sensitivity, especially high-frequency hearing, decreases gradually [68,69]. However, the ability to hear low-pitched sounds is often not affected [70]. Therefore, the web application used a male-sounding (lower) voice for reading, which can be heard more clearly by older adults. This and other age-related physiological changes are factors that must be taken into account as dementia is associated with older age [5].

Finally, in the usability-testing phase, the pilot found that it was sometimes challenging to obtain feedback from people living with dementia on the web application within a few days due to short-term memory difficulties. Some participants noted that they were unable to remember details of their experience or the web application well enough to report on it. Hence, to understand the user experience, it is necessary to find creative solutions such as soliciting real-time feedback during or immediately after using the application.

Defining Attributes

Overview

Following the approach by Walker and Avant [31], after the concept of usability is defined, its essential attributes must also be defined. Particular attributes are mentioned repeatedly in the literature and can be used to distinguish this concept from those that are similar or related. The current definition and characteristics of usability are not entirely applicable to individuals with dementia. Therefore, this study synthesized a definition of usability for patients with dementia based on multiple resources, including dictionaries, a literature review, and data from interviews with people living with dementia and their caregivers. In addition to ease of use, effectiveness, acceptable learnability, and satisfaction, special attention is required for dementia symptoms and aging. Personalization becomes a crucial attribute, with adaptations based on dementia stages, subtypes, and symptoms. It emphasizes the value of simplicity, clear navigation, age-sensitive design, and personalized features, making the design of the technology or interface more specific and intuitive.

Constructed Cases

The application of technology to people living with dementia can be divided into the following five categories: (1) cognitive training and daily living, (2) screening, (3) health and safety monitoring, (4) leisure and socialization, and (5) navigation [71]. Selected clinical cases are listed herein to clarify and illustrate the concept of usability for people living with dementia. The case scenarios presented in this study are a combination of adapted cases from the first author's previous clinical work and fictional scenarios, and all mentioned names are of a fictional nature. On the basis of the work by Walker and Avant [31], the exemplar case contains all the defining attributes of the concept. The borderline case possesses not all but most of the defining attributes of the concept, and the related case is related to the main defining attributes but does not contain all of them. In addition, a contrary case that has no defining attributes of this concept but is contrary to it is presented.

Exemplary Case

Mr Wang is a patient who was diagnosed with mild dementia 6 months ago. He experiences memory impairment, has difficulties in concentration, becomes lost easily, frequently forgets to lock the door and turn off the tap, is unable to plan trips or prepare meals as he once could, and often feels depressed. Nevertheless, he can maintain his daily life. To delay deterioration, stimulate the brain, and relieve emotional distress, his nurse provided him with a tablet computer. A total of 11 apps were preinstalled on the tablet computer based on 3 categories. The creative (art and music) app enables users to produce artwork on a blank canvas by accessing various brush types and a wide array of colors. Simple interactive games allow users to interact with virtual animals that respond to a user's touch and gestures. Relaxation apps allow users to play relaxing background music while the tablet screen displays nature pictures [45].

After 30 minutes of demonstration, guidance, and practical exercises by the nurse, Mr Wang learned how to operate the device, including turning it on and off, charging it, adjusting the volume, navigating the home screen, and starting and exiting apps. He also received a cell phone to contact someone in case of any operation problems. After completing the standard training checklist, Mr Wang returned home with the tablet and used it for 7 days to evaluate it and the apps' effectiveness.

The nurse invited Mr Wang's primary caregivers to observe the status of his use of the device. Mr Wang used the tablet computer for an average of 50 minutes per day, which exceeded the recommended 30 minutes. Mr Wang expressed satisfaction with using the tablet and the apps and was willing to continue using it. According to his caregivers' observations, Mr Wang spent more time on interactive gaming and listening to music. He spent an average of 15 minutes independently using the tablet, and he was able to independently store and charge it. Use of the tablet also enhanced his emotional stability.

Borderline Case

A person living with mild dementia tried to use a mobile app to buy train tickets, and their caregiver, also an older adult, assisted him in its operation (co-use). However, the app's user interface was complicated to operate. They were finally able to buy the ticket using the app, but the process was too time intensive. This scenario involves a user living with dementia, technology, tasks to be performed (buying train tickets), and the consequences of co-use with the patient's caregiver. The patient used the app several times afterward and became more proficient, indicating that the operation of the app is learnable for a person living with dementia. Moreover, compared with visiting the train station to purchase train tickets directly, using the app to buy tickets is more efficient. Although the purpose of using this tool was achieved, that is, it is applicable, the patient was dissatisfied with the complex and time-intensive user experience; therefore, the satisfaction attribute was not met.

Related Case

Mrs Smith has a diagnosis of mild dementia and lives with her family. Her daughter assisted her in downloading a diet and fitness app on her tablet computer to track nutrition, fitness, and health data. The app offered a menu and colorful photos of various diet types as well as daily exercise videos to follow. In addition, users could upload pictures and share their progress and weight control results in the app's discussion forum, where other users could "like" and comment on the posts.

Mrs Smith enjoyed using the app for its vivid food pictures, animated exercise videos, and users sharing positive posts related to fitness progress on the forum; she felt delighted and vibrant when "liking" forum posts. For Mrs Smith, this app was useful, engaging, and a source of pleasure in her life. Hence, usefulness was present as a defining attribute. However, she could not comprehend how to record diet and health information because the operation interface was too difficult to use; the app lacked the learnability attribute. In addition, the app did not achieve the expected outcomes of its design (healthy diet and fitness), although effectiveness was not included as a defining attribute in this case. Despite this, Mrs Smith was satisfied with using this app, fulfilling the satisfaction attribute.

Contrary Case

A patient with severe dementia lives in a long-term care facility and is cared for by nursing staff. Because of his age and symptoms, this patient has a high risk of falling. The staff assisted in outfitting the patient with a medical alert necklace that automatically sent messages to set recipients if the patient had an emergency, such as a fall. Because this product has an automatic detection system, the patient is not required to learn how to use it, and no learnability attribute is present. The patient himself was unable to understand the function and benefits of the product as a result of the deterioration of his cognitive function; he thought something uncomfortable was stuck on his neck and often removed the necklacelike detector. Despite staff perception that it was essential to his personal safety, he was dissatisfied with it. He often removed the detector and failed to carry it, reducing the usefulness and effectiveness of the product.

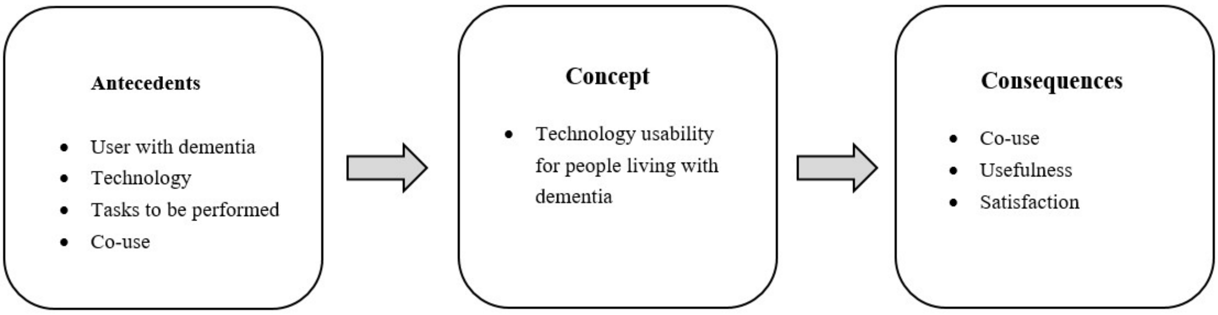
Antecedents

The antecedents of usability for people living with dementia encompass a complex interplay among the individual living with dementia, the technology in use, the tasks to be performed, and the concept of co-use. The usability concept for people living with dementia is profoundly influenced by a complex interplay of social, environmental, and personal factors. The unique needs and capabilities of people living with dementia present various variables that affect usability, making the user living with dementia the most relevant antecedent. However, beyond the individual user, it is essential to consider the broader context of technology use. This includes the availability of space, the skills and knowledge required to operate the technology, existing support systems (such as caregivers or health care professionals), and the financial resources needed to access the technology. Furthermore, depending on the severity of dementia, patients may face greater challenges in using technological tools independently, necessitating co-use or shared use with their caregivers [72]. The concept of "co-use" underscores the importance of social dynamics in usability.

Consequences

The consequences of people living with dementia using technology include co-use, usefulness, and satisfaction. As progressive and irreversible cognitive impairment can affect the capability of people living with dementia to operate technological products, being able to co-use the products is one of the criteria of the consequences of the concept of technology usability. On the basis of the varying degrees of dementia severity, patients who exhibit more pronounced symptoms often encounter greater challenges in independently using technological tools. This situation necessitates a collaborative approach where co-use or shared use with caregivers becomes essential. The need for such support intensifies as the severity of the dementia increases, highlighting the importance of adaptable technological solutions and the involvement of caregivers in the use process to ensure effective and safe interaction with these tools [72]. In addition, the research by Astell et al [73] on the use of interactive multimedia touch screen systems for people living with dementia found that interacting with caregivers through touch screen tablets was intriguing and engaging for people living with dementia. These consequences are similar to the attributes that define usability. Nevertheless, the consequence of usability is the result of the direct evaluation of specific technological applications by people living with dementia, including co-use, perceptions of usefulness, and satisfaction [30] (Figure 2).

Figure 2. Overview of antecedents, attributes, and consequences of technology usability for people living with dementia.



Empirical Referents

Overview

A deeper understanding of the concept of technology usability for people living with dementia can be used as a reference index for clinical practice in assisting those living with dementia in locating suitable technological interventions that promote a healthy and comfortable life. Although the exact definitions and testing of usability vary for different products, their effectiveness is reflected in the actual user operation, that is, whether the device achieves its main goal and is satisfactory for the users (people living with dementia). When testing usability, certain elements must be considered, such as the target users; their learning abilities, desires, and needs; the environment in which they operate; and what advantages the product offers [73]. Usability evaluation methods include quantitative methods such as questionnaires and task completion and qualitative methods such as the "think-aloud" protocol, focus groups, and interviews [74].

Think-Aloud Methods

Among the evaluation methods, the think-aloud (or thinking-aloud) protocol is the most commonly applied qualitative method used to collect data in usability testing. Users are required to speak their thoughts, actions, and perceptions aloud while operating a product, with observers objectively recording the user's speech verbatim without interpreting their behaviors or statements [75]. Customarily, the test is filmed for developer review; developers observe the user process of operating the product as well as users' response to ascertain their experience of the application [76].

System Usability Scale

This is the most widely used and validated questionnaire and comprises a 10-item Likert scale. This simple, standardized questionnaire is advantageous for its objectivity, generality, repeatability, and quantifiability. The questions focus on frequency of use, complexity of operation, consistency, degree of preference, and achievability of the product goal [77]. However, because the think-aloud protocol has higher demands of cognitive load for people living with dementia [76] and the System Usability Scale, a posttest tool, cannot reflect how people living with dementia interact with technology products timely, there is currently no clear, standardized method to assess usability for people living with dementia. Hence, there is still a higher need to design more consistent and reliable evaluation instruments for people living with dementia [19,76].

Observation and Logging

Other primary methods for evaluating usability for people living with dementia are observational methods and logging, which present more objective data, with observations enhanced by video recordings for more reliable results [32,76]. However, observer bias, the presence and perceptions of the observer, can influence both the observer's interpretations of what is seen and possibly the behavior of the participants being observed.

Therefore, it is advised to combine both objective and subjective measures for a comprehensive understanding of usability needs [78,79] and consider the aims of the research to select the proper measuring tool.

We suggest that, when considering usability for people living with dementia, it is necessary to understand the characteristics of users. First, the symptoms and needs of dementia at each stage, the designing purpose, and the tasks to be performed should be understood. Furthermore, dementia mostly affects older adults, so corresponding designs should take into account diverse physical needs, potential sensory loss, and other age-related changes. In addition, primary caregivers spend a lot of time and energy accompanying and caring for people living with dementia. Their firsthand observations, insights, and opinions can be informative when testing products, particularly for technology products designed for co-use. As the disease progresses, changes in condition and symptoms need to be considered. Another suggestion is to design diversified and multifunctional technological products to provide more inclusive and flexible choices and adjust software features to meet individual needs. Product function classification could be upgradable or downgradable as the condition of the user changes, and these functions could be selected by the user.

Furthermore, Sebastian et al [80] have raised a question about the potential of rhetoric in enhancing the adoption of AI; their study results suggest that the adoption of strategic communication techniques (ethos, pathos, and logos) can significantly impact people's willingness to accept AI technologies. Our conceptual analysis also acknowledges the importance of effective communication strategies in facilitating technology adoption. This insight is particularly significant in technology adoption among individuals living with dementia, where trust in and understanding of technology plays a crucial role. Therefore, future research could explore how customized communication strategies based on rhetorical principles can address the concerns and needs of people living with dementia and their caregivers.

Discussion

Clarifying and Validating the Concept of Usability for Individuals With Dementia

To our knowledge, this study represents the first concept analysis specifically focused on usability for individuals with dementia. This paper integrates existing literature and combines empirical data obtained from interviews to relate the concept to specific real-world situations. It offers insights into usability within the context of dementia, covering its practical significance and applications as well as directions for future research.

The concept of usability, particularly for individuals living with dementia, demands a nuanced understanding that accounts for the rapid advancements in technology and its increasing application in supporting these individuals and their caregivers. The specific needs of individuals with dementia, tailored to accommodate common symptoms and optimize their capabilities, underline the critical need for a precise and comprehensive definition of technology usability within this context.

Usability is acknowledged as a multidimensional construct that becomes tangible only when technology is actively used by individuals. The variability of the usability definition, contingent on the context and specific application field, presents a challenge in achieving a unified conceptualization [19,81]. This challenge is further compounded for individuals living with dementia due to the complex interplay between the severity and subtype of dementia and specific technological requirements, including the necessary level of interactivity, technical characteristics, and intended tasks.

Given the diverse severities and progression rates of dementia, individuals experience varying needs across different stages of the condition, necessitating distinct technological interventions and, consequently, different usability requirements at each phase. Therefore, as delineated in Textbox 1, beyond the standard usability attributes—ease of use, effectiveness, efficiency, and satisfaction—additional attributes pertinent to individuals living with dementia include intuitiveness, simplicity, personalization, and adaptability.

Intuitiveness refers to the ease with which users can understand and interact with technology or an interface without previous instruction. When technology is intuitive, individuals living with dementia are more likely to use it independently, fostering a sense of autonomy and confidence. Simplicity, on the other hand, emphasizes clean design and straightforward functionalities that avoid overwhelming the user. It ensures that the cognitive load is minimized, which is particularly important given the cognitive challenges associated with dementia. Together, these attributes create a user-friendly environment that supports the engagement and sustained use of technology by minimizing frustration and maximizing ease of use.

Personalization significantly enhances usability and the overall user experience. Although not a traditional usability attribute, it reflects an understanding of the variability in dementia symptoms and stages, requiring solutions tailored to the individual's changing needs. This approach specifically addresses the challenges associated with various stages and types of dementia. Adaptability complements this concept by ensuring that technology can adjust to the user's changing condition over time, particularly as dementia progresses.

Exploring the Integration With Existing Theoretical Frameworks

The TAM posits that perceived ease of use and perceived usefulness are the 2 main factors affecting one's beliefs, intentions, and attitudes toward using novel technology [20,21]. These factors become even more significant in the context of technology development for patients with dementia, where cognitive impairments necessitate a more detailed and specific consideration of usability. This underscores the need to optimize technology products based on the specific abilities of users. Venkatesh and Davis [22] developed the TAM 2, an expansion of the original TAM, which highlights the importance of social influence and cognitive instrumental processes in technology acceptance and use, including aspects such as subjective norms, voluntariness, and individual experiences. These factors may play a crucial role in determining whether patients with dementia are willing to adopt certain technologies. However, for individuals with dementia, the usability of technology products is particularly critical as they may encounter specific challenges in cognition and perception that are not as pronounced in the general user groups highlighted by the TAM and TAM 2. This means that, for this unique population, perceived ease of use and perceived usefulness remain critical factors but there is also a need to further consider how products can be designed and supported to meet their specific needs.

The STAM, built on the foundation of the TAM and specifically designed to address the needs of older adults, including those with dementia, focuses on technology adoption among older adults [23]. The STAM maintains that perceived usefulness and ease of use, key factors in technology adoption across different age groups, are especially critical for older adults. Moreover, it adds that gerontechnology self-efficacy, gerontechnology anxiety, and facilitating conditions, which are age-related health and ability characteristics more relevant to older adults, are vital in designing technology products for patients with dementia. These considerations emphasize the necessity of considering their cognitive limitations and technology use experience as well as how to minimize barriers to technology use through facilitating conditions.

Therefore, based on the usability for people living with dementia, it is suggested to develop or expand the existing TAMs and theories by (1) incorporating specific factors related to cognitive impairments, adding variables related to cognitive load, information processing speed, and memory retention capabilities; (2) considering contextual and environmental factors such as the home environment, support from care institutions, and the impact of social and cultural backgrounds on technology acceptance and use; (3) emphasizing the importance of user experience design, especially in terms of how design can reduce anxiety and boost confidence among users with dementia, thereby promoting technology acceptance [4]; and (4) focusing on personalized and adaptive design for patients with dementia, expanding the model to include principles of adaptability and personalization according to individual differences, considering the varying needs of people at different stages of dementia [32].

Recommendations for Standardized Usability Testing for People Living With Dementia

We recommend that, when developing a standardized usability test for people with dementia, it is essential to integrate several elements, particularly considering the progression and variability of symptoms. In addressing the usability attributes relevant to people living with dementia, the use of adaptive testing methods is advised. These methods involve designing usability tests that can be customized for different stages of dementia, adjusting protocols based on the cognitive, physical, and emotional states of participants. Due to the progressive nature of dementia, regular re-evaluation is necessary. Immediate feedback after testing is important due to short-term memory difficulties in people living with dementia. To prevent attention deficits or fatigue in people living with mild to moderate stages of dementia, testing durations should be limited as participants might become distracted and fatigued after 30 to 35 minutes of continuous dialogue [33]. Inclusive design principles must consider a broad range of abilities and limitations, ensuring test accessibility for various dementia stages. Finally, collaboration with experts such as health care professionals and dementia specialists is vital for deeper insights into the needs and challenges of people living with dementia.

Potential Frameworks for Usability Assessment for People Living With Dementia

Furthermore, given the unique needs and challenges faced by people living with dementia, addressing the need for a standardized usability assessment specifically tailored to them is important. Some potential frameworks or methods that could be considered or developed for this purpose include, first, human-centered design approach. In this approach, the focus is on involving people living with dementia and their caregivers in the design process by adopting a human-centered design for the intervention, involving an interactive development process that focuses on the users and their needs and requirements [82]. This could include interviews, focus groups, and usability testing sessions with prototypes [74]. Participants are the ones who understand their needs best; using this method, they will also be the designers, involved in the designing phase. It is crucial to incorporate their feedback into the development process to tailor the product to meet their specific capabilities, needs, and preferences. The second potential method is contextual design and observational studies. This method consists of observing people living with dementia interacting with technology in their usual environment. It helps understand how they use technology, what challenges they face, and what aspects of the technology are most beneficial or problematic for them [83]. The third method is heuristic evaluation, a method in which usability experts analyze a product using a set of 10 heuristics [84] and that can be adapted for people living with dementia by involving dementia specialists and usability professionals [85]. The fourth method is longitudinal studies. As dementia is a progressive condition, longitudinal studies can be valuable in assessing how usability needs change over time and how well technology adapts to these changing needs.

Limitations and Future Research Directions

Despite obtaining rich information through interview data, this research still has limitations. One of the limitations is the high homogeneity in terms of the participants’ race and ethnicity, which could potentially impact the generalizability of the research findings. In addition, it is suggested that future research collect data on participants’ educational background and socioeconomic status as these factors may be related to their willingness and ability to use technology products.

Conclusions

This study, through a concept analysis that included interviews with people living with dementia and their caregivers, clarified the definition and attributes of usability tailored for this population. A precise definition of usability in this context is crucial to guide future research and practical applications. This study stresses the importance of considering dementia-specific aspects such as the symptoms and aging process. Customization, guided by the disease’s stages, subtypes, and symptoms, is emphasized as critical. Therefore, the design of interventions for individuals with dementia should prioritize simplicity, clear navigation, age-appropriate esthetics, and personalization to enhance specificity and intuitiveness. Furthermore, it is necessary to consider the antecedents, attributes, and consequences of technology usability for this demographic. Adopting a comprehensive approach is pivotal for developing technology solutions that are finely attuned to the unique needs of people living with dementia, fostering a nuanced understanding of usability in this context.

Acknowledgments

The authors wish to express their sincere gratitude to the McLaw Scholarship, the University of Washington School of Nursing Digital Health Innovation Hub, and the Aljoya Endowed Professorship in Aging for their generous support. The dyadic pilot study was supported by the Alzheimer’s Disease Research Center of the University of Washington [P30AG066509] and the National Institute on Aging (K01AG062681). The financial assistance provided by these entities has been crucial in advancing the authors’ research and enriching their contributions to the field. They also extend their appreciation to the reviewers, whose insightful comments and suggestions significantly enhanced the quality of this manuscript.

Data Availability

The data sets analyzed during this study are not publicly available due to the reuse restrictions outlined in the consent form.

Abstract

Background: Maintaining exercise is essential for healthy aging but difficult to sustain. EngAGE is a socially motivated exercise program delivered over a voice-activated device that targets older adult–care partner dyads.

Objective: This 10-week pilot study aimed to assess EngAGE feasibility and use, obtain user experience feedback, and estimate potential impact on function.

Methods: In total, 10 older adults aged ≥65 years were recruited from an independent living residence together with their self-identified care partners. EngAGE delivered National Institute on Aging Go4Life exercises to older adults daily, while care partners received progress reports and prompts to send encouraging messages that were read aloud by the device to the older adult. Older adults' use was tracked, and physical function was assessed at baseline and follow-up. Follow-up focus group data provided qualitative feedback.

Results: On average, participants completed 393.7 individual exercises over the 10-week intervention period or 39.4 exercises/wk (range 48-492, median 431, IQR 384-481, SD 112.4) without injury and used EngAGE on an average of 41 of 70 days or 4.1 d/wk (range 7-66, median 51, IQR 23-56, and SD 21.2 days). Mean grip strength increased nonsignificantly by 1.3 kg (preintervention mean 26.3 kg, SD 11.0; postintervention mean 27.6 kg, SD 11.6; P=.34), and 4 of 10 participants improved by a minimal clinically important difference (MCID) of 2.5 kg. Further, the time for 5-repeated chair stands significantly reduced by 2.3 seconds (preintervention mean 12, SD 3.6 s; postintervention mean 9.7, SD 2.7 s; P=.02), and 3 of 9 participants improved by an MCID of –2.3 seconds. Furthermore, 3-meter usual walk performance was brisk at baseline (mean 2.1, SD 0.4 s) and decreased by 0.1 seconds (postintervention 2, SD 0.4 s; P=.13), although 5 of 9 participants improved by a MCID of 0.05 m/s. Qualitative results showed perceived benefits, favored program features, and areas for improvement.

Conclusions: We present a pilot study of a new voice-activated device application customized to older adult users that may serve as a guide to other technology development for older adults. Our pilot study served to further refine the application and to inform a larger trial testing EngAGE's impact on functional outcomes, a necessary step for developing evidence-based technology tools.

Introduction

Voice-activated devices offer the possibility of assisting the rising number of older adults with maintaining physical and cognitive function, enhancing social connectivity, and accessing health and social resources from their homes [1,2]. Voice-activated devices reduce technology interface barriers by allowing users to simply talk to interact with a device [3,4]. They have shown promising early acceptability, use, and adoption among older adults, including low-income older adults [5-7]. Given the ease of use and early acceptability, commercial health care platforms incorporating a voice-activated element are on the rise [8,9]. However, the development of evidence-based health content tailored to older adults for use with voice-activated devices is in its infancy. As a result, no examples of developing voice-activated device programs for older adult users are in the literature to serve as a participatory design template.

EngAGE is a novel exercise program customized for older adults that is delivered over an Amazon Echo Show voice-activated device. The program has dual and interconnected aims to improve the physical functioning and social engagement of older adults. EngAGE supports physical functioning by delivering daily exercise routines from the National Institute on Aging (NIA) Go4Life program [10] to older adults in their home. EngAGE supports social engagement by leveraging meaningful social relationships to provide active social reinforcement that encourages behavior change [11], to provide occasions for additional social contact, and to provide passive safety oversight. EngAGE uniquely targets older adult–care partner dyads as paired users, providing a complementary resource that supports both roles. EngAGE was co-designed with older adults and their care partners through iterative, participatory design to ensure ease of adoption and meaningful content—a strategy recommended by experts in the field [12,13]. First, the concept was informally discussed with >40 stakeholders in the field through 1:1 conversations for feedback. Second, static wireframes representing possible program features were presented to predominantly minority older adults and care partners residing in the community around the University of Chicago for feedback in co-design focus groups or 1:1 interviews for homebound participants. Finally, a prototype was presented to predominantly minority older adults and care partners residing in the community around the University of Chicago for feedback in focus groups. At the final set of co-design focus groups, participants were asked to interact with the prototype as well as use a draft command tip sheet. At each stage, feedback was incorporated into the program.

As an extension of our participatory design process, we conducted a pilot study to (1) determine the feasibility of in-home administration of the EngAGE program to older adult–care partner dyads; (2) quantify the use of EngAGE during a 10-week intervention phase; (3) obtain qualitative feedback on the perceived program benefits, favored program features, and areas for improvement; and (4) estimate the potential impact of the EngAGE program on functional outcomes. These findings have relevance to clinicians and researchers exploring the utility of voice-activated devices to deliver health care resources to older adults, and to technology developers seeking to contribute useful and usable voice-activated device tools for the delivery of older adult health care resources. In an era of increasing reliance on telehealth and remote health care delivery and a shortage of geriatrics-trained health care workers [14], we anticipate a growing need for easy-to-use digital interventions for physical, social, and all other aspects of health for older adults and their care partners. Voice-activated devices are candidate technology vehicles for delivering health care programming that may be particularly suited for older adult users; however, deploying participatory design and collecting user input in feasibility studies such as this one help ensure that interventions align with older adults' own preferences, lifestyle, and priorities to support adoption.

Methods

EngAGE

EngAGE is a program that delivers socially motivated exercise routines tailored to older adults in their home on voice-activated devices. The corresponding application was optimized for an Amazon Echo Show or Amazon Fire tablet but can be used on any Amazon Alexa device. It is currently not adapted for use on any other platform (eg, Google Nest). We contracted Orbita, Inc, which is a preferred Amazon Alexa programmer company, to program our EngAGE application. EngAGE leverages a software platform created by our programming partner [15] that has three user portals: (1) a browser, (2) a mobile app, and (3) a voice-activated device. Older adult users primarily interface with the voice-activated device, while care partners interface entirely with the browser and mobile application.

Older adult users activate EngAGE using voice on their screened Alexa device (eg, "Alexa, start EngAGE"). Once started, EngAGE then reads aloud any new messages from their care partner (eg, "You have a new message from [NAME]. Great job doing your exercises! Can't wait to see you this weekend!"). Following this communication, EngAGE delivers exercise routines that alternate daily. The exercises were selected from the NIA Go4Life program [10] and were designed to be carried out with equipment found in the home (Table S1 in Multimedia

Appendix 1). The subset of exercises was selected in consultation with a physical therapist who specializes in aging; they target critical, major muscle groups needed for daily functioning. For each exercise, EngAGE provides audio and visual instructions (eg, “Let’s start arm curls. Find some hand weights, water bottles or soup cans. Stand up. Hold the weights straight down at your sides, palms facing forward. Slowly bend your elbows and lift the weights toward your chest. Keep your elbows at your sides. Hold this position for 1 second. Slowly lower your arms. Do ten arm curls.”) and displays an image of a person completing the exercise. Each exercise is then accompanied by rhythmic music allowing the older adult time to perform the exercise on their own. A total of 13 strength, flexibility, and balance exercises are divided into 2 routines of 6 and 7 exercises each. Each routine begins with a 3-minute warm-up of walking around one’s home or in place. Alternating routines target different muscles to avoid overuse if completed daily. All older adult users are started at a very low intensity with the lowest number of repetitions for each exercise. Users rate the exercise difficulty after completion of each unique exercise. EngAGE then auto-adjusts the number of repetitions for that exercise in subsequent sessions. For example, if an exercise was rated “too easy” 3 times in a row, the number of repetitions would subsequently increase. On the other hand, if an exercise was rated “too difficult” one time, the number of repetitions would subsequently decrease. This process both enables gentle increases in difficulty to promote muscle building and protects against injury that could come from too rapid of a progression.

Care partners interface with the website or mobile app to view their paired older adult’s daily recommended exercise routines and to monitor exercise completion. They also receive a daily email with a summary of exercises completed, whether any exercise was rated “too difficult” by the older adult (as a safety feature), and a prompt to send an encouraging message via the website or mobile application to be read by the older adult’s voice-activated device.

Study Design

We conducted a 12-week pilot study between May 13, 2019, and August 19, 2019, to test the feasibility and to estimate the use and potential functional impact of EngAGE among older adult–care partner dyads. The results from this pilot study were used to inform a randomized clinical controlled trial. Baseline survey and physical performance measures were assessed in person and in the homes of older adult participants. The 12-week pilot was divided into 2 phases: a 2-week run-in phase and a 10-week intervention phase. In-home setup of preprogrammed Echo Show devices and Alexa Fire tablets (eg, using anonymous, study email, Amazon accounts, and study phone numbers) was then conducted over 2 weeks. Research staff ensured connectivity, demonstrated how to use the program, and addressed privacy concerns, including demonstrating Alexa’s muting function, which is useful for protecting private conversations. During the 2-week run-in phase, participants reported any connectivity or program glitches encountered while familiarizing themselves with EngAGE. All problems were addressed and resolved before participants were asked to use the EngAGE program ad-lib over a 10-week intervention phase. Follow-up data collection, including physical performance measures and focus groups, occurred at the end of the intervention phase in the facility. Of note, 1 participant was wheelchair-bound with limited leg function, requiring lower extremity exercise adaptations that were provided in a paper supplement that was given to the participant during setup.

Study Sample

Recruitment and Eligibility

After obtaining institutional review board approval, older adults and care partners were recruited together.

Older Adult Participants

Older adult participant recruitment activities occurred between December 10, 2018, and May 7, 2019, at a single independent living facility in Chicago, IL: a facility already equipped with Alexa Dot devices in about 150 residential apartments. Alexa Dots are voice-activated devices without a screen. The residents who participated in this study were familiar with using the Alexa Dots. The EngAGE program was optimized for use on the Echo Show device, a screened voice-activated device. We selected this participant group because it helped us isolate this study of the EngAGE program experience from the more general experience using a voice-activated device. Adults 65 years and older with unlimited Wi-Fi and data plans were eligible to participate. Older adults were excluded only if they had known moderate to severe dementia or were unable to understand the consent form in a teach-back approach. Participants with early cognitive impairment who were still able to consent were allowed to participate. Functionally impaired adults were encouraged to apply, and the use of walking devices or wheelchairs did not preclude participation. Recruitment of participants took place via in-person presentations and fliers at the independent living facility. Study participants meeting eligibility criteria were consented in person.

Care Partner Participants

Older adults who consented to participate were asked to identify a trusted social contact to act as their care partner. Care partners were eligible if they were 18 years or older, had unlimited Wi-Fi and data plans, and reported being comfortable using web browser and mobile applications. If older adults did not have a care partner in mind (n=2), the team worked with them to identify a staff member they knew and were comfortable with.

Older Adult Measures

Demographics

Older adults self-reported their date of birth, race (Asian, Black or African-American, White, or other race), Hispanic ethnicity (yes or no), gender (female or male), education (≤high school or >high school), marital status (single, engaged or living with a partner, married or civil union, separated, divorced, widowed, or other), number of household members, and monthly household income (≤US $2000 or >US $2000 per month). They also separately reported their access to and use of the internet (yes or no) and any devices (check all that apply: computer, cell phone, smartphone, tablet, television, landline, or other).

Physical Function Measures

Physical Function

We administered 2 functional assessments at baseline and follow-up.

Adapted Physical Frailty Phenotype

The adapted frailty phenotype included 5 components: unintentional weight loss in the prior year (5% or 10 pounds), weakness (average of 3 dominant grip strength measures), exhaustion (2 self-reported questions from the Center for Epidemiologic Studies Depression Scale [16,17]), slowness (average of 3 15-foot usual walks), and low physical activity level (6-item version of the Minnesota Leisure Time Physical Activities Questionnaire [16,18]; Text S1 in Multimedia Appendix 2 [16-19]).

Short Physical Performance Battery

The SPPB consisted of three assessments: 3 static balance poses (side-by-side, semitandem, and tandem stance), a 3-meter usual walk, and 5-repeated chair stands [19] (Text S1 in Multimedia Appendix 2 [16-19]).

Program Use

The software platform [15] that hosts the EngAGE program recorded every exercise completed by the participant and the corresponding level of difficulty ratings throughout the intervention and stored use data on a Health Insurance Portability and Accountability Act–compliant server. Once the participant rated the level of difficulty following each exercise, the exercise was deemed “completed” regardless of the number of repetitions.

Care Partner Measure

Care partners were asked to report their relationship to the older adult participant (eg, friend, family, spouse, or staff).

Follow-Up Focus Groups

Three 1.5-hour focus groups of 2-4 older adult participants were held after the completion of the 10-week intervention phase. The small focus group size accommodated participant availability. This study team’s qualitative specialist (RFN) acted as the moderator for each focus group and guided the discussion using the same semistructured interview guide for each focus group to obtain feedback, with other research team members also contributing to focus group discussion. Prompts included the following topics: how EngAGE fit with pre-existing exercise habits; the role of EngAGE’s social component; participants’ current technology usage; perceptions of EngAGE’s benefits; user interface feedback; and user experience, including favored program features and areas for improvement, barriers to use, and feature evaluation. Care partners completed exploratory interviews or focus groups only, and the findings are not reported.

Analysis

Analytic Approach

Data collected from the mixed methods were analyzed using several steps.

Older Adult Sample Characteristics

Older adult and care partner demographic characteristics were summarized for each group using the number of participants and percent of the sample for demographic categories.

Implementation Experiences

The total number and type of technology glitches reported during the 2-week run-in period were reported.

Program Use

Program use was quantified by summing the number of exercises each older adult completed over the 10-week intervention phase, and then averaging across all participants.

Physical Function Performance

Older adults’ physical performance measures were summarized as means (continuous measures) or frequencies (categorical measures) plus SEs and SDs for each of the 5 physical frailty phenotypes and 3 SPPB components as well as the total scale scores at baseline and follow-up. Each continuous outcome variable was assessed for normality using the Shapiro-Wilk test. Normally distributed baseline and follow-up continuous measures (average 15-foot usual walk, self-reported physical activity energy expenditure, frailty phenotype score, the fastest of two 3-meter usual walks, 5-repeated chair stands, and total SBBP score) were compared using unadjusted, paired, 2-tailed *t* tests. Nonnormally distributed baseline and follow-up continuous measures (average dominant grip strength) were compared using an unadjusted Wilcoxon matched-pairs sign rank test. Categorical variables demonstrated no change; therefore, no statistical tests were conducted. Statistical significance was set at $P<.05$. We additionally calculated the effect size of the change between pre- and postmeasurements. For each measure, we also identified the minimal clinically important differences (MCIDs) based on the literature (as available) to assess the number of participants demonstrating clinical improvement. In many cases, the MCIDs reported in the literature were not well established; therefore, we chose informed but conservative cut points. We reported the number of participants meeting the following MCID criteria: 2.5-kg increase in grip strength [20], 1-point decrease in frailty [21], 0.05-mps increase in 15-foot or 3-meter usual walk [22], 2.3-second decrease in 5 repeated chair stands [23], and 0.5-point increase in SPPB score [24]. The MCID is not established for exhaustion; self-reported physical activity on the 6-item Minnesota Leisure Time Physical Activity Questionnaire; and side-by-side, semitandem, and tandem balance performances. For these measures, we chose to report the number of participants meeting the following: (1) no longer meeting physical frailty “low physical activity” criteria (physical activity), (2) no longer meeting physical frailty “exhaustion” criteria (exhaustion), (3) number able to hold for 10 seconds pre- and postintervention (side-by-side stance), (4) number able to hold for 10 seconds pre- and postintervention (semitandem stance), and (5) number able to hold for 10 seconds pre- and postintervention (tandem stance). We did not report a clinically meaningful change in weight.

Qualitative Results for Perceived Benefits, Favored Program Features, and Areas for Improvement

The qualitative data were analyzed to determine perceived benefits, favored program features, and areas for improvement. Audio recordings of the focus groups were transcribed and deidentified. They were analyzed using Dedoose software [25]. Further, 2 team members (RFN and CS) independently read the transcripts to identify preliminary codes and major theme categories for qualitative analysis. Deductive themes were related to a priori topics of interest that were integrated into the focus group prompts, and inductive themes were based on topics or insights drawn from transcripts themselves. Themes and codes were then organized and compiled into an initial codebook created by the team's qualitative specialist (RFN). The codebook was reviewed by the final coding team (RFN and MHS). Adjustments were made to the codes, themes, and definitions based on discussion options to calibrate the understanding of codes and ensure intercoder agreement of all code definitions. Then, 2 members of the team (RFN and MHS) independently reviewed the transcripts again, labeling appropriate excerpts with corresponding codes from the final codebook. Memos attached to ambiguous excerpts were discussed to reach a consensus, and where needed, adjustments to the codebook were made or recoding was accomplished. Upon completion of coding, any coding discrepancies between coders were discussed and resolved.

Ethical Considerations

This study was approved by the University of Chicago Institutional Review Board (IRB #19-0130).

Results

Older Adult Sample Characteristics

The older adults represented a broad range of ages (range 65-84 years) with 7 of the 10 being 75 years or older. A majority of the sample was female (7 of 10 participants), White (9 of 10 participants), college educated (10 of 10 participants), and lived alone (8 of 10 participants). Further, 9 of 10 participants reported having access to and using a computer and smartphone (Table S2 in Multimedia Appendix 3).

Care Partner Sample Characteristics

Each older adult identified an eligible care partner; of the 10 care partners invited to participate, all consented. Immediately after consenting, 1 discontinued due to schedule conflicts. Of the 9 remaining care partners, 3 identified themselves as a "friend," 3 as a "child," 2 as "staff," and 1 as a "spouse."

Implementation Experiences

Having the necessary Orbita, Inc, software preinstalled on the care partner tablets and in-home setup of the Alexa devices facilitated participation. The 2-week run-in phase with easy access to technology phone support enabled the identification of 32 technical issues, most identified during the first 2 weeks. The majority were for programming glitches (n=20). Other issues addressed included requests to correct spelling errors (n=1), resolve clock inconsistency (n=1), increase the font size (n=1), address poor wireless connectivity (n=1), correct errors in exercise text instructions (n=2), clarify web application capabilities (n=2), remove a floor exercise (n=1), resolve a log-in error (n=1), resolve an EngAGE program setup problem (n=1), and resend the EngAGE program invitation email (n=1).

Program Use

User-level analytic data indicated that the older adult participants cumulatively completed an average of completed 393.7 individual exercises over the 10-week intervention period or 39.4 exercises/wk (range 48-492, median 431, IQR 384-481, SD 112.4). Since each routine included 6-7 exercises, older adult participants completed approximately 6 exercise routines per week. Participants opened EngAGE an average of 41 of 70 days or 4.1 d/wk (range 7-66, median 51, IQR 23-56, SD 21.2 days). Further, 8 of the 10 older adult participants completed at least 2 full strength, balance, and flexibility exercise routines per week on average—the minimum recommended by the American College of Sports Medicine [26]—while 2 of the 10 participants did not meet this threshold (Table 1).

Table 1. Cumulative 10-week use of EngAGE by study participant.

Participant	Exercises completed, n	Days program used, n
1	140	13
2	431	59
3	449	56
4	384	50
5	398	52
6	481	66
7	48	7
8	170	23
9	492	56
10	196	28

Physical Performance

Table 2 and Table S3 in Multimedia Appendix 4 summarize changes in physical performance in specific domains and across the frailty phenotype and SPPB scales. Functional improvements were noted in hand grip strength (mean grip strength pre 26.3 and SD 11 kg, post 27.6 and SD 11.6 kg, *P*=.34, effect size=0.32, 7/10 participants improved, 4/10 participants met MCID criteria); 5-repeated chair stands performance time (excluded wheelchair-bound participant, mean 5-repeated chair stand time pre 12 and SD 3.6 s, post 9.7 and SD 2.7 s, *P*=.02, effect size=–0.93, 6/9 participants improved, 6/9 participants met MCID criteria); and in tandem balance (excludes wheelchair-bound participant, pre 5.9 s, post 6.5 s, *P*=.78, effect size=–0.10, 4 participants held stance for 10 seconds at baseline, 3 participants at follow-up), though only change in 5-repeated chair stands performance time was statistically significant in this small pilot sample. The group (excluding the wheelchair-bound participant) had an equally brisk 15-foot and 3-meter usual walk times at baseline (mean 2.1, SD 0.4 s) and follow-up (mean 2, SD 0.4 s; 15-foot walk *P*=.86, effect size=0.06; 3-meter walk *P*=.13, effect size=–0.57), but 5/9 participants had improved usual walk times in both tests, and 3 and 5 met MCID criteria in the 15-foot and 3-meter walks, respectively. Among those not wheelchair-bound (n=9), all were capable of holding the side-by-side and semitandem balance stances for the full 10 seconds at baseline and follow-up. The mean frailty score at baseline was 0.7 (SD 0.7) and 0.0 (SD 0) at follow-up (*P*=.01) with 6/10 participants showing improvement and meeting MCID criteria. The mean SPPB score at baseline was 10.2 (SD 1.6) and 10.9 (SD 0.6) at follow-up (*P*=.22) with 5/10 participants showing improvement and meeting MCID criteria.

Table 2. Physical function performance measures before and after 10 weeks of EngAGE use among older adults.

Functional measures	Participants, n	Before 10 weeks			After 10 weeks			*P* value[a]	Any improvement, n	Met MCID[b] criteria, n[c]

SPPB total score (range 0-12), mean[d]	9	10.2	0.6	1.6	10.9	0.2	0.6	0.22	5	5

[a] Unadjusted, paired, 2-tailed *t* tests were used for normally distributed continuous variables, Wilcoxon matched-pairs sign rank test was used for nonnormally distributed continuous variables.

[b] MCID: minimal clinically important difference.

[c] Grip strength change: +2.5 kg; 15-foot usual walk: +0.05 m/s; physical activity: no longer meeting physical frailty “low physical activity” criteria; exhaustion: no longer meeting physical frailty “exhaustion” criteria; weight: not reported; frailty: –1 point; 3-meter usual walk: +0.05 mps; 5 repeated chair stands: –2.3 s; side-by-side stance: number able to hold for 10 seconds; semitandem stance: number able to hold for 10 seconds; tandem stance: number able to hold for 10 seconds; Short Physical Performance Battery score: +0.5 points.

[d] Excludes the wheelchair-bound participant.

[e] NR: Not reported.

[f] Statistically significant.

[g] SPPB: Short Physical Performance Battery.

[h] N/A: not applicable.

[i] Not available.

Qualitative Results for Perceived Benefits, Favored Program Features, and Areas for Improvement

Perceived Benefits and Favored Program Features

Focus group participants described several positive outcomes resulting from their use of EngAGE, including improvement in upper and lower physical strength, balance or flexibility, knowledge gained, and social benefits (including adherence, interactions with other participants, and relationships with care partners).

Many of these comments provided “real world” examples that suggested clinically relevant strength improvements. For example, a participant attributed the improvement in grip strength from EngAGE to their ability to open a pickle jar and bottle of wine that their companions were struggling with. Another participant described the benefits derived from sit-stand exercises when using low toilets without grab bars.

Overall, balance and flexibility were less frequently mentioned than strength gains in focus group discussions of program benefits. Both participants who described flexibility improvements had not been previously doing this type of exercise, with one noting that:

> *I am not sure I would have chosen [the hamstring stretch], if I had been asked to pick the exercises I wanted to do.*

That participant also reported balance improvements, and in both cases, these exercises were among the most difficult for her at the start of the program.

The most dramatic of the physical health benefits was described by a wheelchair-bound participant who was provided with adapted EngAGE exercises to accommodate his physical limitations. In focus groups, the participant reported:

> *...one of the benefits to this program is that it had side benefits to me, it helped me lose weight, helped me stop eating so much, and helped me psychologically.*

The participant also reported being able to sleep through the night, due in part to the elimination of nighttime muscle stiffness and spasms, which the participant attributed to the stretching exercises.

Another benefit participants noted was the knowledge gained through the program. Further, A user praised EngAGE for providing greater knowledge about how to perform certain exercises, noting that in their prior experiences with exercise class settings:

> *...by the time I figured how I am supposed to do it we would be moving onto the next thing sometimes. So I like that and I could, sometimes I would pause between the first rep and the second [and] think, ‘okay, now do I know what I am supposed to be doing?’ So I like being able to do that.*

Another participant whose prior exercise regime focused on recumbent biking and walking praised the program for emphasizing the need for a comprehensive range of exercise, stating:

> *It reminded me that I needed exercising for everything.*

This was echoed by another participant who praised the greater self-awareness of the need for comprehensive physical exercise that the program provided, saying:

> *I just realized I was getting lazy and at our age we can't afford to be lazy because I mean the muscles are going to go and they go quickly. So that's forced me to remember and to think about how I'm doing things, and I find myself taking the hard road sometimes simply because I know I can do it and I need to do it.*

Lastly, participants described positive outcomes related to the social component of EngAGE for motivating adherence, contributing to insight regarding the fitness benefits, and strengthening social relationships. Multiple participants reported that having a partner who could monitor their progress aided with their adherence to the program. Further, 1 participant also described the questions that she received from her care partner as “creating a dialogue, forcing you to think about it a little bit and that does help.” These interactions with care partners were occasions for reminding participants of the progress that they had made: “It was always something that would make you, really force you to think about, geez, yes, the sit-stand is really helping. I've really improved that.”

Participants also described benefits related to their relationships with their care partners and other participants. Some of this was related to the encouragement and social support that they received. Interestingly, 2 participants felt that this sort of “rah, rah, your chief cheerleader” support was better suited to the EngAGE messaging format, noting “it might seem a little bit corny if she said it to you in-person but in the email, in the message, it seems great.” Since all participants resided in the same building, participants also described their camaraderie with each other and reported interest in program features that would permit communication across exercisers, with 1 suggesting an interface “almost like a Facebook page.” Further, 1 participant also described the benefits of EngAGE for participants who prefer to exercise alone but still desire social reinforcement, noting:

> *That doesn't mean I don't like to talk about it. It doesn't mean I don't want to interact with somebody about it. I just don't want anybody there while I'm doing it.*

Finally, 1 participant whose care partner was an adult child described the messaging functionality as an opportunity for increased communication on topics unrelated to exercise. Another participant whose care partner was a friend noted that the program “certainly added to communication between us, although we still usually fairly often communicate.”

Areas for Improvement

The most common program criticism was the lack of exercise variety. Study participants wanted more than 2 alternating routines in a week and additional exercise types as skill levels increased. Multiple participants reported the 2 daily alternating routines became “boring” or “tedious.”

Additionally, some participants felt the length of exercise instructions was longer than required, especially once familiar with the exercise, with 1 older adult noting that “the full prompt every time, got to be a little bit much,” and others reporting they began the exercise while still listening to the instructions. In other cases, participants mentioned the length of the repeated exercise sets, with 1 noting:

> *...when I would hit the third one it was starting, I was starting to feel like, is this ever going to end?... And yeah, that was hard. And I'll be honest, I didn't always do the third set.*

Other feedback centered around the functionality of the EngAGE interface. Multiple participants, particularly the more experienced exercisers, requested more control over exercise difficulty rather than the automatic changes based on the exercise rating. Other sources of user frustration included difficulty pausing and returning to the same place when unexpectedly interrupted by a phone call or visitor, difficulty successfully skipping instructions, and exercises not registering as completed. Further, 1 participant found the audio instructions more useful than the written instructions or pictures on the screen:

> *...I basically ignored the screen and listened to the verbal.*

Another theme emerged about care partners not meeting expectations. For example, 1 participant emphasized that:

> *The quality of partner is an issue.*

Another mentioned that:

> *I was kind of hoping that she would get a little more into it, I guess, than she did.*

She further explained that:

> *I would have liked her to ask more questions about the exercises... I think you need more of a dialogue than just a pat on the back or their head.*

Discussion

Summary of Findings

This paper summarizes a participatory design approach for developing new voice-activated device programs with older adult users, and it reports results from the final stage of participatory design, a pilot study. In this pilot study, we found the voice-activated device and EngAGE were feasible to set up on-site. The program was moderately used on average by study participants but with a wide range. User feedback provided targeted opportunities to improve the user experience. We estimated the potential impact on physical function to inform the sample size needed for a subsequent efficacy trial. We found participants were the most likely to experience improvement in chair stand time performance of all outcomes assessed. The results from this pilot study offered feasibility considerations for future aging technology studies, provided a reference range for voice-activated device program use among older users for future studies, recommended sensitive objective and patient-reported outcome targets for older adult exercise trials, and introduced a shift in targeted technology users from the older adult to the older adult–care partner dyad.

This study provided several key feasibility implications for future voice-activated device intervention studies in older adults. First, the in-home device setup and data collection provided for older adults greatly streamlined onboarding and facilitated the completion of important objective functional measures but will be challenging for large-scale studies. Potential strategies to address home technology setup needs for larger scale studies include (1) leveraging the paired care partner to assist the older adult with device setup, (2) using setup instruction manuals that have undergone participatory design with older adults to ensure ease of use paired with telephone support, and (3) partnering with an organization that has existing on-the-ground technology support teams. Remote functional data collection may be carried out using videoconferencing [27] or by leveraging wearable sensors in the future [28-32]. Second, our 2-week run-in phase helped address many technical issues before the intervention phase that could have interfered with a successful intervention adoption. Larger technology intervention studies should consider budgeting for phone and on-the-ground technology support, particularly in the first few weeks of technology use. Third, privacy concerns were not the participation barrier we anticipated they could be. We heavily addressed privacy issues during consent and provided strategies for maintaining privacy during device setup, which may have alleviated concerns up front. Everyone in this group was an existing Alexa user, so future studies may encounter these concerns more frequently. Finally, we had to adapt the EngAGE exercises to accommodate a wheelchair-bound participant; future studies should anticipate functionally limited users and prepare alternative exercises in advance.

In this study, the older adults who were familiar with Alexa at baseline used this program on more than half of the days per week on average, but the wide range of EngAGE program use was an important finding for future tech researchers. Adherence will probably be lower among users with less familiarity with Alexa at baseline or those who are more functionally impaired; therefore, a longer intervention period may be necessary to see significant functional gains in a trial targeting these subgroups. Further, 1 option to boost voice-activated device program use among older adults would be to leverage regular visits from care partners such as a state-sponsored homemaker or paid care partners. The care partners could provide direct technology support and help the older adult use the EngAGE program or other healthy aging programs in the home at each visit.

In our pilot sample of mostly current exercisers, chair stand times improved significantly, and we observed a nonsignificant improvement in dominant grip strength over the 10-week intervention phase. These findings inform the sample size needed for a larger EngAGE efficacy trial in older adults and may serve to inform similar technology-based exercise trials in older adults. The fact that a relatively high-functioning group of older adults exhibited improvement in some aspects of physical performance suggests EngAGE or similar programs may have even greater potential to improve outcomes for less robust older adults.

In addition to informing adjustments needed to the EngAGE program, the results of our qualitative analyses provided insights regarding the potential subjective outcome targets for larger technology-based exercise trials. Several participants self-reported meaningful functional gains in activities requiring the hand (opening a jar) and proximal hip (improvement in standing up from a low seat), suggesting these are sensitive patient-reported outcomes for a larger trial. A small number of participants also noted subjective improvement in flexibility, weight loss, diet, mood, and sleep, which may be helpful outcomes to include in larger studies. Finally, while nearly all older participants in the pilot study were exercisers at baseline, participants described gaining knowledge from the comprehensiveness of the exercises—we did not measure knowledge gains directly but would be important for future studies.

Older adult dyadic relationships within their social network are important to healthy aging [33], but health care technology programs infrequently target both users as a unit. The EngAGE program uniquely leverages existing social relationships to motivate activity while allowing older users to exercise alone and at their own pace—both welcomed features in this pilot sample. This strategy aims to both improve older adult physical independence and simultaneously increase opportunities for social engagement. Most older adult exercisers reported that the care partners successfully provided accountability, promoted adherence, increased social communication, and even encouraged older adults to reflect on their progress. In technology interventions, this partnership could be leveraged even more to assist with things such as device setup, addressing technical issues, monitoring safety, or even participating in a program such as EngAGE with the older user. This pilot study also showed that not all social relationships are equally effective. The most positive responses came from those who had care partners who were thoughtful, creative, and engaging. Further, one strategy for increasing the odds of receiving meaningful exercise motivation might be to increase the number of care partners paired with each older adult or to allow the older adult users to be connected. For example, children, grandchildren, and friends could be paired with a single older adult—a feature that is available on the EngAGE platform. Another strategy might be to provide care partners with tips for motivating healthy behavior. A key message from this pilot is the critical nature of care partners in implementing and sustaining healthy aging behavior among older adults.

Study Limitations

By design, our pilot sample was small, the team and participants were unblinded and the participants' familiarity with Alexa devices enabled us to primarily test the EngAGE program including its use, experience, and potential impact. However, these restrictions limit the generalizability of our findings and could introduce bias. Many of those recruited were higher functioning and better resourced than frail older adults (our ultimate target users). Before this feasibility study, however, our participatory design process included less resourced, physically limited, less technology savvy, and predominantly minority older adults. This sample was selected because they were existing Alexa users and could provide feedback on the EngAGE program experience and not the Alexa experience, allowing us to identify areas we could improve before testing in a more vulnerable group. Future participatory design studies must include functionally impaired and less tech-savvy older adults during development so that their needs and concerns are addressed in the program design.

Conclusion

Voice-activated devices hold great promise for overcoming many technology use challenges for older adults, making them a potential vehicle for delivering healthy aging resources broadly to older adults [2,34]. EngAGE is unique in that it targets older adult–care partner dyads and underwent an iterative participatory design process throughout development with vulnerable users to improve the likelihood of perceived ease of use, perceived usefulness, and technology adoption among all older adults. Our pilot study demonstrated that screened voice-activated devices are well-suited to remote delivery of exercise routines that do not require specialized equipment. Using the NIA Go4Life content, EngAGE appears capable of producing statistically and clinically significant improvements in objective and subjective physical function measures. The social component of EngAGE was, overall, viewed positively as an exercise motivator and as a means of strengthening bonds and increasing communication between dyad members. This study also has important feasibility implications for larger technology program trials, including the need for 1:1 device setup infrastructure and technology support. These findings are relevant to all future aging technology studies but especially to voice-activated device studies.

Acknowledgments

We are grateful to the staff and residents of Admiral at the Lake for their cooperation, support, and overall enthusiasm throughout this project. We are grateful to the National Institute on Aging staff for sharing image files for the Go4Life exercises. The Orbita, Inc, staff were not involved in the analysis, decision to publish, or preparation of this paper. This research was funded by the Chicago Center for Diabetes Translation Research (NIDDK P30 DK092949) and the Dean's Office of the Biological Sciences Division of the University of Chicago Pilot Award (principal investigator MHS). Additional funders include the Carol and George Abramson Fund for Aging and Longevity (principal investigator MHS) and NIA 1K23AG049106 (principal investigator MHS).

Abstract

Background: Older adults adopt and use eHealth systems to build autonomy, competence, and relatedness and engage in healthy behaviors. The motivational technology model posits that technology features, such as those on websites, smart displays, and mobile phones, must allow for navigability, interactivity, and customizability, which spur feelings of self-determination and intrinsic motivation. We studied ElderTree, an online system for older adults that provides on-demand videos of healthy living content, self-monitoring, and weekly researcher-hosted video meetings.

Objective: We aimed to understand the theoretical crossover between the motivational technology model and self-determination theory using features of ElderTree to understand the usability of the technology and how it may support older adults' autonomy, competence, and relatedness.

Methods: Drawing participants from a randomized controlled trial of a mobile health app for older adults with multiple chronic conditions, we conducted qualitative interviews with 22 older adults about their use of the app; the interviews were coded using qualitative thematic analysis.

Results: Older adults did find that features within ElderTree such as content available on demand, good navigation, and weekly researcher-led video calls supported feelings of autonomy, competence, and relatedness, respectively. Individual differences such as a background using computers also influenced participants' experiences with the smart displays.

Conclusions: Participants confirmed the features that increased internal motivation, such as interactivity correlating with feelings of relatedness, but they also found other ways to support autonomous health behavior change beyond narrow views of navigability, interactivity, and customization.

Introduction

Background

With the vast array of health resources available online, many systems to support individual-level health are available to the older adults who may need them. As older adults face a growing number of health concerns—chronic metabolic issues such as diabetes, hypertension, and obesity [1]; physical ailments such as pain or arthritis; and emotional concerns of loneliness and depression [2]—they increasingly seek such health information and services [3]. Web-based health technologies (eHealth) or mobile health (mHealth) technologies delivered through internet-connected devices focus on providing social support and increasing positive health behaviors [4]. One way to understand the adoption and continued use of eHealth technologies is using self-determination theory, which provides insights into the internal and external motivational factors that guide individuals' drive to engage in healthy behaviors.

Self-determination theory, developed by Deci and Ryan [5], identifies 3 needs that drive motivation, specifically, the need for competence, autonomy, and relatedness. Competence is the ability for individuals to feel mastery over their environment, that the behaviors they want to do are within reach [6]. Increasing people's perceived competence increases internalization of motivation to do a behavior and, thus, the likelihood of adopting it [7,8]. The need for autonomy describes the experience of volitional self-direction in thought and action. High levels of autonomy increase intrinsic motivation such that individuals feel more interest and enjoyment in the behaviors [7]. Autonomy is a key factor in many components of well-being as people with high levels of autonomy have lower rates of anxiety and depression and overall higher life satisfaction [9]. The relatedness factor is derived from the need to belong, highlighting how individual-level actions are significantly impacted by our need to be socially accepted and have regular contact with others and to have mutual care for another's well-being [10]. Relatedness includes feelings that people of authority (eg, parents, teachers, and health care providers) provide respect and finding a sense of belonging within one's peer community [6]. While all 3 components function independently, they also support each other in increasing intrinsic motivation [5,11].

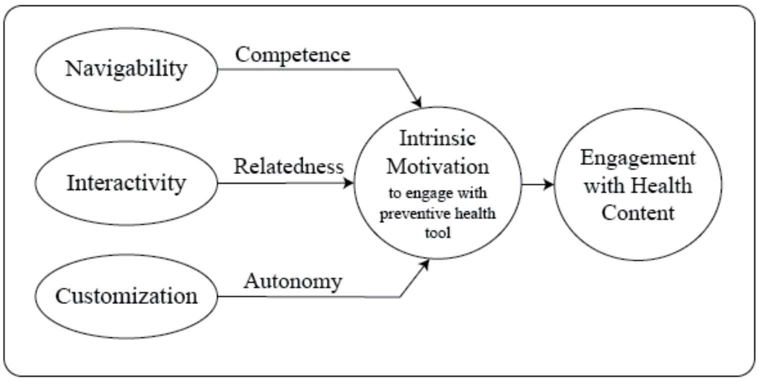
In the context of health technologies, enhancing self-determination can increase an individual's self-efficacy and commitment to healthy behaviors [4,12,13]. Broadly, the impact of self-determination theory on various measures of overall health has been well documented in several meta-analyses [9,14,15]. For example, self-determination factors increase positive health behaviors in the realms of exercise [16,17], mental health [18], and health communication [19]. However, understanding the specific components of eHealth and the way in which they influence autonomy, competence, and relatedness would greatly enhance practitioners' ability to target features that increase positive health behaviors. The goal of this study was to examine how older adults engage with an eHealth tool, describe specific features of the tool, and consider the technological affordances of those features that can support older adults' self-determination, as well as individual-level differences that may influence how the affordances impact the user experience.

Motivational Technology Model and eHealth Applications

The motivational technology model (MTM) is a framework for understanding how technological affordances or perceived and actual properties of the technology that shape and structure its possible uses [20] may impact self-determination. The MTM specifically supports ways in which technology features influence an individual's self-determination (Figure 1 [21]) within the broader framework of the theory of interactive media effects (TIME) [22]. Sundar et al [21] identified technological affordances of navigability, interactivity, and customization that can improve an individual's self-efficacy and intrinsic motivation to use the application for health improvement. Navigability describes how features allow users to easily search for and find the relevant content, which in turn can increase feelings of competence, decrease cognitive load, and improve user satisfaction [23,24]. Features such as menus, search functions, and breadcrumbs and being able to navigate to particular pieces of content all add to navigability [25]. Interactivity, in part, highlights the way in which technology connects people to increase their sense of relatedness. Such computer-mediated peer communication, both receiving messages from others and posting messages to others, shows promise in improving health and well-being [26-28]. Customization refers to how much an individual can make choices about the content or interface, allowing changes to what is available through user-driven tailoring, which increases a sense of autonomous motivation [21]. The MTM theorizes that eHealth tools support intrinsic motivation through the creation and use of technology that increases autonomy, competence, and relatedness, fulfilling needs that drive the motivation to pursue healthy behaviors.

Several studies in the literature specifically look at the overlap between the MTM and self-determination theory. These studies broadly support the links between technological affordances and self-determination [29], with evidence that interactivity increases feelings of relatedness but also competence and autonomy [25] and that customization could also increase all 3 components of self-determination [30]. For example, a cross-sectional study of smartwatches found that participants who rated the tools as interactive, navigable, and customizable also rated the tools as providing them with stronger feelings of relatedness, competence, and autonomy, respectively, and these increased engagement with the health apps [30]. A study of fitness apps using the MTM framework found that apps emphasizing interactivity increased feelings of relatedness, which ultimately increased motivation to engage in physical activity [25]. It also found that interactivity predicted all 3 components of self-determination and that relatedness mediated the relationship with health outcomes [25]. Another study found that the ability to customize physical health trackers increased all 3 components (competence, autonomy, and relatedness) in participants who used them, all of which increased engagement [30]. Finally, a qualitative exploration study using the MTM as a framework for designing a new mHealth app for managing rheumatoid arthritis found trade-offs between navigability and customization, observing that more choices made the interface more complicated [31].

Figure 1. Theoretical motivational technology model of affordances that increase self-determination and promote preventive health behaviors, a focused view based on the work (reproduced from Sundar et al [21], which is published under Creative Commons Attribution 4.0 International License [32]).



Customization as a Tool for Increasing Autonomy

Many more studies have looked at specific eHealth and mHealth features that influence self-determination. For example, customization, such as self-monitoring and providing individualized feedback, is most commonly used in eHealth systems to increase autonomy [33]. Additional research has identified several ways in which customization has influenced feelings of autonomy. An experimental study on mHealth apps found that users' subjective ratings of perceived interactivity, or the degree to which users could customize the content, were positively correlated with autonomous motivation [34]. User-personalized conversations can also increase user satisfaction and general engagement [35]. An mHealth app for increasing physical activity that manipulated customization of the interface was expected to change autonomous motivation. While using the app did not directly influence participants' feelings of autonomy, they did experience moderated mediation through the feeling of perceived control, moderated by a need for autonomy [36]. In mHealth gaming, user customization and content personalization can be persuasive for some types of people [33]. A review of mHealth studies found that participants often requested the ability to personalize their technology and that, if customization options were not available, they opted for other technologies that allowed for customization options [37]. Overall, customization appears to be tied to autonomy, defined by choices within and across apps.

Interactivity to Increase Feelings of Relatedness

Many mHealth apps use interactivity to motivate and support users, create a sense of relatedness and bonding, and encourage continued use. The need for relatedness in health and health care leads humans to find and connect with health care providers as well as other people with similar health conditions [38,39] and is a key component of many online health interventions. In mHealth games, for example, cooperation and competition increase relatedness, such as having collective goals, opportunities to cheer others on or share stories, leaderboards, and individual or group competition [40]. These social features are seen as highly persuasive at increasing positive health behaviors in mHealth [33]. While gamification features are sometimes used in certain types of mHealth apps, health care–focused mHealth apps typically refer to interactivity as one-on-one or one-to-many computer-mediated conversations with health care providers or other system participants, often those struggling with similar chronic illnesses [41]. In the peer-to-peer context, the expression and reception of messages, both via personal messaging and through public posting on social platforms, is related to increases in bonding, social connectedness, and feelings of well-being [26]. In contrast, conversations with providers are often centered on health concerns more than supportive, relationship-building exchanges [42]. The role of eHealth applications in connecting individuals with peers, support networks, and health care providers may support a sense of relatedness in different ways.

Navigability to Increase User Competence

Navigability can describe the ease with which users can move through an interface, and through the creation of a user-friendly site, users feel competent in accessing the content [22]. One measure of competence is the degree to which individuals can navigate and understand the app or web-based tool. The navigability of mHealth apps correlates with increased feelings of competence [25]. Applications with navigable user interfaces obtain more users who use the app for longer compared to apps with complex and cluttered interfaces [43,44]. Notably, navigable apps with better user experience have also been found to be more expensive to build. Overall, specific design features to increase navigability include a simple navigation scheme, clean esthetic style, personalized feedback and tailoring, and user customization [44]. These features can increase usability and enhance the user experience, which may bolster user competence within the mHealth app.

Another measure of competence is the degree to which technology provides users with educational content and increases their knowledge about health topics. mHealth apps can build user competence by providing access to helpful content, knowledgeable or experienced people, or a space to reflect on that content, allowing users to seek subjects and sources that build competence. Doing so has improved competence in a range of contexts: healthy eating [45,46], dementia care [47], and cancer care [45,48]. This same relationship was not observed for sexual health [49] or heart failure [50], suggesting limits to information subsidies.

Intrinsic Motivation and eHealth for Older Adults

From this evidence on the ways in which eHealth affordances of customization, interactivity, and navigability can influence participants' feelings of self-determination and their overall well-being, we expect that older adults, too, would experience increased self-determination when using eHealth tools; however, there are likely some differences from the general population. These differences might be due to age, engagement with eHealth broadly, and the ways in which self-determination is experienced differently by older adults.

Individual person-level characteristics may determine to what degree autonomy, competence, or relatedness create and sustain health behavior change. Advancing age is a significant predictor of reduced technology use [51], health behaviors, and overall health outcomes [52-54]. Older adults are much less likely to adopt eHealth and mHealth technologies [13] unless they have specific utility, such as offering needed social supports [55]. Generally, older adults are most likely to adopt mHealth when they perceive the technology as useful and feel confident in their ability to use it [37].

Higher perceived self-determination for engaging in health behaviors is correlated with improved health status among older adults [56] and linked to increased adoption of mHealth [57]. Age also has a significant impact on need for autonomy, with older people being more autonomy focused [58,59]. Finally, a study about Facebook use and older adults' perceived self-determination and well-being found that the affordance of customization correlated with autonomy; interactivity correlated with relatedness; and, broadly, both correlated with enjoyment of using Facebook [29]. In addition, only feelings of competence correlated with increased well-being; however, Facebook is not an eHealth platform, so these increases were not expected.

ElderTree: An eHealth Application

ElderTree, a website and eHealth application for older adults, provides on-demand videos of healthy living content, self-monitoring, and weekly researcher-hosted video meetings (ie, weekly meetups) [60,61]. The application effectively increases individual well-being and self-determination through encouraging social connections and providing health-focused content [62]. Users have a profile viewable to other study participants and can share content or chat with other users. ElderTree provides weekly updated health content, including blog posts (eg, about hearing aids, alcohol, and sleep); chair-based exercise videos for increased mobility, flexibility, and strength; guided meditation; and other content relevant to older adults, such as finance or just-for-fun videos [11,62]. A weekly health tracker helps users monitor their health in areas such as sleep, mood, medication adherence, and falls. Screenshots are available in Multimedia Appendix 1.

A key part of current ElderTree research is identifying how best to provide content to older adults, so participants are randomized to receive either a laptop or a Google Nest Hub Max smart screen. On the laptop, participants access ElderTree through a web browser. On the smart screen, they access an app triggered by the command "Hey Google, living well." Both systems are touch screen based. Although ElderTree has been designed and studied as a tool for increasing self-determination, the specific technical features that can increase autonomy, relatedness, and competence and their role in self-determination have not been examined. Thus, we pose the following research questions (RQs):

1. In what ways do participants report that ElderTree, including an eHealth tool and weekly video calls, supported their autonomy, competence, and relatedness? (RQ1)
2. In what ways did the constructs of self-determination theory—autonomy, relatedness, and competence—map to the affordances of customization, interactivity, and navigability within ElderTree? (RQ 2)

Methods

Study Design

This study drew participants from the ElderTree study, a randomized controlled trial of adults aged >60 years with multiple chronic health conditions (N=216). Participants were randomized to use the evidence-based intervention (ElderTree) either on a smart display or on a laptop. The full research protocol is available in the work by Gustafson et al [61]. While the original study intended to enroll participants for 12 months, a change in the Google Nest Hub Max interface made the system incompatible with the ElderTree eHealth tool. The study was subsequently ended early and considered a pilot test.

Recruitment

We conducted 22 interviews with participants from the original ElderTree sample pool. This number was selected to allow for enough variation and is generally considered an appropriate sample size for in-depth qualitative interviewing [63,64]. To select participants to interview, the research team first stratified all participants by research arm—laptop or smart display—and by weekly meetup attendance records—people who did not attend the weekly meetups, people who attended the weekly meetups but did not often speak, and people who attended the weekly meetups and most often spoke. In total, 4 to 5 participants from each group were contacted for interviews, capturing a wide variety of participant engagement and experience. Participants were contacted via email, SMS text message, and phone call. Interviews were conducted and recorded, with permission, by the lead author and held over Zoom (Zoom Video Communications) or phone call using a semistructured interview guide [64] after participants gave verbal consent to participate.

The interview guide was developed iteratively by all study authors to identify how participants experienced the affordances of navigability, customization, and interactivity. The interview guide first asked participants generally about their experience using ElderTree, motivations for joining the study and using the tool, how they felt about the navigational experiences, their experiences customizing the tool, and their use of the features that supported interactivity. Participants were also specifically asked about their experience with the weekly meetups. The complete interview guide with probes is available in Multimedia Appendix 2.

Ethical Considerations

To ensure participant privacy and data security, participant contact information remained separate from all other information and on a secure server. Interviews included only participant ID numbers, and all identifiable information was removed from transcripts and notes. Participants were compensated for study enrollment by receiving either a laptop or a smart display, 12 months of internet service, and US $10 for each of up to 4 surveys throughout the study period. The study protocol and interviews received ethics approval from the University of Wisconsin Health Sciences and Minimal Risk Research Institutional Review Board (reference 2020-0868). Survey data were collected in REDCap (Research Electronic Data Capture; Vanderbilt University) as part of the original grant [65].

Coding Process

To code the interviews, the authors used qualitative thematic analysis [66] through inductive and deductive coding to capture relevant themes [67]. The first author started the codebook with themes and codes from self-determination theory [6] and the MTM [21], adding more codes by reviewing the data and finding other salient themes. Coauthors then reviewed and modified the codes. To establish interrater agreement, 2 interviews were microcoded for specific features by 2 reviewers separately and then reviewed together to discuss and resolve disagreements [68]. A total of 2 authors then jointly reviewed 2 additional interviews and discussed the coding schemes identifying other potential new codes. When new codes were identified, all interviews were then recoded for those additional codes. Both reviewers coded all interviews and then combined and deduplicated their codes for final analysis. Data were analyzed using NVivo (version 1.7.1; Lumivero).

Results

Participants

The overall response rate was 88% (22/25) of the contacted participants. Interviews lasted an average of 33.1 (SD 10.4; range 10-50) minutes. Participants, who were aged between 61 and 92 years, were predominantly female (14/22, 64%) and White (17/22, 77%; Table 1).

Linking Self-Determination Theory and the MTM

Customization and Autonomy

Overall, participants discussed several features that led to feelings of autonomy, including content availability and system customization (Table 2). Participants reported customizing when they wanted to exercise and watch curated health or exercise videos and how the content being available anytime supported their autonomous use of the system, particularly for the participants in the laptop condition:

> *Oh, two or three o'clock in the morning I'll be on, on the, you know, the computer, and it was just so good...It's just there and it's available. I love that.* [P06; laptop]

Participants also liked that they were able to access the content themselves without requiring talking to others, again supporting their autonomy:

> *I think it has [helped me] because...it's something to go to without bothering anybody or needing anybody's help.* [P25; laptop]

Participants also customized how they used the application and what they used it for. The ability to use it for many different purposes was present both in the laptop and the smart display group, with participants using it to generally browse the web—"The fact that it, you know, I was able to get to all websites and not just ElderTree, that's another bonus. I'm all over the Y[MCA] and everything" (P06; laptop)—or during the holidays to play Christmas music through the smart screen. The ability to select parts of the intervention that suited their needs was important, allowing them to set goals and engage in physical exercise either with or without the app:

> *Well, I watched them to get the general idea of how to do [the exercises] on my own, if I can do it on my own, and I wouldn't have to actually watch it...[I integrated] the exercises in my daily routine or whatever. Like cooking, or if I'm walking in the house, I'll be incorporating the instructions into what I'm doing, like balancing.* [P23; laptop]

Participants used ElderTree to relax and were happy to have a tool that could help them do so:

> *I would go back to ElderTree after gardening in the evening, to relax.* [P06; laptop]
>
> *It was nice to do the calming exercise. It just took ten minutes to settle my brain...When I wanted to relax, I would listen to the ones that had you close your eyes...the next thing I knew I was asleep!* [P15; laptop]

Participants were able to control their mood by customizing what type of content they accessed on the devices.

Table 2. Components of ElderTree that seemed to support user autonomy, competence, and relatedness and the number of participants reporting that experience by device type [69] (N=22).

Self Determination Theory construct and applicable device types[a]	Description	Participants, n (%)
Autonomy		
Use customization		
Laptop	Accessing content whenever (eg, in the middle of the night) and wherever (eg, bringing the laptop to another state to use it or moving from room to room)	13 (59)
Content customization		
Laptop and smart display	Using the system as desired, including outside ElderTree (eg, music, images, and searches)	2 (9)
Competence		
Content access and navigation		
Laptop and smart display	Being provided with quality content without searching	9 (41)
Content navigation		
Smart display	Figuring out the system and how to navigate	13 (59)
Health competence		
Laptop and smart display	Having access to regularly updated exercise, meditation, and entertainment content	9 (41)
Laptop and smart display	Using the system to learn about physical and mental health, aging well, and managing pain	3 (14)

Features That Detracted From User Autonomy

Table 3 reports specific counts of features that participants reported as detracting from feelings of autonomy, competence, and relatedness. Participants described feeling less autonomous when they were unable to customize the tool to their liking. The specific customization feature of favoriting content for later was used by only 5% (1/22) of the participants. Many did not know about the "favoriting" feature when asked whether they used it, and the participants who did know about it found it frustrating:

> *Instead of having to do down the tree to go find it, you could add [a video to] favorites and you could have "favorite" ones that you do all the time...but that didn't work either.* [P09; smart display]

There were other customization options that participants might have liked. One participant, for example, discussed wanting more self-tracking options, such as for blood pressure.

Participants also wanted the smart display to be portable, saying that “It felt a bit outdated...[the smart display] had to be plugged in, and it was not mobile. We are so used to everything being mobile now” (P04; smart display). The difficulty in customizing the location felt constricting for participants.

Table 3. Components of ElderTree that seemed to detract from user autonomy, competence, and relatedness and the number of participants reporting that experience by device type (N=22).

Self-determination theory construct and applicable device types[a]	Description	Participants, n (%)
Autonomy		
Interest		
Laptop and smart display	Not being interested in using ElderTree	4 (18)
Content customization		
Laptop and smart display	Finding the tool and content not customizable to their needs or wanting more customization options, such as tracking blood pressure	4 (18)
Competence		
Technological issues		
Laptop and smart display	Experiencing technical issues using the system, accessing content, or joining the weekly meetups	14 (64)
Previous work experience with computers		
Laptop and smart display	Not having previous experience with computers or technology	7 (32)
Content newness		
Laptop and smart display	Finding the content stale or not growing with participants’ abilities	6 (27)

Weekly tracker		
Laptop and smart display	Being unable to connect with health care providers about their weekly tracker results (ie, finding that providers did not care)	7 (32)
Discussion boards		
Smart display	Not having knowledge about the feature	4 (18)

[a] Device type has been italicized.

Navigability and Competence

While there were a few examples of how application navigability was related to a participant’s feeling of competence using it, that was not the only way in which they talked about feeling competent with the technology. Participants generally did not discuss the navigability of the application much, but when prompted, many said that they had no problems finding what they needed:

> *Yeah, I did, the ElderTree site was pretty straightforward.* [P24; laptop]
>
> *...it took a little bit to figure it out but eventually I figured it out.* [P31; smart display]
>
> *...if [the technology] is complicated, I’m not prepared to learn.* [P04; smart display]

In this way, competence and navigability were connected. One participant described feeling competent because they did not have to search through a huge number of videos to find ones applicable to them, in contrast to a public website such as YouTube, where they felt less able to find the quality of videos that they were looking for:

> *I was interested in specific kinds of topics that I was able to find. I mean if you go to YouTube, you can find videos about how to maintain your balance, or work at your balance, but it’s so disorganized. Because that’s curated, and I guess that’s a real*

> *benefit of what something like ElderTree accomplished.* [P25; laptop]

Familiar user interfaces and navigation cues on the laptop created feelings of competence, such as using the touch screen:

> *I'm glad I was in the laptop group and was able to do more on a computer. I used the touch screen functionality, I preferred it, but I could use the mouse.* [P53; laptop]

Another participant reflected how it was easier to correct errors using the touch screen, which made the experience more enjoyable:

> *They gave me the mouse and the pad but it's all touch screen...I can just touch it and then like backspace or whatever I need to do and then fix it and go on...It's so awesome for me because that's what I was looking for and, I never, you know, knew that I would enjoy that as much as I do, it just makes it so easy for me.* [P25; laptop]

While some of the smart screen participants had initial trepidation, many had positive experiences after becoming familiar with it, such as one participant who stated the following:

> *It took a little bit to figure it all out but eventually, I got the swing of it. [The smart screen] was kind of fun, something new to figure out.* [P31; smart display]

Other participants described how fun it was to both figure out the new technology and find the content:

> *It was kind of a novelty to have this little piece of equipment that would have a little message every morning, or day depending on what time you listen to, looked at it...I liked going in there and...doing some of the exercises,also, um, asking it to play certain music.* [P12; smart display]

Participants sought new content along with new technologies, and it was the system navigability that supported their desire to try out all the existing content or a drive to look at the application regularly to see when new content was introduced:

> *Overall, I tried every single [exercise video], and some of them I did twice or three times...I tried out everything.* [P01; laptop]

This supported their competence with finding and using health information:

> *I wanted to see what everything was. Late nights, at night, I would do some of the meditations, and movement, too. I liked exploring and was glad to do that because I found things I otherwise wouldn't see.* [P53; laptop]

Several participants mentioned that regularly updated content was a motivator for checking and using the app, such as the inspirational quotes or new content:

> *You know, and I tried, whenever they said something new was on it, I tried to go to it sometime during the week.* [P29; laptop]

The new content motivated them to initially log on to the system and then often kept their attention.

Finally, the content on ElderTree supported users' competence and knowledge of specific health topics, particularly the modules on pain:

> *A lot of us deal with pain. They had good information about pain, and we would use that information.* [P01; laptop]

Another participant found that, again, the pain modules provided important information for how they could handle their pain:

> *There was some videos that went into a lot more detail about pain [on ElderTree] and...it was really interesting.* [P15; laptop]

Inherent in the ability to learn about how to manage pain was the ability to find and watch the video segments about pain or other topics of interest. Participants also learned how to do physical activity movements that could help manage and reduce their pain:

> *Every night, I'd sit there and do two or three of those [mindful movements videos on ElderTree]...to get that shoulder moving again.* [P09; smart display]

Features That Detracted From Competence

Within the system, there were components that the participants discussed negatively, particularly in the smart screen condition. The participants with a smart screen mentioned various issues, such as not being able to log in or their camera not functioning properly for the meetings, which hindered their interest in using the application by reducing their feelings of competence. They described how they wanted to be a part of the video calls or do the exercise videos but that they were challenged by the system and some technological issues:

> *To have to go through all the, all the hoops to get the ah, Google display thing to work...I do have computer skills. It's like, I actually used the original internet back in the seventies.* [P48; smart display]

Another participant found the content helpful but the system cumbersome, so they went outside of it:

> *A lot of the videos I found on YouTube...I wouldn't even try to mess with [ElderTree]. The only time I would use it with ElderTree was when we were online [for the weekly meetups].* [P48; smart display]

Technical troubles were likely to deter participants.

Stale content was also a deterrent for some participants. For one, because new content prompted participants to look at ElderTree and browse, participants mentioned forgetting to use the application when they did not expect anything new, with one participant saying the following:

> *I can't be bothered, because it's not new, it's not on your mind, you don't think about, don't bother going back and having a look at it.* [P04; smart display]

Other participants felt like the content needed to progress with them, to become more challenging as they became more able, such as the following participant, who used ElderTree a lot while they were healing but not as much after they recovered from their surgery:

> *After my shoulder got better, I needed more. I tried the balance ones, but the content got stale.* [P09; smart display]

New content engaged participants, but not having content that grew with them deterred participants from regular use.

Interactivity and Relatedness

To examine the role of ElderTree and the device regarding relatedness, the interviewer asked questions about the weekly meetups and the online discussion board. Table 2 reports resulting counts of specific features that participants reported as supporting autonomy, competence, and relatedness. The researchers found that technological features that increased the interactivity affordance, and participants' feelings of relatedness were closely linked concepts. In times when technology afforded interactivity through an interactive social experience, participants were able to connect with others, interested in doing so, and discussed the importance of that connection. While participants never met in person, nor were they required to attend the weekly meetings, they often found the meetings to be a very impactful part of the study. The meetings connected participants with each other and were discussed as an experience that supported their feelings of being closer to the people in the group. They discussed that being in the meetings gave them "the knowledge that you're not alone and that there are other people fighting through difficulties. It's a whole lot different knowing that than sitting at home by yourself thinking you're the only one going through it" (P29; laptop). Regardless of their similarities or differences, participants felt like they were a part of a group, saying that "Whatever condition you are in, it gives you a way to socialize" (P04; smart display). The participants identified that the group was diverse:

> *It was uplifting to talk to different people...I liked the conversations. Over the phone we got pretty close. We never met, but we had a good group, for such a large group.* [P40; laptop]

The weekly meetups provided opportunities for older adults to learn from others:

> *[The ElderTree Meetup] helps you mentally because just hearing about what other people are going through, and what things have helped them, what resources they used, was very helpful.* [P07; smart display]

Another participant commented that "ElderTree makes us thankful...it gives you another perspective on things" (P22; laptop). The interactivity experienced through the weekly video calls seemed to correspond with feelings of relatedness by providing users with a social network to corroborate the difficulties of growing older and resources for new and ongoing health and social issues.

There were certain technical features as well that increased relatedness by giving participants specific ways to interact with each other, such as the hand-raising function that created organization regarding who could speak:

> *I'm a little shy about speaking up and it can be hard for me but um, it was nice that they had the hand raising function [on Google Meet], because that helped a little bit to be called. So, sometimes, I would wait and then if it seemed like there weren't a lot of people talking, I would raise my hand.* [P15; laptop]

The chat feature within the breakout groups also garnered positive responses from participants, who said that "We had a good time with the chat feature" (P01; laptop) but that they wanted more—"It would be nice to have a chat option, a one-on-one chat within the meetings" (P15; laptop)—to support a smaller community. The breakout groups also created a closer sense of community by encouraging a smaller group to come together and chat:

> *I like the fact that we could all contribute first thing, you know, I mean when they get the breakout groups that was nice because I need a chance to offer what was good for the week and, you know, one good thing or one, you know, thing that wasn't so good.* [P5; smart display]

These structural components supporting interactivity seemed important to participants' feelings of relatedness to other participants and their general engagement with ElderTree.

A few unexpected features of the study design supported participants' feelings of relatedness. Participants reported that emailing or calling study staff when they had a question was particularly helpful, as one participant said:

> *[The ElderTree study staff] were really great. We'd go to them with any question...there was always somebody there that would help.* [P30; smart display]

In addition, participants talked about the importance of the racial and age diversity on the calls, as one participant reported:

> *I am a white person, and I have some interaction with people of other races and backgrounds but not necessarily that much. It was good for me to listen to the gentleman and the ladies that were of other races.* [P07; smart display]

Features That Decreased Relatedness

While many participants appreciated the diversity, some reported feeling like outsiders if they were not like other participants because they were older or healthier than most participants. Specific features of the system were also brought up when asked about whether they felt that they related to other participants. For example, participants reported being uncomfortable not being able to see the other participants when their videos were not on or when there were technical difficulties so they could not share their own video streams:

> *I could get in and my camera wasn't working, so, and I don't like, I like being able to see it if I'm going to be talking to people, I like to have them to be able to see me as well.* [P30; smart display]
>
> *There were people who didn't even have their cameras on. I could only see a handful with video on, many with videos off the whole time. I always had the video on.* [P24; laptop]

The anonymity affordance [20], in which participants could turn off their camera during the video calls, may have decreased a sense of relatedness for some participants who would engage only partially:

> *At the end of every meeting, you know, we did...an exercise dance or whatever, but you do it sitting down. I do not know if it's my own self-consciousness or whatever, but usually I would do it up to a point, but I would turn the video off.* [P24; laptop]

There were a variety of reasons why participants did not want to have their cameras on, such as technical difficulties or because they did not want to share information about themselves, such as them doing an exercise video or showing the inside of their house:

> *I didn't have my camera on because I was at my messy desk downstairs.* [P26; laptop]

One participant commented that it was difficult to truly connect with the other participants because they were only connecting online and not in person:

> *It's hard to look at a video, to be engaged that way, you know, at a deeper level. It's not as if we're in the same room at a party or a live event where you get to see [people] It's harder to replicate and it's harder for me to open up...Maybe it's just my generation, I don't know.* [P22; laptop]

Finally, the weekly health tracker prevented some feelings of relatedness for participants who wanted to discuss it with their physicians:

> *I usually did [the weekly survey]. But I thought they were kind of ridiculous. Because, they were nice for me, but the few times that I got them and took them to my doctors, they didn't give a ding-dang.* [P29; laptop]

Expecting their care team to want the data and finding out that they did not isolated the participants.

Personal Factors That Influenced Intrinsic Motivation to Use ElderTree

Individual participant characteristics influenced how they used the system, such as having work experience with computers or having a learning disposition. Some participants came to the study with an established sense of technological competence gained from years of working with computers. Although many participants were already retired, several talked about how their job required them to use computers and smartphones. Competence in using the ElderTree platform for these older adults was, for some participants, unrelated to how it was laid out and, instead, a function of a participant's lifetime of experiences, such as for one participant, who worked in technical services and would use video calls to troubleshoot issues. Other participants did not enter the study with a lifetime of work experience that involved interactive technology or digital media, and they lacked competence as they entered the study, such as one participant who stated the following:

> *My life was as a secretary, and I said no office machine was going to get the better of me, but the electronic age has.* [P10; smart display]

Other participants mentioned jobs as bus drivers and childcare providers or other jobs that were not completed on a computer, and for some of these participants, the system was not usable based on their past life experiences.

Another driver to use the system was participants' desire to learn technology and engage with something new. Some participants found that the novelty of the technology was what prompted them to use it even if they had no particular health goal, such as one participant who said that his motivation for enrolling in the study was the newness of the technology:

> *I've wanted to learn to do more typing, learn a new technology.* [P11; smart display]

Other participants also positively portrayed their interest in the novelty of a laptop or smart screen or just learning how to incorporate new technology into their lives, such as the following excited claim:

> *I love [technology]. I'm all in. I try to learn as I go, utilize it and that's where you keep your calendar and all appointments.* [P06; laptop]

Individual differences and preferences for exploring new technologies were often discussed by participants as reasons for engaging with or stopping use of ElderTree.

Discussion

Principal Findings

In attempting to understand the crossover between self-determination and the eHealth affordances of customization, interactivity, and navigability, we interviewed 22 participants who used either a smart screen or laptop for a 6- to 12-month period and asked them about their experience, things that motivated them to use the application, components that were useful, and whether and how they connected with other ElderTree participants. We used the frameworks provided by the MTM and self-determination theory to guide our collections and coding. Structuring our questions around core needs of autonomy, relatedness, and competence and tracing connections with customizability, interactivity, and navigability provided new insights into how these affordances shape how older adults use eHealth tools. The participants discussed how the ElderTree application specifically supported all 3 human needs that drive internal motivation. While having a platform that afforded interactivity through discussion boards and a hosted weekly meeting supported participants' feelings of relatedness and got them moving with an exercise video, they also talked about how on-demand, curated videos and hardware that could move around their house allowed them to customize their use of the platform and gave them more autonomy over when they wanted to exercise. Some specific content on ElderTree that participants particularly found beneficial were the pain modules and the calming movements that encouraged stretching and breathing. However, many of the experiences that users had could be benefits of any health application that connects older adults with content and other participants. These benefits need not be unique to the ElderTree platform, but they do require more than just access to content. Confirming previous findings, directly engaging with other study participants and study staff was critical to supporting participant relatedness and general interest in the application [37].

Individual characteristics, such as technological competence, differing interest in the ways in which they could track their own health, and preferences in meetup groups, seemed to reflect differences in how participants used ElderTree. Older adults are closing the digital divide [51], and many are willing to try new eHealth and mHealth options [70]. However, there are individual differences in interest in experimenting with technologies, so considering not only the technological affordances of eHealth platforms but also the personal characteristics, such as through a measure of technological innovativeness [71] or technology adoption [72], may capture individual differences in older adults' interest in the challenges of using eHealth [22] or interest in health-tracking applications [73]. Measures of technology self-competence [71,74,75] may also help describe some of the differences observed among older adults using eHealth to account for the technological comfort and competence that older adults bring to a study, such as being worried that they will break the device or make an irreversible change, and those fears have can have a significant impact on how they see the eHealth and potential outcomes regardless of how navigable it is. This means that some older adults will use the technology even if they do not feel comfortable with the navigation, whereas for others, that will be a barrier [37]. There are many ways in which technological features may impact older adults' experience of using an eHealth application.

Implications for eHealth Designers and Researchers

Future designers creating these technologies can consider that certain eHealth affordances support older adults' intrinsic motivation to engage with health content, such as exercise videos, meditations, and social interactions. Interactivity is a useful way to support relatedness, and ElderTree used scheduled socializing and exercise time through the weekly meetups. While these were generally liked, future implementations could better engage participants through smaller groups that are organized around common interests or health concerns, a finding shared with those of other eHealth studies [31]. Customization, too, supports participants, and in this study, participants asked for several additional customization options, such as including more exercise content of varied difficulty and tracking additional health elements in the weekly tracker, and users in the smart device group asked for the ability to customize where they used the devices, a commonly cited request for supporting autonomy [76]. While we only explored the affordances of interactivity, navigability, and customization based on the MTM, there were several other concepts that may be considered in future work exploring affordances of eHealth applications. ElderTree afforded participants access to newly updated content, which they found was a motivator for engaging in positive health activities, such as meditation and physical activity, and in general can support older adults' healthy aging [77]. Given the complicated nature of defining affordances [78], we defer the work of declaring the aforementioned features as such to future researchers.

The hardware also offered customization options, and future designers could consider technological affordances beyond just what is in the eHealth application itself. In this study, participants used the smart display to play music; read inspirational quotes; and view inspirational, beautiful pictures for enjoyment. People in the laptop group were able to use it for visiting other health- and non–health-related sites or to connect with their family and friends. These extracurricular uses should be considered for their potential to support participants' engagement with health technology and opportunity to engender further health activities.

The last design consideration is that technology use, particularly by older adults, is done in a complex environment in which the other users and available support staff play a critical role in maintaining an individual's interest in the eHealth application. In this way, designers may not be able to successfully deploy an eHealth application into an app store without staff and without synchronous ways for users to connect. ElderTree does this by providing users with unlimited support staff available via phone or email and through hosting weekly calls. Participants brought histories and experiences with technology and social connection and had different abilities and interests to learn and engage.

Limitations and Future Research

This study has several limitations. First, the qualitative research provided a richer understanding of how participants experienced the application, but there was a wide variety within the population. We captured some of that variety in this study, but older adults are incredibly diverse [79], and we likely were not able to fully elucidate all the experiences that the participants had with the affordances of ElderTree. Furthermore, while we attempted to increase the racial and ethnic diversity of the sample, we were not able to reach as many participants of racial or ethnic minority groups as we would have liked. These findings may not reflect the experiences of minority populations, who are often left out of research on eHealth [80], leading to worsening digital divides. Ongoing ElderTree research is prioritizing enrolling a diverse population, and future qualitative studies will be able to reflect that diversity. Additional research should also consider the degree to which participants desire a homogeneous or diverse group, and the potentially different social groups and functions that older adults desire.

Another limitation is that participants likely experienced recall bias in what they remembered about using the system and what modules they used. ElderTree and other eHealth tools often show significant participant attrition [81] such that people use the system more when they first receive it but then stop using it. Future studies should use system logs to quantitatively measure participant use and the relationship between system use and participant self-reported autonomy, competence, relatedness, and well-being to help support the results presented in this paper. Finally, while this study used a Google platform for ElderTree, that platform is no longer compatible with ElderTree, and future studies will be conducted on alternative smart display platforms.

Conclusions

The aging population continues to adopt new technologies, and we need insights to shape the design of eHealth applications to best support older adults. This study found that there was excitement among the participants to use new technologies such as smart screens, although some participants needed extra support to use them most effectively. Self-determination theory can help app designers build products that support older adults with both low and high digital literacy. For example, providing multipurpose technology, such as a laptop, can better support older adults who bring competence and autonomous interest in using it. The MTM and self-determination theory components overlap, but there are also personal differences that have strong influences on how older adults use technology. In this way, future research can include additional eHealth affordances and personal-level characteristics to support individuals' self-determination in engaging in healthy behaviors.

Authors' Contributions

LMC, DS, and MLM devised the study. LMC, DS, MLM, and DHG created the interview guide. LMC conducted the interviews, and GL, SS, and KT supported data collection. LMC and KB coded all responses and conducted data analysis. MLM, DS, AM, DHG, and DG edited the manuscript and provided critical input. DHG is the co–principal investigator of the study. GL is the project manager for the study. KP-R is the study implementation coordinator. AM developed the software for the study. All authors contributed to the design of the study and have approved the manuscript.

Conflicts of Interest

DHG has a small shareholder interest in Center for Health Enhancement System Studies Health, a corporation that develops health care technology for patients and family members struggling with addiction. The other authors have no disclosures to report.

Abstract

Background: Technology is already a part of our daily lives, and its influence is growing rapidly. This evolution has not spared the health care field. Nowadays, a crucial challenge is considering aspects such as design, development, and implementation, highlighting their functionality, ease of use, compatibility, performance, and safety when a new technological tool is developed. As noted in many works, the abandonment rate is usually higher when a user has a terrible experience with these instruments. It would be appropriate to incorporate the final users—whether they are patients, health care professionals, or both—in the stages of instrument design to understand their needs and preferences. Since most apps that fail did not include end users and health care professionals in the development phase, their involvement at all stages of app development may increase their commitment and improve integration, self-management, and health outcomes.

Objective: This study aims (1) to develop semAPP (spatial and episodic memory assessment application), a 360° media–based tool, to assess memory in aging by simulating a real-life situation and (2) to test the usability of the app and the connected experience in an end-user population.

Methods: A total of 34 older adults participated in the study: 16 (47%) healthy individuals and 18 (53%) patients with mild cognitive impairment. They used semAPP and completed qualitative and quantitative measures. The app includes 2 parts: object recognition and spatial memory tasks. During the first task, users have to navigate in an apartment freely and visit rooms, and then they must recognize the right map of the house. In the second task, users are immersed in a living room, and they have to encode and then recall some target objects, simulating a relocation. We deployed this app on an 11.2-inch iPad, and we tested its usability and the experience of users interacting with the app. We conducted descriptive analyses for both the entire sample and each subgroup; we also conducted parametric and correlation analyses to compare groups and to examine the relationship between task execution and the virtual experience, as well as the acceptance of technology.

Results: Both groups judged the app as an easy-to-use tool, and they were willing to use it. Moreover, the results match the idea that usability might be influenced by different factors depending on instrument and personal features, such as presentation, functionality, system performance, interactive behavior, attitudes, skills, and personality.

Conclusions: The findings support the possibility of using semAPP in older patients, as well as the importance of designing and evaluating new technological tools, considering not only the general population but also the specific target ones.

Introduction

Technology integration into our daily lives has become increasingly prevalent and shows no signs of abating. The use of mobile devices and videoconferencing for interpersonal communication among family and friends, as well as the prevalence of programmable household appliances such as the microwave, dishwasher, coffee maker, and oven, serve as illustrative instances of the pervasive presence of technology in our everyday existence. Modern entertainment technology encompasses a variety of sophisticated devices, such as smart televisions equipped with multiple functions, digital video recorders, digital music players, and cameras, among others. These examples illustrate the diverse range of options available in the realm of contemporary entertainment technology. Hence, people are compelled to cultivate additional skills to interact with these technological advancements. Moreover, older people must acclimate themselves to the modifications imposed by the ongoing expansion of technology. One of the key concerns pertains to the provision of training for older individuals to enable them to engage with new technologies securely and proficiently [1]. On one hand, the advancements in technology present significant opportunities for older individuals to derive advantages from these novel innovations. However, many older people hesitate to use technology due to several obstacles, including a lack of assistance, unclear instructions, or a lack of confidence [2]. Generally, age-related problems (eg, the impairment of cognitive abilities), personal perception (eg, computer self-efficacy and anxiety related to the use of technology), and technology-related barriers (eg, interface usability) may influence the experience with technology [3,4]. Even so, the computer tablet is a widely adopted and user-friendly technological solution. The interface exhibits an easy-to-use nature and comparatively lower complexity than alternative interfaces, while also obviating the need for wired infrastructure. Consequently, an increasing number of researchers are using this instrument to provide health care interventions in aging [5]. However, this solution is not exempt from criticism. Vaportzis et al [2] identified several obstacles associated with the use of tablets. The barriers to technology adoption among older individuals include insufficient or overly complex instructions and guidance, limited knowledge or confidence in using devices, concerns about the potential risks associated with technology, health-related obstacles, and the high costs of devices. Additionally, older individuals tend to be slower in adapting to new technologies compared to younger individuals, resulting in lower technology use and less enthusiasm toward its adoption. Notably, the integration of technology into geriatric care is becoming increasingly important, particularly considering the impending shift toward technologically driven cognitive assessment tools.

Technological advancements offer the potential for more precise, efficient, and accessible cognitive assessment tools that can provide real-time data, remote monitoring, and personalized interventions. Traditional assessments are provided through paper-and-pencil tests or computerized tools; however, an open-ended question in the neuropsychological field regards the ecological validity of the employed measures, that is, how to measure cognitive functions reliably and validly [6]. Research suggests that assessment tools do not accurately reflect the demands of the everyday world in predicting cognitive functioning [6,7]. Due to their ability to produce realistic surroundings in a controlled and safe manner, 360° media may be the greatest approach to address this issue and enhance the accuracy of the neuropsychological assessment process [8-11]. In the same way as computer-generated virtual reality games and other interactive experiences are designed to be viewed through headsets, 360° videos and images, sometimes referred to as immersive videos or spherical media, may also be viewed on flat-screen devices like a smartphone or computer by dragging the viewpoint with a mouse or a finger, as well as more immersive devices. Live action in the real world is recorded using special cameras that capture the entire environment. Media are recorded thanks to omnidirectional lenses with a circular fisheye view of the surrounding environment, allowing us to get files of the complete environment. Moreover, they provide the possibility to capture different points of view: by placing the camera on the recorder’s head while a video is being made, the user can obtain a first-person perspective of the action. If not, the user can position the camera anywhere in the scene to view it from the perspective of an outsider (third-person perspective). Because 360° media show the full globe instead of just a small section of it, they are different from 2D videos. Technology and software elements that trick the user into believing they are surrounded by an alternate dimension can also be used to establish a sensation of presence using 360° media [12]. This technology offers several additional advantages including cost-effectiveness, ease of use compared to computer environments, and a user-friendly design [13]. The ability to modify the participant’s position in space and place in a realistic virtual environment also increases the ecological validity of the tests and promotes an embodied experience significantly [14].

Characteristics of 360° media could be attractive for memory testing, boosting the procedure’s precision. Memory plays a central role in various aspects of daily life, such as recalling important information, managing medications, and navigating familiar environments. For older adults, maintaining optimal memory function is essential to ensure their independence, safety, and quality of life. The efficacy or efficiency of processing measures typically show a linear decline with age in the cognitive profile of aging [15], and memory performance, attention, and executive functions are some of the abilities that decline over time [16], risking cognitive impairment when problems are significant. In particular, memory problems may be crucial in predicting the chance of acquiring dementia, such as Alzheimer disease [17,18]. However, the early indications of cognitive impairment are typically ignored because they are confused about the consequences of physiological aging. Thus, a prompt evaluation is the most effective way to ascertain the extent of the problems that distinguish pathological from healthy aging. To stop the progression and avoid disability, it is therefore essential to identify issues swiftly and effectively. Implementing timely neuropsychological evaluations and cutting-edge techniques, such as virtual reality–based approaches that demonstrate enhanced sensitivity for the early detection of cognitive deficits, may represent a promising option [19].

The examination of the challenges that older adults encounter when using technology is crucial to identifying the most efficacious approaches for introducing technology within the clinical domain, given its significant benefits and necessity in this context [20]. The elements that affect older people's adoption and use of technology must be identified to better understand and anticipate their technology use behavior. One of the most significant indicators of the adoption and use of technology is technology acceptance, which is the attitudinal perception and behavioral desire to use technology [21]. Several models or theories have been proposed to explain technology acceptance behavior; among these, Chen and Chan [21] developed the first theoretical model to predict older people's acceptance of everyday technology (ie, the senior technology acceptance model), considering individual attributes, gerontechnology self-efficacy, anxiety, health, and ability characteristics. Moreover, a crucial feature to provide an instrument usable and accepted by users is to design the tool based on the target population, to make sure that the scenario will meet the needs, concerns, and expectations listed by individuals. Thus, understanding and addressing the health care needs of older adults have become increasingly crucial. Among these needs, the evaluation of cognitive functions stands out as a fundamental aspect of comprehensive geriatric care. It is well recognized that including clinicians, user experience (UX) experts, and end users allows for the consideration of useful information targeted at creating a suitable interaction between the patient, the technology, and health care organizations [22]. Since most apps that fail did not include end users and health care professionals in the development phase, their involvement could increase their commitment and improve integration, self-management, and health results. However, when a new app is developed, most tests are improperly provided to a general population engaged in evaluating critical aspects, judging their experience, and predicting the adoption of the presented product.

Based on these considerations, we developed a new app to evaluate memory in aging: semAPP (spatial and episodic memory assessment application), testing the connected experience in a population typically characterized by memory problems: mild cognitive impairment (MCI). We compared their experience with that of the healthy population to expand our knowledge of older people's experience with technology. This study aims to present the UX of a 360° tool designed to assess memory in aging.

Methods

Recruitment

A total of 34 older adults (mean age 74.65, SD 7.64 years) were recruited at the Medical Rehabilitation Department of IRCCS (Istituto di Ricovero e Cura a Carattere Scientifico) Istituto Auxologico Italiano in Milan. Patients and outpatients aged 60 years and older from the clinical institution were selected for this study. During their hospitalizations, comprehensive information regarding the research was provided, and participation was entirely voluntary. Similarly, outpatients received the same information during routine clinical visits, allowing them to make an informed decision to participate in the experiment. The entire sample consisted of 15 (44%) male participants and 19 (56%) female participants. All participants were native Italian speakers and took part voluntarily in the study after signing an informed consent form. Based on an initial neuropsychological assessment, participants were divided into 2 groups: healthy participants (n=16, 47%) and patients with MCI (n=18, 53%). The inclusion criteria were (1) aged 60 years and older (without maximum age limitation) and (2) normal or corrected-to-normal vision. Exclusion criteria were (1) invalidating internist, psychiatric, and neurological conditions that could affect the performances and (2) cognitive impairments certifiable by a score lower than 24 points on the Mini-Mental State Examination, Italian version [23,24]. On the other hand, patients with MCI were identified based on self-reported (or reported by a caregiver) cognitive decline, an objective impairment on the neuropsychological testing, preservation in functional abilities, and no evidence of significant impairment in social or occupational functioning (ie, not demented) [17].

Ethical Considerations

The data collection has been conducted anonymously, according to the Regulation (EU) 2016/679 of the European Parliament and of the Council (General Data Protection Regulation). The study received ethical approval from the Ethical Committee of the IRCCS Istituto Auxologico Italiano (2022_01_25_04) and complies with the ethical principles set out in the Helsinki Declaration. No financial compensation was provided to the participants. All patients provided informed consent for the study and no financial compensation was provided.

semAPP

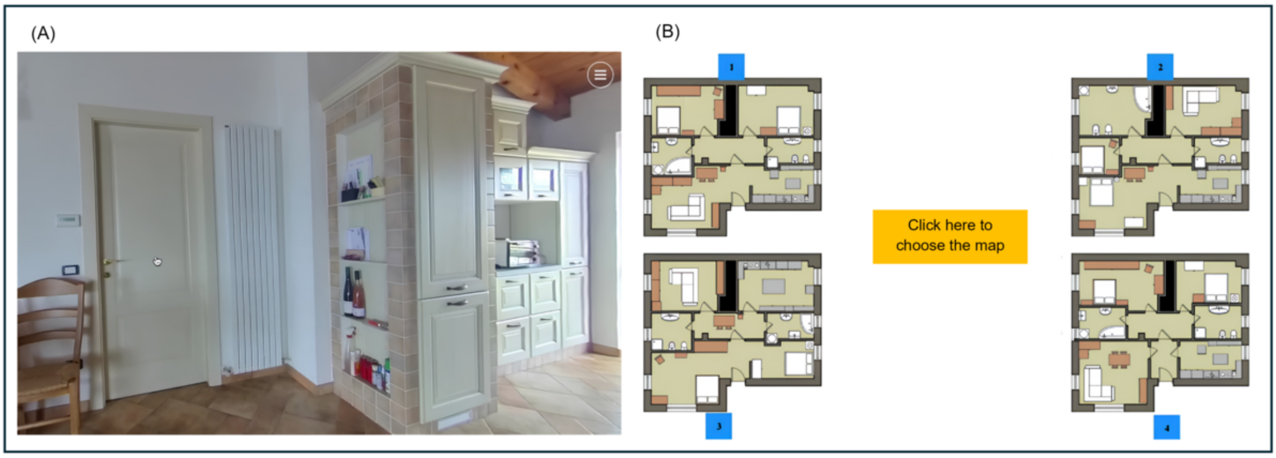
Overview

semAPP consists of 2 memory tasks created with 360° media aimed to assess memory by simulating a real-life situation. The 2 exercises are focused on episodic and spatial memory, respectively. Both are structured into 2 main phases: learning, in which the user has to memorize specific features, and recalling, in which what was learned in the first phase has to be used to answer new requests.

Spatial Memory Task

This task takes place in a virtual home, in which users have to freely explore the diverse rooms and then identify the right map of the apartment (in an allocentric way). The residence encompasses a kitchen area that incorporates a centrally positioned table, along with intricate elements such as appliances, shelves, and furnishings. The spatial configuration of the apartment encompasses the living room with a primary ingress and a portal that grants access to a passageway. The corridor is bordered by 6 doors, each leading to separate rooms, including the living room, 2 bedrooms, and 2 bathrooms. Participants were presented with the instructions to enter the apartment and examine the various rooms while considering their spatial arrangement within the dwelling. The task starts from the dining room and kitchen area. The participant is afforded the freedom to engage in interactions by clicking on the different doors to transition between rooms. Once the participants believe they have completed their exploration of all the rooms, the clinician instructs them to return to the main room to continue with the testing process. Upon activating the main entrance, a set of instructions appears, presenting 4 distinct maps depicting the layout of the previously explored domicile. The request is to look through the available options and identify the appropriate one throughout the maps displayed on the screen in an allocentric perspective (Figure 1). The score is defined by the correct or incorrect response of the participant.

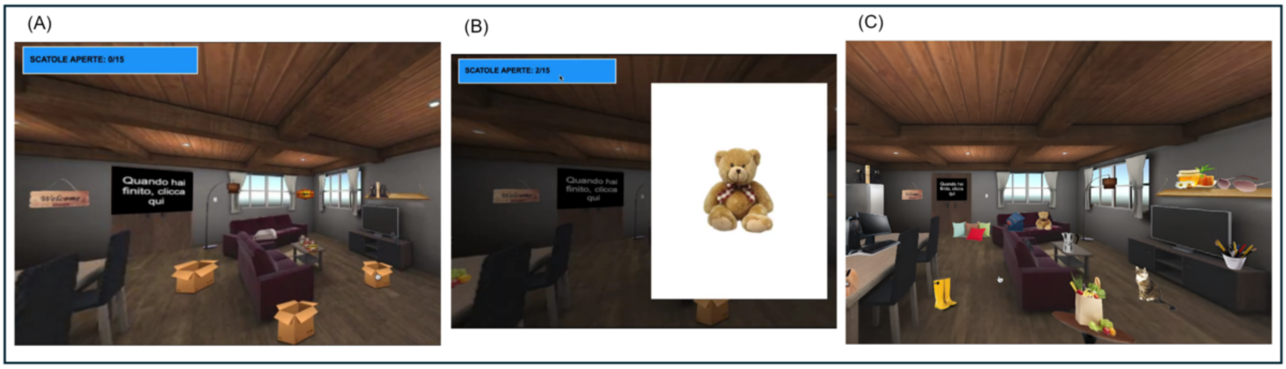
Figure 1. (A) The encoding phase: participants navigate in the 360° house by clicking on each door and (B) the retrieval phase: participants have to choose the right maps of the apartment.



Episodic Memory Tasks

This task is composed of a virtual house with several distinct areas. A total of 45 objects were generated to populate the virtual house and serve as either targets or distractors. Initially, 4 distinct semantic categories were identified: kitchen items, living room items, musical instruments, and home decor items. All the objects mentioned were tangible items that are typically encountered in residential dwellings. In the learning phase, the objective entailed the identification of 15 distinct entities enclosed within various boxes distributed in the house's environments, with each object being easily recognizable. To carry out the task, participants were provided with instructions to open each of the boxes and verbally identify the objects contained within. Specifically, they were instructed to imagine themselves entering Marco's new residence to aid him in relocating his stuff; this aspect was introduced to improve the ecological aspect. Among the 15 target objects, 15 distractors, which shared a semantic category with the target items, were strategically positioned in comparable locations. The task concluded upon the completion of opening all the boxes. At this point, it is advised that participants proceed to select the primary entrance of the house by clicking on the designated area, and a neutral gray environment is presented, accompanied by the following prompt: "Reflect upon the contents of the boxes that were previously opened and record any items that you remember." This phase is referred to as the free recall phase. Following a 10-minute interval, the recalling phase takes place and the user (revisiting Marco's residence) has to navigate the apartment and select objects that have been previously extracted from the boxes by tapping on them. Within the confines of the dwelling, one can observe the presence of various objects that are dispersed throughout the space. These objects are comprised of the contents of the boxes, as well as an additional set of 15 distractors that were initially introduced during the encoding phase and an additional set of new 15 objects, belonging to the same semantic categories as the distractors. Upon selecting an object, a luminous outline emerges, serving as a form of feedback for the user. Users can select and deselect objects. The task concludes when the participant indicates that they have chosen all the objects, selecting the primary entrance of the house by clicking on the designated area (Figure 2).

Figure 2. (A) The encoding phase: participants explore the 360° house and click on each box; (B) participants have to label the objects that appear; and (C) the retrieval phase: participants have to explore the previous environment and click only the objects they previously saw in the boxes.



The scoring considers the number of objects freely recalled and the number of objects recognized during the recall phase. These are divided into target objects, distractors that were displayed during the encoding phase, and the new set of distractors.

Before spatial and episodic tasks, participants underwent a familiarization phase in which they were introduced to the virtual devices within a simulated household setting. During this phase, participants were instructed to navigate through the virtual environment and adhere to the provided instructions. According to the instructions provided in the tablet version, users are instructed to swipe their fingers horizontally and vertically. This directive is used to establish the comprehensibility of the environment's navigability in a complete circle of 360°, as well as to indicate that the objects within said environment possess the capability of being interacted with through clicking. Moreover, participants are requested to select a door to move to a different room. This instruction serves to convey the concept of interactivity within the environment, emphasizing that the act of clicking on the doors enables the transition between rooms. This functionality is integral to the execution of the spatial memory task.

Each scene provided in the app allows users to look around while performing the tasks. At any time, the interaction is provided either through buttons superimposed on the video or through a specific user interface. Instructions are given to the user in the form of written text before the learning and recalling phases. In particular, the virtual environment refers to a tangible living space that has been captured through the use of the Insta360 One X 360° camera configuration.

SemAPP was developed thanks to a new ad hoc platform incorporating preexisting software capable of playing 360° media, in addition to JavaScript and HTML extensions. A group of clinicians and experts in UX participated in the development of the app. Tasks were chosen based on the most common issues in the literature regarding older people at risk of dementia [18,25]. Furthermore, we draw inspiration from numerous well-used tests to assess cognitive deficits in ecological settings [18] and adapt them to 360° technology.

UX Measures

Quantitative and qualitative measures were captured following and during the experience with the app. We use the System Usability Scale (SUS) [26,27], the Senior Technology Acceptance Model (STAM) [28], the Independent Television Commission Sense of Presence Inventory (ITC-SOPI) [29], and the Thinking Aloud Protocol (TAP) [30].

SUS is a self-report tool, introduced by Brooke [26], which provides a global measure of the usability of a system, based on the following criteria: effectiveness (the ability of users to complete tasks using the system, and the quality of the output of those tasks), efficiency (the level of resource consumed in performing tasks), and satisfaction (users' subjective reactions to using the system). The SUS is composed of 10 items, where the participants could indicate their degree of agreement through a 5-point Likert scale (from 1=strongly disagree to 5=strongly agree). SUS scores range from 0 to 100; the higher the score, the more the system reflects the criteria of effectiveness, efficiency, and satisfaction.

The STAM is a questionnaire that explores older people's acceptance of technology and age-related health characteristics. The questionnaire used in this study is a shorter 14-item version of the original one, which aimed to predict older people's multidimensional acceptance of everyday technology. In particular, the factors explored are attitude through technologies, perception of control, anxiety related to technologies, and general health status. For each area, participants must define their degree of agreement with some statements using a 10-point Likert scale ranging from 1=strongly disagree to 10=strongly agree. For each subscale the score ranges from 1 to 10; the higher the score more the results are satisfactory in terms of attitude, control, less anxiety, and health status.

The ITC-SOPI is a self-report scale that explores the individual's feelings during the experience. The questionnaire is structured in parts A and B, which respectively investigate the user's experience after and during the mediated environment. Participants must indicate their degree of agreement through a 5-point Likert scale (from 1=strongly disagree to 5=strongly agree). The specific factors explored through the 42 items of the questionnaire are the sense of physical space, engagement, ecological validity, and negative effects. Each subscale received a maximum score of 5; the higher the score, the better the result.

We use the TAP to investigate a wide range of mental processes and to analyze the cognitive problems people have with learning and using technology. The TAP is a qualitative instrument consisting of detailed observation and documentation of the users' interaction with the proposed system. During the interaction, participants were asked to comment out loud about their thoughts, doubts, and expectations related to the characteristics of the experience. The real-time evaluation is important because it avoids relevant information being lost if it is collected after the experiment [31,32].

Procedures

Participants took part in 2 different sessions, roughly 1.5 hours. The first one consists of a preliminary discussion with the user about the aim of the study, an informative consensus sign, gathering participant personal data (age, sex, and education) and their confidence with technology and electronic devices, and assessing their general cognitive state with a neuropsychological battery. Based on the results of the assessment phase, we assigned participants in one of the 2 experimental conditions: healthy individuals and patients with MCI. In the second phase, the UX measures were implemented. Participants were asked to accomplish the 2 tasks of semAPP in a randomized order. The only information given to participants was to read and follow the instructions on the screen. Experimenters provided more information when participants did not understand the instructions or if they had issues in using the device (according to the TAP). During the experiment, each issue related to the usability (observed by the experimenter or declared by the participant) of the app was reported on the protocol. After completing the tasks, the participants had to fill out questionnaires. We ran the app on an 11.2-inch iPad.

Statistical Analysis

The statistical analysis was conducted using jamovi (version 2.5; jamovi Project). A significance level of *P*<.05 was established for all tests. In the initial phase, we conducted descriptive analyses on demographic and usability data for both the entire sample and each subgroup, namely the healthy control (HC) and MCI groups. Subsequently, parametric analyses, specifically the independent 2-tailed *t* test (also known as the Student *t* test), were performed to compare groups. Subsequently, we performed correlation analyses using the parametric Pearson test to examine the relationship between the virtual task experience, as evaluated by the SUS, and the 4 scales of the ITC-SOPI questionnaire, as well as the measures of older individuals' acceptance of technology known as the STAM. We carefully considered the appropriateness of both parametric and nonparametric methods. To determine the most suitable approach, we initially conducted a graphical analysis of the data. Through this preliminary graphical examination, we observed that the data distribution closely approximates a normal distribution. Moreover, we performed the Shapiro-Wilk test to verify if our samples were from a normal distribution. This visual inspection and analysis suggested that the assumptions underlying parametric tests might be reasonable. Given these observations, we decided to proceed with parametric methods for comparing groups and correlation analyses. Parametric methods can be robust even with smaller samples if the data are approximately normally distributed. This allows us to take advantage of the greater statistical power offered by parametric tests.

Results

Starting with qualitative data, all participants had some difficulties in comprehending the instruction during the familiarization phase. Certain individuals encountered challenges when attempting to engage with the tablet, specifically regarding the execution of finger-dragging gestures on the screen. A substantial number of users encountered difficulties while attempting to execute the exercises due to the challenging nature of exploring the environment, necessitating the need for additional support. Tables 1 and 2 show detailed results of the TAP for the 2 groups.

Regarding the quantitative data, according to Bangor et al [27], the mean score of the SUS indicates that users perceived the app as having a good level of acceptability (mean 70.22, SD 16.46), as shown in Figure 3 [27]. There were no differences between groups.

The results of the STAM scale reveal that users have a positive attitudinal belief toward technology (mean 7.39, SD 2.16 out of 10), as well as a high level of control belief (mean 7.42, SD 2.06 out of 10). However, the MCI group presented a mean average score significantly higher than HC in both variables (*P*=.049 and *P*=.02, respectively). Users presented a medium level of anxiety related to technology (mean 5.81, SD 2.59 out of 10) and considered themselves in good health conditions (mean 7.78, SD 1.50 out of 10). As shown by the ITC-SOPI subscale investigating spatial presence, participants felt a generally low level of being there in the virtual environment (mean 2.82, SD 0.90 out of 5); they experienced a good level of engagement (mean 3.38, SD .64 out of 5) and naturalness of the environments (mean 3.58, SD 0.89 out of 5). Referring to the subscale of negative effects, all participants reported a low score of side effects (mean 1.57, SD 0.53 out of 5), indicating that the use of semAPP did not induce dizziness and cybersickness. Descriptive statistics for demographics and all UX questionnaires in the sample are shown in Table 3.

Moreover, we analyze the correlations between older adults' experience with the virtual assessment task, as measured by the SUS and the ITC-SOPI, and their attitudes and willingness to use the technology, as assessed by the STAM. The objective is to determine whether older adults who exhibit more favorable attitudes toward technology use also perceive the virtual assessment task as more usable and user-friendly (as indicated by SUS scores) and experience a greater sense of presence and immersion during the task (as indicated by ITC-SOPI scores). Considering the total sample, SUS positively correlated with the STAM perception of control (*r*=0.48; *P*=.004) and STAM health conditions (*r*=0.45; *P*=.008) scales: those who perceive the virtual assessment task to be more usable and user-friendly might also more likely to feel a sense of control over the technology they are utilizing and a more positive perception of their health. When we consider separately the 2 groups, the correlation between the SUS and STAM remains in the MCI group, but not in the HC group. Furthermore, there was a positive correlation observed between the ecological validity scale of the ITC-SOPI and the attitudinal beliefs (*r*=0.35; *P*=.04) and control beliefs (*r*=0.42; *P*=.02) subscales of the STAM . Additionally, a positive correlation was found between the STAM health conditions subscale and the engagement subscale of the ITC-SOPI (*r*=0.36; *P*=.04). The observed correlation suggests that individuals who obtained higher scores on the STAM health conditions subscale, which reflects their perception of their health and well-being, demonstrated a greater likelihood of experiencing heightened levels of engagement within the virtual environment. In other words, participants who possessed the belief that the utilization of technology had positive impacts on their well-being exhibited higher levels of immersion and engagement in the virtual experience. This is true when we consider the MCI group alone, not for the HC group. Correlations for the entire sample and each group are shown in Figures 4 and 5.

Table 1. Qualitative usability results of the Thinking Aloud Protocol in the HC[a] group (n=16).

Task	Problem	Solution	Participants, n (%)
Familiarization			
Reading the instructions	—[b]	—	—
Comprehension of the instructions	Difficulties in understanding the instructions concerning the direction of exploration	Clarify the instructions	15 (94)
Device interaction			
	Instructions do not appear in a functional position to read on the screen	Insert the instructions in the middle of the screen	2 (13)

Discussion

Principal Findings

It is necessary to measure cognitive processes in a way that is similar to what happens in real life to provide functional feedback that accurately reflects the patient’s capacity to respond to daily problems. In this study, a novel tablet-based app with 360° media has been developed to solve the issue of the ecological validity of the currently available test, which used abstract settings. With the increasing scientific discussions supporting the use of new technologies in neuropsychological assessment [33], semAPP was developed using 360° content to simulate real-world circumstances.

The idea behind this app was inspired by the evidence that virtual environments, recreating real situations, might enhance the engagement and pleasure of users, as well as measuring ability that reflects what happens in daily life. As cognitive evaluation increasingly relies on immersive technology, it is crucial to develop user-friendly programs that enable academics, physicians, and patients without engineering skills to access cognitive activities. Attention in their design and execution is a critical issue if one wishes to ensure task reliability and validity. Thus, the final users' experience is an essential element in designing instruments that reflect population needs and expectations. On these bases, a team of experts took part in the design of the app, and the prototype was tested on a group of final users. Our data promise to provide an app usable and accepted by users. SemAPP was judged as an easy-to-use tool for all participants who could interact with it independently under the supervision of clinicians; users evaluated semAPP to be usable and they were willing to use it. They were satisfied and expressed interest in using it. The users were fascinated by using the tablet to explore the virtual environment and enjoyed performing exercises in this innovative way. They were also able to accomplish all expected goals without learning a lot of processes or complex actions; they were at ease using the device because they were familiar with it, and many of them claimed to do so frequently. This is in line with the core features of satisfaction, effectiveness, and efficiency used to define usability [26]. Moreover, users who perceived the virtual assessment task to be more usable and user-friendly have also a positive perception of health and a sense of being able to use apps successfully and effortlessly. Our results are independent of groups; this is promising for the future use of semAPP, which is in line with the needs and expectations of a healthy and aging population with MCI. Thus, it could be used effectively and efficiently by different pools of people.

The results derived from the users' ideas about technology show that all users have a positive appraisal of using technology and they believe that using it would be beneficial for their quality of life. They also believe that using the proposed technology might be free of effort and feel a sense of being able to use it successfully. Contrary to our expectations, these features are significantly higher in the MCI group. The results could be explained by the clinical condition. Patients with MCI are conscious of their deficits, and they could be more engaged in having positive feelings with the app to improve their abilities [34]. All users experience a sense of apprehension when they are faced with the possibility of using technology, for example, due to the fear of making some mistake; this is common in aging [35]. Additionally, older people feel themselves in a good health condition related to biological, psychological, and social capabilities, which decrease with aging (ie, as age increases, there is a decrease in the perception of good health) [35].

Investigating the experience with the virtual scenes, participants reported that the app offered them a sense of engagement and the natural environment, as shown by the ITC-SOPI. However, they detected a generally low level of being in the virtual environment, which may be attributed to the low degree of immersion offered by the tablet. We chose the tablet because it can be used more quickly and easily than other tools for reproducing 360° media, even without the guidance of a therapist or caregiver. However, the media were deployed on a flat screen in a less ecological situation than a head-mounted display, for example. This feature may influence the feeling of immersion [14]. On the other hand, side effects and cybersickness were minimal.

Our findings also support literature that suggests that engagement and a sense of ecological validity improve when users have expectations of positive feelings in using technology, potentially beneficial effects for quality of life, no effortlessness, and a sense of being able to use technology successfully [36,37]. In other words, users' ideas are closely related to how they encounter and evaluate experiences, reflecting anticipated behavior, direct attention, and interpretation, influencing the perceptions of the product [38]. Likewise, older adults who believed that the use of technology had positive impacts on their well-being exhibited higher levels of immersion and engagement in the virtual experience. These results reinforce how a greater likelihood of experiencing heightened levels of engagement within the virtual environment is linked to personal expectations.

Some technical and interface problems were brought up by the TAP during the study, and it is possible that these issues could be resolved by making the instructions clearer and adding the possibility of hearing them. To solve the issues related to interacting with the tablet, we could add a specific training phase focused on the technical use of the device. Thanks to these upgrades, the app should be easier to use.

Nevertheless, while several virtual reality instruments exist to assess memory, only a limited number leverage the unique advantages of 360° media, using computer-generated scenarios [39]. Additionally, some of these tools are delivered using sophisticated solutions, such as head-mounted displays, which can present significant barriers to adoption among elderly individuals [11,40]. Older adults often hesitate to use such advanced technology due to various perceived obstacles [2]. In contrast, semAPP is a highly customizable app designed to be delivered through a range of devices, from smartphones to head-mounted displays. This flexibility offers a more accessible and user-friendly solution that accommodates the varying technological comfort levels of older adults, striking a balance between environmental control and realism.

Given the promising data and the potential of semAPP, further research is essential to fully integrate the app into existing health care frameworks. Integrating our app into these systems would streamline the collection and accessibility of data, enhancing the overall efficiency of cognitive assessments. Additionally, by facilitating remote evaluations through telemedicine, semAPP can become a usable and valuable tool for managing and monitoring cognitive health in aging populations.

Limitations

This work is not exempt from limitations. The market for 360° devices currently offers a few benefits that might give the measurements obtained a higher ecological worth. However, because of the lack of active navigation and the restricted opportunity for engagement within the surroundings, the low degree of immersion that 360° media distributed with tablet exhibits represents one of their most significant drawbacks. In the given context, this can be detrimental in terms of involvement and emotions of naturalness. However, for older people who lacked the necessary abilities to work with more sophisticated technologies, the absence of these characteristics might have been seen as a benefit rather than a limitation.

Despite the widespread adoption and user-friendly nature of tablets as a technological solution, potential biases and variances may arise due to differing levels of familiarity and comfort with technology among participants. While many participants reported frequent tablet use and demonstrated familiarity with the device, they might initially encounter challenges with the 360° media, which possesses distinct characteristics compared to traditional media. These challenges could indicate that differences in technological familiarity can introduce biases and variances in the data, potentially affecting the validity of the findings. Although the participants were able to accomplish all expected goals, we will incorporate a familiarization phase before the test to mitigate these limitations. This phase is designed to acclimate participants to the specific media, ensuring they have sufficient exposure and comfort with the new media format, thereby standardizing their level of comfort and familiarity.

Taking our sample size into account is essential. Based on prior research that used a small number of participants to measure usability [41], as also highlighted by Virzi [42], we chose to use a small number of users. Most usability issues, according to the researchers, are discovered in 4 to 5 individuals, who are progressively less likely to divulge fresh information. We chose 34 users to represent a range of demographics, technical proficiency, and technology knowledge; yet many of them noted the same usability issue at the TAP.

Finally, the heavy reliance on self-reported data may introduce subjective biases. Implementing additional objective measures, while beneficial, is challenging with an older adult population and limits capturing UX in a manner that is both simple and well-accepted. Nonetheless, future research should consider integrating objective measures to complement self-reported data providing a more comprehensive assessment.

Even with its limitations, these findings support the usability of 360° assessment, implementing the objective evaluation of ecological situations. However, additional work will be implemented to improve the problems revealed by the TAP and to explore the validity of the instrument.

Conclusions

We developed a new 360° tool to assess memory in aging, and we explored its usability and the correlated experience in using it. We focused on 2 different populations: healthy older adults and patients with MCI, to examine possible differences in terms of usability and, thus, to verify if our app was designed to be used by both target user groups excellently. Our results were satisfactory, showing the achievement of goals relating to the possibility of using the app by the target sample, with a positive experience.

Our research also supports the importance of a user-centered approach that adapts the app to the target population, analyzing the needs and clinical conditions of older people. To achieve this goal, we require a team of clinicians who have clinical competencies and UX experts. They designed an app focused on the clinical features of patients, in line with the major requirement to create the best possible experience in terms of usability and accessibility of the app. Our findings support the idea that users' thoughts about technology might influence how the product is seen, as well as the experience in the virtual environments (ie, the engagement and sense of being there). Given the complexity of human experiences, the usability and effective use of an instrument potentially depends on a great variety of parameters. The experience presupposes that all personal and technological factors are connected, interact, and change one another and the experience is what comes out of this process [36]. In this panorama, evaluating the product while considering end users could be crucial. Researchers must be aware that, depending on the personal experience and clinical condition at hand, users can have different experiences with the same product [43]. Indeed, if we do not consider the end user's experience, there may be a potential mismatch between the designers' intentions and users' actual anticipation.

Abstract

Background: It is a contemporary and global challenge that the increasing number of older people requiring care will surpass the available caregivers. Solutions are needed to help older people maintain their health, prevent disability, and delay or avoid dependency on others. Technology can enable older people to age in place while maintaining their dignity and quality of life. Literature reviews on this topic have become important tools for researchers, practitioners, policy makers, and decision makers who need to navigate and access the extensive available evidence. Due to the large number and diversity of existing reviews, there is a need for a review of reviews that provides an overview of the range and characteristics of the evidence on technology for aging in place.

Objective: This study aimed to explore the characteristics and the range of evidence on technologies for aging in place by conducting a scoping review of reviews and presenting an evidence map that researchers, policy makers, and practitioners may use to identify gaps and reviews of interest.

Methods: The review was conducted in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews). Literature searches were conducted in Web of Science, PubMed, and Scopus using a search string that consisted of the terms “older people” and “technology for ageing in place,” with alternate terms using Boolean operators and truncation, adapted to the rules for each database.

Results: A total of 5447 studies were screened, with 344 studies included after full-text screening. The number of reviews on this topic has increased dramatically over time, and the literature is scattered across a variety of journals. Vocabularies and approaches used to describe technology, populations, and problems are highly heterogeneous. We have identified 3 principal ways that reviews have dealt with populations, 5 strategies that the reviews draw on to conceptualize technology, and 4 principal types of problems that they have dealt with. These may be understood as methods that can inform future reviews on this topic. The relationships among populations, technologies, and problems studied in the reviews are presented in an evidence map that includes pertinent gaps.

Conclusions: Redundancies and unexploited synergies between bodies of evidence on technology for aging in place are highly likely. These results can be used to decrease this risk if they are used to inform the design of future reviews on this topic. There is a need for an examination of the current state of the art in knowledge on technology for aging in place in low- and middle-income countries, especially in Africa.

Introduction

Background

The World Health Organization (WHO) estimates that the global population aged 60 years and older will increase from 12% to 22% between 2015 and 2050, with the most dramatic increase in low- and middle-income countries (LMICs) [1]. This will change the age composition in populations globally. Demographic aging refers to shifts in the age composition of populations where the proportion of the population that consists of older people grows significantly. The fact that people are now living longer than ever and that they are expected to continue doing so is the result of positive developments in public health and survival [2]. Yet, demographic aging is also one of the key challenges of our time [3].

This concern is caused by how demographic aging will impact nation states. As people grow older, they tend to become increasingly reliant on both formal and informal care. For instance, older people are more likely to have functional limitations, need assistance with everyday tasks, and need medical care [4-6]. Moreover, older individuals have lower incomes, which compound the challenges of their increasing need for care [7]. As a result, nation states have a variety of systems in place to care for older people, including systems of shouldering the cost of that care.

In countries where welfare and care systems are heavily subsidized, demographic aging is predicted to lead to heavy financial strain and a decreased quality of life for older people, unless solutions that cater to the need to maintain good health and affordable health care into a longer set of retirement years are developed [8]. Still, the adverse consequences of demographic aging will be even greater in LMICs. In LMICs, welfare systems often function poorly or are nonexistent, meaning that the burden of caring for older people falls on families or on the older individuals to care for themselves. This has caused concerns that LMICs will “grow old before growing rich” [7].

To neutralize the overwhelming demand for health care, solutions are needed to enable older people maintain their health for longer and postpone or avoid disability and dependency [1,9,10]. Against this background, interest in technology that enables older people to age in place while maintaining their dignity and quality of life has grown rapidly over the past 2 decades [11].

Aging in place is a concept that refers to the shared responsibility of individuals and public authorities to enable older people to continue to live safely, relatively independently, and comfortably in the community either in their current home or in appropriate housing, regardless of age, income, or level of competence [1,12-14]. The idea is that policies and public services should address the challenges posed by demographic aging by finding alternatives to traditional forms of older adult care and creating solutions that are less resource-intensive. In welfare states where health and care services are heavily subsidized, this shift toward less resource-intensive solutions generally refers to options that maintain a high quality of life for older people while simultaneously preventing or delaying the need to relocate to a nursing home or becoming dependent on care [15], as well as to solutions that minimize the use of resources in nursing homes and other forms of formal care, without compromising their quality. Meanwhile, in LMICs, the main challenge is that welfare systems are weak and even nonexistent. Assistive technology and related services are marginal and not available for the majority, particularly for the poor rural populations. Ensuring assistive technology for all, including the growing number of older adults, requires resources and build-up of competence through a sustainable systems approach [16]. In this context, innovations are needed in service delivery, and community-based models as well as adaptation of existing assistive technology and development of new and contextually relevant assistive technology are needed to ensure that older people live well and as autonomously as possible [17].

Technologies that enable aging in place encompass a wide variety of technologies designed to monitor or support the health and activities of older people or strengthen their contact with others [11,15]. In some cases, older people are the intended users, but technology can also be used to establish links between older adults and their circles of care. Technologies for aging in place include both high- and low-tech solutions, including but not limited to mobility devices, information and communication technologies, assistive technologies, sensor technology, telemedicine, health monitoring, games, wearables and medication reminders, and the internet of things [15,18-27].

Rationale

Alongside the interest in technology that can enable older people to age in place, the number of publications on this topic has increased dramatically. In this context, literature reviews can be important tools for researchers as well as practitioners, policy makers, and decision makers who need to navigate current debates and access syntheses of the available evidence. Yet, to date, there is no review of the available published reviews that provide an overview of the range and characteristics of the evidence on technology for aging in place.

While reviews of reviews on technologies for aging in place do exist, they typically limit the scope to health conditions, diseases, technologies, or caring practices, for instance, by focusing on the self-efficacy of older people using technology to self-manage chronic obstructive pulmonary disease, hypertension, heart failure, or dementia at home [28]; on the effects of digital technologies on older people’s access to health and social care [29]; on the promotion of physical activity in older people using mobile health (mHealth) and eHealth technologies [30]; or on how mHealth technology may support aging in place [31] and procedures of user-centered usability assessment for digital solutions [32].

Objective

The objective of this review of reviews is to explore the characteristics and the range of evidence on technologies for aging in place by conducting a scoping review of reviews in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for

Scoping Reviews) [33]. The PRISMA-ScR checklist is available in Multimedia Appendix 1.

By exploring the included reviews, we are particularly interested in what year and in which journals they are published, which review methods that characterize reviews in this field, and whether there are any reviews that are explicitly concerned with LMICs. By LMICs, we mean the countries identified by the Organization for Economic Co-operation and Development as having low-income or middle income economies, which may be updated from time to time by the Organization for Economic Co-operation and Development [34]. In exploring the range of evidence presented in reviews on technologies for aging in place, we are particularly interested in which types of populations, technologies, and problems they have been concerned with.

Methods

Eligibility Criteria

We included literature reviews in English about technology for older people or older adult care, including informal care, that we were able to access. To ensure the quality of our sources, we limited our scope to peer-reviewed literature reviews that have been published in academic journals. For the same reason, we only included reviews where the methods were clearly described. We did not apply any limits to the year of publication.

Information Sources

Our method of selecting databases included making a list of the most relevant journals in the field that the authors were aware of (Multimedia Appendix 2). The complete list was sent to a panel of experts consisting of members from the WHO and the International Society of Gerontechnology, who were asked to add any potentially relevant journals missing from the list. After the list was considered complete, the authors identified the databases where these journals were indexed. The final selection of databases was Web of Science (Table 1), PubMed (Table 2), and Scopus (Table 3). The searches in Web of Science and Scopus were conducted on September 13, 2022, and the search in PubMed was conducted on September 14, 2022.

Search

A search consisting of the terms “older people” and “technology for ageing in place” with alternate terms was conducted using Boolean operators and truncation. The search was adapted to the rules for each database.

Selection of Sources of Evidence

The search resulted in a total of 7274 identified studies, that is, 3131 from Scopus, 2402 from PubMed, and 1741 from Web of Science. We used Covidence (Veritas Health Innovation) to organize the review process. After 1827 duplicates were identified and removed, 5447 studies were screened using the eligibility criteria (see Textbox 1). The original list of eligibility criteria contained items 1-7. However, after we identified a retracted paper, we decided to add exclusion criterion 8 “retracted paper.” The title and abstract screening resulted in the exclusion of 4973 studies. The full-text screening resulted in the further exclusion of 130 studies, and the remaining 344 studies were included in the data charting process. Figure 1 illustrates this process.

Textbox 1. Eligibility criteria.

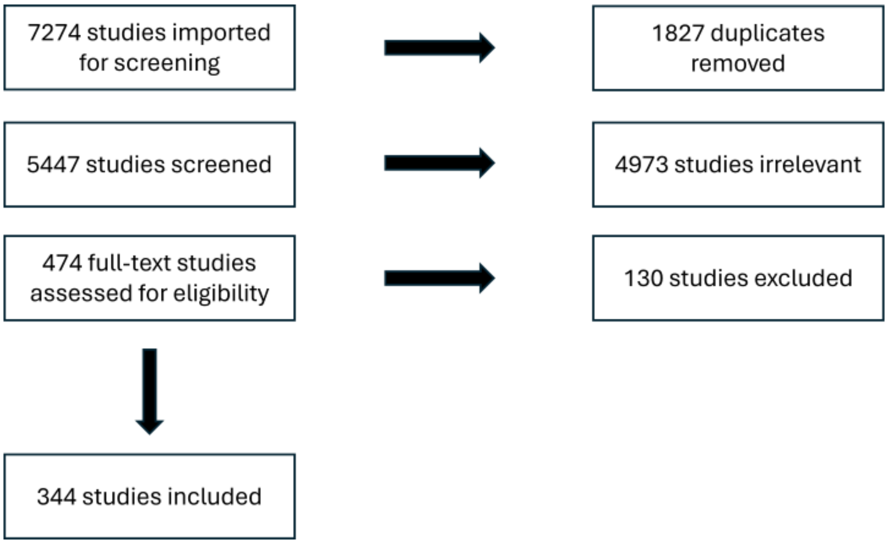
Inclusion criteria

- Literature reviews
- Journal paper
- Peer-reviewed research
- Able to source full text
- Methodologically sound
- About technology for aging in place
- English

Exclusion criteria, with a short label for Covidence

- Not a literature review—Papers that do not review the literature
- Not a journal paper—Anything that is not a paper meaning: book chapters, conference proceedings, protocols, reports, preprints, etc
- Not research—editorials, opinion pieces, press, etc
- Unable to source—currently unable to access full text currently
- Method not described—Reviews that do not clearly describe their methods
- Thematically irrelevant—Not about technology for aging in place
- Not in English
- Retracted paper

Figure 1. Screening process flowchart.



Data Charting Process and Data Items

The data were extracted using the data extraction template feature in Covidence. The extraction of data was organized in line with our objectives and research questions. Tables 4 and 5 provide an overview of the relationship between the research questions and the extracted data.

Table 4. Research questions and charted data that relate to the characteristics of reviews on technologies for aging in place.

Research question	Extracted data
During what years were the reviews published?	Year of publication
In which journals have the reviews been published?	The name of the journal where they are published
Which review methods characterize the reviews?	The named review methods they refer to
Is there an explicit concern with LMICs?[a]	If they refer explicitly to LMICs (yes or no)

[a] LMIC: low- and middle-income countries.

Table 5. Research questions and charted data that relate to the range of evidence in reviews on technologies for aging in place.

Research question	Extracted data
Which populations are they concerned with?	The population specified in the review
Which types of technology are they concerned with?	The technology specified in the review
What type of problems are they concerned with?	The issues of interest specified in the review
What is the relationship between the populations, problems, and technologies the reviews have dealt with	The type of technology and the issues of interest specified in the review

All authors participated in the choice of databases and establishing the search terms and eligibility criteria. EL constructed the search string and conducted the final search. All authors participated in the screening process. The full-text papers were extracted by the authors JMB, MG, and AHE. All authors participated in the data synthesis and presentation of the findings.

Results

Characteristics of Evidence on Technologies for Aging in Place

Multimedia Appendix 3 shows an overview of the data and sources that correspond to this section. The number of reviews of evidence on technology for aging in place has increased dramatically over the past few years (Table 6). The earliest review included in our search was published in 2001 [35]. A total of 20 reviews were published between 2001 and 2010. By comparison, 142 reviews were published between 2015 and 2020. Note that the table only includes reviews published before September 13, 2022, when our search was conducted.

From 2020 to 2021, there was a near doubling in number of reviews. Since our search was conducted at the beginning of September 2022, the figure does not show the full extent of published reviews in 2022. However, it is likely that the trend will continue upwards. The included reviews were published in 183 unique journals. Of those, most journals have only published 1 or 2 reviews since 2001. Only 12 journals have published more than 5 reviews in total since 2001 (Table 7).

Table 6. Number of reviews by year of publication (n=344).

Year of publication	Reviews, n
2001	1
2002	0
2003	0
2004	1
2005	1
2006	0
2007	5
2008	4
2009	6
2010	2
2011	4
2012	8
2013	12
2014	14
2015	6
2016	16
2017	23
2018	23
2019	33
2020	47
2021	88
2022	50

Table 7. Overview of 12 journals that have published 5 or more reviews on technologies for aging in place since 2001.

Journals	Reviews, n
Clinical Interventions in Aging	5
Healthcare	5
Assistive Technology	6
Journal of Telemedicine and Telecare	7
Maturitas	8
JMIR Aging	10
International Journal of Environment Research and Public Health	11
Sensors	11
The Gerontologist	11
Disability and Rehabilitation: Assistive Technology	13
International Journal of Medical Informatics	16
Journal of Medical Internet Research	17

The reviews refer to 15 unique types of review methods. Of these, the most common were systematic reviews (n=144) and scoping reviews (n=60). The third most common review method was to provide a detailed account of the procedures but refrain from referring to a specific type of review method (n=98). While there were only 13 integrative reviews and 6 narrative reviews, the fact that most other review methods only occurred once or twice made the narrative reviews common by comparison (Table 8).

Table 8. Overview of the data analysis methods used in the included reviews.

Data analysis method	Reviews, n
Systematic review	144
Scoping review	60
Integrative review	13
Narrative	6
Mini-review	5
Review of reviews	5
Rapid review	2
Umbrella review	1
Targeted review	1
Meta-interpretive review	1
Focused literature review	1
Descriptive review	1
Clinical review	1
Critical interpretive synthesis	1
Conceptual review	1
Comprehensive review	1
Comparative literature review	1
Reflective review	1
Unspecified	98

Only 1 review referred explicitly to LMICs [36]. This review aimed to identify policy gaps in the delivery and availability of assistive health technology and medical devices for aging populations, particularly in LMICs, and found that practical, life-enhancing support for older people through assistive health technology, medical technology, and related health and social services is a neglected issue.

Range of Evidence on Technologies for Aging in Place

Populations

Multimedia Appendix 4 shows an overview of data and sources that correspond to this section. Some reviews dealt with more than one type of population.

The included reviews dealt with populations in three ways by (1) describing the population in terms of older people or different types of caring roles (n=253), (2) describing the population in terms of a particular health condition or diagnosis (n=73), or (3) not specifying the population (n=43).

Of the included reviews, 253 described the population in terms of people and the roles they play in the context of aging. Of those reviews, an overwhelming majority only included studies on older people (n=220). Of the included reviews, 12 reviews dealt with formal and informal caregivers or combinations of these 3 different populations (Table 9).

Table 9. Overview of the populations in 253 reviews that described the population in terms of people and the roles they play in the context of aging.

Populations	Reviews, n
Older people	220
Formal caregivers	1
Formal caregivers and informal caregivers	2
Informal caregivers	5
Older people and formal caregivers	5
Older people, formal caregivers, and informal caregivers	4
Older people and informal caregivers	16

In total, 73 reviews described the population in terms of older people as well as individuals from other age groups, with a particular diagnosis or health problem. These reviews included studies about people of different age groups with different cognitive impairments exclusively (n=41) or in combination with other health problems (n=2). Notably then, these reviews included evidence based on studies of younger people as well as older people. Table 10 provides an overview of the diagnoses and health problems that these reviews used to conceptualize the populations.

In total, 43 reviews did not specify the population at all. Instead, they referred to the context of aging in place. These reviews were typically concerned with the technical functionality of devices rather than the interplay between what the technology offers and the intended users and their problems.

Table 10. Overview of the diagnoses and health problems used to conceptualize the population in reviews about older people and others with a particular diagnosis or health problem (in total n=73 reviews).

Diagnoses and health problems	Reviews, n
Cancer	1
Cardiovascular diseases	1
Cardiovascular diseases, diabetes, and asthma	1
Chronic conditions	7
Cognitive impairments	41
Cognitive impairments, cardiovascular diseases, and chronic obstructive pulmonary disease	1
Cognitive impairments, neurological disorders, falls, and cardiovascular disease	1
Complex needs	1
Decline in hand grip and dexterity	1
Diabetes	1
Falls	4
Falls and frailty	1
Frailty	6
Frailty and decreased hearing	1
Hip injuries	1
Loneliness and social isolation	2
Mental health	2

Types of Technology

Multimedia Appendix 5 shows an overview of the data and sources that correspond to these results. Some reviews dealt with more than one type of technology.

We identified 69 different types of technology that reviews have been concerned with and 5 substantive strategies that the reviews have used to conceptualize the technology with which they are concerned. Two of the 345 reviews used other strategies for conceptualizing technology. One was about co-designed technologies [37]. The other was about what they termed as consumer technology as well as smart environments [38].

The first and most common strategy (n=140 reviews) is to refer to technology by using descriptive technical terms such as "sensors" [39-48], "artificial intelligence" [49-52], "GPS" [53-55], or "games" [56-60]. The reviews that used this strategy covered 31 different types of technology exclusively or in combination with each other. Most of these reviews were focused on robots or robopets (n=47), information and communication technology (n=23), smart environments (n=17), or sensors (n=10).

The second strategy (n=65) is to conceptualize technology by the purpose of the technology in relation to a disease or type of health challenge that the technology addresses or is believed to be able to address, for instance, by using terms such as "technology for dementia" [61-70], "technologies for social connectedness" [71-75], "technology for frailty" [76-78], "technology for safety" [79], or "technology for falls" [60,80-84]. Most of the reviews that relied on this strategy dealt with assistive technologies (n=28).

The third strategy (n=30 reviews) is to refer to technologies in terms of their intended purpose in caring services or practices that they are part of. Such terms include "teleopthamology" [85], "monitoring technologies" [86,87], "telerehabilitation" [88-93], "technology for home health care" [94,95], or "technology for pain management" [96]. Most reviews that relied on this strategy were concerned with telerehabilitation (n=7) or technology for health information (n=6).

The fourth strategy (n=29 reviews) is to describe the type of technology by using umbrella terms that broadly refer to the use of technology to enable older people to age in place, for instance, by defining the technology of interest in terms of "technology for ageing in place" [11,97-99], "gerontechnology" [100-102], "welfare technology" [103-105], "technology for healthy ageing" [106,107], or "technology for older people" [22,32,108-112].

The fifth strategy (n=75 reviews) is to describe the type of technology the review is concerned with by way of concepts that refer to the use of technology as part of a broad range of caring services, strategies, and practices, such as, for instance, telecare [113-119], telemedicine [120-125], e-interventions [126], or eHealth [127-143]. Most reviews that used this type of concept to describe the technology they are concerned with dealt with mHealth (n=18), eHealth (n=17), or telehealth (n=18).

What Types of Problems Have the Reviews Dealt With?

Multimedia Appendix 6 shows an overview of the corresponding data and sources. Some reviews dealt with more than one type of problem. We identified 49 unique problem topics and 4 principal types of problems.

The first type of problem is related to different types of care services or caring practices (n=60 reviews). Most of these reviews dealt with problems related to the context of home care (n=30), caring practices in nursing homes or other long-term care institutions (n=11), or rehabilitation (n=7). By contrast, other topics occurred only once or twice, that is, problems related to caregiver burden [144,145], dementia care [146], emergency care services [147], informal care [148], and health information services [149,150].

The second type of problem is issues related to the management of health-related issues or diseases in the context of aging in place (n=128 reviews). Of those, most dealt with problems related to cognitive impairments either exclusively (n=61) or in combination with one or several other health problems (n=10), that is, cognitive impairment and mental health [151-155], or cognitive impairment, stroke, cardiovascular disease, and falls [156]. Other problems that were featured relatively frequently included falls and balance–related issues (n=19), frailty (n=8), chronic conditions (n=8), and depression (n=5). Meanwhile, other problems related to the management of other health-related issues and diseases featured only once or twice, despite being common health challenges for older people (for instance, Parkinson’s disease [157,158], malnutrition [159], dental health [160], eye diseases [85], and pain [96,161]).

The third type of problem relates to the experience of aging in place (n=82 reviews). The most common topics in this category were loneliness, including social isolation or connectedness (n=21 reviews), older peoples’ self-care or self-management (n=19 reviews), and active aging (n=16 reviews). Other topics in this category include healthy aging [106,111,137,162-165], information needs [166], quality of life [97,167-173], quality of life and older people’s self-care and self-management [174,175], and activities of daily living exclusively [176-179] or in combination with other topics such as loneliness [180,181], or quality of life [182].

The fourth type of problem relates to the research and development of technology. This was the most common type of problem (n=285 reviews). The overwhelming majority of reviews that dealt with this type of problem were concerned with barriers and drivers of use and acceptability (n=114), the effect or implications of technology (n=86), or the combination of these 2 topics (n=21). Other common topics included uptake or scalability (n=15), user involvement (n=11), ethical considerations (n=14), feasibility (n=10), and cost-effectiveness or use (n=7).

Notably, problems related to home care (n=30), loneliness (n=21), cognitive impairments (n=71), barriers and drivers of use and acceptability (n=114 reviews), and the effect or implications of technology (n=86) have been heavily emphasized. Meanwhile, others such as cost-effectiveness or use of technologies (n=7), health information needs (n=1), malnutrition (n=1), dental health (n=1), eye diseases (n=1), and pain management seem underprioritized by comparison.

What Are the Relationships Between the Problems, Technologies, and Populations That the Reviews Have Dealt With

Multimedia Appendix 7 shows an evidence map that provides an overview of the relationships between problems, technologies, and populations that the reviews have been concerned with. Some reviews deal with more than one population, technology, and type of problem. Multimedia Appendix 8 shows an overview of the corresponding data and sources.

As illustrated in the evidence map (Multimedia Appendix 7), many reviews draw on an evidence base that is not specific to older people or their caregivers.

This is particularly notable in the reviews on the following topics: barriers and drivers of use and acceptability, cognitive impairment, and the effect or implications of technology. The same observation applies to the following types of technology such as assistive technologies, robots, technology for dementia, technology for falls, technology for frailty, telehealth, and technology for Alzheimer disease.

Summary of Evidence

In exploring the range and characteristics of reviews on technology for aging in place, we found that the number of reviews, as well as the pace at which they are published, has increased dramatically over time. While some journals such as *JMIR Aging*, *Disability and Rehabilitation: Assistive Technology*, the *Journal of Medical Internet Research*, and *The Journal of Medical Informatics* have published more reviews on this topic than others, the literature is scattered over 183 unique journals. Most reviews on this topic are systematic reviews (n=144).

In exploring the range of reviews on technology for aging in place, we identified 3 principal ways that reviews have dealt with populations. Specifically, the 3 ways are describing the population in terms of older people or different types of caring roles (n=253), in terms of people affected with a particular health condition or diagnosis (n=73), or not specifying the population (n=43). These may be considered as methods of conceptualizing populations. We identified 88 unique types of technology that the reviews have dealt with. We also found that there are strong tendencies for reviews to synthesize the evidence on broad and unspecific categories of technology such as “ICT” or “robots” rather than to concentrate on a particular device (a notable exception is a review on personal alarms [183]). Moreover, we identified 5 strategies that the reviews draw on to conceptualize technology. Those strategies are to (1) refer to technology by using descriptive technical terms; (2) conceptualize technology by way of the purpose of the technology about a disease or health issue; (3) refer to technologies in terms of their purpose in caring services or practices; (4) use umbrella terms that broadly refer to the use of technology to enable older people to age in place; and (5) use concepts that refer to the technology as part of caring services, strategies, and practices. We also identified 4 principal types of problems and 49 unique subtypes of problems that the reviews have dealt with. The four principal types are problems related to (1) different types of care services or caring practices, (2) the management of health problems or diseases, (3) the experience of aging in place, and (4) the research and development of technology. The evidence map (Multimedia Appendix 6) demonstrates the relationships between the populations, technologies, and problems studied in the reviews and illustrates the gaps. Notably, many of the reviews on the most studied technologies and problems draw on studies that are not specific to older people or the context of aging in place, either by not specifying the population at all or by including studies on patients of all ages, meaning that topics studied only by such reviews should also be considered gaps.

Discussion

Summary of Evidence

Together, these results speak to the need for regularly updated overviews of ongoing debates in the field. However, they are also illustrative of the challenges that such overviews must overcome. For instance, the lack of conceptual hegemony means that any attempt to describe the technologies that the reviews have been concerned with in purely technical terms fails to grasp the diverse ways that technology is understood in this field. A more fruitful approach is to categorize them according to the different ways that they understand and deal with technology. Used as methodological tools, the strategies of defining populations, conceptualizing technology, the typology of problems, and the overview of the relationships presented here can inform the design of future reviews and enable researchers to purposefully identify gaps and publications that are likely to be of relevance to each other despite conceptual differences that may obscure their similarities.

It is notable that only 1 review was explicitly concerned with LMICs, considering that the greatest growth in older people globally will be in LMICs [1], particularly in Africa where the population of 60 years and older is expected to increase by more than 100% by 2050 [184]. Similarly, it is notable that in the included reviews, relatively little attention has been paid to formal and informal caregivers. Both formal and informal caregivers play important roles in the context of technology for aging in place. Both formal and informal caregivers frequently speak and act on behalf of older people, especially older people with cognitive impairments when technology developers seek to identify user needs or evaluate the usefulness of the technology [185-188]. In doing so, they act as gatekeepers who shape what types of technology are developed and offered to older people, and equally important, which are not [109]. Both formal and informal caregivers are often the intended users of technology that is meant to enable older people to age in place. Thus, the politics of their lives and working conditions as well as the quality and type of care they are able to provide to older people are shaped by what the technology affords and prohibits [189-191]. Yet, the purpose of the technology is aimed at the needs of the older person or efficiency-related goals in care organizations rather than the improvement of the care workers' working environment or care burden. Additionally, like all users, both formal and informal caregivers are not just impacted by technologies that enter their lives but they also shape the technology in turn [188,192-199], meaning that the implications that the technology will have in practice are never given beforehand and must always be studied in the context of use [185,187,200,201]. Finally, both informal and formal caregivers must frequently improvise and adapt the technology to render it functional [192,202-205]. Thus, both formal and informal caregivers play important roles in shaping the practices, politics, and services that the technology affords or delimits in the lives of older people who age in place. These roles have been thoroughly described in the literature. Yet, they seem overlooked in reviews on technology for aging in place.

It is problematic that so many reviews concerned with problems related to technologies for aging in place draw on an evidence base that is not specific to older people. Older people frequently have other needs than younger people even when they share a diagnosis because the aging body presents specific challenges, which increase the risk of illnesses, falls, disability, and death [206]. It is therefore unlikely that reviews that do not focus explicitly on older people are able to grasp and address the specificity of the challenges that older people face as part of aging in place. This primarily concerns reviews on the topics of barriers and drivers of use and acceptability, cognitive impairment, and the effect or implications of technology. It also concerns reviews about assistive technologies, robots, technology for dementia, technology for falls, technology for frailty, telehealth, and technology for Alzheimer disease. While these topics and technologies have frequently been addressed, the value that reviews that do not specify their population or that base their arguments on studies of people of all ages (see Multimedia Appendix 6) is limited, and there is a need for more targeted and age-specific syntheses reviews to better address the unique requirements of older individuals and their caregivers. The strong tendency for reviews in this field to concentrate on broad and unspecific categories of technology, such as "ICT" or "robots" means that there is no straightforward way for practitioners to use these reviews as support in decision-making processes regarding the potential usefulness and challenges related to specific devices.

Limitations

Despite the many methodological strengths of the design of a scoping review of reviews, there are some limitations to be considered. These include the potential for bias in the review process, the difficulty ensuring the quality and reliability of the included reviews, and the potential for the review to be influenced by the perspectives and priorities of the researchers conducting the review. Considering the broad eligibility criteria chosen for this review, the results may be considered representative of the characteristics and range of evidence on technologies for aging in place. However, the inclusion of more databases could have expanded the data set even further, and potentially relevant literature that does not use the term aging in place explicitly may have been missed. Moreover, this review has not sought to explore or synthesize the results of the included reviews nor have we considered the quality of the included reviews.

Conclusions

The number of published reviews on this topic in the past few years in combination with the rate at which they are published suggests that redundancies and a lack of fruitful synergies between them are likely. The breadth of variation concerning how reviews have dealt with populations, conceptualizations of types of technology, and problems demonstrates the conceptual differences that must be bridged to remedy this problem.

Together, these results underscore the necessity for improved coordination and collaboration among reviews while also recognizing the potential benefits of more standardized vocabularies.

The insights gained from the methods of dealing with populations, strategies for conceptualizing types of technology, and the types of problems identified in this study may be used methodologically to identify commonalities and connections that may otherwise be obscured by differing conceptual frameworks.

There is an urgent need for an examination of the current state of the art in knowledge regarding technology for aging in place in LMICs. Developing a deeper understanding of the conditions surrounding aging in LMICs, especially in Africa, and the implications those conditions have for the roles that technology may play and not play in the lives of older people and their circles of care should be an essential focus of the research agenda.

Acknowledgments

The scoping review was conducted by SINTEF as part of a collaboration among SINTEF, WHO, and the International Society for Gerontechnology (ISG) that aim to ensure an emphasis on older people within the current global momentum on AT. The authors would like to thank Espen H Aspnes, former vice president of ISG who leads Pillar II in this collaboration, to which the result of this review contributes. We also wish to thank Professor Sue Levkoff (ScD, MSW, SM), College of Social Work, the University of South Carolina. Endowed chair in SeniorSMART, as well as other members of the International Society for Gerontechnology (ISG) and The WHO contributed to discussions and workshops during the planning stage of this review. For their contributions to the selection of databases, we especially thank Dr Callista Kahonde, researcher and assistant lecturer at Stellenbosch University; Centre for Disability and Rehabilitation Studies, and Anna Spånt Enebuske, MSSc and research officer at The Swedish Municipal Workers' Union, Finally, we thank our colleague Sandra Klonteig MSc, SINTEF Digital, for her contributions during the data extraction phase, and Mr Sebastian M Bergschöld for his contributions to the evidence map. This study was funded by SINTEF.

Abstract

Background: With the population aging, the number of people living with dementia is expected to rise, which, in turn, is expected to lead to an increase in the prevalence of missing incidents due to critical wandering. However, the estimated prevalence of missing incidents due to dementia is inconclusive in some jurisdictions and overlooked in others.

Objective: The aims of the study were to examine (1) the demographic, psychopathological, and environmental antecedents to missing incidents due to critical wandering among older adult MedicAlert Foundation Canada (hereinafter MedicAlert) subscribers; and (2) the characteristics and outcomes of the missing incidents.

Methods: This study used a retrospective descriptive design. The sample included 434 older adult MedicAlert subscribers involved in 560 missing incidents between January 2015 and July 2021.

Results: The sample was overrepresented by White older adults (329/425, 77.4%). MedicAlert subscribers reported missing were mostly female older adults (230/431, 53.4%), living in urban areas with at least 1 family member (277/433, 63.8%). Most of the MedicAlert subscribers (345/434, 79.5%) self-reported living with dementia. MedicAlert subscribers went missing most frequently from their private homes in the community (96/143, 67.1%), traveling on foot (248/270, 91.9%) and public transport (12/270, 4.4%), during the afternoon (262/560, 46.8%) and evening (174/560, 31.1%). Most were located by first responders (232/486, 47.7%) or Good Samaritans (224/486, 46.1%). Of the 560 missing incidents, 126 (22.5%) were repeated missing incidents. The mean time between missing incidents was 11 (SD 10.8) months. Finally, the majority of MedicAlert subscribers were returned home safely (453/500, 90.6%); and reports of harm, injuries (46/500, 9.2%), and death (1/500, 0.2%) were very low.

Conclusions: This study provides the prevalence of missing incidents from 1 database source. The low frequency of missing incidents may not represent populations that are not White. Despite the low number of missing incidents, the 0.2% (1/500) of cases resulting in injuries or death are devastating experiences that may be mitigated through prevention strategies.

Introduction

Background

With the population aging, the number of people living with dementia will increase. Currently, approximately 55 million people have dementia globally [1]. With approximately 10 million new diagnoses each year, the total number of cases is expected to rise to 78 million by 2030 [1]. Canada is no exception to this trend, with at least 546,000 people currently living with dementia [2]. By 2030, the number of Canadians with dementia will reach at least 1,712,400 [3].

The disease burden cost associated with dementia is sizable in Canada. It was estimated that the direct costs (eg, long-term care) associated with dementia was CAD $10.4 billion (US $7.52 billion) in 2016, and it is expected to double by 2030 [2]. Half of the global cost of dementia is attributed to informal care (ie, family members and friends) [1]. It is estimated that, on average, care partners spend 26 to 35 hours per week caring for persons with dementia [1,4]. This overwhelming number of caregiving hours is attributed to personal care (ie, personal care such as bathing, feeding, and assisting with toileting) [5] and vigilance as a prevention strategy to prevent unattended exits, ultimately keeping persons living with dementia safe in their homes [6].

With increasing numbers of people living with dementia, the prevalence of missing incidents due to critical wandering is rising as well (refer to section *The Concept of Missingness and Critical Wandering and Its Risk Factors: A Brief Theoretical Background*). However, research on prevalence estimation on missing incidents due to critical wandering is inconclusive in some jurisdictions and overlooked in others. Limitations of the prior literature on this topic exist. First, there is a lack of consistency on reported prevalence [7], leading to disparate statistics; for example, McShane et al [8] reported that 40% of people with dementia become lost, and 5% do so repeatedly. The Alzheimer's Association estimated that 60% of people with Alzheimer disease will wander [3], and a considerably larger set of studies showed that the prevalence of wandering varies from 11% to 60% [9,10]. Second, previous studies included low sample sizes from limited secondary data sources (eg, data not retained for >5 years) [11] such as police data and data obtained from newspaper report or social media [12-15], leading to a limited scope of the statistical analyses. Third, prevalence studies have been completed in the United States [16,17], Japan [18-20], and South Korea [21,22], leaving the prevalence of missing incidents among people with dementia in Canada largely unknown. This is an important gap in our knowledge because Canada has distinct social, health care, and geographic features as well as a harsh climate, making it challenging to extrapolate data from other countries for its unique context. As a result, the prevalence and risk factors of missing incidents due to critical wandering for Canadians living with dementia remain largely unknown.

Objectives

The aims of this study were to examine (1) the demographic, psychopathological, and environmental antecedents to missing incidents due to critical wandering among older adult MedicAlert subscribers; and (2) the characteristics and outcomes of the missing incidents. We used a retrospective descriptive design. The sample included 434 older adult MedicAlert subscribers (hereinafter MedicAlert subscribers) involved in 560 missing incidents between January 2015 and July 2021.

The Concept of Missingness and Critical Wandering and Its Risk Factors: a Brief Theoretical Background

Missingness is the phenomenon of going missing [11]. A missing person is an "individual that cannot be found" [23]. A missing person is "an individual whose whereabouts are unknown to members of their familial, social or professional networks where there is concern for either their own safety and wellbeing or that of others" [24]. A person can go missing intentionally or unintentionally. A person who goes missing unintentionally is said to be lost if the person is (1) "confused with current location in respect to finding other locations" and (2) "unable to reorient" [23]. In this research, we analyzed missing incidents related to persons (older adults) who go missing unintentionally. People living with dementia are at risk of unintentionally getting lost due to critical wandering. "Critical wandering" occurs when an individual living with dementia "leaves an institution or home [with or without the consent of their care partner] and is unaware of his or her situation in terms of place and/or time" [7]; the person is lost. Critical wandering is a necessary (but not a sufficient) condition for a missing incident to occur. A missing incident of a person living with dementia can occur when, for instance, this person is left unsupervised for a few minutes and has an episode of critical wandering [25]. Therefore, critical wandering and missing incident are 2 distinct concepts, although the literature in this field acknowledges that the former could lead to the latter [26].

Antecedents or risk factors influence the mechanisms preceding and contributing to missing incidents [11,26,27]. One way to classify antecedents is to determine whether characteristics are intrinsic (demographic and psychopathological or neurocognitive antecedents) or extrinsic (situational or environmental antecedents) to the missing individual. Demographic antecedents comprise sex, gender, age, and ethnicity of the missing individual. Psychopathological or neurocognitive antecedents are manifestations of behaviors related to cognitive or psychological impairment or mental illness, disorders, or distress. Finally, environmental antecedents may include social, cultural, political, economic, and weather conditions [11]. Another way to classify antecedents is to determine whether they are fixed or variable. A fixed antecedent is one that does not vary within individuals over time (eg, ethnicity). Conversely, a variable antecedent changes over time (eg, the age of an individual) [28]. Missing incidents can lead to consequences or outcomes for the missing person and their care partners [26]. For a missing person, these outcomes can range from returning home safely to minor injuries, major injuries, or even death [26].

MedicAlert Service

MedicAlert is a Canadian-based service that can assist first responders and Good Samaritans in identifying an individual who has gone missing and connecting them with their care partners to help them return to their place of residence. The 2 primary tools used in the service are a medical ID object and a personal health information record. The ID object, which is typically in the form of a bracelet, contains key health conditions and a unique MedicAlert ID number specific to the individual. The MedicAlert ID number can then be used by authorized personnel to access a subscriber's personal health information record, which contains extensive details about the subscriber's medical conditions and medications as well as information on previous wandering history if provided by the subscriber or care partner. It is important to recognize that information is self-reported instead of provided by, or confirmed with, health providers, that is, a MedicAlert subscriber or care partners are at liberty to disclose details about the person's situation and medical condition when the person goes missing. This information is relayed via a 24/7 hotline or by direct digital access by police dispatchers. When the missing person is found, the hotline operator or the police dispatcher notifies the care partners about the missing person's location [29]. By linking care partners, first responders, and Good Samaritans, the goal is to safely return the missing person back home.

Methods

Ethical Considerations

The University of Waterloo ethics review board approved this study (43164).

Study Design and Sample

We used a retrospective descriptive design. The sample included 434 older adult MedicAlert subscribers involved in 560 missing incidents between January 2015 and July 2021. Data were obtained from the MedicAlert subscriber and hotline call operators databases and summary notes made by hotline call operators. Both databases are linked through a unique MedicAlert subscriber ID number.

Variables and Measures

We obtained information on the variables described in Textbox 1 (refer to Multimedia Appendix 1 for more details).

Textbox 1. Study variables.

Variable and description

- Demographic antecedents: age, sex at birth, ethnic background, official Canadian languages spoken, province, and primary contact
- Psychopathological antecedents: medical conditions
- Environmental antecedents: domicile (urban vs rural) and living arrangement

Characteristics of the missing incidents: mode of mobility, the time of day and season in which the missing incident occurred, the family care partner's involvement in response to the missing incident, who reported and found the missing person, point last seen or where the person was missing from, location in which the person was found (actual and self-reported), number of missing incidents, repeated missing incident history (actual and self-reported), mean time to the first missing incident (in days), mean time between missing incidents (in days), and survivability

Procedures

Missing Incident Selection Procedure

Detailed information about the missing incidents were obtained from the summary notes made by the MedicAlert hotline operator when a call was received at the MedicAlert call center. These notes are documented by the operator each time a call is received and were in free-text format. We included missing incidents in which the MedicAlert subscribers (1) were aged ≥65 years, (2) went missing unintentionally, and (3) there was clear indication that the subscriber was actually lost (indications of disorientation or confusion or spatial navigation challenges). We excluded missing incidents that (1) were false positive reports (eg, GPS devices were activated and generated a record in the hotline access database, miscommunication between family members, and missing incident calls created for training purposes), (2) were a duplicate missing incident in which several follow-up calls were associated with the same missing incident, or (3) did not contain enough information from which to extract data.

Upon receiving the data set, 8 team members (including the authors) immersed themselves in the data set. Each read 60 different call summary notes and made notes on their contents in relation to the free-text fields in the MedicAlert subscriber database (eg, domicile [urban vs rural]; refer to Multimedia Appendix 1 for more details). Team members shared their observations during 2 subsequent meetings, and these were used to create a preliminary coding framework, including key definitions and the operationalization of each variable (refer to the next subsection for more details). Two team members, hereinafter referred to as analysts, screened, extracted, and coded relevant information from the summary notes made by the MedicAlert hotline operator using the coding framework. The analysts then completed a calibration exercise in which they independently applied the inclusion and exclusion criteria as well as coded 10 included missing incidents. The calibration exercise was conducted as follows: first, 10 cases were selected randomly; next, 2 researchers independently assessed the cases based on the inclusion and exclusion criteria; and, finally, the 2 researchers met and debriefed on the main causes of disagreements. In the calibration process, the team achieved a 90% agreement (ie, percentage of agreement calculated as the number of times a set of ratings is the same divided by the total number of units of observation that are rated). The analysts then screened and coded data for another 100 missing incidents (registries) independently and checked each other's work. The coding framework was revised to improve the clarity of the definitions and the operationalization of the codes. The analysts met weekly to discuss missing incidents that were unclear or required a second opinion and revised the coding framework to increase clarity. When the coding framework was revised, the analysts reviewed the previously coded data against the revised coding framework and recoded as necessary. The analysts also sought feedback from the first author when conflicts arose in their screening and coding. In total, 7045 missing incidents were screened from the hotline access MedicAlert database; after applying the inclusion and exclusion criteria, 6485 (92.5%) incidents were excluded. The 6485 missing incidents were excluded due to false positive reports (n=5093, 78.84%), not enough information from which to extract data (n=1076, 16.66%), no indications of disorientation or confusion or spatial navigation challenges (n=270, 3.8%), and MedicAlert subscribers being aged <65 years (n=46, 0.65%).

Categories Generation and Operationalization of Variables

After the data set was cleaned, variables regarding antecedents to the missing incident were coded categorically based on previous research [30,31] and following Statistics Canada classifications whenever possible [32]. As some variables were stored in the form of free text, categories were generated inductively from the information contained in the free text (refer to the preceding subsection; eg, missing incident notes compiled by the hotline operator). Finally, all variables were operationalized as follows: dichotomous variables were coded as *0* or *1* (eg, MedicAlert subscriber's sex), and each polytomous variable was represented by a set of binary variables, whose values codified each variable category.

Data Analyses

We used descriptive statistics, including mean and SDs, to summarize the central values of distributions for continuous variables. We used the chi-square and Fisher exact—in the case of small, expected counts—tests for comparing categorical variables. Where appropriate, *t* tests (2-tailed) or the Mann-Whitney *U* test (2 independent groups, 2-tailed) and 1-way ANOVA (2-tailed) or the Kruskal-Wallis rank sum test (>2 groups, 2-tailed) were used for determining the difference between groups for continuous variables. Where appropriate, we used Cramer V and Pearson and Spearman ρ to determine correlations or associations between variables. As this was a retrospective descriptive study, each variable was examined separately [31]. Statistical analysis was conducted using SPSS software (version 28.0; IBM Corp). The α was set at .05.

Results

Demographic, Psychopathological, and Environmental Antecedents to Missing Incidents Among MedicAlert Subscribers

Table 1 shows the demographic and environmental antecedents to missing incidents among MedicAlert subscribers. Overall, 434 MedicAlert subscribers were involved in 560 missing incidents between January 2015 and July 2021. Regarding psychopathological or neurocognitive antecedents, in 79.5% (345/434) of the cases, MedicAlert subscribers self-reported living with dementia, and the remaining 20.5% (89/434) self-reported having other medical conditions, the most prevalent being short- and long-term memory loss and mental health issues such as depression, schizophrenia, and anxiety disorder. However, it is important to keep in mind that these data are self-disclosed at the time of subscribing to MedicAlert and thus may underestimate the true prevalence of dementia in this sample. The average age of the MedicAlert subscribers was 82.56 (SD 7.4) years, with a little more than half (230/431, 53.4%) identifying as female. The most prevalent age groups were 75 to 84 years (177/434, 40.8%) and 85 to 94 years (168/434, 38.7%), together representing 79.5% (345/434) of the sample. White older adults represented the vast majority (329/425, 77.4%) of the subscribers. In 55.8% (240/430) of the cases, the subscribers spoke English, with an additional 18.1% (78/430) who spoke another language or other languages in addition to English; notably, 11.6% (50/430) of the subscribers spoke neither of the 2 official Canadian languages, English and French. MedicAlert subscribers primarily resided in Ontario (199/341, 58.3%), British Columbia (57/341, 16.7%), or Quebec (50/341, 14.7%); and a vast majority (331/341, 97.1%) lived in urban areas. Living arrangements included with family (277/433, 64%) and in a facility (90/433, 20.8%), although 13.1% (57/433) reported living alone. Most of the subscribers (309/341, 90.6%) listed family members as their primary contact.

[e] Arab or West Asian (eg, Armenian, Egyptian, or Iranian), Latin American, South Asian, Korean, Mediterranean, Aboriginal (eg, Inuit, Métis, or American Indian), Filipino, Caribbean or West Indian (St Lucian or Antiguan), Southeast Asian, and Japanese.

Table 2 shows the history of missing incidents among MedicAlert subscribers. Subscribers self-reported no prior history of missing incidents at the time of subscribing to MedicAlert in 10.4% (45/433) of the cases, while 89.6% (388/433) disclosed having been involved in missing incidents repeatedly. Surprisingly, data from actual repeated missing incidents (ie, data that we accessed using the hotline access database) showed the opposite pattern: most of the subscribers went missing repeatedly in only 16.4% (71/434) of the cases. MedicAlert subscribers self-reported that the most common places to be found were outdoor public spaces (eg, highway or street; 184/308, 59.7%) or indoor public or communal spaces (eg, libraries; 85/308, 27.6%).

Table 2. Missing incidents history (unit of analysis: MedicAlert subscriber).

Missing incidents history	Persons without dementia and persons living with dementia, n (%)	Persons without dementia, n (%)	Persons living with dementia, n (%)	Statistical test (persons without dementia vs persons living with dementia), chi-square (*df*)	*P* value
Missing incident history (self-reported; n=433)				0.9 (2)	.64
None	45 (10.4)	7 (1.6)	38 (8.8)		
Repeated (1[a]-4 times)	327 (75.5)	67 (15.5)	260 (60)		
Habitual (>4 times)	61 (14.1)	14 (3.2)	47 (10.9)		
Repeated missing incident history (actual; n=434)				2.1 (1)	.14
No	363 (83.6)	79 (18.2)	284 (65.4)		
Yes	71 (16.4)	10 (2.3)	61 (14.1)		
Possible locations for the missing person to be found (self-reported; n=308)				4.4 (3)	.22
Outdoor public space[b]	184 (59.7)	34 (11)	150 (48.7)		
Indoor public or communal space[c]	85 (27.6)	18 (5.8)	67 (21.7)		
Private home in the community[d]	32 (10.4)	11 (3.8)	21 (6.8)		
Hospital (day program or day clinic)	7 (2.3)	1 (0.3)	6 (1.9)		

[a] After the first incident.

[b] Highway, street, alley, intersection, park, parking lot, outdoor bus stop, construction, or cemetery.

[c] Grocery store, shopping mall, train station, church, recreation center, library, physician's office, bus, train, police station, or gas station.

[d] House, apartment, condominium, age ≥65 years condominium but without supportive living services.

The statistical tests in Tables 1 and 2 showed that MedicAlert subscribers with dementia and those without who were involved in missing incidents were similar with respect to mean age, ethnic background, official Canadian languages spoken, province of residence, population density, living arrangement, primary contact, possible location to be found during a missing incident (self-reported), missing incident history (self-reported), and repeated missing incident history (actual missing incidents); no statistically significant differences were found between the groups. MedicAlert subscribers with dementia and those without who were involved in missing incidents are significantly different (χ^2_3=7.8; *P*=.05) in terms of age groups. This result means that the prevalence of critical wandering was higher among older age groups of people with dementia, with the peak prevalence between ages 75 and 84 years declining somewhat among the older-aged adults.

Characteristics of the Missing Incidents

Demographic and Psychopathological Antecedents

Missing incidents mostly involved people living with dementia (345/434, 79.6%) and those who were (1) female (230/431, 53.4%); (2) from the age groups 65-74 years (72/434, 16.6%), 75-84 years (177/434, 40.8%), and 85-94 years (168/434, 38.7%); (3) White (329/425, 77.4%); (4) English speaking (345/430, 80.2%); (5) living in an urban area (331/341, 97.1%); (6) mostly from Ontario (199/341, 58.4%), British Columbia (57/341, 16.7%), and Quebec (50/341, 14.7%); and (7) living with a family member (277/433, 64%) or in a facility (90/433, 20.8%).

Locations

Locations were analyzed in terms of point last seen or where the MedicAlert subscribers were missing from and located. MedicAlert subscribers were most frequently missing from private homes in the community (96/143, 67.1%) or residential living facilities (27/143, 18.9%); there were no statistical differences regarding the locations from which MedicAlert subscribers with dementia and those without went missing. Regarding the locations they were found, the most common places (313/382, 82%) were outdoor and indoor public spaces. Importantly, we found a statistically significant difference between point last seen or where the MedicAlert subscribers were missing from and where they were located (χ^2_{25}=42.3; *P*=.02; refer to Table 3 for more details). This result indicates that the MedicAlert subscribers were relatively active, with some degree of mobility. Even more interestingly, we found a moderate positive association between the possible locations to be found (self-reported) and the actual location where the person was found (Cramer V=0.213; *P*=.002).

Table 3. Characteristics of missing incidents. Point last seen or where the person was missing from and location in which the person was found (unit of analysis: missing incidents).

Characteristics of missing incidents (locations)	Persons without dementia and persons living with dementia, n (%)	Persons without dementia, n (%)	Persons living with dementia, n (%)	Statistical test (persons without dementia vs persons living with dementia), chi-square (*df*)	*P* value
Point last seen or where the person was missing from (n=143)				3.4 (5)	.64
Private home in the community	96 (67.1)	20 (14.8)	76 (51.7)		
Residential living facility[a]	27 (18.9)	5 (4)	22 (15.4)		
Indoor public space[b]	8 (5.6)	1 (0.7)	7 (4.7)		
Other	5 (3.5)	2 (1.3)	3 (2.7)		
Hospital (day program or day clinic)	5 (3.5)	0 (0)	5 (3.4)		
Outdoor public space[c]	2 (1.4)	0 (0)	2 (1.3)		
Location in which the person was found (n=382)				10.2 (6)	.12
Outdoor public space	202 (52.9)	42 (11.3)	160 (40.6)

Residential living facility	11 (2.9)	2 (0.5)	9 (8.8)		
Other	4 (1.0)	3 (0.8)	1 (0.3)		
Combination of >1 of the aforementioned locations	2 (0.5)	0 (0)	2 (0.5)		

[a] Long-term care center, assisted living facility, supportive living facility, lodge, or group home.

[b] Grocery store, shopping mall, train station, church, recreation center, library, or physician’s office.

[c] For example, highway, street, alley, intersection, park, or parking lot.

Mode of Mobility

While missing, the most common mode of traveling was on foot (248/270, 91.9%). The second most common mode of mobility was public transportation (12/270, 4.4%; refer to Table 4 for more details).

Table 4. Characteristics of missing incidents. Mode of mobility (unit of analysis: missing incidents; valid cases n=270).

Characteristics of missing incident	Persons without dementia and persons living with dementia, n (%)	Persons without dementia, n (%)	Persons living with dementia, n (%)	Statistical test (persons without dementia vs persons living with dementia), chi-square (*df*)	*P* value
Mode of mobility				2.3 (6)	.89
On foot[a]	248 (91.9)	57 (21.1)	191 (70.7)		
Public transit[b]	12 (4.4)	3 (1.1)	9 (3.3)		
Receiving a ride from someone else[c]	3 (1.1)	1 (0.4)	2 (0.7)		
Driving own car	2 (0.7)	0 (0)	2 (0.7)		
Other	2 (0.7)	0 (0)	2 (0.7)		
Combination of several of the aforementioned modes	2 (0.7)	0 (0)	2 (0.7)		
Long-range or transregional transit[d]	1 (0.4)	0 (0)	1 (0.4)		

[a] Walking.

[b] Bus, light rail transit, subway, or streetcar.

[c] Hitchhiking.

[d] Train, airplane, noncommuter bus, or ferry.

Temporality (Time and Seasonality)

Table 5 shows the temporality of missing incidents in terms of the time of day and season the person was reported missing. In general, missing incidents occurred mostly in the afternoon (262/560, 46.8%) and the evening (174/560, 31.1%), while the most common seasons for these incidents were summer and fall followed by spring (222/560, 39.6%; 154/560, 27.5%; and 113/560, 20.2%, respectively).

No statistical differences for the temporality variable by persons living with dementia and those without were found.

Table 5. Characteristics of missing incidents. Time and seasonality (unit of analysis: missing incidents; n=560).

Missing incident characteristics (time and seasonality)	Persons without dementia and persons living with dementia, n (%)	Persons without dementia, n (%)	Persons living with dementia, n (%)	Statistical test (persons without dementia vs persons living with dementia), chi-square (*df*)	*P* value
Time of day				7.2 (2)	.03
Afternoon (noon to 5:59 PM)	262 (46.8)	61 (11)	201 (35.1)		
Evening (6 PM to 11:59 PM)	174 (31.1)	40 (7.1)	134 (23.3)		
Morning (midnight to 11:59 AM)	124 (22.1)	15 (3.9)	109 (19.2)		
Season				3.3 (3)	.34
Summer (June 1 to August 31)	222 (39.6)	47 (8.4)	175 (31.3)		
Fall (September 1 to November 30)	154 (27.5)	34 (6.1)	120 (21.4)		
Spring (March 1 to May 31)	113 (20.2)	17 (3)	96 (17.1)		
Winter (December 1 to February 28)	71 (12.7)	18 (3.2)	53 (9.5)		

People Involved in the Missing Incident

Table 6 shows the people involved in the missing incidents in terms of the care partner involvement with MedicAlert in response to the missing incident. In the majority of cases (375/518, 72.4%), the family care partner had an involvement in response to the missing incident with MedicAlert, with no statistically significant difference found between the groups (people with dementia and those without). In 96.1% (467/486) of the cases, the MedicAlert subscribers who went missing were located by someone other than the care partner. In most of the cases, either first responders (232/486, 47.7%) or Good

Samaritans (224/486, 46.1%) found the missing person. Again, no statistically significant difference was found between the groups involved in the missing incidents.

Table 6. Characteristics of missing incidents. People involved in the missing incident (unit of analysis: missing incidents).

Missing incident characteristics (people involved in the missing incident)	Persons without dementia and persons living with dementia, n (%)	Persons without dementia, n (%)	Persons living with dementia, n (%)	Statistical test (persons without dementia vs persons living with dementia), chi-square (*df*)	*P* value
Natural care partner involvement in response to incident with MedicAlert (n=518)				0.4 (1)	.54
Yes	375 (72.4)	80 (15.4)	295 (57)		
No	143 (27.6)	27 (5.2)	116 (22.4)		
Who reported and found the missing person (n=486)				1.3 (3)	.72
First responder[a]	232 (47.7)	54 (11.1)	178 (36.6)		
Good Samaritan[b]	224 (46.1)	48 (9.9)	176 (36.2)		
Family member or friend[c]	19 (3.9)	4 (0.8)	15 (3.1)		
Other	11 (2.3)	1 (0.2)	10 (2.1)		

[a] Police, search and rescue member, fire department, or ambulance or paramedic.

[b] The Good Samaritan noticed that something was off with the missing person and called the hotline or was asked by the missing person to call the hotline; they were not formally involved in searching for the missing person.

[c] Informal care partner.

Outcomes of the Missing Incidents

Table 7 shows the outcomes of the missing incidents in terms of the number of missing incidents, repeated missing incidents, mean time to the first missing incident (in days), mean time between missing incidents (in days), and survivability. Overall, 22.5% (113/500) of the missing incidents were repeated missing incidents, with the mean number of missing incidents per MedicAlert subscriber being 1.290 (SD 0.914; range: 1-11). Moreover, the number of missing incidents per MedicAlert subscriber was almost the same for people living with dementia (mean 1.290, SD 0.801) and those without dementia (mean 1.300, SD 1.265). The mean time to the first missing incident (since registering with MedicAlert) was 343.8 (SD 376.2) days (mean 11, SD 11.3 months), whereas the mean time between missing incidents was shorter, that is, 328.0 (SD 366.6) days (mean 11, SD 10.8 months). This is expected because the mean time between missing incidents takes into account repeated missing incidents. In terms of survivability, only a small percentage of cases (46/500, 9%) involved people undergoing harm while missing; even more rare were missing incidents in which MedicAlert subscribers were found deceased (1/500, 0.2%). There was a trend toward adverse outcomes for MedicAlert subscribers living with dementia: they experienced increased repeated missing incidents and injuries (but these results were not statistically significant, *P*=.30), short mean time to the first missing incident (but these results were not statistically significant, *P*=.20), and short mean time between missing incidents (but these results were not statistically significant, *P*=.15). In other words, they went missing more frequently (1 missing incident every 317.08 days) than those subscribers who did not have dementia (1 missing incident every 370.41).

Table 7. Outcomes of the missing incidents.

Missing incident characteristics (outcomes)	Persons without dementia and persons living with dementia	Persons without dementia, n (%)	Persons living with dementia, n (%)	Statistical tests (persons without dementia vs persons living with dementia)			*P* value
				Mann-Whitney *U* test	*z* score	Chi-square (*df*)	
Missing incidents (n=434)	Mean 1.290 (SD 0.914; range 1-11)	1.300 (1.265)	1.290 (0.801)	14,412 (persons without dementia: n=89; persons with dementia: n=345)	−1.386	—[a]	.17[b]

MTFI[c] (n=434)	Mean 343.79 (SD 376.20; range 6-2249)	374.82 (410.35)	335.79 (365.09)	14,000 (persons without dementia: n=89; persons with dementia: n=345)	−1.282	—	.20[b]
MTBI[d] (n=434)	Mean 328.02 (SD 366.62; range 6-2249)	370.41 (411.34)	317.08 (354.00)	13,844 (persons without dementia: n=89; persons with dementia: n=345)	−1.429	—	.15[b]
Survivability (n=500), n (%)				—	—	4.9 (4)	.30[e]
No apparent injuries or compromised health	453 (90.6)	94 (18.8)	359 (71.8)				
Injuries or compromised health requiring emergency services and transfer to hospital	35 (7)	8 (1.6)	27 (5.4)				
Minor injuries or health issues requiring some treatment at home[f]	10 (2)	1 (0.2)	9 (1.8)				
Deceased	1 (0.2)	1 (0.2)	0 (0)				
Injuries and concern for health requiring follow-up care[g]	1 (0.2)	0 (0)	1 (0.2)				

[a] Not applicable.

[b] Mann-Whitney *U* test.

[c] MTFI: mean time to the first missing incident.

[d] MTBI: mean time between missing incidents.

[e] Chi-square test.

[e] Getting *Band-Aids*, pain medications, cleaned up, and so on.

[f] Physician visit, walk-in clinic, and so on.

Discussion

Principal Findings

This retrospective descriptive study examined demographic, psychopathological, and environmental antecedents to missing incidents due to critical wandering among MedicAlert subscribers, as well as the characteristics and outcomes of these incidents. In doing so, we used a national registry of persons as a secondary data source of information (ie, the MedicAlert database). To date, much of the knowledge about missing individuals with dementia and those without is based on studies with small sample sizes that use social media and newspaper reports from the United States or elsewhere [7,11]. Thus, we aimed to address these limitations by using an extensive secondary data set. To our knowledge, this is the first study that has shed light on the phenomenon of missingness and critical wandering of individuals with dementia and those without in Canada. In addition, we were able to report the prevalence of repeated missing incidents, based on this database, an important figure that has been absent in previous studies.

The demographic characteristics of our study population showed that people involved in missing incidents were mostly older adults (345/434, 79.6%), female older adults (230/431, 53.4%), living in the most populated provinces in Canada (306/341, 89.7%), and living in urban areas with at least 1 family member (309/341, 90.6%). Importantly, the majority of MedicAlert subscribers (345/434, 79.5%) involved in missing incidents self-reported living with dementia. More interestingly, except for age group, we did not find statistically significant differences between the people living with dementia and those without with respect to demographic, psychopathological, and environmental antecedents to missing incidents due to critical wandering. In addition, MedicAlert subscribers were most frequently missing from private homes in the community (96/143, 67.1%), as expected; were found in a different place than where they were last seen (313/382, 82%; most commonly outdoor and indoor public spaces); and were traveling on foot (248/270, 91.9%) and by public transportation (12/270, 4.4%), and during the afternoon (262/560, 46.8%) and evening (174/560, 31.1%). Subscribers were located mostly by first responders (232/486, 47.7%) and Good Samaritans (224/486, 46.1%). In terms of outcomes, overall, MedicAlert subscribers were involved in 1 missing incident, with the mean duration between missing incidents being 11 (SD 10.8) months and the time elapsed between subscribing to MedicAlert and the first missing incident being 11 (SD 11.3) months. Finally, the vast majority of MedicAlert subscribers involved in missing incidents were returned home safely (453/500, 90.6%), reports of harm and injuries were very low (46/500, 9.2%), and death was a rare event (1/500, 0.2%).

We found that missing incidents involved mostly older adults (345/434, 79.6%), female older adults (230/431, 53.4%), and White older adults (329/425, 77.4%), with the majority living in urban areas in cities in Ontario, British Columbia, and Quebec provinces (306/341, 89.7%). These demographic results are consistent with previous studies [30,33,34] and can be explained by the fact that these groups were more prevalent in our sample and because our sample was not a representative sample. The higher prevalence of missing incidents among female older adults can be attributed to the higher prevalence of female older adults living with dementia because dementia typically affects people at a 2:1 female-to-male ratio [2]. As there is evidence that demographic characteristics may serve as risk factors for missingness [11,35,36], the next logical step is to determine whether the demographics variables we explored in this study are factors for missingness in this sample. In this study, we did not identify statistically significant differences between people living with dementia and those without with respect to all our variables. The most plausible explanation for this is that these 2 groups of people are essentially the same, that is, they have dementia and memory loss, a risk factor that can lead to critical wandering and, in turn, a missing incident. Another plausible explanation for the lack of between-group differences could be that the individuals (1) had dementia but did not disclose their medical condition at the time of first subscribing to MedicAlert, (2) had dementia but did not know about their diagnosis, or (3) did not have dementia at the time of registration but developed dementia over time or by the time they went missing.

We found that the majority of MedicAlert subscribers involved in missing incidents self-reported living with dementia (345/434, 79.5%). Importantly, among those who were involved in missing incidents but did not self-report living with dementia (89/434, 20.1%), memory loss was self-reported as a medical condition. Our result is aligned with previous studies that found that persons with mental or cognitive disabilities (eg, those with Alzheimer disease or dementia) are more prone to going missing [31,37,38]. The literature reports that neurocognitive deficits from dementia predispose individuals to missing incidents and contribute to the inability to independently return home. These neurocognitive deficits could include memory deficits, such as declarative memory (remembering facts and events), episodic memory (short-term memory for recent events and contexts), and visual agnosia (inability to recognize objects or places). In addition, executive function impairments and disease-related changes to visuospatial and subperceptual processing (especially in unfamiliar locations), which typically manifests as difficulty with navigation, can explain why an individual living with dementia cannot independently return home [26].

The prevalence of MedicAlert subscribers who repeatedly went missing was lower in the hotline database in comparison to repeated missing self-reported variables. This result was anticipated because previous studies suggest that care partners are reluctant to contact emergency services, such as 911 or programs to locate older adults who are having an episode of critical wandering and have gone missing [37]. As a self-reported variable, this result could be attributed to overreporting by care partners. However, more objective explanations can be given. First, care partners often initiate the search within their homes or places last seen, and because many persons with dementia are found near the place that they were last seen, either on their own property or in their own neighborhood, the care partner could locate the missing person before their decision to request assistance from external organizations [31,37]. Second, it is possible that care partners subscribed their family member into the MedicAlert program as a preventative measure. For individuals who repeatedly had episodes of critical wandering in the past, care partners could have implemented their own measures or interventions to avoid missing incidents, including MedicAlert subscriptions. The literature reports that these interventions include avoiding lapses of supervision, whether planned or unplanned, through the use of technology (eg, GPS) to monitor and locate missing older adults with dementia [39]. Finally, it might be possible that care partners chose not to use the MedicAlert hotline to locate missing individuals to avoid attention and stigma associated with a formal search if initiated. Numerous studies have reported that the uses of technologies and programs by people living with dementia and their care partners aiming to reduce the risks of getting lost have highlighted the importance of discreet technologies that are unnoticeable to reduce stigma [40,41].

Our study paves the way for new services and interventions that can be offered by MedicAlert. The services may include implementing preventative strategies to decrease the risk of going missing through threshold alerts in mobile phone apps. According to the literature, a leading feature being implemented in mobile phone apps were alert systems, such as wandering alerts [42]. These apps could send threshold alerts or reminders to care partners when the mean time between missing incidents and the mean time to the first missing incident for a particular MedicAlert subscribers is approaching. The same can be true for common months or the time of day that MedicAlert subscribers tend to go missing. As many MedicAlert subscribers were located mostly by first responders and Good Samaritans, another option to explore is the use of a mobile alert app to engage community volunteers to help locate missing persons with dementia. Community ASAP, a mobile alert system that engages community citizens as volunteers to look for missing persons with dementia, has demonstrated to be an accurate and useful app [43].

For MedicAlert subscribers involved in missing incidents, many were returned home safely (453/500, 90.6%), with few reported harms or injuries (46/500, 9.2%), and death was rare (1/500, 0.2%). Regarding mortality rates when a person with dementia goes missing, the literature shows high variability (between 0.7% and 32%) [44,45]. In this study, the low reports of harm and death can be explained mainly by 2 factors. First, the environmental conditions at the time the MedicAlert subscribers went missing were favorable: subscribers went missing in urban areas while traveling on foot (248/270, 91.9%) or using public transportation (12/270, 4.4%) during the day (262/560, 46.8%) in the warmest months of the year (eg, low chance of severe weather; 358/560, 63.9%). The literature reports that the causes of high mortality rates in people with dementia who go missing include severe weather; driving; and walking near roadways, bodies of water, or in isolated areas [46,47]. These scenarios were very different from what we found in our study. Second, we found that in a high proportion of missing incidents (504/560, 90%), the MedicAlert subscribers were wearing their ID bracelet. We could intuitively affirm that the MedicAlert program prevents injuries and saves lives, but this affirmation would have to be demonstrated in a formal study. Therefore, a next logical step would be to conduct a study to determine whether the MedicAlert program addresses the problem for which it was designed, that is, to help those who are having an episode of critical wandering to return home safely. Our study also shows what some investigators have determined regarding the potential interrelatedness of risk factors for going missing [48]. While most of the outcomes during missing incidents were positive (death was rare), the complex interplay of demographic, psychopathological, and environmental antecedents of MedicAlert subscribers need further exploration.

Study Limitations
