Future research should focus on training and staffing concepts for nursing. First, performing televisits is a new approach to care and needs specific education. While the need for specific curricular training in telemedicine has already been identified for medical students [50-53], it should also be integrated into nursing education. Second, a notable finding in the follow-up questionnaire was that most televisits were conducted by a small number of nurses with some performing a significant number whereas most only conducted a few (>10 televisits: 4/19, 21%; <10 televisits: 15/19, 79%), Therefore, future research should explore whether certain nurses should specialize in televisits within a nursing facility whereas less qualified nurses or nursing assistants could focus on other nursing tasks. Maybe this would lead to workforce optimization. In theory, telemedically advanced nurses could also use telemedicine for telenursing, that is, for advising and supporting nursing assistants via telemedical solutions.

Conclusions

An action-oriented CM approach made it possible to achieve long-term implementation of televisits in NH 1. Abandoning synchronous televisits in favor of asynchronous ones improved the workflows and was a critical facilitator of long-term implementation. Strong leadership, as well as sustained training of the nurses, also contributed to this success. The implementation of televisits had positive effects on the HCPs. They experienced an improvement in their clinical skills and a higher professional recognition. According to the nurse managers, their psychological distress also decreased. Performing televisits did not save time for the nursing staff in comparison to scheduling and assisting a GP in in-person home visits. Instead, the nurses believed that televisits led to a slight increase in their time spent on organizing the assessment of the patient. CM aspects must be considered to achieve long-term implementation.

Acknowledgments

This study was conducted within the AIDA project (Arbeitsentwicklung in der Altenpflege) funded by the European Regional Development Fund 2014 to 2020 of the European Union and by the state of North Rhine-Westphalia, Germany. The authors acknowledge and thank the nursing homes "Stiftung Evangelisches Alten- und Pflegeheim Gemünd" (Schleiden, Germany) and "St. Gereon Seniorendienste gGmbh" (Hückelhoven, Germany), as well as Ekaterini Karidas-Moitzheim, Ines Ferber, Arno Brauckmann, Gerd Palm, and Jan Fabry for their cooperation and support.

Authors' Contributions

TM and AF conceptualized and designed the study. SV organized the initial training of the health care providers. HG and PFF provided advice on the qualitative research. AF, MC, and PFF obtained research funding. TM collected, managed, and analyzed the data. TM interpreted the findings and drafted the manuscript. All authors contributed substantially to its revision. All authors approved the published version of the manuscript. TM takes responsibility for the paper as a whole.

Conflicts of Interest

MC is the chief executive officer and cofounder of Docs in Clouds TeleCare GmbH, a company that purchases telemedical solutions including the TeleDoc system, which was used in this study. AF worked part time as chief medical officer for Docs in Clouds TeleCare GmbH until March 2023. All other authors declare that they have no other conflicts of interest.

Abstract

Background: During the COVID-19 pandemic, there was a rapid adoption of telehealth care services as a public health strategy to maintain access to essential health care. In Australia, there has been increasing optimism for the expansion of telehealth services. However, little is known about the patterns and determinants of telehealth adoption among older adults, with concerns that an expansion of telehealth services may only be of benefit to those who already have better access to health care.

Objective: Leveraging data collected by The Sax Institute's 45 and Up COVID Insights study between November 2020 and April 2022, the objective of this study was to identify and describe the sociodemographic and health-related determinants of telehealth adoption and use among a cohort of older Australians. We hypothesized that health-related factors would be key determinants of telehealth adoption for Australians aged ≥65 years during the COVID-19 pandemic.

Methods: A repeated cross-sectional design was used. The relationships between telehealth use (classified as low, moderate, or high) and selected sociodemographic and health-related characteristics were assessed using logistic regression techniques. Variable selection and findings were situated within the Technology Acceptance Model, the Unified Theory of Acceptance, and the Use of Technology theoretical frameworks.

Results: Of the 21,830 participants aged ≥65 years, the proportion who indicated adopting telehealth ranged from 50.77% (11,082/21,830) at survey 1 in 2020 to 39.4% (7401/18,782) at survey 5 in 2022. High levels of telehealth use were associated with being female, aged <85 years, living in a major city, cohabiting with others, and being from the most socioeconomically disadvantaged areas (deciles 1-3). Individuals with a disability, chronic disease, multimorbidity, and lower perceived quality of life and those experiencing missed or delayed care were significantly more likely to use telehealth across all levels ($P<.001$). A temporal association was observed, whereby participants who engaged with telehealth services before or early in the pandemic (as assessed in survey 1) were more likely to continue telehealth use when assessed in survey 5 in 2022 (*P*<.001).

Conclusions: This research contributes to the broader understanding of telehealth adoption and use among older adults. As telehealth models of care expand, there is an opportunity to tailor these services to the needs of older adults, particularly those living with chronic diseases and multimorbidity, by using targeted strategies that overcome barriers to accessing specialized health care services.

Introduction

Overview

The COVID-19 pandemic triggered a rapid transformation in the delivery of health care. Because of adaptive necessity, in-person visits to health care providers were augmented through the widespread adoption of digital technology mediums [1]. In countries such as Australia, telehealth was incentivized as a national public health strategy to facilitate remote patient and practitioner interactions, given social distancing and lockdown measures [2-4]. Noting that telehealth and telemedicine are often used interchangeably within the literature [5], this paper uses telehealth to denote the delivery of health care services at a distance by health care professionals for remote patient engagement (synchronous or asynchronous), using information and communication technologies (ICTs), such as telephone or video mediums [6].

Before the COVID-19 pandemic, telehealth services in countries with high income, such as Australia, Canada, New Zealand, and the United States, had been established to facilitate access to health care services across vast geographic distances [2,7]. The sustained integration and adoption of telehealth services pose ongoing challenges, as evidenced by a notable decline in use after the acute pandemic phase [8,9]. Barriers to telehealth integration and adoption are well documented [10]. These include health care consumer and provider resistance and skepticism [8,10], concerns over patient safety (inability to undertake hands-on assessments) [8], confidentiality and privacy of medical information [4,6,10], a lack of digital technology infrastructure [8,10], socioeconomic disadvantage [4,6,11], varying levels of digital technology literacy [10], increasing age [4,6,8,10,12], education levels [10], and poorly designed platforms [10]. Since the start of the pandemic, there has been increasing optimism for the expansion of telehealth services to increase equity of health care access for those living outside of metropolitan areas in which poor health outcomes are increased. This is particularly relevant given the backdrop of the ever-increasing prevalence of noncommunicable chronic disease, multimorbidity, and aging populations [1,6,8,13,14]. A central concern is whether the expansion of telehealth services will genuinely improve health care access or disproportionately benefit those who already have better access to health care [4,6,15-17].

Background

"The digital divide" has become increasingly prevalent in discussions around technology use, including telehealth [4,12]. The term encompasses the socioeconomic, ICT resource-related, and other accessibility disparities and their impacts on vulnerable groups. These groups typically include people of cultural and linguistic diversity (CALD); those with chronic disease, multimorbidity (defined as having more than one chronic disease), or disability; older adults; those living in rural and remote geographic areas; and those of lower income [4,12]. A recent systematic review by Haimi and Gesser-Edelsburg [6] highlighted a gap in the literature regarding telehealth engagement among older adults (aged ≥65 years) during the COVID-19 pandemic. Of the 11 reviewed studies, it was evident that although telehealth service availability increased, telehealth adoption and participation among older adults was low [6]. This is particularly concerning given that older people were more likely to develop severe disease, with those experiencing multimorbidity at even higher risk, emphasizing the need for further studies to identify challenges with telehealth adoption among this age group [6].

In Australia, where 1 in every 6 people is aged ≥65 years and where a significant proportion reside outside of metropolitan areas, challenges with the equitable provision of health care services are exacerbated [18-21]. There is considerable demand among policy makers for upscaled telehealth service models, particularly given the distinctive characteristics of older Australians [20]. A total of 50% of people aged ≥65 years are affected by disability [18], whereas 85% have at least 1 chronic disease, with 60% reporting multimorbidity [14]. For these people, overcoming barriers to telehealth adoption becomes imperative.

Dykgraaf et al [4] suggest that the adoption of telehealth by older Australians extends beyond conventional barriers, such as personal socioeconomics, ICT ownership, and internet or network connectivity issues. They propose that barriers to the adoption of telehealth involve a more nuanced interplay of factors related to digital literacy rather than digital deprivation, as well as being influenced by practical factors related to physical and cognitive health, trust and familiarity with technology, and ease of use, particularly during the COVID-19 pandemic [4]. Broader research suggests that for older people, attitudes, perceptions, and experience of digital technologies influence their intention to adopt these mediums, with characteristics such as age, gender, education, health status, social influences, and income identified as influencing (barriers and enablers) factors [15,22,23].

In this context, the Technology Acceptance Model provides a valuable framework and lens for examining the factors that determine an individual’s potential acceptance or rejection of technologies, including telehealth [24]. Originally developed by Davis [25], the Technology Acceptance Model is an adaption of the well-established Theory of Reasoned Action [24]. Although the Theory of Reasoned Action primarily focuses on understanding the motivational factors and determinates of health-related behaviors [26], the Technology Acceptance Model was tailored to elucidate the influencing factors related to information technology use [24,27]. Grounded in the concept that people tend to engage in behaviors that have a positive effect, the Technology Acceptance Model posits that perceived usefulness and perceived ease of use are the main determining factors underlying technology adoption. These factors are influenced by antecedent personal factors (attitudes) that impact behavioral intention and actual technology use [24]. The Unified Theory of Acceptance and Use of Technology, a recent extension of the Technology Acceptance Model, explains the individual influencing factors related to technology use across four constructs: (1) performance expectancy, the degree to which an individual believes the technology with help them; (2) effort expectancy, the degree of perceived ease of use; (3) social influence, the degree to which an individual perceives how others view the importance of using the technology is for them; and (4) facilitating conditions, the degree to which the individual believes that infrastructure exists to support their use of the technology [28].

The circumstances surrounding the COVID-19 pandemic present a unique opportunity to observe the real-world dynamics in telehealth adoption at the population level. The expansion of services and forced adoption of telehealth acts as a natural experiment for exploration, whereby external circumstances dictate the implementation of an intervention [29]. Mao et al [15] analyzed data from the Irish Longitudinal Study on Aging collected during the COVID-19 pandemic (COVID-19 wave, June to November 2020). Their findings suggest health-related factors (chronic conditions, multimorbidity, and poor mental health) and, to a lesser extent, sociodemographic factors (younger age [<70 years] and socioeconomic disadvantage) are determinants of telehealth use. A study conducted by Choi et al [12] analyzing data from the United States National Health and Aging Trend Study-COVID supplement (collected in 2020) similarly observed health-related factors (chronic conditions, impairments with activities of daily living, and moderate levels of mental distress) and younger age (<80 years) as determinants of telehealth use [10].

Leveraging data collected by The Sax Institute’s 45 and Up COVID Insights substudy, the objective of this study was to identify and describe the sociodemographic and health-related determinants of telehealth adoption and use among a cohort of older Australians. Consistent with the Technology Acceptance Model and Unified Theory of Acceptance and Use of Technology, we hypothesized that health-related factors will be key determinants of telehealth adoption and use for older Australians during the COVID-19 pandemic. These findings will contribute to our understanding of factors that influence telehealth adoption beyond conventional barriers for older Australians, working toward equity of health service provision for this population [4,28].

Methods

Study Design

This study uses survey data collected by The Sax Institute’s 45 and Up COVID Insights substudy (hereon referred to as COVID Insights study). Conducted in the state of New South Wales, Australia, between November 2020 and April 2022 [30], the COVID Insights study is an extension of the larger 45 and Up prospective longitudinal cohort study. The COVID Insights study covers critical themes addressing health care use, mental health and well-being, financial aspects, COVID-19 preventive measures, and lifestyle behaviors.

Population

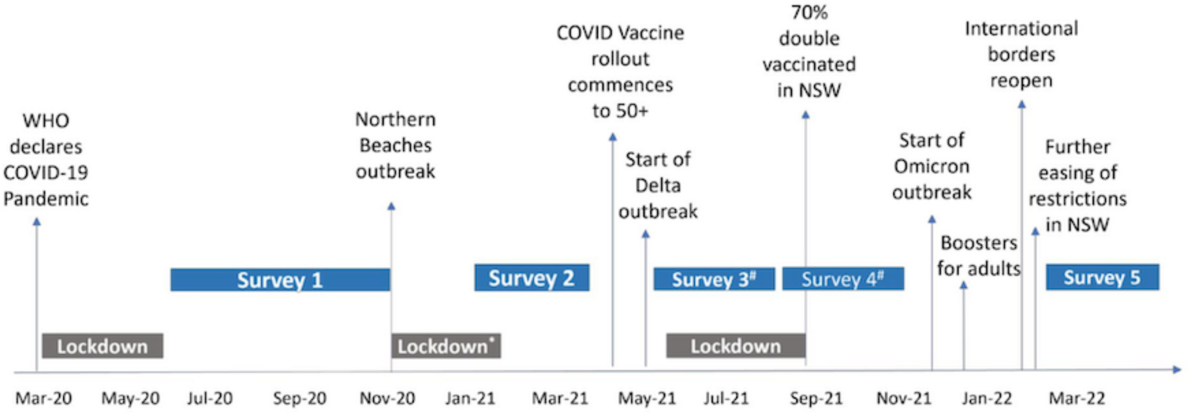
The Sax Institute’s 45 and Up Study, initiated between 2005 and 2009, has recruited a total of 267,357 participants from New South Wales [31]. Recruitment methods have been previously published [31]. Prospective participants were drawn at random from the Services Australia Medicare enrollment database, with those aged ≥80 years and residents of rural and remote areas intentionally oversampled [31]. About 19% of those invited to the study consented to participate. Consenting participants were followed up every 5 years in waves. Because of the large number of participants, surveys were also distributed in phases. For example, the wave-2 follow-up surveys were distributed in 4 phases between 2012 and 2015, with wave-3 follow-up surveys distributed across 3 phases between 2018 and 2020 [31].

The 45 and Up COVID Insights study was established in 2020 through collaborative efforts with key health industry stakeholders and policy makers and engaged 32,115 participants between November 2020 and April 2021 [30]. The cohort was formed through 2 distinct recruitment methods [30,32]. Method 1 involved reaching out to existing 45 and Up Study participants (n=85,299) who were completing their routine wave-3 (phase 3) follow-up survey. During the period between July and December 2020, these participants were asked to complete an additional COVID supplement survey, resulting in 28,840 participants expressing interest in the COVID Insights study [30,32]. From this group, 15,252 completed both the COVID supplement survey (which featured variables similar to the COVID Insights survey 1) and COVID Insights survey 2, officially joining the substudy at this time point [30,32].

Method 2 encompassed the distribution of invitations to a random sample of existing 45 and Up Study participants (n=60,000) between November and December 2020. Of these invitations, 40,000 were sent by email and 20,000 were distributed through traditional mail-in postal procedures. A total of 16,863 participants responded, completed the COVID Insights survey 1, and were successfully recruited to the substudy [30,32]. Five COVID Insights surveys were developed for rapid data collection and were strategically administered over various pandemic time points between 2020 and 2022, as displayed in

Figure 1 [33]. All follow-up surveys (COVID Insights surveys 2-5) were exclusively administered via the web.

Figure 1. COVID Insights Survey administration, pandemic outbreaks, and pandemic policy implementation in New South Wales, Australia. The number sign (#) from surveys 3 and 4 indicates that data were collected in 3 consecutive month-long tranches. NSW: New South Wales; WHO: World Health Organization. *Lockdown in place across Sydney's Northern Beaches with some restrictions for Greater Sydney.



Participants

Of the 32,115 participants available for analysis, 21,830 participants aged ≥65 years who completed telehealth adoption questions were identified. This subset was chosen for the current analysis as it aligns with the Australian Institute of Health and Welfare's age criterion for older adults [21] and is supported by the age classification used in the systematic review by Haimi and Gesser-Edelsburg [6] for ease of comparison across data sets.

Variable Selection

Using a repeated cross-sectional design and guided by previous research and the Technology Acceptance Model and Unified Theory of Acceptance and Use of Technology frameworks, a comprehensive set of sociodemographic and health-related variables was considered for analysis. Specifically, these frameworks helped us to select a set of variables aimed at understanding the individual influencing factors related to perceived usefulness, ease of use, performance expectancy, effort expectancy, social influence, and facilitating conditions [28]. Therefore, we included the following variables: age, gender, CALD, disability status, chronic disease and multimorbidity status, carer status, housing type, number of people in the household, geographic location (as per the Accessibility/Remoteness Index of Australia [34]), socioeconomic disadvantage (as per the Socioeconomic Indexes For Areas [35]), information related to cigarette smoking and alcohol consumption, vehicle driving, experiences of missed or delayed health care, Kessler–6 psychological distress scores [36], De Jong Gierveld Loneliness scores [37], and general quality of life ratings.

Sociodemographic and Health-Related Variables

With the exception of smoking, alcohol consumption, vehicle driving, missed or delayed care, Kessler–6, De Jong Gierveld scores, and quality of life ratings, all other listed sociodemographic and health-related variables were packaged as static variables for the COVID Insights study [32]. This means they were either derived from the wider 45 and Up Study or collected as part of the COVID Insights survey series and do not change over time [32]. Participants were identified as people of CALD if they were born outside of Australia, New Zealand, the United Kingdom, Ireland, Canada, the United States, or South Africa. In addition, individuals who indicated speaking a language other than English at home were classified as people of CALD [32]. Chronic conditions were assessed by asking participants whether a doctor had ever told them that they had cancer, cardiovascular disease, stroke, diabetes, asthma, arthritis, Parkinson disease, or chronic kidney disease. With count data only supplied, multimorbidity was determined by the number of chronic diseases reported, indicating the presence of >1 concurrent chronic disease. Individuals residing in outer regional, rural, and very remote geographic localities were combined into one category because of the small samples of participants within these subgroups. The socioeconomic disadvantage area deciles, in which decile 1 equates to the most disadvantaged areas, were collapsed into 3 categories for ease of interpretation.

The missed or delayed care variable was derived from participant responses to whether they had experienced missed or delayed health care from a general practitioner visit, hospital visit, specialist doctor, or prescription medication visit. The mental health of participants was assessed using mean Kessler–6 scores. Kessler–6 scores range from 0 to 24; higher scale scores indicate more serious mental distress [36,38], with a cutoff point of ≥13 suggesting probable mental illness [38]. Mean De Jong Gierveld Loneliness (short form) scores were used. The scale comprised 3 positively framed questions and 3 negatively framed questions, with responses provided as "Yes," "More or less," or "No" [37]. Only positive (Yes) and neutral responses (More or less) to the 3 negatively framed questions are counted, resulting in scores ranging from 0 to 3, whereby 0 indicates no emotional loneliness and 3 suggests intense emotional loneliness [37]. Mean general quality of life scores were derived from responses to a 5-point rating scale, whereby lower scores indicate better quality of life (eg, 1=excellent and 5=poor).

Telehealth Variables

Telehealth use was defined as the use of health care services via telephone or video call. Questions related to telehealth adoption and use were assessed in surveys 1, 4, and 5. In the initial survey (administered between July and December 2020), participants were asked whether they had used telehealth services since January 2020, which is defined as an appointment with a health care provider by video or telephone instead of an in-person visit. Participants were asked to specify whether the telehealth mode was via telephone or video call at this time point only. In survey 4 (administered between September and November 2021), participants were asked whether they had used telehealth (via telephone or video call) in the last 3 months and for which purposes (eg, a regular check-up, medical diagnosis or advice, initial consultation, follow-up consultation, receive test results, or treatment or therapy review). In survey 5 (administered between March and April 2022), participants were again asked whether they had used telehealth (via telephone or video call) in the past 3 months and which health care provider they saw (general practitioner, specialist doctor, pharmacist, nurse, mental health care [eg, psychologist or counselor], physiotherapist, occupational therapist, dietitian).

For this analysis, participants who indicated telehealth use across the 3 surveys were categorized on the basis of their individual level of telehealth use as follows: no adoption (did not use telehealth at any survey); low use (used telehealth at 1 of the 3 surveys only); moderate use (used telehealth at 2 surveys); and high use (used telehealth at all 3 surveys).

Statistical Analysis

All sociodemographic, health-related, and telehealth-related variables were summarized and reported using descriptive statistics. To investigate the determinants of telehealth use (dependent variable), a multinomial logistic regression model was developed using the selected sociodemographic and health-related characteristics as independent variables. Data were pooled across all 3 surveys (surveys 1, 4, and 5). Participants with missing data on any of the analysis variables were excluded. An additional logistic regression analysis was conducted to explore the determinants of telehealth adoption, specifically investigating whether prior telehealth adoption, assessed in survey 1, predicted telehealth use in survey 5. All variables were checked for independence and multicollinearity, satisfying these assumptions with telehealth variables organized into mutually exclusive and exhaustive categories. All analyses were conducted by a statistician (SM) using R programming language (version 4.3.0; R Development Core Team) within The Sax Institute’s Secure Unified Research Environment. The criterion for statistical significance was set at the .05 α level.

Ethical Considerations

For The 45 and Up Study, all participants provided written informed consent with approval obtained from the University of New South Wales, Human Research Ethics Committee (HC210602) [31]. The COVID Insights study was approved by the University of New South Wales, Human Research Ethics Committee (reference HC200597) [30] with approval for the current analysis also obtained by the authors institutional Human Research Ethics Committee (reference H23582).

Results

Sociodemographic, Health-Related, and Telehealth-Related Characteristics

Table 1 displays the sociodemographic and health-related characteristics of the cohort, categorized by telehealth use across surveys. Inspection of baseline sociodemographic and health-related characteristics at survey 1 (n=21,830) revealed most participants were women, were not people of CALD, lived in a house, lived with ≥1 other person, resided in a major city, and did not have carer responsibilities. Regarding health, most did not live with a disability but were impacted by chronic disease. Most had not experienced missed or delayed health care because of the COVID-19 pandemic. Mean Kessler–6 scores were <13, and mean De Jong Gierveld Loneliness scores were <2. The cohort reported relatively high levels of perceived quality of life. The cohort was assumed to have adequate levels of technology literacy as surveys 2 to 5 were administered electronically. When assessed at survey 4, most participants reported regular use of a smartphone (7166/7890, 90.82%) and computer device (6809/7890, 86.3%).

[a] All values in the table have been rounded to two decimal places nearest as such percentages may not sum up to exactly 100% because of rounding error and missing data.

[b] Missing: survey 4 (n=272).

[c] Responses to these questions were not elicited at these timepoints and reflect the change in survey questions overtime.

[d] Missing: survey 1 (n=1) and survey 5 (n=1).

[e] Missing: survey 1 (n=1) and survey 4 (n=1).

[f] Missing: survey 1 (n=182) and survey 5 (n=38).

[g] ARIA: Accessibility Remoteness Index of Australia.

[h] Missing: survey 1 (n=33), survey 4 (n=28), and survey 5 (n=31).

[i] Socioeconomic disadvantage lower rankings indicate most disadvantaged.

[j] Missing: survey 1 (n=10,034).

[k] Missing: survey 1 (n=14), survey 4 (n=9), and survey 5 (n=7).

[l] Multimorbidity refers to those who have indicated having >1 chronic disease.

[m] The missed or delayed care variable includes those indicating missed or delayed care pertaining to a visit to a general practitioner, hospital, specialist, and prescription medication (missing survey 1, n=10,034; survey 4, n=13,859; and survey 5, n=15,984).

[n] Kessler–6—scores are summarized on a scale of 0-24, with higher scores indicating greater distress; scores ≥13 indicating probable mental illness.

[o] Missing: survey 1 (n=266).

[p] De Jong Gierveld Loneliness Scale is scored on a scale of 0-3, with scores of 3 indicating intense emotional loneliness and 0 indicating no loneliness.

[q] Missing: survey 1 (n=230).

[r] Quality of life rating scores are based on a Likert scale of 1-5 (1=excellent; 2=very good; 3=good; 4=fair; 5=poor).

[s] Missing: survey 1 (n=10,034).

A decreasing trend in telehealth adoption was evident across survey time points. Adoption was highest at survey 1 in 2020, with 51.77% (11,082/21,830) of the cohort using telehealth services (telephone or video), indicative of both prepandemic and early pandemic adoption (official announcement of the pandemic in March 2020, with lockdown measures occurring up until May 2020). The proportion of users had decreased at survey 4 to 43.19% (7890/18,268), capturing use in response to the COVID-19 Delta outbreak and associated lockdowns occurring in 2021. The lowest levels of use were observed in survey 5, with only 39.4% (7401/18,782) of participants using telehealth at this time point (capturing use following the vaccination rollout in 2022). As per Table 2, when assessed in survey 4, a total of 42.72% (3371/7890) of participants indicated that they were more likely to use telehealth for a follow-up consultation or to receive test results (2901/7890, 36.81%). A smaller proportion (1608/7890, 20.38%) indicated using telehealth for initial health care consultations or to receive a medical diagnosis or advice (1693/7890, 21.46%). By survey 5, telehealth was primarily being used for general practitioner appointments (5634/7401, 76.12%) or specialist health care appointments (1421/7401, 19.2%), with most participants (4629/7401, 62.55%) preferring a hybrid health care model involving both telehealth and in-person care.

Table 2. Telehealth-related cohort characteristics[a].

Telehealth-related characteristics	Used telehealth		
	Survey 1 (n=11,082)	Survey 4 (n=7890)	Survey 5 (n=7401)

Logistic Regression Models

The results of the multinomial regression model, identifying sociodemographic and health-related determinates of telehealth use, are presented in Table 3. Women were more likely to engage with telehealth services across all categories (low, moderate, and high) compared with men (*P*<.001), with odds ratios indicating an increasing likelihood of use. Individuals aged ≥85 years were significantly (*P*=.01) less likely to exhibit high telehealth use compared with the reference group (aged 65-74 years). Living alone was associated with lower odds of moderate (*P*=.002) and high (*P*<.001) telehealth use when compared with living with others. Inner regional residents and those in outer regional, rural, and very remote areas were less likely to use telehealth at moderate and high levels (*P*<.001) compared with major city dwellers. Individuals from areas of socioeconomic disadvantage (deciles 1-3) were more likely to use telehealth than those with lower levels of socioeconomic disadvantage (deciles 8-10; *P*=.02).

Table 3. Multinomial logistic regression model of sociodemographic and health-related determines of telehealth use (n=10,518)[a].

High	0.31	5.88	<.001	1.36 (1.23-1.51)

[a] *Z* scores (Wald *z* test).

[b] Reference category for telehealth use was 0=did not use telehealth at all.

[c] SEIFA: Socioeconomic Indexes For Areas.

[d] Mean scores were derived from repeated measures.

In terms of health-related determinates, the presence of a disability, chronic disease, or multimorbidity was positively associated with all levels of telehealth use, with a clear trend of increasing odds from low to high levels observed. Experiences of missed or delayed health care were linked to higher odds of using telehealth across all levels. Higher levels of psychological distress were related to an increased likelihood of moderate (*P*=.01) and high (*P*<.001) telehealth use. An inverse relationship between loneliness and moderate (*P*=.02) and low levels (*P*=.01) of telehealth use was evident, with lower loneliness scores associated with higher odds of telehealth use. A lower quality of life was significantly associated with telehealth adoption across all levels (*P*=.004 to *P*<.01), with a notable increase in odds from low to high levels observed.

As displayed in Table 4, a strong positive association was found between early telehealth adoption (measured in survey 1) and subsequent telehealth use (measured in survey 5; *P*<.001). Having a chronic condition (*P*=.006) or multimorbidity (*P*<.001) was significantly associated with ongoing telehealth use at survey 5. The interaction between early telehealth adoption and having a chronic condition or multimorbidity was not significant.

Table 4. Survey effect, telehealth adoption, and ongoing use.

Telehealth use in survey 5 is predicted by?	Coefficient	*Z* score	*P* value
Telehealth adoption at S1[a]	1.11	12.15	<.001
Has a chronic condition	0.21	2.76	.006
Has multimorbidity	0.57	7.81	<.001
Has a disability	0.63	0.72	.47
Interaction effects			
Telehealth adoption at S1[a] and chronic conditions	0.05	0.51	.61
Telehealth adoption at S1 and multimorbidity	0.01	0.08	.93

[a] S1: survey 1.

Discussion

Principal Findings

We aimed to investigate the sociodemographic and health-related determinants influencing telehealth adoption and use among a cohort of older Australians during the COVID-19 pandemic. The objective was to contribute to a comprehensive understanding of the factors influencing adoption and use, surpassing traditional barriers related to ICT ownership and access and motivated by a central concern that the expansion of telehealth services outside of pandemic conditions may exacerbate health care disparities.

Our analyses have revealed a unique set of determinants related to varying levels of telehealth use, suggesting a more nuanced interplay of factors that extend beyond sociodemographic determinants [4]. High telehealth use was significantly more prevalent among women, individuals in the younger age brackets (<85 years), city-dwelling residents, those living with others, and those from the most socioeconomically disadvantaged areas (deciles 1-3).

These results challenge traditional assumptions regarding the digital divide, specifically that low socioeconomic status and ICT ownership are barriers to telehealth adoption for older adults. Rather, our findings are consistent with arguments made by Dykgraaf et al [4], who suggest that for older people, digital literacy, trust, and familiarity are significant factors that can influence the adoption and use of telehealth. These results support our hypothesis and complement the findings by Mao et al [15] and Choi et al [12], affirming that health-related factors are critical determinants of telehealth adoption and use for older Australians. Individuals with a disability, chronic disease, multimorbidity and lower perceived quality of life and those experiencing missed or delayed care were more likely to exhibit telehealth use across all levels, highlighting the importance of telehealth as a supportive tool for managing complex health needs during the pandemic and out of pandemic conditions.

In addition, our findings have revealed that early or prior experience with telehealth is a significant predictor of its sustained use. Participants who engaged with telehealth before or early in the pandemic (as assessed in survey 1) were more likely to continue its use. This suggests that initial exposure and satisfaction with telehealth services are important predictors of adoption and long-term use for this population. The psychosocial factors of loneliness and psychological distress were linked to moderate levels of telehealth use, inferring that telehealth may have also played a role in mitigating mental health challenges by providing continued access to these health professionals.

Moreover, the study affirms the central concern that the expansion of telehealth services during the COVID-19 pandemic may have disproportionately benefited certain groups. For example, telehealth use was observed to be higher among those living in major cities, suggesting that older adults residing outside of city areas were less likely to adopt and use telehealth, potentially exacerbating health care disparities for those living in these underserviced geographic areas.

Although telehealth emerged as a supportive tool for many older people experiencing complex health conditions, it is important to acknowledge that a large proportion of the cohort did not adopt telehealth. A modest uptake of telehealth services was observed during the initial phase of the pandemic that was not sustained, declining over time even when ICT ownership was not a limiting factor. These findings are congruent with observations made by Haimi and Gesser-Edelsburg [6] and Lee et al [3], whereby increased telehealth service availability was not met by increased telehealth adoption or use. In particular, Lee et al [3] analyzed Australian Medicare data evaluating trends in telehealth and in-person health care visits (March 2020-2021). Similar to our findings, they observed an early surge in telehealth use during the introduction of initial lockdown restrictions with an associated decrease with in-person health care visits. Over time, in-person health care visits increased as telehealth visits decreased, suggesting a New South Wales population preference (personal and medical professional) for in-person health care [3].

Given our findings, further exploration of the interplay between sociodemographic and health-related factors as barriers and enablers to telehealth adoption use is warranted. Situating our results within the 4 domains of the Unified Theory of Acceptance and Use of Technology framework (ie, performance expectancy, effort expectancy, social influence, and facilitating conditions) may offer additional insights into an individual's decision-making process related to telehealth adoption and integration into routine health care management [28].

Performance Expectancy

Our findings emphasize the significant influence of health-related determinants on telehealth adoption and ongoing use. This aligns with the concept of performance expectancy, whereby a person's decision to adopt a technology is influenced by the degree to which they believe the technology will help them [28]. Our findings indicate that an individual's decision to adopt telehealth was significantly related to poorer health with those experiencing disability, chronic disease, or multimorbidity more likely to adopt and use telehealth across all levels. Moreover, experiencing missed or delayed care, experiencing psychological distress, and reporting a low perceived quality of life were also associated with moderate levels of telehealth use compared with those in the relevant reference groups. A systematic review by Wang et al [22] highlighted performance expectancy as a significant determinant of technology adoption among older adults. In this study, individuals reporting higher numbers of physical conditions and disability were found to be more willing to adopt long-distance caregiving technologies, including telehealth, to support their health and independence [22]. In addition, Mao et al [15] and Choi et al [12] similarly observed chronic conditions, multimorbidity, impairments with activities of daily living, and mental distress were determinants of telehealth use among their cohorts of older adults, further supporting the proposition that perceived health benefits drive technology adoption and use among older populations.

Effort Expectancy

Our findings did not directly access effort expectancy, defined as perceived ease of use [28]; however, they do suggest an indirect relationship. Indicators, such as early or prior adoption and patterns of telehealth use, assist in explaining this construct. The logistic regression results revealed that early or prior exposure to telehealth (as assessed in survey 1) was a predictor of its sustained use in survey 5. Furthermore, in survey 1, approximately 50% of participants indicated that they probably would recommend telehealth to others, with an additional 21% indicating a definite willingness to endorse the use of telehealth services. These findings imply that initial, positive experiences with telehealth foster adoption. In addition, the high preference for telephone modes of telehealth (88.95% in survey 1) and low preference for video modes (3.16% in survey 1) suggests that familiarity with ICT mediums influences adoption. These observations collectively support the notion that perceived ease of use is a key factor influencing telehealth adoption among older adults.

Dykgraaf et al [4] emphasize the significance of ensuring that telehealth services are user-friendly in their design, supporting the need for telehealth platforms to use familiar technology and intuitive interfaces, particularly for enhancing usability by older people. Moreover, Choi et al [12] observed that ICT ownership and having the knowledge to use technology were significant enablers of telehealth use during the COVID-19 pandemic, suggesting that both familiarity with technology and the knowledge to use it are essential requisite skills required for adoption. This may be especially pertinent for those aged ≥85 years, who, in our analysis, were found to be less likely to exhibit high levels of telehealth use when compared with their younger peers. These results are again congruent with findings by Choi et al [12], whereby those of older age (>80 years) demonstrated decreased odds for telehealth use. Bridging this aspect of the digital divide is crucial, as a lack of ICT access and digital skills is a known barrier to telehealth adoption for older people [4,12]. However, according to Kruse et al [10] technology acceptance in older age groups may be more aligned with preferences for in-person health care, declaring that public policy may not help in this area and that health care providers may need to accept this preference.

Social Influence

The role of social influence, defined as how individuals perceive the importance others place on using telehealth, also appears to play a role in an older person's decision to adopt and use telehealth. In our analysis, individuals living with ≥1 other person were significantly more likely to adopt and have high use of telehealth compared with those who live alone ($P<.001$), suggesting an enabling effect. This could be through direct encouragement or through indirect influence of observing other's positive experiences with telehealth. Wang et al [39] identified social support as a critical element in fostering telehealth adoption for older adults. A systematic review investigating factors influencing the acceptance of technology for aging in place additionally revealed the social environment as a determining factor [40]. In particular, the influence of children, health professionals, and caregivers was associated with technology adoption. The enabling effects of social influence on technology adoption are also suggested to increase as personal dependence on health care services increases, with older people being more open to influence by others, given their changing health circumstances [28].

In addition, from our analysis, approximately 50% of participants who used telehealth in survey 1 indicated that they probably would recommend telehealth to others, with an additional 21% indicating a definite willingness to endorse the use of telehealth. These findings suggest that a positive experience with telehealth may influence its social advocacy, with telehealth services being recommended to others. Similarly, poor experiences with telehealth may negatively affect the social advocacy of telehealth. For example, a mixed methods social media survey ascertained the experiences of telehealth use among a general population of Australians (>18 years, n=369) during the COVID-19 pandemic [9]. Findings from this study revealed that for many users, their telehealth experience was poor, as the service did not meet their health care needs and expectations. Contributing factors included a lack of visual cues, eye contact, and body language; an inability to be physically assessed; poor audio quality; poor connectivity; being seen by unknown health care providers; and feeling rushed when using telehealth services [9]. Experiences such as these will influence social advocacy for the use of telehealth services and are particularly relevant given that our findings indicate that approximately 24% of our sample that used telehealth probably will not and 3% definitely will not recommend telehealth services to someone else.

Facilitating Conditions

Facilitating conditions, reflecting the degree to which a person believes that infrastructure exists to support their use of the technology, also influenced telehealth adoption [28]. Although the infrastructure required to support telehealth was in place and incentivized, it was less likely to be adopted or used by those living in inner regional, outer regional, rural, and very remote areas. It is well known that the IT infrastructure required to support telehealth varies in Australia especially for those living outside of city areas, thus limiting access [20]. Given that both moderate and high telehealth use were more likely to occur for participants living in a major city, it may be that underdeveloped digital technology infrastructure also led to disproportionate telehealth service access during this time [20].

Implications of Findings

When considered alongside the principal findings, the expansion of telehealth services necessitates a nuanced understanding of the diverse factors that influence telehealth adoption and use behaviors, particularly for older Australians. This study revealed that high telehealth use was prevalent among women, those younger than 85 years, those residing within major cities, those who live with others, and those of socioeconomic disadvantage. The observed higher frequency of telehealth use among women compared with men suggests potential gender-related barriers to telehealth adoption. Gender differences in telehealth use have been noted in various studies. Choi et al [12] found that gender was not a significant predictor of telehealth use. In contrast, Mao et al [15] reported that women, especially those with chronic conditions and poorer mental health, were more likely to use telehealth compared with men. A more recent study by Haimi and Sergienko [41] also observed that women significantly increased their use of telehealth services during the COVID-19 pandemic across different types of telehealth services.

A recent rapid review by Turcotte et al [42] found age and gender to be moderating factors (barriers and enablers) for telehealth use, highlighting that older men, in particular, might face barriers related to mental health care that could affect their telehealth adoption. They noted that further research is required to understand gender differences in telehealth service use. To increase the frequency of telehealth adoption and use among older men, targeted strategies could include addressing specific concerns related to technology use, providing gender-sensitive training and support, and highlighting the benefits of telehealth for managing health conditions that are more prevalent among men. Encouraging health care providers to actively engage older male patients in discussions about telehealth options may also help increase adoption rates.

The provision of telehealth services for chronic disease and disability management shows promise as being associated with high telehealth use. Early or prior telehealth experiences that are perceived as positive and that use familiar technology require thoughtful consideration, potentially facilitating sustained use among this cohort. Telehealth technology is well positioned to overcome geographic barriers, particularly as specialist health care professionals in Australia, required to treat and manage chronic disease and disability, are concentrated within metropolitan areas [20]. However, significant investments are required to support information technology infrastructure for those living outside of city areas. As IT infrastructure improves, piloting specialist chronic disease telehealth models of care that link city specialists to those outside of these areas, using hybrid telehealth modes (combining in-person and telehealth), is one area for future research. To increase older adults' willingness to adopt and use telehealth, subjective improvements, such as increasing awareness about the benefits of telehealth, providing user-friendly interfaces, and ensuring positive initial experiences with telehealth services, are essential. In addition, offering personalized assistance and training to build confidence in using telehealth technology may enhance the willingness to adopt telehealth into their nonpandemic health care routines.

Limitations

The insights derived from this large-scale study on telehealth adoption and use during the COVID-19 pandemic by people aged ≥65 years are instrumental in understanding behavioral trends. However, the study's cross-sectional nature limits our ability to infer causality despite identifying a temporal association between early telehealth use and sustained adoption. Self-reporting can introduce bias, potentially skewing the motivations behind telehealth use, especially given the variation in wording of questions across surveys. This is particularly relevant as, although we observed a higher reliance on telephone-based telehealth compared with video-based telehealth in the survey 1 time point, the question was not asked uniformly across surveys, and we could not provide trends of telephone and video telehealth use over time. Although the size of the cohort lends credibility to the generalizability of our findings, it does not fully capture individual longitudinal experiences or control for all potential confounding variables. In addition, the high level of technology literacy within our cohort might not reflect the broader older Australian population, who may encounter different challenges, as indicated by the underrepresentation of culturally and linguistically diverse participants. There is a clear need for longitudinal studies to trace the telehealth adoption journey over time and to consider a more diverse population to enhance the applicability of the findings.

Conclusions

This study investigated the sociodemographic and health-related determinants influencing telehealth adoption and use among a cohort of older Australians during the COVID-19 pandemic. Our findings revealed that health-related characteristics, including those living with a disability, having a chronic disease, and multimorbidity, were significant predictors of telehealth adoption and ongoing use. Early or prior telehealth adoption was also found to be associated with its sustained use, independent of health-related factors, highlighting the importance of initial positive user experiences, familiarity with technology, and ease of use of the telehealth platforms required for this population. This research contributes to the broader understanding of telehealth adoption and use among older adults and highlights the necessity for targeted strategies to support its integration into routine health care delivery for older adults. As the world continues to navigate the pandemic and witnesses the increasing prevalence of noncommunicable chronic disease, our findings provide a foundation for policymakers and health care providers to optimize telehealth services, thereby promoting equitable health care access and supporting the well-being of older populations.

Acknowledgments

This research was completed using data collected through The 45 and Up Study [43]. The 45 and Up Study is managed by The Sax Institute in collaboration with major partner Cancer Council NSW and partners the Heart Foundation and the NSW Ministry of Health. The authors thank the many people participating in The 45 and Up Study and The 45 and Up COVID Insights Study. They also thank The 45 and Up Study investigators for access to The 45 and Up COVID Insights research project data. The authors would like to acknowledge Charles Sturt University's Sustainability Team and Sturt Scheme for granting funds to access The 45 and Up COVID Insights Study data and the Spatial Analysis Team for providing research design and analysis support. The lead author, SF, is supported by the Charles Sturt University-Sturt Scheme. The contributions by authors CES and MN were supported by the Three Rivers Department of Rural Health, which is funded under the Australian Government's Rural Health Multidisciplinary Training Program. Open access publication was supported through the Charles Sturt University Tri-Faculty Open Access publishing grant scheme.

Data Availability

The data sets analyzed for this study are not publicly available as they are privately owned and accessed through The Sax Institute. All data analyzed during this study are included in this published article.

Abstract

Background: Demographic change is leading to an increasing proportion of older people in the German population and requires new approaches for prevention and rehabilitation to promote the independence and health of older people. Technical assistance systems can offer a promising solution for the early detection of nutritional and physical deficits and the initiation of appropriate interventions. Such a system should combine different components, such as devices for assessing physical and nutritional status, educational elements on these topics, and training and feedback options. The concept is that the whole system can be used independently by older adults (aged ≥70 years) for monitoring and early detection of problems in nutrition or physical function, as well as providing opportunities for intervention.

Objective: This study aims to develop technical and digital elements for a measurement and training station (MuTs) with an associated app. Through focus group discussions, target group requirements, barriers, and favorable components for such a system were identified.

Methods: Older adults (aged ≥70 years) were recruited from a community-based setting as well as from a geriatric rehabilitation center. Focus group interviews were conducted between August and November 2022. Following a semistructured interview guideline, attitudes, requirements, preferences, and barriers for the MuTs were discussed. Discussions were stimulated by videos, demonstrations of measuring devices, and participants’ ratings of the content presented using rankings. After conducting 1 focus group in the rehabilitation center and 2 in the community, the interview guide was refined, making a more detailed discussion of identified elements and aspects possible. The interviews were recorded, transcribed verbatim, and analyzed using content analysis.

Results: A total of 21 older adults (female participants: n=11, 52%; mean age 78.5, SD 4.6 years) participated in 5 focus group discussions. There was a strong interest in the independent measurement of health parameters, such as pulse and hand grip strength, especially among people with health problems who would welcome feedback on their health development. Participants emphasized the importance of personal guidance and interaction before using the device, as well as the need for feedback mechanisms and personalized training for everyday use. Balance and coordination were mentioned as preferred training areas in a MuTs. New training options that motivate and invite people to participate could increase willingness to use the MuTs.

Conclusions: The target group is generally open and interested in tracking and optimizing diet and physical activity. A general willingness to use a MuTs independently was identified, as well as a compelling need for guidance and feedback on measurement and training to be part of the station.

Introduction

Background

As a result of demographic change, the proportion of older people (aged ≥67 years) in the total population in Germany is steadily increasing. It is predicted that, by 2040, a quarter of the total population will be older than 67 years. This demographic change is leading to a decline in the working population, including in the health and care sectors. In this context, new approaches to prevention and rehabilitation are needed to enable older people to live longer, more independent, and healthier lives [1,2]. This pursuit of longer independence and well-being is known as healthy aging and aims to maintain mental, physical, and social health for as long as possible. The 2 important elements of healthy aging are a balanced diet and regular physical activity. These 2 elements not only influence each other, but are also linked to other determinants, such as cognitive health [3]. Individuals aged >80 years, women, those with multiple comorbid conditions, and older adults living alone are at higher risk for malnutrition [4,5]. Among older people living in the community, the prevalence of being at risk of malnutrition, as measured by the Mini Nutritional Assessment or Mini Nutritional Assessment Short Form, is 19% and is significantly associated with reduced physical functioning, reduced independence in activities of daily living, and the presence of physical frailty and sarcopenia [6,7]. Low physical activity is generally associated with an increased risk of death; in particular, people who spend >10 hours a day sitting have a significantly increased risk of death [8]. For people with sarcopenia, that is a significant loss of muscle mass, function, or strength, or any combination, exercise training and nutritional interventions are among the most effective interventions to improve strength, walking speed, and balance [9]. In addition to structural and health system conditions, the health literacy of older people plays a crucial role in healthy aging. Although health literacy in Germany is somewhat higher than in other European countries, 54% of people aged >76 years have limited health literacy and may have limited knowledge about the importance of a balanced diet and sufficient physical activity in older age [10]. Older adults with low health literacy have been found to have lower levels of physical activity [11,12]. In the area of dietary adherence, current evidence from systematic reviews suggests that improving self-efficacy expectations is a key factor in the long-term implementation of healthy eating habits [12,13]. Accordingly, strategies such as psychological models should be used to increase participants' self-efficacy expectations. To be able to respond to problems in these areas at an early stage, it would make sense to regularly check the nutritional and physical status of older people. In practice, however, such screening and advice are often not carried out due to a lack of resources and information about available interventions [14].

A technical assistance system could be an approach for the early detection of nutritional and physical activity deficits and the initiation of appropriate measures. Several approaches already exist to enable older adults to self-report nutrition and physical activity parameters. Parts of the geriatric assessment can already be automated [15-17]. In addition, there are programs that support older people to independently implement interventions to improve dietary and physical activity behavior [18-21]. However, most of these programs are interventions without automated assessment and are targeted at people with high functionality or specific medical conditions. A technical assistance system that can objectively measure the nutritional and physical activity status of community-dwelling older adults, as well as provide individualized feedback and training, could help to identify deficits at an early stage for secondary prevention, prevent negative health outcomes, and reduce the burden on the health care system.

However, before developing such a system, it is important to analyze in detail the general acceptance of older people for it, as well as their needs and their specific requirements for implementation and design.

Aim

The aim of the study was to identify technical and digital elements that could be integrated into the technical assistance system to develop a system that is as effective and usable as possible. In addition, the target group's requirements for the system and the general conditions for its use were determined.

Methods

Ethical Considerations

The study was approved by the ethical review board of the Carl von Ossietzky Universität Oldenburg (registration 2022-089). We conducted the study in accordance with the Declaration of Helsinki [22], as amended, and the underlying data protection regulation. Reporting followed the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist for interviews and focus groups [23]. All participants included in the study provided written informed consent.

Participants

We recruited the participants from a geriatric rehabilitation center and in the community in the northwest of Germany.

Flyers were placed on the wards of the geriatric rehabilitation center and the electronic patient database was checked by a member of the study team for patients aged >70 years without known cognitive impairment. These patients were contacted and informed about the study.

Recruitment of the older adults in the community was done by placing flyers and organizing information sessions in various community-based organizations and settings, for example, sports groups for older adults, community or church-run public meeting places, and classes for older adults.

Interested people were approached in a face-to-face meeting to answer questions about the project and, if consent was given, to check the inclusion criteria. Inclusion criteria were (1) aged

≥70 years; (2) the presence of malnutrition according to the Mini Nutritional Assessment Short Form (0-7 points) or the presence of 1 or more risk factors for malnutrition: weight loss in the last 3 months, reduced food intake in the last 3 months, or a reduced BMI (<23 kg/m²) [24]; and (3) presence of 1 or more signs of reduced mobility (walking speed <0.8 m/s and Short Physical Performance Battery <8 points). Exclusion criteria were (1) lack of ability to give consent and (2) insufficient ability to understand the study content and procedure or the German language. Eligible persons were interviewed for sociodemographic data (sex and age), and technology commitment was assessed using a questionnaire by Neyer et al [25] with a 5-point Likert scale with 12 items about personal contact, interest, and general use of technology. A higher score indicates a higher technology commitment [25].

Once 6 suitable participants agreed and their eligibility was checked, a date for the focus group was arranged. All focus groups were held in person. To minimize the burden on the participants, the focus groups were held in the rehabilitation center, in the rooms of the respective sports club or senior citizens' program, or the facilities of the study team, depending on the participants' preference. There were no repeated discussions, and each participant was only allowed to take part in 1 focus group.

Interview Guide

On the basis of the project objective, which was the development of a measurement and training station (MuTs) and corresponding app that could be used independently, key issues were identified for discussion in the focus groups. This was done through discussions within the project team involving people from different professions, such as nutritionists, physiotherapists, physicians, and computer scientists. For the selection of the health data and sensors to be presented, it was checked which possibilities for autonomous recording already exist and which parameters have already been identified in other work in other contexts as relevant for older adults, such as activity sensors, which can have a motivational effect to increase activity. In terms of training equipment, the aim was to represent different training areas and types of training. The areas chosen were endurance (bicycle ergometer), balance (oscillatory platform), coordination and cognition (exergaming system), strength training using body weight (3D depth image–based training correction), and everyday training (exercise stairs). The devices presented were also selected to ensure that independent training was possible. In the first phase of the focus groups (focus groups 1-3), these 5 training options were presented to the participants. In focus groups 4 and 5, only the 3 variants that had received the highest approval in the previous groups were shown. These were the oscillating platform, the exergaming system, and the 3D depth image–based training correction.

The guide was pretested with a pilot focus group of community-dwelling older adults and minor adjustments were made. The selection of devices was also discussed in the pilot focus group, and it was emphasized that the opportunity for participants to contribute their own experiences and wishes regarding measurement and training devices could and should be included in the discussions. The participants of the pilot focus group were not involved in the focus groups 1 to 5). The final interview guide covered 4 main topics in the first focus groups (focus groups 1-3) presented in Textbox 1.

Following the first 3 focus groups, the semistructured guide was adapted to obtain more detailed information on the previously identified relevant aspects. The revised interview guide used in focus groups 4 and 5 included 4 main themes presented in Textbox 2.

Textbox 1. Main topics covered in focus groups 1 to 3.

Relevant health data and measurement tools for independent use

- Presentation of different health data and measurement devices
- Participants were asked to mark on paper with photos of the devices what they were interested in and what they could imagine using
- Open discussion on the participants' choice

Exercise or training options that are of interest for use in the measurement and training station (MuTs)

- Presentation of different training devices through videos
- Each participant should enter numbers from 1 (most likely to be used in the MuTs) to 5 (least likely to be used) in an overview of training devices
- Open discussion about the participant's choice

Frequency and amount of time the participants were willing to spend in the MuTs

- Brainstorming: Participants were asked to express their thoughts on the frequency of measurement and training, and statements were written on posters

Using the MuTs and receiving instructions

- Participants were asked to express their thoughts and needs, and statements were written on a large poster

Textbox 2. Main themes included in focus groups 4 and 5.

Usability of an electronic device for measuring handgrip strength (KForce Grip, Kinvent Biomecanique) and requirements for a corresponding evaluation screen

- Demonstration of the handgrip strength measuring device and testing by participants
- Open discussion on thoughts and experiences during measurement
- Presentation of 3 different mock-ups of the grip strength feedback screen; each participant was given 3 printouts and asked to mark what they liked and disliked
- Open discussion on the comprehensibility of the mock-ups and ideas for improvement

Abilities and requirements for self-administered questionnaires

- Demonstration of how to complete the questionnaire on the tablet, with participants trying it out and watching a video of how to complete it on the screen

Exercise or training options that are of interest for use in the measurement and training station

- Presentation of different training devices through videos
- Brainstorming on the pros and cons of the training options

Frequency and amount of time for additional training at home with a corresponding tablet

- Demonstration of the exercise diary on the tablet for participants to try out
- Brainstorming: Participants were asked to express their thoughts on the frequency of measurement and training, and statements were written on posters

Procedure

All focus groups were structured in a standardized way. First, the participants were welcomed and made comfortable with drinks and snacks. Then, a short input was given on the importance of a healthy diet and sufficient physical activity for older adults. The links between diet and physical activity were also discussed. This was followed by a presentation of the project idea of developing a MuTs, accessible to the public, where older people can independently measure their nutritional and physical activity status and have the opportunity to complete a training program and continue training at home using an app. A 3D model of a prototype of the MuTs was shown to give the first spatial impression of such a MuTs. Then, the interviewers introduced themselves and explained their role in the project. The participants were then asked to introduce themselves to the group.

The discussion started following the semistructured interview guide. For each topic, a short prompt was used, for example, showing videos of the use of the different training devices, and field notes were taken. To facilitate discussion, participants were also asked to mark their favorite aspects of health data, measurement devices, and training options with stickers or rank them in order of importance. After the semistructured guide was completed, participants were asked whether they wanted to add anything. Finally, the focus groups were closed by thanking the older adults for their thoughts and discussions. The transcripts of the focus groups were not returned to the participants for organizational reasons.

All interviews, except focus group 2, were conducted by the same 2 female interviewers together (LH and MS). The interviewers are a physiotherapist and a nutritionist working as scientific researchers in the field of technical assistance systems for nutrition and mobility in older adults. Focus group 2 was conducted by MS and VQ, who are a male physician and a computer scientist. At the beginning of each focus group, the aim of the project and the researchers involved with their expertise and credentials were introduced.

The focus group discussions were audio recorded. The length of the focus groups varied from an average of 76 (SD 6.2) minutes in the first 3 focus groups to an average of 96 (SD 11.5) minutes in focus groups 4 and 5.

Analysis

The audio recordings were transcribed by 1 person using f4 software (f4, audiotranskription) in the form of an extended semantic transcription. When identifiable aspects were mentioned, this text was deleted and replaced by neutral words, for example, city. Pseudonyms were used to distinguish between the speakers. All transcripts were checked against the audio recordings by a study team member. A structured qualitative content analysis was conducted according to the concept of Kuckartz [26]. Computer-assisted coding was performed using MAXQDA 2022 software (MAXQDA Analytics Pro 2022; VERBI Software). Two members of the study team (LH and MS) derived main categories a priori from the interview guide. Subcategories were generated inductively during the coding process. LH and MS performed the coding process independently and then discussed the categories and coding critically until consensus was reached. Code saturation was checked by analyzing how many new categories could be found using additional focus groups [27]. The project's participatory research council, consisting of older adults (aged ≥70 years), reviewed and critically discussed the material and categories for discrepancies in interpretation or understanding.

Results

Overview

A total of 21 older adults (female participants: n=11, 52%; mean age 78.5, SD 4.6 years) participated in the focus group discussions. In round 1, only 2 (33%) of the originally recruited 6 people participated in the first community-based focus group. It was, therefore, decided to conduct a second community-based focus group in this round with n=5 participants (42% of the total from the second round). Of the 9 older adults in the second round, 5 (55%) older adults participated in the community-based focus group and 4 (45%) in the rehabilitation focus group. The characteristics of the participants of the 5 focus groups are shown in Table 1.

The content analysis of the focus groups 1 to 3 revealed 6 main categories with 19 subcategories (Multimedia Appendix 1). After focus group 1, there were 17 (89%) subcategories out of 19 subcategories. The 2 new subcategories were both created after the analysis of focus group 2. Focus group 3 did not produce any new subcategories. In the focus groups with the revised interview guide, 5 main categories with 15 subcategories were found (Multimedia Appendix 2). In focus group 4, a total of 14 (93%) subcategories of the 15 subcategories were found in the focus group that took place in the rehabilitation center. Moreover, 1 additional subcategory was found in the community focus group (focus group 5).

Table 1. Overview of participants characteristics (N=21).

	Round 1			Round 2	
	Rehabilitation (n=5)	Community 1 (n=2)	Community 2 (n=5)	Rehabilitation (n=4)	Community (n=5)
Sex (female), n (%)	3 (60)	1 (50)	2 (40)	1 (25)	4 (80)
Age (y), mean (SD)	82.8 (3.1)	78.5 (0.5)	76.6 (3.6)	78.3 (4.0)	77.8 (5.1)
SPPB[a] (score),mean (SD)	4.8 (1.3)	8.5 (0.5)	9.6 (1.7)	7.5 (1.8)	7.8 (2.2)
MNA-SF[b] (score), mean (SD)	7.8 (2.8)	9.4 (1.9)	9.5 (0.5)	8.5 (3.5)	7.8 (1.0)
TC[c] (score), mean (SD)	30.8 (8.8)	36.0 (1.0)	37.2 (5.1)	45.0 (6.0)	42.8 (8.6)

[c] TC: technology commitment.

Round 1

Health Data and Measurements

Participants expressed a general interest in different types of health data. Most of them were also very interested in self-measurement in the MuTs. Some health data were already regularly measured at home by older adults, such as blood pressure and the number of steps. They also mentioned that measuring health data is of special interest if they have a disease or health limitation related to these health data, especially in the discussion about cardiovascular diseases. The participants discussed that health data should be assessed every time they visit the MuTs, with some people also expressing concerns about measuring too much data because of the psychological stress that can be caused by a huge amount of different data and not listening to themselves and how they feel:

> *What's the point of all these measurements and, um, these people wearing these watches and all that.... I want to live and not control myself all the time.* [Female, 79 years]

As different types of health data were shown and discussed, we found that handgrip strength measurement was largely unknown to our participants. After explanation, most participants expressed interest in this parameter. Different opinions were expressed regarding the assessment of oxygen saturation. Some participants were very interested and explained that this health data would be useful in combination with a fitness tracker to assess physical activity. However, some participants also had concerns about the interpretability of this data.

Measuring activity was relevant for almost all participants but more as an assessment in everyday life and not as part of every visit to the MuTs. Measuring activity during the visit to the MuTs was discussed, and it was expressed that it would be biased if activity was only measured during the visit. Some participants expressed that it should be combined with the collection of other health data, such as pulse or oxygen saturation.

The evaluation of cardiological health data in the MuTs was discussed intensively. Participants were especially interested in pulse and blood pressure data and mentioned that these are the data that most of them measure at home. In particular, people with cardiovascular disease expressed a general interest in this type of health data. Other cardiological data, such as electrocardiography (ECG) and heart sounds, were described as data that should be assessed and evaluated by physicians and not as part of MuTs:

> *Um, and ECG less, because that's a story that I think is a bit more difficult in terms of effort and too many mistakes can be made. Um, I think it's very difficult when there are methods that are easy, ok, but yes.* [Male, 77 years]

Using Measuring Devices

The handling of the different devices (blood pressure monitor [wrist and upper arm], fitness tracker [wrist and clip], and hand dynamometer) was described as relatively easy by all participants, with the exception of the upper arm blood pressure monitor, where participants reported difficulties with the readability of the display. Some devices were already used regularly by participants, most commonly blood pressure monitors (wrist) and fitness trackers. People who already used devices also reported varying degrees of difficulty or compliance with regularly monitoring their blood pressure, and some mentioned that they did not rely on the results. The use of a home emergency call system was raised as an issue by the participants, and including some kind of emergency call system in the MuTs was seen as highly relevant. In general, participants expressed a preference for devices that can measure multiple health outcomes and include some form of direct data transfer to the MuTs:

> *But if I could go to the station and wear this watch and it would immediately measure my steps, pulse and oxygen. That would be very good. So, for me, the difference is that if I go there specifically, I can use more complex things, they give me more.* [Female, 78 years]

Physical Training Variants

To ensure a good training environment, several aspects should be met. These include the relevance of the exercises to everyday life (eg, steps should have real heights, and the training should aim to make everyday life easier and should be individually tailored to the problems of the participants). Another important aspect that was frequently mentioned was safety during the training. For example, the risk of falling should be reduced using handrails.

Although familiar devices would be easier to use, they would be less attractive if they were already available at home. Sports clubs are visited by some participants; further training should only take place if training is not available at the sports club. Instructions from the physician about which sports to avoid are taken very seriously. An advantage of the MuTs over training at home is that there is space for all the training equipment and the availability of new, additional training equipment that participants may not have at home.

Training should challenge different areas and be adapted to the ability of the user. In general, training balance to prevent falls, training reaction time, cognition, and muscle strength for improve everyday activities were described as important. Training should also be fun, enjoyable, and motivating. An insight into one’s own past results would encourage ambition; comparison with the training results of others was rejected. An overly technical look of a training device could be a deterrent.

An overview of the participants’ comments on the different training devices is given in Multimedia Appendix 3. Overall, devices for training coordination and balance were rated higher than those for training endurance. In addition, devices offering training options that are less available in everyday life were preferred.

Range of Use

Almost all participants emphasized that the use of the MuTs should not restrict other areas of life. In many cases, other activities would already compete with the use of the MuTs and take up more time in the lives of older people. In addition, the participants emphasized that self-motivation, the distance to the MuTs, and the travel possibilities had a great influence on the extent to which the station would be used:

> *And I would, um... once a week, because I also want to do other things than for my body, I also want to do something for my mind and for my social life. And I also need time for that. And of course, I need more time for everything than I used to. You have to go slower to get there...yes, everything takes more time.* [Female, 78 years]

One participant expressed that the MuTs should not replace medical examinations but only support or relieve the physician at times when there are no serious health problems.

Many participants stated that they would be guided by official recommendations for use, such as information on the frequency at which training begins to have a positive effect, or how often to measure which health parameter. It was generally stated that the MuTs would not be used spontaneously but would have to be planned in advance by the participants. Participants indicated that they would like to stay between 15 and 90 minutes. Participants most often indicated that 30 to 45 minutes would be appropriate, that a shorter duration would not be worth the journey, and that a longer duration would reduce strength and concentration.

Expectations and Requirements for Using the MuTs

All participants considered human involvement to be an important prerequisite for the use of the MuTs. The initial introduction should always be given by a person, and there should also be the possibility to contact this person in the course of the use of the station if there are any uncertainties or problems. Aspects mentioned regarding the use of the MuTs instructions for measurement or training were asking questions, repeating instructions, or skipping instructions if they were already known. Disadvantages mentioned in the course of use due to the lack of a real trainer were that the station does not provide social interaction to alleviate loneliness and that interaction with a real trainer would lead to more fun, better results, and higher motivation:

> *I have problems with voices talking to me and telling me what to do. That it’s not a person at all. So, for example, with this instruction of what to do, um, it wasn’t clear to me when I was watching, when she said it, should I do it right away or should I listen to it all together and then do it?... And that’s when a certain aggression starts to develop against this machine voice.* [Female, 78 years]

If the health parameters measured in the MuTs deteriorated significantly, a physician should definitely be involved, or the person should be advised to have the change checked out by a physician. Particularly in the case of cardiological measurements, such as an ECG, there was little confidence in a measurement taken on the station, and the importance of involving a physician was highlighted.

The general usability of a touch system to control the MuTs is considered to be good and is already known from other situations (supermarket checkout). Short and simple sentences would be important for the usability of the MuTs, as well as sufficient volume for the audio output to enable people with hearing impairments to use them. For structuring purposes, information should be broken down into small action steps, as it is feared that comprehension may be impaired in the MuTs due to anxiety, excitement, fatigue, or pain.

Round 2

Measuring Handgrip Strength via an Electronic Measurement Device

Although there was no prior knowledge or expectation of handgrip strength measurement, the participants showed great interest and understanding of the relationship between overall muscle status and the measured value. After an explanation of the handgrip strength parameter and its significance, many participants emphasized that they would find regular monitoring useful. The fact that the measurement required little equipment and was quick and not very strenuous was rated positively. Several participants described the process of measuring handgrip strength as logical or not difficult. Opinions differed as to whether instructions should be given once before the first measurement or before each measurement. Options for this were written or audio instructions:

> *And I think it's really good when you're guided through it. So, I start and then it says "next" and then the next picture comes up and then there's the hint again. Something like I have to press again or I have to press now. So, I think that explains it quite well at the beginning because you can see it.* [Female, 74 years]

Many participants emphasized that it should be easy to log in for measurement. A familiar system such as ID cards should be used for registration, or access data should be entered manually.

Presenting and Interpreting Results of Handgrip Strength Measurement

The focus groups generally showed a good understanding of the various examples of graphs showing the results of the grip strength measurements used to stimulate discussion. In general, the diagrams should be short and clear, have strong contrasts, and not be overloaded with too much information (especially text). All participants were in favor of including a cut-off value in the figures so that they could interpret whether their own handgrip strength corresponded to the corresponding standard values and, if necessary, estimate the amount of deviation. An overview of previous measurements would be important to be able to assess one's own development over time.

A graph showing a comparison with other study participants was discussed intensively. Most participants were against a comparison. The comparison was not relevant to them, not interesting, and not very meaningful:

> *That's the thing, I have too much information, I don't need it. I want to know my results.* [Male, 73 years]

Answering Questionnaires on a Touch Screen

To stimulate discussion, participants were shown how to complete a questionnaire on a tablet in the session and a video of the questionnaire being completed on a 139.7 cm touch screen. A general comment was that it would depend on the prior technical knowledge of the participants as to whether problems would arise in completing digital questionnaires. If there was little prior knowledge, an introduction to the technology would be helpful. Further support should be provided depending on the technical skills of the participants:

> *I would have to learn how to deal with it. It's a foreign object to me.... But I would learn, probably.... I would want to learn it, yes.* [Female, 74 years]

The font size of the questions on the tablet was found to be easy to read. However, the legibility on the screen at the station was even better. The advantages of completing the questionnaire at the station were the better clarity and larger font size. Filling in the questionnaire was said to be quicker because everything was immediately visible and there was no need to scroll. Other participants suggested that it was quicker to complete the questionnaire on the tablet. It was also noted that the time window for completing the questionnaire on the tablet was flexible.

Contextual factors were particularly criticized when the questionnaire was completed at the station. The main concern was that the time spent at the station to complete the questionnaire would be significantly longer and that the user would be under time pressure from waiting participants. The perceived time pressure would lead to a lack of concentration and influence response behavior. Another concern expressed by 1 participant was that the data entered could be seen by other participants and that privacy could no longer be guaranteed. It was also criticized that completing the questionnaire in the MuTs was less convenient than at home and that it did not make sense to go to the MuTs just to complete the questionnaire there:

> *You can sit down, you can sit down quietly and concentrate.* [Male, 73 years]

Physical Training Variants

In general, all 3 training options (oscillatory platform, exergaming system, and 3D depth image–based training correction) were well received, as shown in Multimedia Appendix 3. The exergaming system received the most positive feedback and generated the most interest. The various advantages and disadvantages of the 3 training options presented and discussed are summarized in Multimedia Appendix 3. In this focus group phase, the participants also discussed which form of presentation of the 3D depth images they would prefer when using the camera system. The color image was the preferred form of presentation, as the sequence of steps in the exercise is easier to recognize and the exercise is shown more clearly due to the higher contrast.

In general, the adaptability of the training to different performance levels would be important. Regardless of the type of training, many participants considered balance training to be very important and some also considered coordination training to be very important. Participants described how older people were more likely to use familiar equipment. New equipment that requires extensive instruction was more likely to be rejected. Complicated equipment could also be overwhelming for older people. Equipment with multiple components, a lot of technology, or a high susceptibility to faults was rated as complicated. Experiences were reported that frustration quickly sets in, and successes become less visible:

> *Especially the potential for failure. The more you build in, isn't it, the more you run the risk of failing again in the whole story. The simpler it is, the less you can have a mistake somewhere in there.... That also frustrates you. You also want to see some success, or it's not like that.* [Male, 83 years]

Continuing Exercises at Home

As part of this discussion, a digital training plan for the autonomous performance of simple physical exercises at home was shown and found useful by the participants. The training plan itself and the symbols used (exercise duration and number of repetitions) were understood by all participants. The font size and readability were also rated positively. One person with little experience of using tablets was initially very reluctant to use the device and expressed concern about breaking something.

The desired frequency of use per week varied considerably. Most participants favored a training frequency of 2 to 3 times per week, assuming a training duration of 20 to 30 minutes per session.

One of the most frequently mentioned factors influencing the implementation of home exercise was how it could be integrated into the participants' daily lives and how flexible it would be. Both the physical condition of the participants and their own sporting activities or social life were seen as competing with a home exercise program. Adequate space or exercises that do not take up much space would also be a prerequisite for exercising at home. Motivation to exercise also depends on whether success is visible, whether the exercises are variable, and whether exercising has already become an integral part of the participant's everyday life:

> *You might have to move a carpet or two to avoid falling. But that's, that's quite feasible. So, if you...seriously want to do it, you'll find a way.* [Male, 79 years]

Discussion

Principal Findings

The aim of the study was to identify technical and digital elements that could be integrated into the technical assistance system to develop a system that is as effective and usable as possible. In addition, the target group's requirements for the system and the general conditions for its use were determined.

We were able to conduct 3 focus group discussions with older people living in the community and 2 focus group discussions in a geriatric rehabilitation center. Our focus group discussions revealed general interest and openness among the target group to track and optimize nutrition and mobility independently.

When discussing relevant health data and the competence of older people to record it independently in the MuTs, we observed that the willingness and interest to perform measurements seemed to be greater, especially if there was already a health limitation. Similar observations were made in the study by Bian et al [28], which investigated the use of a home sensor system for frailty diagnosis. People who described themselves as healthy and physically active saw less sense in using certain sensors. In the study by Seinsche et al [29], willingness to use an exergame-based telerehabilitation device was evaluated by focus groups. They found that the willingness to use technical devices with a meaningful purpose was even more pronounced than the general willingness to use technology. This demand for a perceived benefit from the use of an assistive technology system had already been observed in an earlier focus group study with older people [30].

Participants in our focus groups were mostly positive about the use of technical measurement devices to collect health data. They were confident enough to use almost all the devices presented independently after receiving instruction. The fact that it often seems to be a prejudice that older people tend to have problems with technology has also been shown in other qualitative studies conducted with older people on the development of MuTs [28,29,31]. The studies by Bian et al [28] and Seinsche et al [29] describe that older people have few problems using technology and are interested in modern technologies. They note that it is particularly important to build confidence and self-efficacy in using technology and that general knowledge of how to use it is usually less of a problem.

Possibly, another factor contributing to the acceptance of automated health records is the age of the study participants. The average age of the participants in our study was 78.5 years. This makes them slightly older than participants in other publications (average age 71.3-76.6 years) on older people's willingness to use and perception of autonomous technical assistance systems in the area of nutrition and activity [28,29,32]. Our study and the other aforementioned studies showed a general willingness to use such systems. On the other hand, a study of people aged >85 years in a nursing home showed that these people were less interested in monitoring their health status [33].

People using the MuTs should also be able to get direct feedback on their measurements and training. For our target group, issues such as simple visualization, reporting of cut-offs and trends, and step-by-step instructions are important. A study of people with multimorbid chronic conditions also described how a simple digital representation of health data could help, as the graphs and tables they receive from their physicians are often not easy to understand [31]. A point also raised by our participants was the synchronization of measurements in a system and their interpretable presentation; this point was also discussed as very important by older people in a study of requirements for sensor-based frailty assessment at home [32].

Despite the general willingness and openness to the possibility of early detection of changes in nutritional and physical activity outcomes and targeted training, it was clear that human involvement was desired. The presumed desired level of involvement varied between the opinion that it would be sufficient if a qualified person introduced the user to the use of the MuTs and the opinion that independent use would not be possible without the constant presence of qualified staff. Therefore, the MuTs should be set up in a public place that is connected to the research facility or, for example, to a physiotherapy practice or a medical facility. Our findings reflect the findings of a scoping review of web-based interventions to promote healthy lifestyles in older adults. The review identified 5 papers that addressed the issue of support. Results of the review showed that although the need for human involvement was emphasized, the desired level of support varied from purely web-based support to a personal introduction to the system to face-to-face sessions with a trainer [34]. Similar results were found in a focus group study with older people on the use of an exergame telerehabilitation program. Participants also felt that human involvement and the possibility of human contact would be important to them [29]. Participants in our focus groups also discussed the desire for a means of contact and the interest in integrating an emergency system. The importance of human involvement in the use of automated measurement systems is also apparent in a qualitative study of the development of a home-based frailty assessment. Participants described concerns about the loss of personal contact with health care professionals when measurements were taken by sensors [32]. In our focus groups, participants also expressed that they would generally welcome a reduction in the burden on physicians and other health care professionals but that the station should rather be used for monitoring over time and that professional advice should be sought if there are signs of health problems, for example, by making an appointment with a physician. During the discussion on the collection of cardiological health data, it also became clear that measurements that are perceived as more complicated or demanding (such as ECG) should be carried out by a physician.

The results of our focus groups indicated that participants were less concerned about data protection and their privacy. Although it was discussed that it would be important for other participants not to be in the same room when completing questionnaires on the MuTs screen, there were no comments about the concerns about general data security or worries about unauthorized access to data collected in the station. In general, there seem to be different perceptions and needs of older people in terms of privacy and data security. While some studies using sensor-based systems in the home environment to collect health data seem to be more associated with concerns about these parameters, and there are also increased concerns in the context of using apps to support the recording of various disease-related symptoms [28,31,32], a study of exergame-based telerehabilitation also reported fewer concerns among participants about data security [29]. Interestingly, the study by Bian et al [28] also explicitly opposed the use of cameras. In our focus groups, participants were shown the analysis of exercise performance using 3D depth cameras, and different types of recording were also discussed, with the color image being the most popular. It is likely that a key difference between our study and the study by Bian et al [28] is that in the study by Bian et al [28], the cameras were installed in the participants' home environment, and in our study, they were installed in the MuTs. This may suggest that, in this context, a more comprehensive collection of health data could be carried out with sensor technology that may be less accepted in the home environment for people who still have sufficient mobility to visit a MuTs.

The results of this study must be considered in the context of a number of limitations. No systematic sampling strategy was used, and the study was not stratified by age or sex. In particular, the second focus group in the rehabilitation center had fewer female participants than the actual proportion of women in this age group in the German population [35]. Recruitment in the rehabilitation center was particularly challenging: As inpatient geriatric rehabilitation in Germany usually lasts about 3 weeks, the focus group appointment had to be arranged quickly after the participants had given their consent and also had to be coordinated with the patients' other therapy measures and appointments. In addition, 1 ward was closed during recruitment due to a COVID-19 outbreak, and patients from this ward could not be recruited. In addition, the main diagnosis of people in geriatric rehabilitation was not recorded. It is, therefore, possible that rehabilitants responded differently depending on their main diagnosis. This cannot be verified with the available data. In general, it cannot be ruled out that more homogeneous focus groups would have allowed for different responses and opinions. Moreover, it is also possible that the focus groups were composed of people who were generally more interested in nutrition, exercise, and technology.

Conclusions

For older people with initial health limitations in particular, the regular use of a MuTs could be a promising approach to enable independent monitoring of nutrition and physical activity status. Important requirements and prerequisites for the development of a MuTs were collected, which will be developed and evaluated with the involvement of the target group. In particular, aspects such as the necessary level of supervision by a real person on site and the independent usability of several measuring and training devices in the context of using the MuTs should be given special consideration in further development.

Acknowledgments

The authors would like to thank all participants involved in the study. The authors are grateful to Fenja Asendorf for her assistance in transcribing the focus groups.

Data Availability

The data generated during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

LH and RD contributed to the study concept and design. LH, MS, and VQ contributed to the acquisition of data. LH, MS, MF, and VQ contributed to the analysis of data. LH contributed to drafting the manuscript. MS, VQ, MF, and RD revised the manuscript for important intellectual content. All authors read and approved the final manuscript.

Abstract

Background: Higher-level functional capacity (HLFC) is crucial for the independent living of older adults. While internet use positively impacts the health of older adults, its effect on HLFC and how this effect varies with educational attainment remains uncertain.

Objective: This longitudinal study aimed to investigate whether internet use could mitigate the risk of HLFC decline and if this benefit extends to older adults with lower levels of education.

Methods: The data were sourced from the Japan Gerontological Evaluation Study (JAGES), encompassing 8050 community-dwelling adults aged 65 years and older from 2016 to 2019. The study focused on those who remained self-sufficient from 2016 to 2019, identifying participants with independent HLFC in 2016. The Tokyo Metropolitan Institute of Gerontology Index of Competence defined HLFC operationally, consisting of 3 subscales, namely instrumental activities of daily living, intellectual activity, and social role. The primary variable was the frequency of internet use in 2016; participants who reported using the internet were classified as internet users, while those who answered “No” were identified as nonusers. The study compared the effects of internet use on HLFC decline across educational levels of ≤9 years, 10-12 years, and ≥13 years using Poisson regression analysis adjusted for robust SE to calculate the risk ratio (RR) and 95% CI for HLFC decline in 2019.

Results: After adjusting for demographic and health condition risk factors, internet use was significantly linked to a decreased risk of HLFC decline in older adults over 3 years, including those with lower educational levels. Internet users with ≤9 years of educational attainment experienced a suppressed decline in the total score (RR 0.57, 95% CI 0.43-0.76; *P*<.001); instrumental activities of daily living (RR 0.58, 95% CI 0.38-0.91; *P*=.02), intellectual activity (RR 0.60, 95% CI 0.41-0.89; *P*=.01), and social role (RR 0.74, 95% CI 0.56-0.97; *P*=.03) compared with nonusers. Participants with 10-12 years of education showed suppression rates of 0.78 (95% CI 0.63-0.98; *P*=.03), 0.59 (95% CI 0.39-0.90; *P*=.01), 0.91 (95% CI 0.63-1.31; *P*=.61), and 0.82 (95% CI 0.68-1.00; *P*=.05), respectively, and those with ≥13 years displayed suppression rates of 0.65 (95% CI 0.51-0.85; *P*=.001), 0.55 (95% CI 0.36-0.83; *P*=.01), 0.64 (95% CI 0.37-1.10; *P*=.11), and 0.83 (95% CI 0.64-1.08; *P*=.17), respectively.

Conclusions: These findings indicate that internet use supports the maintenance of HLFC independence in older adults with higher education and those with lower educational levels. Encouraging internet use among older adults with lower levels of education through future policies could help narrow functional health disparities associated with educational attainment.

Introduction

Maintaining Higher-Level Functional Capacity Is Essential for the Independent Living of Older Adults

The World Health Organization Scientific Group on the Epidemiology of Aging suggests using autonomy or independence in life functioning as a health index for the older adult demographic [1]. In Japan, over 70% of older adults express a desire to continue residing in familiar surroundings and at home; they prefer to receive nursing care services at their residence, even if such care becomes necessary [2]. The Ministry of Health, Labour, and Welfare is advocating for the development of a comprehensive community support and service system known as the community-based integrated care system. This initiative aims to uphold the dignity of older adults and support their independent living within their local communities throughout their lives [3]. Nonetheless, even with this system, the gap between average and healthy life expectancy, referred to as the restriction period for daily life, stands at 8.7 years for men and 12.1 years for women [4].

Lawton [5] defined and systematized 7 hierarchical competencies for older adults: life maintenance, functional health, perception and cognition, physical self-maintenance (corresponding to basic activities of daily living), instrumental self-maintenance, effectance, and social role in the order of increasing complexity. "Instrumental self-maintenance" corresponds to instrumental activities of daily living (IADL) as the capability to maintain one's life independently at home. "Effectance" is associated with engagement in intellectual activities, such as leisure and creativity, and "social role" corresponds to the ability to engage in intimate societal interactions. A study analyzing a nationally representative sample in Japan revealed that most community-dwelling older adults exhibit proficient functional capacity (eg, IADL, intellectual activity, and social role), although this capacity tends to diminish with age [6] and often deteriorates before declines in basic activities of daily living are observed [7]. Further research indicates that, after retirement, older adults aged ≥65 years' experience a gradual decline in their higher-level functional capacity (HLFC; IADL, intellectual activity, and social role) [8] and that HLFC is linked to mortality as well as medical and long-term care expenses [9,10]. Consequently, HLFC emerges as a modifiable health factor vital for sustaining independent living among older adults, highlighting the importance of preventing HLFC loss.

Addressing the Impact of Educational Disparities on HLFC Maintenance Is Imperative for All Older Adults

The capacities of older adults are likely influenced by the cumulative effect of health inequalities, which are exacerbated by factors, such as gender and education level, over the lifespan [11]. Longitudinal research in Japan has shown a significant correlation between HLFC and educational achievement [6], with additional studies indicating notably poor IADL among older adults with lower levels of education [12-15]. To facilitate independent living across this demographic, it is crucial to propose intervention strategies aimed at mitigating the decline in HLFC, including measures to enhance IADL capabilities, irrespective of educational background. Despite this need, established strategies for enabling older adults to decelerate the HLFC decline, especially among those with minimal educational attainment, remain scarce.

The Internet May Have a Positive Effect on the HLFC of Older Adults

In Japan, the number of older adults using the internet in the past year has risen by 10.5% among those aged 60-69 years, 12.7% among those aged 70-79 years, and 7.5% among those aged 80 years and older, compared with 4 years earlier [16]. The spread of information and communication technology (ICT) among older adults is not limited to Japan but is also observed globally [17]. ICT has been demonstrated to yield numerous health benefits [18-39]. However, the relationship between internet use and HLFC has been the subject of limited research. Digital illiteracy, often attributed to a lack of education, emerges as a principal factor behind the digital divide, particularly among older populations [40]. Consequently, the effectiveness of the Internet in enhancing HLFC may be diminished for older adults with lower educational levels. Nevertheless, from the perspective of addressing health disparities, it is crucial to ascertain whether the internet can play a role in preventing HLFC loss among older adults with minimal education.

Aims of This Study

To ensure that all older adults, irrespective of educational background, can maintain independent living, this study seeks to examine whether internet use can mitigate the risk of HLFC decline. In addition, it investigates whether such benefits extend to older adults with limited education. Until now, no research has explored the relationship between internet use and HLFC across different levels of educational attainment. This study aims to determine whether internet use can reduce the risk of HLFC decline among older adults with lower educational backgrounds, focusing on 3 subscales, which are "IADL," "intellectual activity," and "social role," by categorizing individuals aged ≥65 years based on their educational levels.

Methods

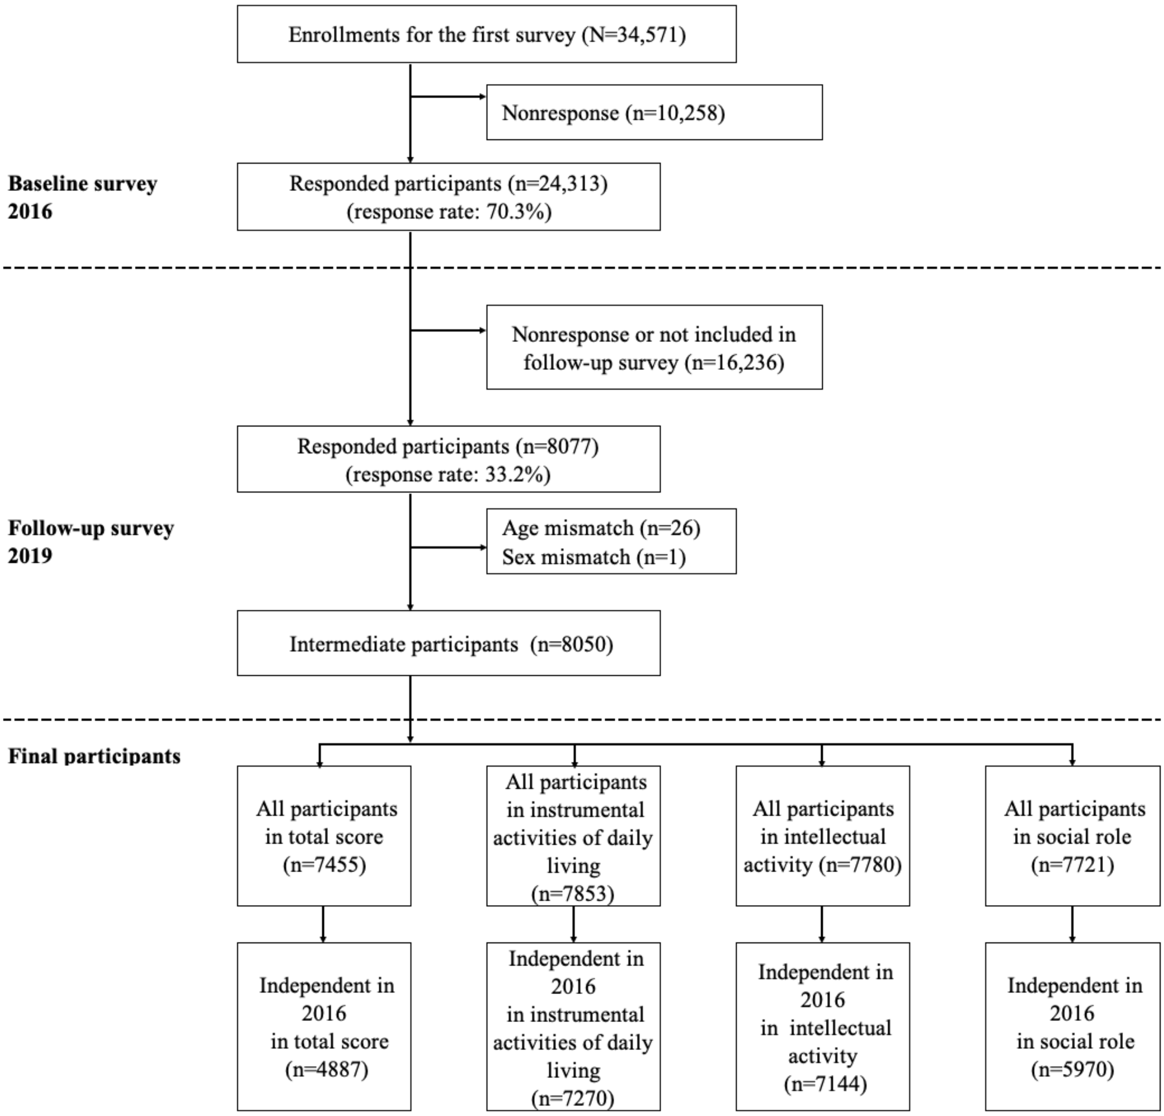
Design, Setting, and Study Participants

Data were collected from the Japan Gerontological Evaluation Study (JAGES), a triennial community-based survey tracking older adults in Japan [41]. Longitudinal panel data from surveys conducted in 2016 and 2019 were used. The baseline survey took place between September 2016 and January 2017, with self-reported questionnaires dispatched to 34,571 independent community-dwelling individuals aged ≥65 years. Of these, 24,313 responded (response rate 70.3%).

The follow-up survey was carried out between November 2019 and January 2020. From the 24,313 baseline respondents, 8077 participated in the follow-up survey (response rate 33.2%). We excluded 27 responses due to discrepancies in reported age (n=26) and sex (n=1) between the baseline and follow-up surveys, leaving 8050 participants for analysis. In Japan, 81.6% of older adults in the community live independently [4]. Given the Japanese long-term care prevention project's goal to avert HLFC decline among community-dwelling older adults, this demographic was deemed the most appropriate for the study.

Thus, the study focused on individuals who maintained their independence in 2016. Participants were selected based on their independent HLFC (total score of 3 subscales, namely, IADL, intellectual activity, and social role) in 2016. Those who did not meet the criteria for independent HLFC in 2016 were excluded, resulting in a final analytical sample of 4887 individuals in total score, 7270 in IADL, 7144 in intellectual activity, and 5970 in social role. A flowchart detailing the participant selection process is provided in Figure 1.

Figure 1. Participant recruitment process for the study.



Ethical Considerations

This study was approved by the Ethics Committee of the National Center for Geriatrics and Gerontology (No. 992, 1274-2), the Ethics Committee of Chiba University (No. 2493, 3442), and Hamamatsu University School of Medicine (approval number: 91-123). Informed consent was obtained by requiring all respondents to select an acceptance checkbox on the questionnaire before returning it. The study used anonymized data. The participants were not compensated.

Outcome Variable: HLFC

HLFC was assessed using the Tokyo Metropolitan Institute of Gerontology Index of Competence (TMIG-IC) [7], which is grounded in the Lawton Instrumental Activities of Daily Living Scale. This 13-item index comprises three subscales of competence, each requiring a yes or no response, which are (1) IADL (5 items: the capability to travel by train or bus, shop for daily necessities, cook, pay bills, and manage a bank and postal savings account); (2) intellectual activity (4 items: the capacity to complete paperwork, read newspapers, read books or magazines, and interest in health-related articles or television programs); and (3) social role (4 items: the capability to visit friends' homes, offer advice to family members or friends, visit ill individuals, and initiate conversations with young people; Table S1 in Multimedia Appendix 1). The TMIG-IC is extensively used as an HLFC evaluation tool. Scores for each subscale were calculated by summing the responses (yes=1 and no=0), with a higher score indicating greater competence. The maximum scores for the total score, IADL, intellectual activity, and social role are 13, 5, 4, and 4 points, respectively. Based on previous research [42,43], we defined a decline in HLFC subscales as (1) a reduction of ≥2 points in the total score, (2) a reduction of ≥1 point in IADL, (3) a reduction of ≥2 points in intellectual activity, and (4) a reduction of ≥2 points in social role. Participants with a high total score (12 or 13 points), IADL (5 points), intellectual activity (3 or 4 points), and social role (3 or 4 points) were considered to have maintained integrity in HLFC subscales, respectively. In this study, intactness in subscales was classified as "independent," and decline in subscales was classified as "dependent," respectively.

Explanatory Variables

Internet Use

The 2016 frequency of internet use served as the variable for internet use. The pertinent question was "Have you used the Internet or emails in the past year? If yes, please specify the frequency." The response options were "1. no," "2. yes (less than a few times a month)," "3. yes (two to three times a week)," and "4. yes (almost every day)." Those who reported yes (2, 3, and 4) were categorized as internet users, and the response "1. no" identified internet nonusers.

Educational Attainment

Educational attainment was gauged by the completed years of schooling (≤9, 10-12, and ≥13 years).

Covariates

Covariates included sex, age (65-69, 70-74, 75-79, 80-84, and ≥85 years), annual household equivalized income (3 quantiles: low, middle, and high), employment status (never employed, retired or not employed, and employed), marital status (married, widowed, divorced, never-married, and other), living arrangement (living with someone or living alone), self-rated health (good or poor), BMI (<18.5, 18.5-25, 25-30, and >30 kg/m^2), diseases under treatment (hypertension, diabetes mellitus, stroke, cardiac diseases, cancer, and respiratory diseases; no or yes) [9,44], depression (no or yes), and population density (metropolitan, urban, semiurban, and rural). The 15-item Geriatric Depression Scale was used, defining mild depression as >5 points and severe depression as >10 points [45,46]. For depression data, responses with up to 2 missing items were included, with missing values replaced by the mean of the answers of respondents to the items. Population density was calculated for each municipality by dividing the population by the habitable land area, resulting in the number of residents per km² per unit area. Municipalities were then categorized based on the population density of the habitable area into 4 groups, that are metropolitan (≥4000/km²), urban (1500-3999/km²), semiurban (1000-1499/km²), and rural (<1000/km²). Missing data for each variable were assigned to missing groups, except for sex, age, and population density.

Statistical Analysis

A descriptive analysis delineated the baseline characteristics of the study participants, differentiating between internet users and nonusers, and assessed the correlations between internet use and HLFC, as well as educational attainment and HLFC in 2016. Items missing from the 2019 HLFC variable, along with missing and other items from the educational attainment variable, were excluded from the analysis. HLFC changes in 2019 were set as binary outcomes, some showing a common prevalence (>10%). Therefore, we used Poisson regression analysis, adjusted for robust SE, and computed the risk ratio (RR) and 95% CI for the decline in HLFC in 2019 while avoiding overestimation [47]. To examine the impact of educational attainment on the association between internet use and HLFC decline, we conducted stratified analyses by educational level using a single model with all covariates included simultaneously. Significance tests were performed for each main effect and interaction, with statistical significance set at *P*<.05. Statistical analyses were carried out using Stata SE/15.0 (Stata Corp).

Results

Characteristics of Participants

The baseline characteristics of internet users and nonusers in 2016 are presented in Table 1. While no significant gender disparity in internet use was observed (*P*=.01), a strong correlation between educational attainment and income with internet use was noted (both *P*<.001). In addition, an inverse relationship between age and internet use was identified. The internet use rate was significantly higher among those who were currently working or had worked in the past compared with those who had never been employed (*P*<.001). Similarly, individuals residing in metropolitan and urban areas demonstrated a significantly higher internet use rate than those in rural areas (*P*<.001). Cross-tables that compare internet use or educational attainment with HLFC are depicted in Tables 2 and 3 and Table S2 in Multimedia Appendix 1. Older adults who used the internet showed higher independence across all subscales, including the total score, IADL, intellectual activity, and social role, compared with those who did not use the internet (Table 2). The lower the educational attainment, the fewer the number of older adults who exhibited independence in the total score and all subscales (Table 3).

Table 1. Characteristics of study participants by internet use in 2016 (n=8050). Those with missing values for internet use in 2016 were omitted (n=524).

Variables	Internet use (2016)		*P* value

[a] IADL: instrumental activities of daily living.

[b] Missing values were omitted for the total score and 3 subscales.

[c] Cutoff values for "independent" in Tokyo Metropolitan Institute of Gerontology Index of Competence (TMIG-IC): "total score 12-13/13 points," "IADL 5/5 points," "intellectual activity 3-4/4 points," and "social role 3-4/4 points" [42,43].

[d] Cutoff values for "dependent" in TMIG-IC: "total score 1-11/13 points," "IADL 1-4/5 points," "intellectual activity 1-2/4 points," and "social role 1-2/4 points."

Moreover, among all subscales, the proportion of older adults independent in social roles was the lowest. In addition, the relationships exhibited similar trends across responses to the TMIG-IC's 13 questions (Table S3 in Multimedia Appendix 1). The baseline characteristics of the participants by educational attainment in 2016 indicated an inverse relationship between age and educational attainment (Table S4 in Multimedia Appendix 1).

Results of the Poisson Regression Analysis

Upon categorizing the independent individuals of each subgroup by 3 levels of educational attainment in 2016, we analyzed their internet use. The results revealed that internet users exhibited a suppressed decline in independence across the total score, IADL, intellectual activity, and social role subscales in 2019. Notably, among older adults with lower levels of education, significant suppression effects were observed in the total score and all subscales (Table 4).

Table 4. Associations between internet use in 2016 and suppression of higher-level functional capacity (HLFC) decline in 2019, segmented by educational attainment. In 2016, study participants were older adults with "independent" total score, IADL[a], intellectual activity, and social role. Items missing in the 2019 HLFC variable were excluded from the verification targets.

Educational attainment (years) and internet use	HLFC

[a] IADL: instrumental activities of daily living.

[b] RR: risk ratio.

[c] Risk ratio with adjustment for sex, age, annual household equivalized income, employment status, marital status, living arrangement, self-rated health, BMI, diseases under treatment, depression, and population density.

[d] Both missing and other items from the educational attainment variable were excluded from the verification targets.

[e] Not applicable.

Compared with nonusers, internet users with ≤9 years of educational attainment experienced a reduced decline in the total score in 2019 (RR 0.57, 95% CI 0.43-0.76; *P*<.001) and in the subscales of IADL (RR 0.58, 95% CI 0.38-0.91; *P*=.02), intellectual activity (RR 0.60, 95% CI 0.41-0.89; *P*=.01), and social role (RR 0.74, 95% CI 0.56-0.97; *P*=.03). Similarly, those in the 10-12 years of educational attainment group showed a mitigated decline in the total score (RR 0.78, 95% CI 0.63-0.98; *P*=.03), IADL (RR 0.59, 95% CI 0.39-0.90; *P*=.01), intellectual activity (RR 0.91, 95% CI 0.63-1.31; *P*=.61), and social role (RR 0.82, 95% CI 0.68-1.00; *P*=.05). The group with ≥13 years of educational attainment demonstrated a lesser decline in the total score (RR 0.65, 95% CI 0.51-0.85; *P*=.001), IADL (RR 0.55, 95% CI 0.36-0.83; *P*=.01), intellectual activity (RR 0.64, 95% CI 0.37-1.10; *P*=.11), and social role (RR 0.83, 95% CI 0.64-1.08; *P*=.17; Table 4). No interaction was identified between internet use and educational attainment (Table S5 in Multimedia Appendix 1).

Discussion

Principal Findings

This study explored the relationship between internet use and the maintenance of independence in HLFC among older adults, including the varying impacts based on educational attainment, through analysis of panel data from longitudinal surveys in 2016 and 2019. In this extensive population-based analysis, internet use among older adults was significantly linked to the suppression of HLFC decline, irrespective of educational level. Specifically, significant effects in mitigating decline were notable in all HLFC subscales, including IADL, intellectual activity, social role, and the total score, particularly in older adults with low education (≤9 years). These findings indicate that older adults with lower levels of education could benefit from internet use in suppressing HLFC decline. To our knowledge, this is the inaugural study to assess the relationship between internet use and the mitigation of HLFC decline among older adults with low education, by segmenting based on their educational attainment, an aspect challenging to enhance retrospectively.

HLFC Can Contribute to the Independent Living of Older Adults

Many older adults prefer to remain in their familiar residences [2]. Hence, maintaining a relatively independent HLFC, which encompasses capabilities, such as using public transportation, shopping, cooking, accessing information from various sources, and socializing with family, friends, and acquaintances, is crucial for fostering independent living. However, functional capacity tends to diminish with age [6], posing a risk of encountering numerous health challenges [9,10]. Consequently, preserving and enhancing HLFC plays a pivotal role in promoting the health of older adults and potentially extending their capability to live independently within their communities.

HLFC Could Benefit from Improved IADL Through Internet Use

A digital divide among older adults has been linked to educational disparities [40]. Moreover, a survey in Japan highlighted a digital divide wherein internet use among older adults is increasing, while the proportion of lower-income individuals using the internet remains low [16]. This study corroborated that older adults with lower education or income levels were less likely to be internet users compared with those with higher education or income levels. However, numerous studies have documented the health improvement effects of ICT use, including the internet, irrespective of educational attainment or income. Our findings align with previous research, indicating that internet and email use can likely mitigate and improve the risk of IADL decline [34,35]. IADL impairment may signal early reductions in physical and cognitive functions, potentially leading to adverse health outcomes, increased incidents of heart failure, and mortality among older adults [48]. Factors associated with IADL include social isolation [49], depression [50,51], subjective health [50,52], cognitive function [52], intellectual activity [53-55], social role [54,55], community-level social capital [56], and social participation [57,58]. The health improvement effects gained through internet use, such as mitigating social isolation and loneliness [24,27,29,33,35-39], preventing and reducing depression [21-23,32,33], maintaining good subjective health [23,33,35], reducing dementia risk [19], enhancing cognitive function [18,20,31], and fostering social participation [28,39], overlap with factors related to IADL. Our results suggest that internet use may aid in suppressing HLFC decline by enhancing factors associated with IADL, a key component of HLFC.

The benefits of internet use are interrelated. For instance, internet users exhibit lower levels of social isolation compared with nonusers [37], and ICT use has been shown to reduce social isolation among older adults through 4 mechanisms: connecting with the external world, acquiring social support, pursuing activities of interest, and enhancing self-confidence [27]. In addition, while nonusers demonstrated a decline in social contact, internet users maintained stable social connections and alleviated loneliness [36], consistent with findings that social contact and perceived social support mediate the relationship between social media communication and reduced loneliness levels [38]. Internet use alleviates loneliness [24,29,33,35,36,38,39] and contributes to improved self-rated health, reduced chronic illnesses, increased subjective well-being, and fewer depressive symptoms through the mediated effect of decreased loneliness [33]. Beyond preventing and ameliorating depression [21-23,32,33] and enhancing self-rated health [23,33,35], positive effects on cognitive function [18,20,31] have also been reported. Moreover, beneficial impacts on well-being [25,26,33,35,39], quality of life [22], and health literacy [30] have been confirmed. Thus, the influence of internet use on the daily lives of older adults may be substantial.

Many older adults in Japan use the internet to connect with family, friends, and acquaintances and to discover interesting information [16]. Given that internet use constitutes an "intellectual activity" in itself, using it for instrumental, informational, and social purposes [39] may further mitigate the decline in "intellectual activity" activities, such as "completing paperwork," "reading newspapers," "reading books or magazines," and "showing interest in health-related articles or television programs."

Increased social participation [28] and diverse volunteer activities [39] through internet use could establish a foundation for exchange relationships that encourage actions, such as "visiting friends' homes," "offering advice to family members or friends," "visiting ill individuals," and "initiating conversations with young people," thereby preventing the decline in social roles. Strong associations between good intellectual activity and social role with remaining independent in IADL [53,54], along with reports that impairments in social role and intellectual activity not only often precede IADL disability but also significantly forecast the onset of IADL disability [55], suggest that enhancements in "intellectual activity" and "social role" through internet use could lead to improved IADL and, subsequently, help suppress the overall decline in HLFC.

Internet Use May Mitigate Educational Inequality in HLFC

Socioeconomic disparities were evident across all subscales of HLFC, underscoring educational inequalities [6] (Table 3 and Table S2 in Multimedia Appendix 1). Consequently, to address health disparities among older adults in the community, it is imperative to implement strategies to preserve the HLFC of older adults, especially those with lower levels of education, although enhancing educational attainment retrospectively poses a significant challenge.

This study found that even at baseline, older adults who used the internet tended to maintain higher levels of independence in terms of the total score, IADL, intellectual activity, and social role compared with nonusers. Furthermore, longitudinal analysis revealed that internet use significantly curbed the decline in HLFC among older adults, irrespective of their educational background.

Recognized for fostering social participation among older adults [28], internet use may counteract the trend where wealthier or more educated older adults are more engaged in social activities [59]. Social participation can diminish the risk of loneliness across socioeconomic statuses, potentially serving as a countermeasure to health disparities [60]. Moreover, community activity participation has been identified as a key mediator in the relationship between educational level and incident functional disability among older adults aged 65-74 years [61], suggesting that enhanced social participation through internet use [28] may mediate the link between educational inequality and HLFC in this study. In addition, internet use may serve as a proxy for continuous educational attainment, with its protective effects independent of "past" education levels; instead, these effects may rely on middle- and late-life cognitive activity [19]. Late-life cognitive activity has been shown to impact subsequent cognitive health [62], suggesting that this study may illustrate how internet use later in life, as a form of continuous educational attainment, could improve educational inequality in HLFC.

Limitations

This study has several limitations. First, since internet use was assessed in 2016, changes in use by 2019 were not captured. However, even previous internet use experiences may have contributed to suppressing HLFC decline in older adults, warranting further investigation into the impact of internet use duration. Second, the study did not account for the purpose of internet use. The analysis encompassed a broad range of internet activities, including communication, health and medical information search, navigation, online shopping, banking, and stock trading. These activities represent the majority of internet use by older adults, suggesting the study's findings broadly reflect the positive impact of diverse internet use on maintaining HLFC independence. Third, the validity and reliability of the TMIG-IC as an evaluative tool for HLFC were not addressed. With the changing lifestyles of older adults, there is a call for developing scales that can measure higher levels of HLFC reflective of these changes. In addition, considering the psychological aspects of IADL, future studies might benefit from using scales with psychometric properties. Fourth, our data included only 2 waves. We acknowledge that interpreting results from only 2 time points requires caution because longitudinal data with 3 or more time points would provide a stronger basis for capturing dynamic links between exposures and outcomes [63]. Finally, using data from the JAGES study, comprising healthy participants, might have led to overestimating the association between internet use and HLFC independence.

Conclusion

In conclusion, this study indicates that internet use can support the maintenance of HLFC independence among older adults with higher education and those with lower education levels. Internet use can mitigate declines in key components of HLFC, such as IADL, intellectual activity, and social role, which are essential for independent living in familiar communities, even for older adults with low educational attainment. These findings underscore the importance of promoting internet use among older adults to support their independence. Moreover, engaging with more devices and applications is linked to fewer functional limitations, higher life satisfaction, and greater goal attainment [35]. Thus, expanding internet access and use among older adults, particularly those with lower education, is vital for reducing functional health disparities attributed to educational attainment.

Acknowledgments

This study used data from the Japan Gerontological Evaluation Study (JAGES). This study was supported by grants from the Japan Society for the Promotion of Science (JSPS) KAKENHI (grant JP15H01972), Health Labour Sciences Research (grant H28-Choju-Ippan-002), the Japan Agency for Medical Research and Development (AMED; grants JP18dk0110027, JP18ls0110002, JP18le0110009, JP20dk0110034, JP21lk0310073, JP21dk0110037, JP22lk0310087), Open Innovation Platform with Enterprises, Research Institute and Academia (OPERA; grant JPMJOP1831) from the Japan Science and Technology Agency (JST), the Innovative Research Program on Suicide Countermeasures (1-4), the Sasakawa Sports Foundation, the Japan Health Promotion and Fitness Foundation, the Chiba Foundation for Health Promotion and Disease Prevention, the 8020 Research Grant for fiscal year 2019 from the 8020 Promotion Foundation (adopted number 19-2-06), Meiji Yasuda Life Foundation of Health and Welfare, Shizuoka National Health Insurance Organization, and the Research Funding for Longevity Sciences from the National Center for Geriatrics and Gerontology (grants 29-42, 30-22, 20-19, and 21-20).

Authors' Contributions

AT conceptualized the study and prepared the draft of the manuscript. AN, YM, KK, and TO planned and arranged the data acquisition. AN, YM, and CK prepared the data for the analyses. AT, AN, and YM performed the statistical analysis. All authors were involved in the study concept and design and acquisition, analysis, or interpretation of the data. All authors gave final approval and agreed to be accountable for all aspects of the work.

Conflicts of Interest

None declared.

Abstract

Background: Health care systems are increasingly encouraging patients to use patient portals and participate in video visits. However, there is limited information about how portal use differs among older adults.

Objective: This study aimed to understand how patient portal and video visit use differed by age, race, and ethnicity among older adult patients with access to the same digital health resources.

Methods: This cross-sectional study used electronic health record and survey data for adults aged 65 to 85 years who were members of a large Northern California health care delivery system throughout 2019 and 2020. The electronic health record cohort (N=471,152) included 320,686 White, 35,892 Black, 44,922 Latino, 20,786 Chinese, 28,732 Filipino, 8473 South Asian, 6716 Japanese, 2930 Vietnamese, and 2015 Korean adults. Racial and ethnic group and age group (65 to 75 years vs 76 to 85 years) differences in having a patient portal account by December 2020, the performance of 2 portal activities (sending ≥1 message to a clinician in 2019 or 2020 and viewing ≥1 laboratory test result in 2020), and having ≥1 video visit during 2020 were examined. Modified log-Poisson regression was used to examine prevalence ratios for portal and video visit use, comparing racial and ethnic groups to White adults and Asian ethnic groups to Chinese adults after adjusting for sex and age. Data from a 2020 member survey were used to compare internet use factors among 2867 White, 306 Black, 343 Latino, 225 Chinese, and 242 Filipino adults.

Results: Black, Latino, and Filipino adults were less likely to have a patient portal account than White adults, and Filipino adults were less likely to have a patient portal account than Chinese adults. Black, Latino, Filipino, Korean, Vietnamese, and South Asian adults were less likely to have sent messages and viewed test results than White adults, while Chinese and Japanese adults' use of these features was similar to that of White adults. Filipino, Vietnamese, and Korean adults were less likely to have performed the aforementioned activities than Chinese adults. Video visit use was lower among Black and Latino adults and higher among Chinese and South Asian adults compared with White adults (aged 76 to 85 years) and lower among Filipino, Korean, and Vietnamese adults compared to Chinese adults. Survey data suggested that underlying differences in internet use may partially explain the lower use of messaging by Black, Latino, and Filipino adults compared with White and Chinese adults.

Conclusions: Patient portal and video visit use differed by race, ethnicity, and age group among older adult patients with access to the same patient portal. Internet use factors may contribute to these differences. Differences in patient portal and video visit use across Asian subgroups underscore the importance of disaggregating use data by Asian ethnicity.

Introduction

Background

Clinicians and patients are increasingly communicating and accessing health information electronically using patient portals [1,2]. Patient portals enable patients and their health care proxies to access selected health information in the patient's electronic health record (EHR), exchange messages with health care providers, view laboratory test results, order prescription refills, and schedule appointments, among other health care–related activities [3]**.** These patient portal activities, grouped under the umbrella of asynchronous telehealth, can be conveniently undertaken by both patients and clinicians at any time and from any location with internet service. Video visits, a form of synchronous telehealth, enable patients and health care providers to interact face to face from different locations. Video visits improve access and convenience for patients and can reduce clinic visit–related costs (eg, transportation and copays) [4-8]. Video visits also help address outpatient health care worker shortages and reduce physician burnout [9,10], although evidence is mixed for these outcomes and whether they ultimately reduce health care delivery costs [11]. Video visit use greatly increased in 2020 during the COVID-19 public health emergency as delivery of health care shifted from in-person clinic visits to video and phone visits when in-person care was not necessary [12-15]. During this time, Medicare reimbursed clinicians for virtual visits at the same rate as in-clinic visits, and many health insurers temporarily waived copays for video visits for commercially insured members [16,17].

Patient portals have the potential to enhance the patient-clinician relationship; improve health status; and increase self-management behaviors, including adherence to therapy [18]. Older adults stand to benefit a great deal from the ability to use patient portals and video visits. As a demographic group, they have a high burden of chronic health problems [19], with concomitant higher use of prescription medications, laboratory tests, medical visits, and the need to communicate with their health care providers outside of scheduled visits. Portals provide a convenient way to send and receive detailed communications rather than leaving brief phone messages with support staff during regular business hours. Portals also give patients and their proxies 24/7 access to viewing laboratory test results, appointment scheduling, ordering prescription refills, and viewing medical and visit history. Video visits can make it easier for older adults to access health care when in-clinic examinations or tests are not needed, especially for those who are frail, have mobility limitations, or have transportation-related difficulties. Video visits can also enable spouses and other caregivers to participate in scheduled visits in a way that is not always possible in clinic-based visits.

While the use of patient portals and video visits has been increasing among older adults, it remains substantially lower among middle-aged and younger adults. Philpot et al [20] used the term "digital determinants of health" to describe barriers to the use of patient portals and video visits, including lack of access to an internet-enabled device and webcam (for video visits); lack of high speed or broadband internet at home; lack of digital health literacy, skill, or confidence in the ability to use digital health technologies; concerns about privacy and security; cognitive or physical impairment that limits the use of a computer or touchscreen devices, internet, or complex websites; and lack of technical assistance from others [3,21-24]. In several studies, successful use of digital health tools by older adults depended on older adults' motivation and the support that they received [25].

While several studies have documented racial and ethnic group differences in patient portal and video visit use among general and disease-specific populations of US adults [26-31], there is a lack of contemporary data regarding racial and ethnic group differences in use of patient portal functions and video visits among US adults aged ≥65 years in health care systems that provide access to patient portals and video visits for all patients. Using 2013 to 2014 EHR and survey data to examine patient portal use and factors associated with use among Kaiser Permanente Northern California (KPNC) health plan members aged 65 to 79 years, our team previously observed that Black, Latino, and Filipino adults were less likely than White and Chinese adults to have to a patient portal account; to have signed into the patient portal at least once; and to have used the patient portal to send a secure message, view laboratory test results, or order prescription refills at least once by the end of 2013 [31]. In the same study, a mailed survey conducted in a random subset of health plan members in winter 2013-2014 found that Black, Latino, and Filipino, but not Chinese, adults were less likely than White adults to have access to digital tools, to have experience performing a variety of web-based tasks, to feel they were capable of going on the internet to obtain health information, and to be interested in using web-based health information modalities [31]. However, this early study was limited to those from 5 racial and ethnic groups aged 65 to 79 years and did not examine racial and ethnic differences in patient portal use among younger or older subsets. In addition, video visit use was not examined because video visits were not widely offered until 2020.

Since the start of the COVID-19 pandemic, health care providers have increasingly transitioned to the use of patient portals as a primary platform for sharing laboratory test results and other health care–related information with patients, for bidirectional messaging with patients to address health concerns rather than having phone calls, and for patients to self-schedule nonurgent appointments and order prescription medication refills on the web rather than through a call center. This transition could potentially exacerbate existing disparities in health information access and disparities in access to and use of digital health tools [32], the latter recently termed as gaps in digital health equity

[33] or health "techquity" [34]. Given well-documented evidence of racial and ethnic disparities in access to and use of the internet [27,35-38], it is important to understand the extent to which racial and ethnic differences in the use of patient portal functions and video visits occur among older adults. Furthermore, as ethnic diversity increases within the older adult population, especially within the Asian population, it is important to learn how the use of patient portals and video visits may vary across Asian ethnic groups, a currently understudied segment of the US population.

This Study

Our study addresses the aforementioned knowledge gaps by analyzing contemporaneous EHR and survey data for older members of a large Northern California health care delivery system. We first documented racial and ethnic differences in health plan patient portal and video visit use among adults aged 65 to 85 years whose preferred language for written materials in the EHR was English, including comparisons among Asian ethnic groups. We then used data from a health plan member survey for a subset of adults in the EHR cohort to examine educational attainment and internet use factors that might contribute to the differences in patient portal use across racial and ethnic subgroups.

Methods

Ethical Considerations

This work was conducted in accordance with procedures approved by the Kaiser Permanente Northern California (KPNC) Institutional Review Board. For the EHR cohort study (IRBnet #1279536-6), the KPNC Institutional Review Board waived the requirements to obtain informed consent and privacy rule authorization for use and disclosure of protected health information. The secondary analysis of the 2020 Member Health Survey data and linkage of survey respondent data to EHR data for the survey cohort study fell within the scope of the original 2020 Member Health Survey research protocol approved by the KPNC Institutional Review Board (IRBnet #1539606-3) which waived the requirement to document informed consent and privacy rule authorization for use and disclosure of protected health information.

Setting

KPNC is an integrated health care delivery system that provides primary and specialty health care, laboratory testing, and pharmacy services to a racially, ethnically, and sociodemographically diverse membership that includes >3.2 million adults who mostly reside in the Greater San Francisco Bay Area, Sacramento area, Silicon Valley, and the Central Valley. The KPNC adult membership has been shown to be very similar to the insured population of Northern California adults with regard to sociodemographic and health characteristics [39,40]. Since 2007, KPNC has maintained a patient portal as part of its website that enables members to communicate with their health care team and member services using secure messages; view laboratory test results, immunizations, past office visits, prescriptions, and health conditions; order prescription refills; and schedule or cancel nonurgent appointments [41]. To use the patient portal, members must register for and activate a patient portal account and sign onto the portal with their user ID and password to perform portal activities. During the study period (2019-2020), members were able to set up and activate their patient portal account or reset their password through the health plan's website or a Kaiser Permanente app for immediate use. Some patient portal content was available in Spanish but not in other non-English languages.

Study Population

EHR Cohort

The EHR study cohort was a subset of a 2019 EHR-based research cohort created to study demographic differences in health status and health care use in a very large (>2.4 million) cohort of adults aged 25 to 89 years who were KPNC members throughout 2019. More detail on how the demographic cohort was created can be found in an earlier publication [42]. The cohort for this study (N=471,152) comprised 320,686 (68.06%) non-Hispanic White (White); 35,892 (7.62%) African American or Black (Black); 44,922 (9.53%) Hispanic or Latino (Latino); 28,732 (6.1%) Filipino; 20,786 (4.41%) Chinese; 8473 (1.8%) South Asian; 6716 (1.43%) Japanese; 2930 (0.62%) Vietnamese; and 2015 (0.43%) Korean men and women who were aged 65 to 85 years on December 1, 2020. All adults had English as their preferred written language in the EHR and were KPNC members for all 24 months from 2019 to 2020.

Survey Cohort

The KPNC Member Health Survey is an English-only self-administered (mail or on the web) research survey that collects information about sociodemographic and health characteristics and the use of digital information technology. Survey details are published elsewhere [43,44]. Because the 2020 Member Health Survey sample was drawn from the same source cohort used to create the EHR cohort for this study, the survey cohort is a subset of the larger EHR cohort. The survey sample included 2867 White, 306 Black, 343 Latino, 225 Chinese, and 242 Filipino adults aged 65 to 85 years who answered survey questions pertaining to internet use factors. Only the 2 largest Asian ethnic groups are represented as the other 4 Asian ethnic groups had too few respondents to examine as a subgroup. Of the 52.9% (4269/8065) of adults aged 65 to 85 years in these 5 racial and ethnic groups who responded to the survey, a total of 93.9% (3983/4269) answered internet use questions.

Study Variables

EHR Cohort

A description of the methods used to assign race and ethnicity, including the use of language preference in the EHR, member survey sources, and surname assignment can be found in an earlier 2019 publication appendix [42]. Age on December 1, 2020 (integer variable), was determined from the date of birth. Sex was restricted to male or female as indicated in the EHR. Chronic cardiovascular conditions (diabetes, hypertension, ischemic heart disease, and heart failure) were assigned using International Classification of Disease Tenth Revision outpatient visit and problem list diagnoses from 2018 to 2019.

We used data abstracted from KPNC EHRs to create the following 4 variables: (1) indication of an activated patient portal account by December 1, 2020; (2) history of having sent ≥1 secure message to a clinician during 2019 or 2020; (3) history of viewing laboratory test results during 2020 if ≥1 laboratory test result was released during 2020; and (4) history of having ≥1 video visit during 2020 if the person had ≥1 ambulatory visit in a department that offered video visits during 2020. Because sending a secure message was not restricted to a subset of the population that experienced a particular event (ie, having a laboratory test released during the year), we ascertained this outcome over a larger 2-year window to allow more time for patients to have sent a secure message. Video visit use was only examined for 2020 due to its infrequent use before the onset of the COVID-19 pandemic emergency in March 2020. Because an activated patient portal account was necessary for sending secure messages and viewing laboratory test results, we examined differences in the use of these patient portal functions by all patients and by patients who had an activated portal account by the end of 2020. An activated patient portal account was not required for a video visit. Starting in March 2020, most outpatient visits were conducted by video or phone due to the COVID-19 pandemic.

Survey Cohort

We examined 6 variables from survey data and 3 variables from EHR data. Educational attainment was examined as a 3-level variable: high school graduate or less, some college or associate degree, or bachelor's degree or higher. Use of the internet was based on the question, "Do you use the internet (go online) to get information, watch videos, fill out forms, pay for things, etc.?" Response options included "Yes, I use it by myself;" "Yes, but someone else helps or uses it for me;" or "No, I don't use the internet." Access to a desktop, laptop, or tablet computer was based on a "yes" to the question, "Do you have access to a desktop, laptop, or tablet computer that you can (or could) use to go online (use the internet)?" and access to an internet-capable device was assigned based on having a computer, tablet, or smartphone. Internet users were asked, "Can you easily print information/forms you get from the internet?" Respondent data were linked to EHR patient portal use data: having an activated patient portal account by June 2020, sending ≥1 message using the patient portal between January 2019 and June 2020, and having a video visit in 2020.

Statistical Analyses

EHR Cohort Analyses

All analyses were performed using SAS (version 9.4; SAS Institute). For each patient portal use variable and video visit use, we examined portal use statistics for the 9 racial and ethnic groups, overall, and for those aged 65 to 75 and 76 to 85 years within the racial and ethnic groups. Chi-square tests were used to compare demographic groups, with the largest group (White adults) serving as the reference. Chinese adults were used as the reference group for comparisons among the 6 disaggregated Asian ethnic groups. Previous KPNC research on the use of digital information technologies and patient portal functions found that Chinese adults were more likely to use the internet, obtain health information from websites, and use the patient portal than Filipino adults [31,35].

Because the racial and ethnic groups being compared were very large, very small differences in percentages that were statistically significant were not always meaningful. We thus made an a priori decision to use a between-group absolute difference of ≥5 percentage points as the threshold for meaningful difference. Hence, for descriptive analyses pertaining to the EHR cohort, all demographic differences described in the Results section met the criterion of an absolute difference of ≥5 percentage points and a chi-square P value of <.05 for differences in proportions. Modified log-Poisson regression models were used to estimate adjusted prevalence ratios (aPRs) with 95% CIs for each portal use outcome using White or Chinese groups as reference and controlling for sex and age as a continuous variable. As the portal use outcomes being modeled were not rare events and we were comparing group-level prevalence rather than individual likelihood of portal outcome use, the aPR is a more appropriate measure of association than an adjusted odds ratio derived from a logistic regression model, which can inflate the strength of association [45].

Survey Cohort Analyses

Survey respondents were assigned poststratification population weighting factors so that the analytic weighted sample would more closely approximate the age, sex, and racial composition of adults aged 65 to 85 years with English written language preference in the 2019 KPNC membership (ie, the same population that was used for the EHR cohort). To prevent variance inflation, population weights were normalized (rescaled) so that the number in the analytically weighted sample would be equivalent to the number of survey respondents while maintaining the same age-sex-racial-ethnic composition of the population-weighted sample. Normalized weighting factors were created by multiplying the population weighting factors by the reciprocal of the sum of the survey population weights divided by the total number of survey respondents.

All analyses were performed using weighted survey data with SAS (version 9.4). Cross-tabular analyses were used to produce estimates of internet use, device access, and portal use for each racial and ethnic group. To test for racial and ethnic group differences, we used modified log-Poisson regression models that adjusted for age (5-year age group) and sex (female vs male) and for age, sex, and education (≤ high school graduate and some college or associate degree vs ≥ bachelor's degree). Modified log-Poisson regression models were also used to examine the association of internet use status with patient portal use after controlling for demographic characteristics, reporting aPRs with 95% CIs.

Results

EHR Cohort

Demographic and Health Characteristics of the EHR Study Cohort

As presented in Table 1, all 9 racial and ethnic groups had approximately the same mean age, but Chinese and South Asian groups had higher proportions of adults aged 65 to 75 years compared to White adults. The South Asian group had a higher proportion of men. Black, Latino, Filipino, and South Asian groups had higher proportions of adults with a chronic cardiovascular condition (diabetes, hypertension, ischemic heart disease, or heart failure). Among the Asian ethnic groups, compared to the Chinese group, the Japanese and Korean groups had higher proportions of adults aged 65 to 75 years, whereas the Filipino and South Asian groups had higher proportions of adults with chronic cardiovascular conditions.

Table 1. Characteristics of racial and ethnic groups in the electronic health record study cohort of adults aged 65 to 85 years (N=471,152).

Characteristic	White (n=320,686)	Black (n=35,892)	Latino (n=44,922)	Chinese (n=20,786)	Filipino (n=28,732)	Japanese (n=6716)	Korean (n=2015)	Vietnamese (n=2930)	South Asian (n=8473)
Sex (%)									
Male	45.1	40.7	44.2	47.7	41	41.4	40.9	51.4[a]	57.2[a]
Female	44.9	59.3	55.8	52.3	59.0	58.16	59.1	48.6	42.8
Age, Mean (SD)	73.5 (5.2)	73.1 (5.3)	73.1 (5.3)	72.8 (5.2)	73.0 (5.2)	73.8 (5.4)	73.7 (5.1)	72.1 (4.8)	72.5 (5.0)
65 to 75 (%)	66.3	68.7	68.4	72.8[a]	70	63.4[b]	65.4[b]	76	73.2[a]
76 to-85 (%)	33.7	31.3	31.6	27.2	30	36.6	34.6	24	26.8
≥1 chronic cardiovascular condition[c] (%)	63.8	83.7[a]	73.1[a]	63.4	84.9[a,b]	67.4	64.4	66.5	77.9[a,b]

[a] Racial-ethnic group differed from White adults by ≥5 percentage points and the difference was statistically significant at *P*<.001.

[b] Asian ethnic group differed from Chinese adults by ≥5 percentage points and the difference was statistically significant at *P*<.001.

[c] Chronic cardiovascular conditions included diabetes, hypertension, ischemic heart disease, or heart failure diagnosis.

Patient Portal Account Status by the End of the Year 2020

As presented in Table 2, ≥80% (range 81%-94%) of adults aged 65 to 85 years in each of the 9 racial and ethnic groups had an activated patient portal account by the end of 2020. The lowest percentage was seen for Black adults aged 76 to 85 years (73%), and the highest percentage (95%) was seen for White, Chinese, and Japanese adults aged 65 to 75 years. In all age groups, Black, Latino, and Filipino adults were less likely to have an activated portal account than White adults, and Filipino adults were less likely to have an activated portal account than Chinese adults. After adjusting for age and sex, Black, Latino, Filipino, and Vietnamese adults, respectively, were 14%, 10%, 7%, and 5% less likely than White adults to have a patient portal account, and Filipino adults were 7% less likely than Chinese adults to have a patient portal account (Figure S1 in Multimedia Appendix 1). More than 90% of adults (range 92%-99%) with an activated portal account by December 2020 also had an activated account in 2019 (data not shown).

Table 2. Racial and ethnic group differences in patient portal and video visit use from 2019 to 2020 by adults aged 65 to 85 years, overall and by age group.

	White	Black	Latino	Chinese	Filipino	Japanese	Korean	Vietnamese	South Asian
Had a patient portal account by the end of 2020[a]									
All aged 65 to 85 years, n (%)	320,686 (94.1)	35,892 (80.8)[b,c]	44,922 (85.4)[b,c]	20,786 (93.9)	28,732 (87.3)[b,c,d]	6716 (93.1)[c]	2015 (89.4)	2930 (91.7)	8473 (93.6)

Had ≥1 video visit in 2020 (adults with ≥1 ambulatory visit in 2020)[a]									
All aged 65 to 85 years, n (%)	286,687 (48)[b]	32,374 (43.6)[b]	40,815 (43.4)[b]	17,902 (52.8)[b]	25,678 (47.1)[c]	5778 (49.6)[b]	1791 (44.4)[b,c]	2569 (46.9)[c]	7688 (54.4)[a]
Those age 65 to 75 years, n (%)	187,475 (50.6)	22,132 (46.2)	27,593 (46.1)	12,848 (54.4)	17,905 (47.9)[c]	3562 (53)	1150 (46.3)[c]	1930 (47.5)[c]	5615 (54.3)
Those aged 76 to 85 years, n (%)	99,212 (42.9)	10,242 (37.9)[a]	13,222 (37.8)[a]	5054 (48.8)[a]	7773 (45.3)[c]	2216 (44)	641 (41)[c]	639 (45.2)	2073 (54.7)[a,c]

[a] n: total number of adults in this age subgroup used as the denominator to calculate the percentage.

[b] Meaningful difference between this racial-ethnic group and White adults based on ≥5 percentage point difference that was statistically significant at *P*<.05. Differences remained statistically significant after controlling for age and sex.

[c] Meaningful difference between those aged 65 to 75 years and 76 to 85 years within this racial or ethnic group based on ≥5 percentage point difference that was statistically significant at *P*<.05. Differences remained statistically significant after controlling for age and sex.

[d] Meaningful difference between this Asian ethnic group and Chinese adults based on ≥5 percentage point difference that was statistically significant at *P*<.05. Differences remained statistically significant at *P*<.05 after controlling for age and sex.

Use of Secure Messaging Through the Patient Portal During 2019 and 2020

There was substantial racial and ethnic variation in the use of secure messaging, ranging from a low value of 54% for Black adults to a high value of 80% for White adults. The lowest percentage was seen for Black adults aged 76 to 85 years (44%) and the highest percentage was seen for White adults aged 65 to 75 years (83%). Significant racial and ethnic differences in the percentage of adults who sent ≥1 secure message in 2019 or 2020 were seen in the overall 65- to 85-year age group and both age subgroups (Table 2). Black, Latino, Filipino, Korean, and Vietnamese adults in all 3 age groups and South Asian adults aged 65 to 85 years and 65 to 75 years were less likely than White adults to have sent a secure message during that time, and in all but the South Asian group, adults aged 76 to 85 years were less likely to have sent a secure message than adults in the 65 to 75 years age group. Among Asian ethnic groups, Filipino, Korean, and Vietnamese adults in all 3 age groups were less likely than Chinese adults to have used secure messaging. After adjusting for age and sex, Black, Latino, Chinese, Filipino, Korean, Vietnamese, and South Asian adults, respectively, were 33%, 25%, 6%, 26%, 24%, 18%, and 8% less likely than White adults to have sent a secure message (Figure S2 in Multimedia Appendix 1). Filipino, Korean, and Vietnamese adults, respectively, were 21%, 19%, and 13% less likely than Chinese adults to have sent ≥1 secure message. The same racial and ethnic differences were seen in the subset of adults who had an activated portal account by the end of 2020, but some of the meaningfully significant age-specific differences within racial and ethnic groups in the full population were nonsignificant among those with activated accounts (Table 3).

Table 3. Racial and ethnic differences in patient portal use during 2019 and 2020 among adults aged 65 to 85 years, overall and by age group, restricted to adults who had an activated patient portal account by the end of 2020.

	White	Black	Latino	Chinese	Filipino	Japanese	Korean	Vietnamese	South Asian
Sent ≥1 secure message in 2019 or 2020[a]									
Overall cohort, aged 65 to 85 years, n (%)	301,855 (85.2)	28,991 (67.1)[b,c]	38,346 (71.2)[b,c]	19,511 (81.2)	25,090 (68.6)[b,c,d]	6255 (81.3)[c]	1801 (68.4)[b,d]	2687 (72.7)[b,d]	7931 (79.6)[b]
Aged 65 to 75 years, n (%)	203,219 (86.7)	20,832 (69.5)[b]	26,928 (73.2)[b]	14,385 (82)	17,922 (70.6)[b,d]	4060 (83.4)	1187 (69.1)[b,d]	2058 (74)[b,d]	5818 (79.4)[b]
Aged 76 to 85 years, n (%)	98,636 (81.9)	8159 (61.1)[b]	11,418 (66.4)[b]	5126 (79.1)	7168 (63.6)[b,d]	2195 (77.4)	614 (66.9)[b,d]	629 (68.7)[b,d]	2113 (80.2)
Viewed laboratory results ≥1 time in 2020 (adults with ≥1 laboratory result released in 2020)[a]									
Overall cohort, aged 65 to 85 years, n (%)	263,937 (88.8)	25,652 (71.9)[b,c]	34,263 (77)[b,c]	16,818 (88.2)	22,242 (77.6)[b,c,d]	5425 (87.7)[c]	1577 (78.7)[b,d]	2355 (82.3)[b,d]	7072 (85.9)
Aged 65 to 75 years, n (%)	180,024 (90.4)	18,691 (74.3)[b]	24,410 (79.4)[b]	12,655 (88.9)	16,260 (79.6)[b,d]	3610 (89.6)	1066 (80.1)[b,d]	1832 (83.2)[b,d]	5292 (86.1)
Aged 76 to 85 years, n (%)	83,913 (85.3)	6,961 (65.3)[b]	6961 (65.3)[b]	4163 (86)	5952 (72.1)[b,d]	1815 (83.7)	511 (75.7)[b,d]	9853 (71.3)[b]	1780 (85.5)

[a] n: total number of adults in this age subgroup used as the denominator to calculate the percentage.

[b] Meaningful difference between this racial-ethnic group and White adults based on ≥5 percentage point difference that was statistically significant. Differences remained statistically significant at *P*<.05 after controlling for age and sex.

[c] Meaningful difference between those aged 65 to 75 years and 76 to 85 years within this racial or ethnic group based on ≥5 percentage point difference that was statistically significant at *P*<.05. Differences remained statistically significant after controlling for age and sex.

[d] Meaningful difference between this Asian ethnic group and Chinese adults based on ≥5 percentage point difference that was statistically significant at *P*<.05. Differences remained statistically significant after controlling for age and sex.

Viewed Laboratory Test Results Using the Portal During 2020

Among adults aged 65 to 85 years with ≥1 laboratory test result released in 2020, the percentage of those who viewed laboratory results using the portal ranged from 67% for Latino adults to 84% for White adults. The lowest percentage was seen for Black adults aged 76 to 85 years (49%) and the highest was seen for White adults aged 65 to 75 (87%). Black, Latino, Filipino, Korean, and Vietnamese adults in all age groups and South Asian adults aged 65 to 75 years were less likely to have viewed laboratory test results using the portal than White adults (Table 2). In all age groups, Filipino, Korean, and Vietnamese adults were less likely to have viewed laboratory results on the web than Chinese adults. In all racial and ethnic groups except Vietnamese and South Asian groups, adults aged 76 to 85 years were less likely to have viewed laboratory results using the portal than adults aged 65 to 75 years. Adjusting for age and sex, Black, Latino, Filipino, Korean, Vietnamese, and South Asian adults aged 65 to 85 years were 30%, 21%, 19%, 15%, 11%, and 5%, respectively, less likely than White adults to have viewed a laboratory test result using the portal during that year, and Filipino, Korean, and Vietnamese adults were 17%, 14%, and 9% less likely than Chinese adults to have done so (Figure S3 in Multimedia Appendix 1). The same racial and ethnic differences were seen among adults who had a portal account in 2020, except for the South Asian group (Table 3).

Video Visit During 2020

Among adults who had ≥1 ambulatory visit with a department that offered video visits during 2020, the percentages of those who used this modality ranged from a low value of 43% for Black and Latino adults to a high value of 54% for South Asian adults in the 65 to 85 years age group (Table 2). The lowest use was seen for Black and Latino adults aged 76 to 85 years (38%) and the highest (54%) for South Asian adults in all age groups and Chinese adults aged 65 to 75 years. Overall, South Asian adults were more likely than White adults to have had a video visit. Otherwise, differences between White adults and the other racial and ethnic groups were observed only in the 76- to 85-year age group (Black and Latino adults were less likely and Chinese and South Asian adults were more likely to have had a video visit during 2020). Filipino and Korean adults in all age groups and Vietnamese adults aged 65 to 85 years and 65 to 75 years were less likely to have had a video visit than Chinese adults, and South Asian adults aged 76 to 85 years were more likely to have had a video visit than Chinese adults. Adjusting for age and sex, Black, Latino, and Korean adults, respectively, were 10%, 10%, and 7% less likely, and Chinese and South Asian adults were 9% and 12% more likely than White adults to have had a video visit in 2020. After adjusting for age and sex, Filipino, Japanese, Korean, and Vietnamese adults, respectively, were 11%, 5%, 15%, and 12% less likely to have had a video visit than Chinese adults (Figure S4 in Multimedia Appendix 1).

Survey Cohort

Racial and Ethnic Group Differences in Educational Attainment

Black and Latino adults were less likely than White and Chinese adults to have a bachelor’s degree or higher and more likely to have low educational attainment (≤ high school graduate), while educational attainment for Filipino adults was not significantly different from White or Chinese adults (Table 4). Chinese adults were more likely to have a higher educational attainment (at least a bachelor’s degree) than White adults. Among White, Black, and Filipino adults, older adults aged 76 to 85 years (vs those aged 65 to 75 years) were more likely to have low educational attainment.

Table 4. Comparison of educational attainment, digital information technology use, and patient portal use across White, Black, Latino, Chinese, and Filipino health plan members aged 65 to 85 with English language preference[a].

	White (%)	Black (%)	Latino (%)	Chinese (%)	Filipino (%)
Educational attainment					
High school diploma or less	17.2[b,c]	22.7[b,c,d]	40.4[b,d]	10.7[d]	16.8[c]
Some college or associate degree	33.9	44.2	35.8	26.7	26.4
Bachelor's degree or higher	48.9[b]	33.1[b,d]	23.8[b,d]	62.6[d]	56.7[e]
Uses the internet (alone or with help) to get information or watch videos (all adults)	93[e]	83.7[b,d,e]	84.9[b,d,e]	94.3[e]	87.9[b,d,e]
Uses the internet without help					
All adults	86.2[e]	71.3[b,d,e]	71.9 [b,d,e]	90.5[e]	67.2[b,d,e]

Had ≥1 video visit during 2020 (whether the user had ≥1 outpatient visit in 2020)[g]					
All adults	50.7[f]	46	51.3[f]	56.7	51.5
Internet users only	53[f]	51.3	56[f]	57.3	53.6

[a] Estimates are based on 2020 Member Health Survey data weighted to the age, sex, and racial and ethnic composition of the health plan's adult membership in 2019. Unweighted Ns for racial-ethnic groups are as follows: n=2867 White adults, n=225 Chinese adults, n=306 Black adults, n=343 Latino adults, and n=242 Filipino adults and internet users: n=2655 White adults, n=213 Chinese adults, n=255 Black adults, n=286 Latino adults, and n=206 Filipino adults. Survey respondents are a subset of the adults in the electronic health record study cohort.

[b] Prevalence significantly (*P*<.05) differs from that of Chinese adults after adjusting for age and sex.

[c] Within racial and ethnic groups, the percentage is significantly (*P*<.05) higher among those aged 76 to 85 years versus those aged 65 to 75 years after adjusting for sex (data not shown).

[d] Percentage significantly (*P*<.05) differs from that of White adults after adjusting for age and sex.

[e] Within racial and ethnic groups, the percentage is significantly (*P*<.05) lower among those aged 76 to 85 years versus those aged 65 to 75 years after adjusting for sex (data not shown).

[f] Computer, tablet, or smartphone.

[g] Patient portal use data for survey respondents were abstracted from their electronic health records.

Factors Associated With Digital Information Technology Use

Black, Latino, and Filipino adults aged 65 to 85 years were less likely than both White and Chinese adults to use the internet (with or without help; Table 4). Among internet users, Black, Latino, and Filipino adults were significantly less likely to use the internet without help than both White and Chinese adults.

Black and Latino adults were also less likely to have an internet-capable device than White adults, but this difference was not seen among internet users. Furthermore, Black, Latino, and Filipino adults were less likely than both White and Chinese adults to have access to an internet-enabled computer, and Filipino internet users were less likely than White internet users to have computer access. Among adults who used the internet, 10% to 16% did not have a printer they could use to print information from the internet or emails. Among all 5 racial and ethnic groups, adults aged 76 to 85 years were less likely to be internet users and to be able to use the internet without help than those aged 65 to 75 years. Among White, Black, and Chinese adults, those aged 76 to 85 years were also less likely to have an internet-capable device than those aged 65 to 75 years.

Demographic and Internet Use Factors Associated With Differences in Patient Portal Use

Similar to the full EHR cohort, Black and Latino adults in the survey population were less likely to have a patient portal account than both White and Chinese adults. However, in contrast to the EHR cohort, Filipino adults did not significantly differ from either White or Chinese adults in the survey cohort (Table 4 and model 1 in Table 5). Moreover, similar to the EHR cohort, Black, Latino, and Filipino adults were less likely to have sent a message to their physician through the patient portal than both White and Chinese adults (from January 2019 to June 2020).

Table 5. Prevalence ratios showing racial and ethnic group differences in percentages of adults aged 65 to 85 years in the survey population who sent ≥1 secure message, after adjusting for demographic and internet use characteristics.[a]

Model	Reference group	
	White adults, aPR[b] (95% CI)	Chinese adults, aPR (95% CI)
Model 1: adjusted for age[c] and sex		
White adults	Reference	1.02 (0.92-1.13)
Black adults	0.66 (0.58-0.75)	0.67 (0.58-0.79)
Latino adults	0.81 (0.73-0.90)	0.83 (0.72-0.95)
Chinese adults	0.98 (0.89-1.09)	Reference
Filipino adults	0.72 (0.62-0.83)	0.73 (0.62-0.86)
Model 2: adjusted for age[c], sex, and education[d]		
White adults	Reference	1.05 (0.94-1.16)
Black adults	0.69 (0.60-0.78)	0.72 (0.61-0.84)
Latino adults	0.87 (0.78-0.97)	0.91 (0.79-1.05)
Chinese adults	0.95 (0.86-1.06)	Reference
Filipino adults	0.71 (0.62-0.82)	0.75 (0.63-0.89)
Model 3: adjusted for age[c], sex, education[d], and internet use		
White adults	Reference	1.04 (0.94-1.14)
Black adults	0.73 (0.64-0.82)	0.75 (0.65-0.88)
Latino adults	0.89 (0.81-0.99)	0.93 (0.81-1.06)
Chinese adults	0.97 (0.88-1.07)	Reference group
Filipino adults	0.75 (0.65-0.86)	0.78 (0.65-0.92)

[a] For these analyses, demographic and internet use data were collected from the 2020 Kaiser Permanente Northern California Member Health Survey and were linked with electronic health record data regarding secure message use from January 2019 through June 2020. Respondent data have been weighted to reflect the age, sex, and racial and ethnic composition of the adult health plan membership in 2019. The aPR estimates the percentage of adults in a racial or ethnic group who sent ≥1 secure message during the study period compared to the percentages of White or Chinese adults who did so, after adjusting for covariates using log-Poisson regression models.

[b] aPR: adjusted prevalence ratio.

[c] Age in 5-year intervals (65-69, 70-74, 75-79, and 80-85 years).

[d] Education is a 3-level variable, with ≤ a high school graduate and some college or associate degree compared to ≥ a bachelor's degree.

Among all adults, after adjusting for age, sex, education, and racial and ethnic groups, internet users were nearly 70% more likely to have a patient portal account than nonusers (aPR 1.66, 95% CI 1.51-1.83) and >4 times more likely to have sent a message through the patient portal (aPR 4.18; 95% CI 3.19-5.48) than nonusers. Within individual racial and ethnic groups, after adjusting for age, sex, and education, internet users were 40% to 60% more likely to have a patient portal account than nonusers (White users: aPR 1.62, 95% CI 1.45-1.82; Black users: aPR 2.09, 95% CI 1.47-2.97; Latino users: aPR 1.78, 95% CI 1.35-2.35; Filipino users: aPR 1.41, 95% CI 1.11-1.79; and Chinese users: aPR 1.42, 95% CI 0.91-2.21; *P*=.12) and >3 times more likely to have sent a message through the patient portal (White users: aPR 4.33, 95% CI 3.12-6.02; Black users: aPR 5.70, 95% CI 2.35-13.84; Latino users: aPR 5.12, 95% CI 2.11-12.40; Chinese users: aPR 3.78, 95% CI 1.06-13.46; and Filipino users: aPR 1.76, 95% CI 0.87-3.55; *P*=.11). Educational attainment was not associated with having a portal account or with sending a message through the portal after controlling for internet user status.

As presented in Table 5 (models 2 and 3), adjusting for internet user status, in addition to age, sex, and education, did not reduce racial and ethnic group differences in the use of the patient portal to send a message to a health care provider. Black, Latino, and Filipino adults were less likely to have sent a portal message than White adults, and Black and Filipino adults were less likely to have sent a portal message than Chinese adults.

Demographic and Internet Factors Associated With Video Visit Use in 2020

Approximately half (46% to 57%) of the older adults in the survey population who had at least 1 outpatient visit from a department that offered video visits had ≥1 video visit during 2020, and similar to the full EHR cohort, no significant racial and ethnic group differences were observed. After adjusting for age, sex, and education, being an internet user was associated with approximately 2-fold greater use of video visits in the overall study population (aPR 2.28, 95% CI 1.79-2.90), but analyses by racial and ethnic groups found that this difference was only among White (aPR 2.71, 95% CI 1.91-3.85), Black (aPR 3.21, 95% CI 1.45-7.11), and Latino (aPR 1.85, 95% CI 1.09-3.15) adults. After adjusting for age, sex, and internet use, educational attainment was neither significantly associated with video visit use in the overall study population nor any of the racial or ethnic groups.

Discussion

Principal Findings

In this study, we examined how the use of a health plan patient portal and video visit use differed across racial and ethnic groups in a population of insured older adults whose preferred spoken language was English and who had access to the same health plan patient portal during 2019 and 2020. Using EHR-derived data, we documented lower use of patient portal functions (sending messages and viewing laboratory test results) among Black, Latino, Filipino, Korean, and Vietnamese older adults compared to similarly aged White and Chinese adults; similar use of these patient portal functions among Chinese, Japanese, and South Asian older adults compared to White adults; and lower use of these patient portal functions among older adults (those aged 76 to 85 years) compared to younger (those aged 65 to 75 years) groups. We then used survey information for a subset of White, Black, Latino, Chinese, and Filipino respondents in the EHR cohort to explore potential factors that might contribute to lower engagement in patient portal activities observed in EHR cohort analyses for Black, Latino, and Filipino adults compared to White and Chinese adults.

Overall and for both age groups, Black, Latino, and Filipino adults were less likely to have an activated patient portal account and less likely to have sent messages and viewed laboratory results using their portal account than White adults. Korean, Vietnamese, and South Asian adults did not differ from White adults in having a portal account but were less likely to have used the portal for sending messages and viewing laboratory results. Chinese and Japanese adults did not generally differ from White adults on any of the portal use outcomes, but older Japanese adults (aged 76 to 85 years) were less likely to send secure messages than White adults.

Furthermore, our analyses of racial and ethnic differences in secure messaging and viewing of laboratory results by patients with an activated patient portal account showed that these differences were not simply associated with the lack of an activated patient portal account, although age group differences were attenuated in some cases. Racial and ethnic variations in the video visit use were mainly evident in the 76 to 85 age group, where Black and Latino adults were less likely and Chinese and South Asian adults were more likely to have had a video visit than White adults.

The survey data elucidated factors that might account for the lower patient portal use among Black, Latino, and Filipino adults compared to White and Chinese adults. Black and Latino adults had lower educational attainment than White, Filipino, and Chinese adults, which has been identified as a barrier to the use of the internet and patient portals among older adults in previous research [31,35,46]. Black, Latino, and Filipino adults were less likely to be internet users and to have an internet-enabled computer or tablet, and Black and Latino adults were less likely than White and Chinese adults to have any internet-capable device. While Black, Latino, and Filipino adults who were internet users were more likely than nonusers to have a patient portal account and to have sent a message using the portal, their use of patient portal messaging remained lower than that among White and Chinese adults after controlling for internet user status. Finally, we found that not being an internet user was associated with a lower prevalence of video visit use for older Black and Latino adults, but not for White, Chinese, and Filipino adults.

Our study results are consistent with previous research that found lower rates of patient portal use among US Black, Latino, and Asian older adults compared to White adults [26-30] and among older versus younger Medicare-age adults. Importantly, our study provides novel and contemporary information about racial and ethnic and age group differences in patient portal and video visit use among US Medicare-age adults whose primary language is English. A major contribution is the provision of disaggregated data for Asian ethnic groups, demonstrating variation in the patient portal and video visit use among Asian ethnic groups and identification of factors that may contribute to a lower portal use among the selected ethnic groups.

The survey data for a subset of adults in the EHR cohort suggest that the lower percentages of Black, Latino, and Filipino older adults using patient portal functions compared to White and Chinese adults may in part be due to their lower overall internet use. Internet user status is a barrier to patient portal use that could potentially be removed by providing free or subsidized laptop or tablet computers and printers along with Wi-Fi or data plans for those who do not use the patient portal due to financial barriers. In addition, training on how to use the internet and patient portal for those who lack these skills can be offered. However, the survey data also suggest that factors beyond access to and skills in using the internet may contribute to the observed demographic disparities in patient portal use, especially among adults aged >75 years who do not have as much experience as adults aged 65 to 75 years in using digital information technologies. These factors could include how comfortable and articulate the patient is with composing written digital communications, how important it is to the patient to be able to ask follow-up questions during clinical interactions, and the extent to which patients feel that solely exchanging written messages decreases their sense of interpersonal connection with health care providers [35,47,48].

The disparities we identified in patient portal use and internet use capabilities have implications for a US health care system that is increasingly shifting to using patient portals to share health-related information with patients and to enable bidirectional communication between patients and their health care team. Specifically, to increase patient portal use by Medicare-age adults and to reduce racial, ethnic, and age-related disparities, health plans and community-based institutions, such as libraries and older person centers, should offer skill training, technical support and written instructions, and ongoing encouragement specific to performing patient portal activities for adults who do not use the patient portal on their own but want to learn [20,31,49,50]. This recommendation is supported by a 2023 national survey that found that 24% of older adults whose health plan had a patient portal thought it would be helpful to receive training or a tutorial on patient portal use [48]. Health plans may need to consider loaning or subsidizing the purchase of a low-end internet-enabled computer or tablet with accessories for older adults who do not own one. Research has shown that many older adults find it easier to complete online tasks that involve entering information using a computer with a keyboard and mouse, rather than a touch screen tablet or smartphone [51].

In the first full year of the COVID-19 pandemic, only half of the adults aged 65 to 85 years who had an outpatient visit opted to have a video visit, with lower percentages in the 76 to 85 years age group and among Black and Latino adults compared to White adults in that older age group. While we cannot determine whether the lack of video visits is due to patient preference or digital health access barriers, Medicare and other health insurers should consider parity for phone and video visit reimbursement so that health care systems and clinicians are not financially incentivized to schedule video or in-clinic visits rather than phone visits if doing so is not aligned with patient preferences.

Finally, we want to clearly state that lower use of patient portal functions and video visits by some racial and ethnic groups and by adults aged >75 years should not be construed as lower access to care. Patients are able to get messages to health care providers by contacting the health plan's regional appointment and advice call center and are able to obtain laboratory test results by a system-generated mailed letter or by requesting a call from their health care team. In addition, patients who had an outpatient visit but not a video visit would have had that visit by phone or in person.

Limitations and Strengths

Our study has several limitations. First, our EHR cohort was restricted to KPNC members whose preferred language for written materials was English. This restriction was by design because an adult unable to read English and without a proxy user who can read English would have had difficulty interacting with the existing patient portal, which had only basic Spanish text as a second web page language, no functionality in other non-English languages, and limited ability to send secure messages in languages other than English. However, the exclusion of those whose preferred written language is not English limits the generalizability of the study results to adults who can read and understand written English well. Previous studies found large disparities in the use of patient portals and video visits between adults with limited English proficiency and adults with English as their preferred language [52-57]. Our analyses also did not account for health status or recent interactions with the health care system, which have both been shown to influence patient portal access and use [30]. Another limitation is that we had survey data for relatively small samples of Black, Latino, Chinese, and Filipino adults, limiting the statistical power to examine differences between racial and ethnic groups, and no survey data for other Asian ethnic groups. Furthermore, we lacked survey data to examine factors beyond educational attainment and access to digital devices and the internet that have been shown to influence and contribute to patient portal use, including competency and comfort in accessing information on the internet, eHealth literacy, privacy and security concerns, patient communication preferences, physical and cognitive limitations, and availability of high-speed broadband internet in the home [3]. Finally, the study population was restricted to members of 1 Northern California health plan with an older adult membership that is better educated than the general older adult population and that serves a geographic area of the United States that has relatively good high-speed broadband access [35].

However, our study also has several strengths, including a sociodemographically diverse EHR cohort with very large numbers of adults in each of the 9 racial and ethnic subgroups examined. These large subgroup sizes enabled us to document the prevalence of patient portal engagement and video visit use across racial and ethnic groups and by age group within racial and ethnic groups. We believe that this is the first study to document and compare patient portal and video visit use data for such large groups of older adults among 6 different Asian ethnicities and to be able to additionally compare findings across 2 age strata within each ethnic group. In doing so, we found that reporting engagement with patient portal functions and video visit use in just the aggregate 65 to 85 years age group in many instances masked substantially lower engagement with these portal functions in the 76- to 85-year versus 65- to 75-year age group (for all racial and ethnic groups except South Asian group). Another study strength is the examination of patient portal and video visit use based on EHR data rather than self-report and the examination of demographic differences for 3 patient portal outcomes. Finally, we used contemporaneous survey data from the same study population to explore associations of educational attainment and internet access factors with sending messages using the patient portal and having video visits.

Conclusions

Racial and ethnic group and age group differences in patient portal and video visit use persisted in 2020 in a community-dwelling Medicare-age population that had access to the same patient portal and received care from the same health care delivery system. Contemporary survey data suggested that internet use factors may contribute to lower use among older Black, Latino, and Filipino adults compared to White and Chinese adults. Patient portal use also varied across Asian ethnic groups, underscoring the importance of disaggregating data by Asian ethnicity. Our research highlights the importance of health care providers assessing older adults’ capabilities for engaging with patient portals and video visits, providing training and ongoing technical support to those who are not currently using the patient portal or those who want to improve their navigation skills, making digital equipment accessible when needed, and maintaining nondigital health modalities for health-related communications, including letters, hard copy information (eg, visit summaries, results, instructions, and benefit information), and phone visits. Future research is needed to identify cost-effective ways to reduce racial and ethnic disparities and age-related disparities in the use of patient portals and video visits among older adults and to serve older adults with limited English proficiency.

Abstract

Background: In Quebec, the shortage of nurses during night shifts compromises the safety and quality of resident care, particularly in small residential and long-term care centers ("Centres d'hébergement et de soins de longue durée"; CHSLDs) located in rural areas. The need to ensure the continuous presence of nurses 24 hours a day in CHSLDs has become more pressing, forcing some facilities to implement exceptional measures such as on-call telephone services to ensure access to a nurse. In light of these challenging circumstances, the Direction nationale des soins et des services infirmiers of Quebec's Ministère de la Santé et des Services sociaux has rolled out a teleconsultation pilot project.

Objective: This study aims to explore nurses' and nursing assistants' experience of integrating teleconsultation during night shifts in rural CHSLDs with ≤50 residents.

Methods: The 6-month pilot project was rolled out sequentially in 3 rural CHSLDs located in 2 administrative regions of Quebec between July 2022 and March 2023. A total of 18 semistructured interviews were conducted with 9 nurses and nursing assistants between February and July 2023.

Results: Participants' experiences revealed that teleconsultation provided significant added value by improving clinical, administrative, and organizational practices. Some practices remained unchanged, indicating stable workflows. Workflow optimization through an expanded scope of practice ensured efficient and safe continuity of care. Enhanced collaboration between nurses and nursing assistants led to improved care coordination and communication. The leadership played a significant role in clarifying professionals' roles and in supporting effective adaptation to teleconsultation.

Conclusions: This pilot project represents a significant step forward in improving care for CHSLD residents in Quebec. Teleconsultation not only makes it possible to overcome recruitment challenges and ensure the continuous presence of nurses during night shifts but also optimizes professional practices while ensuring the safety and quality of care provided to residents.

Introduction

The Health Care Situation for Older Adults in Quebec

The health care landscape in Quebec, particularly for older adults, presents numerous challenges and opportunities for improvement. Health and social services professionals work in an environment that is both demanding and constantly evolving. Thanks to scientific progress and medical advances, Western populations, including those in Quebec, are enjoying increased life expectancy. According to the latest demographic data, Quebec is facing a significant aging of its population, and approximately 25% will be considered older within the next decade [1]. This demographic shift creates specific health care needs, particularly in settings, such as residential and long-term care centers (Centres d'hébergement et de soins de longue durée; CHSLDs), where vulnerable populations often require extensive care and support. However, increased longevity often comes with multiple comorbidities and chronic conditions that necessitate holistic care approaches addressing physical, psychological, social, and functional needs [2].

For the past several years, the Quebec government has implemented programs enabling older adults to remain at home for as long as possible [3]. Maintaining older adults' autonomy in their own living environment reduces pressure on health care facilities while providing personalized, high-quality care [4]. However, older adults living in CHSLDs often experience chronic illnesses that lead to significant disabilities and severe functional limitations [5]. It is estimated that 3% to 4% of Quebecers aged ≥65 years reside in CHSLD [6]. The main reasons why older adults move to long-term care facilities include neurocognitive disorders, chronic pathologies, severe degenerative diseases, and mental health problems [6,7]. These particularly susceptible residents require rigorous attention from multidisciplinary care teams.

The Role of the Nurse and Nursing Assistant in CHSLDs

Nurses play a central and essential role in Quebec's CHSLDs [8]. To become a nurse, candidates must complete college- or university-level education and successfully pass a professional examination regulated by the Order of Quebec Nurses (Ordre des infirmières et infirmiers du Québec; OIIQ). Nurses ensure a continuous presence for residents, assess their physical and mental condition, develop therapeutic nursing plans (TNPs) to coordinate interventions, and prescribe treatments with the approval of their professional regulatory body, under defined conditions. The OIIQ stresses the importance of nurses' contribution to CHSLDs, across all shifts, given the residents' fragility and the growing complexity of clinical situations [9].

In addition to nurses, nursing assistants also play a fundamental role in CHSLDs. They complete a 2-year vocational training program and must pass a professional examination regulated by the Order of Quebec Nursing Assistants (Ordre des infirmières et infirmiers auxiliaires du Québec [OIIAQ]). Working closely with the nurses, they take part in the entire care process within their professional scope of practice [10]. Their interventions are based on verbal or written medical orders, the TNP, organizational protocols, and the rules governing care. The renewed position of the OIIAQ highlights the nursing assistants' skills and the significance of their contribution to the quality of care and services provided in CHSLDs.

In Quebec, CHSLDs are integrated within regional health and social service structures. The management of these facilities is overseen by local administrators and supported by a range of clinical managers. Multidisciplinary teams work in CHSLDs, but the residents' primary needs are largely met by professional nursing teams and personal support workers.

A key aspect of nursing roles in CHSLD is the dynamic collaboration between the nurses and the nursing assistants. The work environment in CHSLDs often features a strict hierarchy, where decisions are shared using a top-down approach [11]. This hierarchical structure is reflected in the collaboration between the nurse and the nursing assistant, which is generally characterized by a supervisory relationship [12]. This type of hierarchy can generate tensions, undermining collaboration [13] and professional identity [14]. Because of their heavy workloads, nurses and nursing assistants rarely have time to exchange ideas, collaborate, and organize the division of tasks [11]. Nevertheless, when they are able to work collaboratively, the partnership between the nurse and the nursing assistant in CHSLDs is particularly beneficial [15,16]. Such collaboration fosters better professional communication [17] and high-quality care for residents [18].

Workforce Challenges in CHSLDs and Implications for Resident Safety

In Québec, the shortage of nursing staff is particularly acute in rural areas, where attracting and retaining personnel is a persistent challenge. Long-term care is often perceived as an unattractive and difficult sector [7]. Consequently, CHSLDs have experienced staff shortages for several years, a situation that was exacerbated further by the COVID-19 pandemic. To address this, various initiatives have aimed to improve the perception of working in CHSLDs [6]. In the meantime, administrative solutions, such as employing independent workers, overtime, or on-call telephone services, have been used to meet staffing needs. Despite the financial incentives for nurses to take night shifts, this work schedule remains unattractive due to its impact on social [19] and personal health [20]. This is particularly problematic in rural areas, where the availability of nursing expertise is even more limited during night shifts.

The literature indicates that a considerable number of adverse events occur during the night in CHSLDs [21]. Without an on-site nurse, staff are forced to transfer residents to hospital emergency rooms to obtain the care they need [22]. Yet, if there are not any unexpected incidents, the skills of night nurses are often underused. They end up performing support tasks that could be carried out by other professionals, such as nursing assistants or orderlies [23]. Although it is frequently considered as a way of overcoming the challenges of recruiting care staff, replacing a nurse with a nursing assistant in an older adult's residence amounts to a halfway solution [17]. Researchers agree on the relevance of reviewing the management of time dedicated to care [24], adopting mechanisms to optimize professional expertise [6], and improving care by exploring innovative approaches that are tailored to the CHSLD environment [11].

The Potential of Teleconsultation in CHSLDs

Faced with challenges that potentially compromise the quality and safety of resident care in CHSLDs, the Quebec government introduced a teleconsultation pilot project for small, rural CHSLDs. This initiative, the first of its kind in the province, aimed to provide web-based access to nurses' expertise during night shifts when nursing assistants were present at residents' bedside.

Inspired by on-call telephone service practices, this initiative enabled nursing assistants to consult a nurse by regular phone calls when a resident experienced a health issue. The teleconsultation pilot project formalized improved nursing practice by integrating organizational and technological innovations.

The deployment of the pilot project was carried out in accordance with strict criteria established by Quebec's Ministère de la Santé et des Services sociaux (MSSS). The project sought to enhance the quality of care provided to residents while ensuring that nursing expertise was readily accessible, even in the most challenging circumstances. Teleconsultation is based on a new organization of care, requiring that institutional documents governing the practices of nurses and nursing assistants be updated, while respecting their separate scopes of practice. The addition of technological tools enables the nursing assistant, who is on-site at the CHSLD, to benefit from the expertise of a remote nurse in real time when a resident's health situation requires it. To develop this practice effectively, the innovations must work together to meet the needs of all stakeholders [25]. The teleconsultation project uses the Microsoft Teams platform, with nursing assistants using tablets and nurses using laptops, making real-time communication possible.

Although telehealth practices are already well established in long-term care facilities internationally [26], they are yet to be adopted in Quebec CHSLDs. The literature shows that teleconsultation improves access to health care and services when they are needed while optimizing coverage by health care professionals beyond business hours [27-29]. In addition, residents benefit from quick and easy access to an in-depth assessment by a competent health care professional [30].

One of the critical reasons for focusing on small CHSLDs is the chronic shortage of health care staff, particularly during night shifts when nursing expertise is limited. By leveraging teleconsultation and IT tools, this pilot project helps address these workforce issues, allowing small CHSLDs to provide timely and appropriate care even with reduced on-site staff. Teleconsultation offers a solution to help mitigate the ongoing challenges related to recruitment and retention, particularly in rural settings where staffing is a persistent issue. The integration of teleconsultation enhances health care accessibility and helps ensure continuity of care for residents, thus reducing the burden on overworked personnel.

Successful implementation of teleconsultation services relies on close collaboration between the players involved, healthy relationships [31], and intuitive IT systems that support access to all data relevant to the remote care management of residents [32,33]. Thus, it is important that we study the rollout of the nursing teleconsultation pilot project in small CHSLDs and its impact on the professional practice of nurses and nursing assistants.

Objective

The aim of this study is to explore nurses' and nursing assistants' experience of the integration of teleconsultation during night shifts in rural Quebec CHSLDs with ≤50 beds.

Methods

Study Design and Setting

The 6-month pilot project was rolled out in 3 rural CHSLDs located in 2 administrative regions of Quebec. The regions were selected by the MSSS for the alignment with the project's outlined criteria, which include facilities situated in semiremote and remote areas, those already experiencing nursing shortages during the night shift, and those reporting issues and risks related to the shortages. In addition, at least 30% of all CHSLD facilities in the territory have a capacity of ≤50 beds. The rollout was conducted sequentially from July 2022 to March 2023 at different sites. During the project, participants documented 19 clinical situations using teleconsultation and 14 clinical situations without teleconsultation. According to the organization's previous year's statistics regarding on-call telephone services, the number of clinical situations remains similar year over year. This attests to the stability of the environment, providing an appropriate context to study the implementation of teleconsultation. Given the innovative nature of the pilot project, an exploratory qualitative study was conducted to understand the impact of implementing teleconsultation in nighttime nursing care.

Data Collection

In total, 2 interview guides were designed, tested, and validated by the research team. The first guide, comprising 12 open-ended questions, aimed to identify the barriers and facilitators to the implementation of teleconsultation. This guide provided a better understanding of the context and experiences surrounding the pilot project's deployment. The study was guided by key factors influencing the implementation of health innovations, as outlined in the framework proposed by Chaudoir et al [34], along with the Consolidated Framework for Implementation Research [35]. The second guide, including 12 open-ended questions, focused on assessing the impact of newly introduced workflows on nurses and nursing assistants in the context of teleconsultation. This guide was based on a comprehensive literature review associated with nursing roles [36], the use of nursing resources [37], and the scope of professional practice [38]. According to the findings, 3 distinct levels of nursing practice were identified—clinical, administrative, and organizational—allowing a thorough assessment of the contributions made by both nurses and nursing assistants. By using both interview guides, the research provides a more holistic and nuanced understanding of the phenomenon under study. The interview guides are included in Multimedia Appendix 1.

In addition, a web-based sociodemographic data collection form, created on the Google Forms platform, was also shared with and completed by participants, enabling the collection of information about their current employment, work experience, and academic background. Participants were contacted by email, which included the research consent form, interview guides, and the project poster. The consent form explained the context, project objective, procedure and duration, anticipated benefits, and anonymity and confidentiality.

Participants

Participant recruitment was done using nonprobability sampling [39], through which participants were identified by pilot project managers. To be eligible, participants had to be nurses or nursing assistants, have a formal employment relationship with the organization, and have used teleconsultation during the 6 months that it was deployed in the CHSLDs. A total of 8 nurses and 7 nursing assistants were contacted by the research team between March and July 2023. In total, 62% (5/8) nurses and 57% (4/7) nursing assistants consented to participate. The remaining individuals did not respond to the email invitation.

Pursuant to an agreement with the Direction nationale des soins et services en soins infirmiers of the MSSS, the semistructured interviews were conducted during the participants' working hours or, if this was not possible, participants were compensated for the time devoted to the interview according to the conditions of their work agreement. Regarding this directive, only 22% (2/9) of the participants conducted the interviews during off-hours.

A total of 2 semistructured interviews, each with a duration of 60 minutes, were conducted in French. Of the 9 participants, 3 (33%) were interviewed via videoconference (Zoom; Zoom Video Communications, Inc), and 6 (67%) were interviewed by phone, according to each participant's preference. The main researcher (VN) conducted the interviews associated with the first guide, drawing on her previous experience in this specific field. In contrast, the coresearcher (MCL) conducted the interviews associated with the second guide due to her nursing qualifications and knowledge of the profession. All interviews were audio recorded with participants' permission, and then transcribed in compliance with ethical and confidentiality standards. The deidentified recordings were transcribed verbatim by a third-party transcription service bound by a confidentiality agreement. Participants were given the option to review the transcripts of each interview, but none of the participants chose to receive the transcripts.

No additional recruitment process was necessary, as information redundancy indicated data saturation [40]. Each participant completed 2 semistructured interviews, resulting in a total of 18 interviews conducted with 5 nurses and 4 nursing assistants between March and July 2023. The participants had no personal or professional relationship with any members of the research team.

Data Analysis

Interview data were processed using NVivo software (version 14; Lumivero). Each interview was transcribed verbatim immediately after it had been conducted and analyzed by the research team. Validation and reflexivity steps were integrated throughout the analysis process to ensure compliance and authenticity of the approach.

Before beginning the analysis, we planned to structure the data using a 3-level framework (clinical, administrative, and organizational), as it aligned with our understanding of nursing and nursing assistant practices. This framework was supported by relevant literature [36-38]. The clinical level relates to the care provided directly to residents, the administrative level concerns the organization of interventions, and the organizational level focuses on innovative initiatives.

Initially, the research team familiarized themselves with the data by reading and rereading the transcripts to gain an in-depth understanding of the content. This immersive experience confirmed the suitability of the 3 levels of the framework and revealed interactions between the levels, such as how the organizational level influences the administrative level, which in turn impacts the clinical level.

Following familiarization, the team engaged in a systematic coding process, identifying key themes and categories that emerged from the data. The coded data were then regrouped into categories that reflected the interactions among the 3 levels of practice. In addition, participants' lived experiences and perspectives regarding the deployment of the pilot project were categorized as either hindering or facilitating factors. The directed approach to qualitative data analysis, as used here, aligns with previous research aimed at better understanding nursing practice and its impact [41].

Workflows, inspired by lean methodology, played a central role in understanding the practices of nurses and nursing assistants. These workflows ensured the smooth flow of operations to improve performance and create value [42]. The clinical approach to nursing encompasses tasks such as data collection, analysis, planning, intervention, and outcome assessment related to the care and services provided directly to residents. The administrative and organizational levels of nursing practice have an overarching influence on these workflows, serving as the foundation for clinical activities.

The integration of teleconsultation impacted nurses' and nursing assistants' practices in various ways. The research team categorized key findings at each level of practice based on their impact on workflows. Enhanced practices added value to workflows by improving the quality of interventions, while unchanged practices demonstrated an inherent stability in CHSLDs despite the integration of this new technology.

To finalize the analysis process, data organization and interpretation allowed the research team to identify 3 major underlying themes: leadership, collaboration, and impact on residents.

Ethical Considerations

Ethics approval was obtained from the research ethics committee of the Outaouais Integrated Health and Social Services Centre before the beginning of the study (reference number 2022-353_195), in Quebec, Canada. All participants gave their consent electronically before beginning the survey. Participation was anonymous and voluntary. The privacy rights of the study participants were observed. The study participants did not receive monetary compensation. The study's findings will be disseminated through presentations at conferences and publications in peer-reviewed journals using anonymized data. Findings will also be shared through presentations to various MSSS stakeholders and the nursing community.

Results

Characteristics of Participants

The sociodemographic data collection form provided a brief portrait of the study participants. All 9 participating interviewees completed the form. In total, 5 (56%) of the participants were nurses and 4 (44%) were nursing assistants. Of these participants, 7 (78%) worked full time, while 2 (22%) worked part time. In terms of educational background, 3 (33%) participants had a vocational diploma, 2 (22%) had a college diploma, and 4 (44%) had a university degree. It is important to note that, in Quebec, it is possible to become a member of the OIIQ and enter the nursing profession with a college or university degree.

The participants' experience of working in CHSLDs varied: 33% (3/9) of the participants had been working there for <5 years, 33% (3/9) had between 5 and 10 years of experience, 22% (2/9) had between 11 and 20 years of experience, and 11% (1/9) participant had >21 years of experience. According to the literature, a nurse with ≥5 years of experience in a specific field can be considered an expert [43].

The integration of teleconsultation into their professional practice led to a variety of responses and experiences for participants. Their diverse reactions highlighted the benefits and challenges associated with implementing new technology in long-term care. The subsequent sections present nurses' and nursing assistants' perceptions of the impact of teleconsultation on the 3 levels of their practice examining areas where it created unchanged practices, demonstrating stability, and where it introduced enhanced practices, enabling the illustration of optimized workflows when using teleconsultation.

Unchanged Practices

Unchanged practices reflect an inherent stability within CHSLDs, even with the integration of teleconsultation. This stability indicates that certain fundamental aspects of care delivery and professional interactions have remained consistent, despite the introduction of this new technology.

Organizational Level

Participants were asked to share their views on their level of involvement in planning the pilot project. Most (8/9, 89%) of the participants agreed that they had been presented with well-defined, predeveloped content at the teleconsultation information meetings. This approach came as no surprise to participants, who said they were satisfied with this aspect:

> *Everything was already in place. Basically, they worked together, the manager, the project manager, and our administrative officer. When we first heard about the project, everything was already in motion, it was already set up. The binders were already made. The step-by-step instructions were already inside. All our protocols too. I'd say we didn't really participate. We just kind of stepped into the project, then set it in motion, that's all. We weren't consulted beforehand.* [Participant 6]

However, the nurses and nursing assistants did say that they wished they had been involved in the initial reflection and decision-making on the pilot project:

> *Well, I could have shared my opinion, and some ideas too.* [Participant 3]
>
> *I'd say that everything was really well structured and complete. That's why I didn't have anything to add. But of course, if they had asked my opinion, I would have wanted to participate, of course, to share my point of view.* [Participant 6]

In this regard, participants shared some of the issues associated with the planning. They expressed dissatisfaction with the time frames determined by the managers:

> *We had time, but it kind of dragged on at some point. You know, you tell yourself: Well, are we going to do it or not? When are we starting? We've all been trained. It's been three months, but nothing is happening yet. That's why, you know, I thought it took a long time to get started.* [Participant 2]
>
> *It was pretty drastic. It was like "OK, you're getting teleconsultation training..." Uh, what's that? We were kind of thrown into it, and we were a bit taken aback.* [Participant 7]

Finally, participants wished they had had ongoing support throughout the pilot project, not just at the start:

> *The project was launched and we just went on from there. Then, there was no real support from the manager.* [Participant 6]

Participants highlighted a relevant point related to professional maturity, experience, and ease. Having significant work experience contributes to the enrichment of professional practice every day, not just within the context of the pilot project. Professional maturity, in the nursing field, refers to the ability to apply clinical judgment with confidence, adapt to complex situations, demonstrate autonomy in decision-making, and help improve the interventions carried out with residents:

> *Maturity, yes, that...well, there's training and all that, but there's not just that, there's life experience. If I'd been a new nurse, I'd have been very uncomfortable. After all, I have over twenty years' service.* [Participant 1]
>
> *Prior to the teleconsultation program, even a few years ago, nursing assistants were already covering*

> *the nighttime shifts. Then, at some point, they abolished that, and decided that they needed a nurse on duty 24-7. So, you know, the rest of us were already used to it, because I've always worked nights, so I was used to the process. So for me, it wasn't anything new.* [Participant 4]

Administrative Level

Participants discussed the various aspects of working collaboratively, including documentation in the resident's medical record. The experiences suggest that the rules of documentation were not implemented in a standardized way. Some participants documented too much, others just enough, while some opted to enter information later. However, according to 1 participant, this phenomenon had already been observed before the implementation of teleconsultation:

> *In the morning, the nursing assistant would tell me: "I gave her a Tylenol, she had pain in such and such a place. It was already in the TNP, so I didn't need to consult on this." Indeed, it was fine, but I would, let's say, write my note, then enter the nighttime call for such-and-such a case, confirm with the TNP, and everything, so it was fine.* [Participant 1]
>
> *There's a lack of information being shared, but that, as I say, is not just because of teleconsultation, not at all. It's a generalized issue.* [Participant 8]

Another unchanged element, at the administrative level, is the importance afforded to residents' families and loved ones. The nurses and nursing assistants maintained a special focus on this relationship, upholding the same values and principles:

> *It hasn't changed the practice. That's why this aspect hasn't been integrated as such. We'll talk about it with the family, but really, you know, the "We're now using video teleconsultation" aspect, well, there were people who weren't even aware of the fact that there wasn't a nurse on site during the night.* [Participant 6]
>
> *Well, Mom fell last night. I was the one on duty, and then I took care of her. They won't ask me if I used teleconsultation or not. They just need to ask me if there are any after-effects, if there's anything wrong.* [Participant 2]

Clinical Level

Participants highlighted a number of limitations associated with a virtual assessment of residents' physical and mental condition. As with on-call telephone services, certain practices, such as palpating residents and managing certain clinical situations, are incompatible with teleconsultation:

> *I'm actually someone who likes to move around, who likes to see things in real life to validate certain information, to palpate, you know, to conduct a fuller assessment.* [Participant 6]
>
> *Many, many of our residents suffer from cognitive decline and unfortunately they don't understand. They didn't understand the instructions; they don't understand when we speak to them. They can't see us in the camera. You know, because it's nighttime, they're often sleepy as well. It's not always easy.* [Participant 1]

Despite the integration of teleconsultation, the sense of responsibility, clinical judgment, and desire to provide safe, high-quality care and services to residents remains unshaken. Teleconsultation has not changed the values and principles of nursing assistants:

> *My decision-making would probably have been the same, with or without teleconsultation, once I came here. It didn't change my decision-making.* [Participant 2]
>
> *I'm still part of the same order, I still have the same scope of practice to uphold. So, from my standpoint, my responsibilities remain the same. Just because you have a tablet doesn't mean you're protected. No, it gives us an additional tool, but we still have to use our judgment.* [Participant 8]

Enhanced Practices

Enhanced practices refer to the added value brought to workflows by improving the quality of interventions. These advancements not only streamline processes but also elevate the standard of care provided, resulting in more effective and responsive support for residents.

Organizational Level

Participants praised the rigorous planning of the pilot project and the quality of training. Presentations were clear and the content was well documented:

> *I think the training was well done; we were well trained.* [Participant 2]

In addition, the sessions dealt with updating and creating clinical tools tailored to teleconsultation:

> *For example, we didn't used to have algorithms. That was something new with teleconsultation.* [Participant 4]
>
> *We updated all our protocols, you know, to raise awareness. We updated "Are the collective prescriptions correct?" So, you know, we did a good job of updating, which should be ongoing, but which, well, isn't necessarily done as part of day-to-day activities.* [Participant 5]

In addition, the training sessions prompted group discussions on professional roles, professional order guidelines, understanding the scope of practice, and recognition of the expertise of other disciplines:

> *It's when we did the training with the project officer. Well, with the eligibility criteria, you know, exclusions and so on. We realized that, oops, sometimes our nursing assistants were being very autonomous. We've now rectified that. I think we adjusted well after that.* [Participant 6]
>
> *Inevitably, with everything being more up to date like this, I don't need to communicate with my nurse as much. I'm more independent.* [Participant 7]

In addition, participants appreciated the attention paid to their concerns and the opportunity to provide immediate feedback during the training sessions:

> *We were asked if there were things we thought should be added, things that were missing.* [Participant 9]

> *But more so in connection to, say, the material we put in the case, the forms, the step-by-step instructions. Yes, we were consulted. We were asked if there were things they thought we should add, things that were missing. They were also available if we wanted to add anything along the way.* [Participant 8]

Administrative Level

Teleconsultation enabled the remote nurse to contribute to the coordination of interventions in real time and adjust the resident's medical record. For example, the remote assessment of a resident's physical and mental condition was immediately documented in the TNP, enabling the nursing assistant to intervene according to her scope of practice when the health situation changed unexpectedly:

> *Well, with teleconsultation, I changed an TNP remotely...with this tool, we're able to directly change things remotely.* [Participant 5]

> *The fact of sending prescriptions, the fact of sending notes, of sending everything directly to the home, I find that it...How can I say this? It decreases the risk of errors in the end.* [Participant 8]

Another element mentioned by participants was predictability. Because the pilot project was formalized, supported, and recognized by the organization, nurses and nursing assistants knew in advance when teleconsultation was taking place and who would be involved. This enabled better care planning, made it easier to anticipate potential needs, and gave nurses and nursing assistants a greater sense of security:

> *If I see that the patient...I know that in two hours his third dose will be due, then I'm going to get organized.* [Participant 1]

Some participants noted a marked improvement in the design and writing of the TNP, believed to be attributable to a growing awareness of the need to optimize the nursing assistants' scope of practice. In the context of nursing teleconsultation, the TNP is written jointly by the nurse and the nursing assistant to target residents' health problems efficiently. The nursing assistant exercises full autonomy when updating the TNP, adapting it to the resident's health-related condition and needs, and proposing relevant interventions:

> *I think this process, with the night nurses, forces us to have nice TNPs. So, you know, it may have been...That was during our first calls. But shortly after, we got back on track.* [Participant 5]

> *We also established plans, well, our TNPs. We really updated them to enable [nursing assistants] to be autonomous.* [Participant 6]

Clinical Level

Participants noticed that the pilot project helped improve the professional bond between the nurse and the nursing assistant. During the calls, a knowledge-sharing and coaching process was established between them. The nurse ensured a real-time virtual presence for the nursing assistant, guiding them, suggesting interventions, and supporting their practice:

> *You know, we were able to work a bit as a team there. In the sense that, you know, she could suggest things that I could pay more attention to.* [Participant 3]

> *It means I can talk to my nursing assistant. Then, it's like we're really comfortable; it's like we're together. I think that makes it easier to conduct the interventions.* [Participant 8]

The rollout and updating of the pilot project–related clinical tools clarified professional roles and fostered the achievement of full autonomy with confidence. For example, the addition of decision-making algorithms, improved TNP writing, and adjustments to nursing protocols built nursing assistants' confidence and contributed to their empowerment. This process facilitates decision-making, promotes the development of clinical judgment, and improves professional ease:

> *For example, we didn't used to have algorithms. That was something new with teleconsultation. Yes. When there's a situation that's a little ambiguous, you feel like you're sitting on the fence. Then you're not sure which side to choose. Well, you follow your algorithm and it leads you straight to the correct way of doing things.* [Participant 4]

> *I'd say it's generally going well. I haven't experienced any ambiguous situations. The thing is that teleconsultation can only make it even better. I think the fact of talking to and also seeing your nursing assistant...I think it can only bring positive elements in that regard...being able to exchange with them as such.* [Participant 6]

Finally, participants stated that teleconsultation enhances remote nursing by enabling visual inspection. Assessing the physical and mental condition of a symptomatic resident is the responsibility of the nurse, requiring professionalism, diligence, and conscientiousness. Teleconsultation provides valuable visual support to nurses, enabling them to observe clinical situations directly, make more accurate assessments, and monitor the evolution of the resident's health condition. Furthermore, the addition of this tool also benefits the nursing assistant, fostering more enriching discussions with the nurse and enabling a better understanding of the situation, thus refining the chosen intervention:

> *For me, teleconsultation using a tablet was a practical way of getting a visual. It helps justify a problem. Then, afterwards, once you have visualized the problem, you can find more solutions to solve it. So I found that it was like an additional tool to support and reinforce my role and responsibilities.* [Participant 4]

> *We have a lot of patients who are agitated and aggressive. This video aspect is good, because I can see in real time what the patient is doing, without having to go there myself. It's a situation. Otherwise, in the case of a wound, you know. You can see it.* [Participant 6]

Table 1 summarizes the unchanged and enhanced practices for each level of practice.

Table 1. Enhanced and unchanged practices by level.

Level of practice	Enhanced practices	Unchanged practices
Clinical level	• Collaborative team dynamics during teleconsultation, where knowledge is shared between remote nurses and nursing assistants, reinforcing their respective professional roles • Remote nurses' clinical decisions are reflected in the TNP[a] in real time • Addition of visual support to improve data collection, situation analysis, and intervention implementation	• Palpation remains impossible when using teleconsultation • Certain clinical situations make teleconsultation-based assessment difficult • Professionalism is ensured in the interest of providing exemplary care
Administrative level	• Improved clinical communication enabling the remote nurse to make additions to the medical record • Proactive drafting of the TNP to reinforce collaboration between remote nurses and nursing assistants for optimal professional practice	• Resident medical record documentation rules are not implemented in a standardized way • Communication is maintained between nursing professionals and residents' families and loved ones
Organizational level	• Openness and availability of project managers to provide information at the start of the project • Complete and tailored training program • Updated protocols, rules governing care, collective prescriptions, and additional clinical tools • Enhanced scope of practice-related knowledge	• Professional nursing team members not solicited enough during the planning phase of the pilot project—change management • Professional experience and maturity are essential to rolling out teleconsultation

[a] TNP: therapeutic nursing plan.

Discussion

Principal Findings

Overview

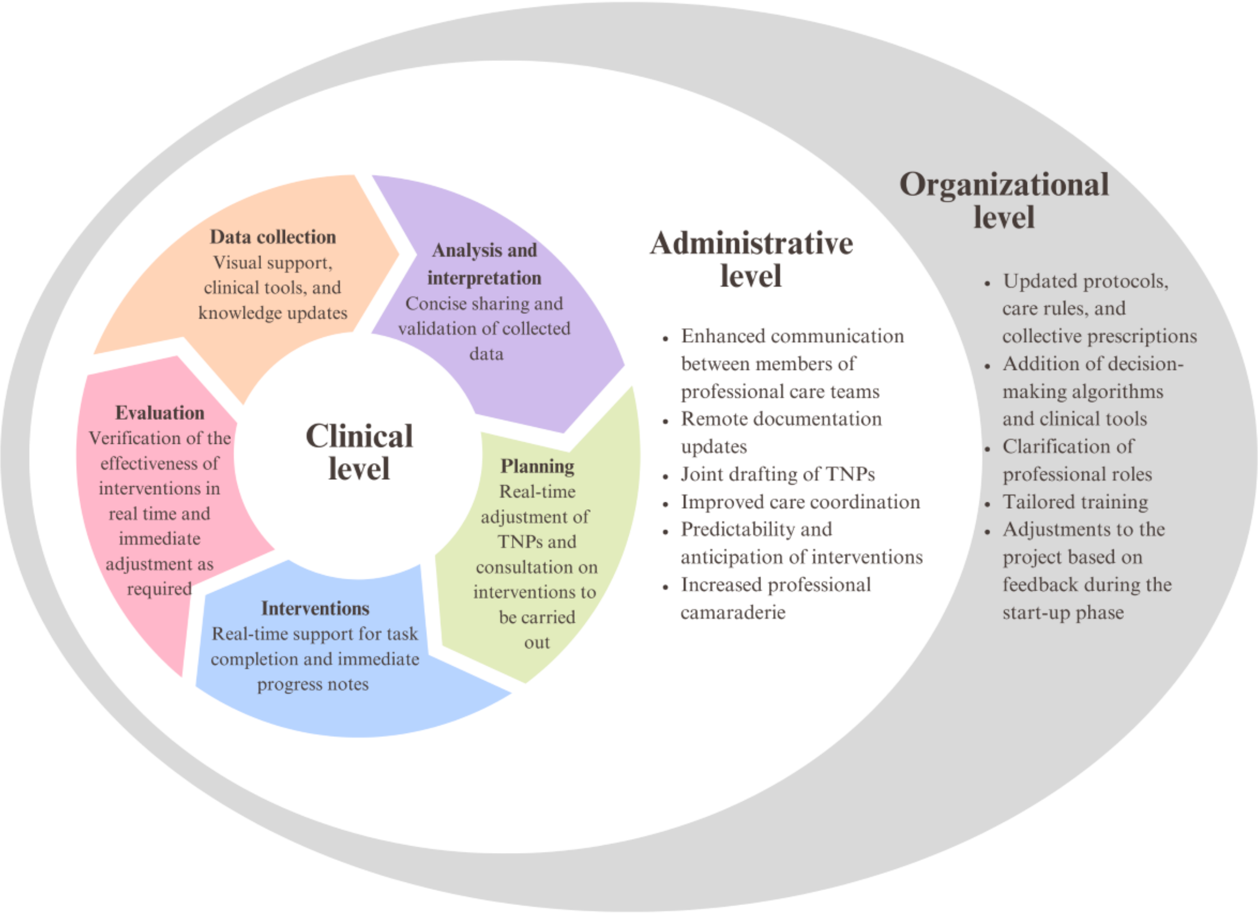
The implementation of teleconsultation elicited a diverse range of responses from participants, revealing both unchanged and enhanced experiences. These findings underline the benefits of adopting new health care technologies. The nurses' and nursing assistants' perceptions highlighted several positive aspects where teleconsultation introduced beneficial changes. Figure 1 illustrates the workflows optimized by teleconsultation in nursing and shows the interactions between different levels of practice and their associated benefits. The organizational and administrative levels supported clinical practice, which is represented by the clinical approach in nursing. From planning to assessment, each step benefited from the integration of technology and increased collaboration within the care team. Real-time documentation, visual support, role clarity, and proactive communication ensured seamless continuity of care, with an emphasis on efficient and safe interventions.

However, the experience also raised concerns about administrative management, change management, and compliance with documentation rules. Nevertheless, most (8/9, 89%) participants enjoyed the structure and quality of the training courses as well as the clarification of professional roles and the opportunity to update and implement clinical tools tailored to teleconsultation. Participants did not report any scope creep during the pilot project.

Although teleconsultation enhanced certain aspects of nursing practice, namely by facilitating care coordination and boosting professional confidence, it also required adjustments to optimize integration. These findings underline the importance of appropriate support and careful planning to maximize the benefits of such technological innovations in long-term care settings.

The qualitative findings will be discussed around 3 cross-cutting topics. It is important to note that they emerged from the data analyses: leadership, collaboration, and impact on residents.

Figure 1. Workflows optimized by teleconsultation in nursing. TNP: therapeutic nursing plan.



Leadership

Overview

Nurses' and nursing assistants' workflows were improved through an extended scope of practice, which can be attributed to the leadership exercised during the teleconsultation project. Interventions and discussions initiated by project managers clarified scopes of practice, eliminating ambiguities, and building the confidence of nurses and nursing assistants [44]. This led to an increased commitment from participants and extended the scope of practice. The literature has highlighted that clinical leadership can be exercised in a caring way to improve the quality of interventions with residents [45]. The OIIAQ's recent work to strengthen the role of nursing assistants [46] is embodied by this teleconsultation pilot project, demonstrating how a supportive environment can promote optimal practice [47].

Nurses' leadership is also linked to their experience and professional maturity. The leadership exercised by an expert nurse leads to positive results for residents and care teams alike [45,48]. Indeed, most (8/9, 89%) interviewees had >5 years of experience working with older adults, and the literature supports the view that expertise contributes to the success of teleconsultation projects [49,50].

Shared Governance

Shared governance is an important concept for the development of high-level leadership among nurses and nursing assistants. Researchers have pointed to a gap between managers' and nurses' vision, sometimes making it difficult for these 2 groups to communicate [51]. During the pilot project, participants were not always asked about their perspectives, leading to dissatisfaction with the planning and the intensity of follow-up.

Shared governance, involving nurses and nursing assistants from the outset of the pilot project, could have improved the planning of health care projects, refined the prioritization of initiatives, and promoted ongoing improvement [52]. Moreover, it would enable project managers to better meet the technology-related needs and expectations of end users: the nursing staff [53].

Collaboration

Overview

Nurses' and nursing assistants' workflows were improved by strengthening their collaborative relationships. Teleconsultation consolidated these relationships, leading to optimized care planning, intervention coordination, and access to clinical documentation.

First, teleconsultation enabled nurses to share information with the nursing assistant and complete clinical documentation in real time, thereby reducing the number of interpretation errors.

This synchronous and asynchronous communication ensured better continuity and coordination of care [54]. The care team was able to access progress notes, prescriptions, and the TNP as required [55,56]. However, despite these benefits, there were issues related to the implementation of documentation. Although documenting interventions is a professional obligation [57], studies have shown that nursing notes are sometimes superficial, affecting the quality and continuity of care [58]. This highlights the importance of integrating users, processes, and technology [59,60].

Second, the collaborative dynamic between nurses and nursing assistants was strengthened by a clear definition of their roles. Project managers played a decisive role in optimizing the use of people's skills [44]. However, professional development remains a contextual phenomenon, influenced by local and organizational factors [61,62]. By harmonizing nurses' and nursing assistants' contributions, they fostered collaborative practice and improved communication within teams [63].

Finally, team stability is crucial to strengthening collaborative relationships. It helps establish a climate of trust between colleagues, which is essential to ensure optimal professional practice [64]. The pilot project demonstrated that collaboration, underpinned by effective consultation, enables the achievement of targeted objectives and the provision of care tailored to residents' needs [65].

Predictability

Teleconsultation improves schedule predictability, an important consideration for nursing staff [66]. Clearly identifying the schedule or timetable of night shifts, during which telecommunication would be used, facilitated collaboration between nurses and nursing assistants, enabling them to anticipate and respond proactively to residents' needs. For example, a jointly drafted TNP improves care management for residents with recurring health problems [57]. The nursing assistant can then rapidly carry out the necessary interventions safely and with confidence.

In addition, teleconsultation reduces the need for mandatory overtime, preserving nurses' physical and psychological health [67,68]. Teleconsultation makes it possible to organize required interventions in advance to ensure the continuity and safety of care [69].

Impact on Residents and Their Loved Ones

Overview

Interviews with nurses and nursing assistants revealed that the well-being of residents, as well as that of their families and loved ones is a constant and central concern. Every intervention, whether or not it includes the use of teleconsultation, must be of impeccable quality, ensuring the well-being of residents at all times. Therefore, it is obvious that when using teleconsultation, nurses' and nursing assistants' workflows must establish the resident as the top priority.

Clinical Aspect of Practice

Participants demonstrated unwavering professionalism and respect for professional values when using teleconsultation. They recognized both the benefits and limitations of the technology. During complex clinical situations, they intervened with greater confidence and ease. Because it involves the use of a camera, teleconsultation facilitates the physical assessment of a resident's condition. However, participants were also aware of situations where teleconsultation was less suitable and recognized the imperative need to comply with the professional and ethical standards in remote practice.

The amount of literature on integrating technology into health care is growing rapidly [70]. Recent initiatives on remote clinical monitoring [71] have led to the publication of nursing practice standards that also consider technological practices [50]. Participants agreed that teleconsultation is a useful additional tool but that it can never replace a full physical examination or direct interaction with the resident. A similar case study on teleconsultation also concluded that this modality of care does not replace the presence of a nurse with the resident but can effectively support clinical practice when the situation allows [72]. In short, pilot project participants demonstrated a strong commitment to and rigorous professional integrity in providing safe, high-quality care to residents.

Involvement of Family and Loved Ones

The active presence of residents' families and loved ones in the organization of care and services in CHSLDs is not only desirable but also essential. The teams who took part in the pilot project set up a communication plan to inform residents' families and loved ones of this initiative, encouraging them to ask questions as needed. Nurses and nursing assistants then discussed the specifics of the pilot project when obtaining consent for the residents to participate, providing an opportunity to clarify certain aspects, to chat with their families and loved ones, and to reinforce existing bonds of trust.

The literature on this subject supports the participants' observations. Introducing the technology-based project to residents' families and loved ones and obtaining their formal consent is essential [71]. Strengthening the relationships between care staff and the residents' families and loved ones is highly beneficial. The integration of technology in long-term care facilities is now widely accepted [73] and promotes the involvement of residents' loved ones in clinical decisions [74].

Finally, this integrated approach to leadership, collaboration, and resident-centered health care in a teleconsultation context illustrates how these elements depend on each other to optimize practices and improve clinical and organizational outcomes.

Limitations and Future Research

Despite the rigorous methods used as part of the study, certain limitations must be considered to improve the interpretation of the results and more accurately target the prospects for teleconsultation in long-term nursing care during night shifts. First, the pilot project was conducted in 2 Quebec regions, it involved 3 rural CHSLDs, and the sample size was limited to 9 participants. However, it is important to note that these participants used teleconsultation for 6 months, logging 19 clinical situations, a number similar to data collected by the CHSLDs over the same period in the previous year. This exploratory study was conducted in small care settings, where care teams are limited by the number of residents, justifying the scope of the study. Nevertheless, caution is paramount when generalizing the results to other regions or similar contexts.

To broaden our understanding and increase the effectiveness of teleconsultation in long-term nursing care during night shifts in small, rural CHSLDs, several avenues of research may be considered. Expanding this research to a larger number of small CHSLDs in different regions would improve the representativeness and generalizability of the results. A larger sample would more accurately capture the context-specific and organizational variability.

In addition, a comparative analysis of different geographical and organizational settings would be relevant to identify the factors that influence the success of teleconsultation. This type of analysis would shine a light on best practices and the conditions required for successful implementation.

It would also be worthwhile to assess the long-term impact of teleconsultation on quality of care, resident and caregiver satisfaction, and associated costs. Longitudinal studies could provide valuable data on the benefits and challenges of this approach over an extended period.

Finally, exploring the impact of teleconsultation from the residents' and families' point of view would enable us to understand their perceptions, the elements with which they were satisfied, and their concerns. This perspective could provide crucial insights, helping to adjust practices and improve the care experience.

In addition to this study, developing continuing education programs on the use of teleconsultation technology for health care professionals in rural settings could facilitate the adoption of teleconsultation and optimize the use of these tools. Establishing standardized protocols for the integration of teleconsultation into daily care routines could also foster greater efficiency and broader adoption of this technology.

Conclusions

The implementation of nursing teleconsultation in rural CHSLDs with ≤50 beds has shown promising results in terms of improved workflow, interprofessional collaboration, and the quality of resident care. Nurses' and nursing assistants' perceptions revealed tangible benefits such as real-time documentation, increased visual support, and proactive communication. These elements promoted the efficient and safe continuity of care while highlighting the need for adequate support and careful planning to maximize the benefits of this technology.

Their experiences also highlighted challenges such as administrative management, change management, and compliance with documentation rules. Nevertheless, the structured training and clarification of professional roles were widely appreciated, contributing to the successful implementation of teleconsultation without any reported scope creep.

In total, 3 main themes emerged from the data analysis: leadership, collaboration, and impact on residents. Leadership played an important role in clarifying scopes of practice and building nurses' and nursing assistants' confidence. Collaboration was enhanced through synchronous and asynchronous communication, enabling better care coordination. Finally, the predictability of schedules and the involvement of residents' families and loved ones ensured more proactive care management tailored to the residents' needs.

Although teleconsultation cannot entirely replace the physical presence of nurses, it has been shown to be a valuable tool to support clinical practice and improve the quality of care in CHSLDs. To optimize the integration of teleconsultation, ongoing development of appropriate support and training strategies is essential while also promoting shared governance and the active involvement of residents' families and loved ones. These measures will help maximize the benefits of this technological innovation and guarantee high-quality resident-centered care.

In short, this study demonstrates that nursing teleconsultation represents a promising technological advance to optimize professional practice and strengthen team collaboration. In light of these findings, it is essential that we carry out in-depth discussions on the future of virtual nursing to better understand and efficiently integrate this practice in long-term care settings.

Acknowledgments

This study design was funded and supported by Ministère de la Santé et des Services sociaux in Quebec, Canada. The authors are most grateful to the health professionals and managers of the Centre intégré de santé et de services sociaux de Chaudière-Appalaches and Centre intégré universitaire de santé et de services sociaux de la Mauricie-et-du-Centre-du-Québec. The authors would like to express their thanks to everyone who participated in interviews and discussions.

Authors' Contributions

VN and MCL conceptualized and designed the study, collected the data, conducted the interviews, performed analysis, and wrote the first draft of the manuscript. All the authors (VN, MCL, and VP) have read, revised, and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Globally, cancer predominates in adults aged older than 60 years, and 70% of older adults have ≥1 chronic condition. Cancer self-management interventions can improve symptom management and confidence, but few interventions target the complex needs of older adults with cancer and multimorbidity. Despite growing evidence of digital health tools in cancer care, there is a paucity of theoretically grounded digital self-management supports for older adults. Many apps for older adults have not been co-designed with older adults to ensure that they are tailored to their specific needs, which would increase usability and uptake.

Objective: We aim to report on the user evaluations of a self- and symptom-management app to support older adults living with cancer and multimorbidity.

Methods: This study used Grey’s self-management framework, a design thinking approach, and involved older adults with lived experiences of cancer to design a medium-fidelity app prototype. Older adults with cancer or caregivers were recruited through community organizations or support groups to participate in co-designing or evaluations of the app. Data from interviews were iteratively integrated into the design process and analyzed using descriptive statistics and thematic analyses.

Results: In total, 15 older adults and 3 caregivers (n=18) participated in this study: 10 participated (8 older adults and 2 caregivers) in the design of the low-fidelity prototype, and 10 evaluated (9 older adults and 1 caregiver) the medium-fidelity prototype (2 older adults participated in both phases). Participants emphasized the importance of tracking functions to make sense of information across physical symptoms and psychosocial aspects; a clear display; and the organization of notes and reminders to communicate with care providers. Participants also emphasized the importance of medication initiation or cessation reminders to mitigate concerns related to polypharmacy.

Conclusions: This app has the potential to support the complex health care needs of older adults with cancer, creating a “home base” for symptom management and support. The findings from this study will position the researchers to conduct feasibility testing and real-world implementation.

Introduction

Cancer morbidity and mortality increase with age for most cancers [1,2]. With the rapidly aging population, the number of older adults (≥65 years) with cancer is estimated to double globally by 2035 [1] and triple in those aged ≥80 years in the next decades [3]. In Canada, 2 in every 5 older adults aged ≥70 years are diagnosed with cancer, accounting for 28.2% of all deaths [4]. Approximately 70% of older adults with cancer have pre-existing illnesses that occur with aging [5]. Having multiple conditions alongside cancer can lower one’s functional and cognitive status, increase the likelihood of treatment complications, and negatively impact health outcomes [1,3,5].

Given the possible deleterious side effects of cancer-related treatments, older adults and their families require self-management support during the cancer care trajectory [6,7]. Self-management refers to the ability to manage treatment effects and psychosocial changes arising as a result of illness [7]. Within the context of cancer, self-management refers to one’s ability to manage the effects of diagnosis and treatment [7]. Self-management encompasses the capacity to manage the symptoms, treatment, physical and psychosocial consequences, and lifestyle changes inherent in living with cancer [6]. Self-management support programs are often tailored to the needs and abilities of patients and their relatives [6] and comprise several core skills and responsibilities, including problem-solving, resource use, partnering with health care providers, decision-making, self-tailoring, and action planning [7]. These core skills help people with cancer and their caregivers to actively manage the illness and treatment effects, thereby reducing the effects on daily functioning and improving health [7]. For those with multimorbidity, there is more to manage, and engaging in self-management may be more challenging. Interventions that support this complexity are needed.

Digital health tools present opportunities for self-management support for older adults and caregivers [8]. A recent study by Leigh and colleagues [9] found that 68% of older adults aged ≥60 years owned and used smartphones and were interested in using mobile health apps to self-manage heart failure conditions. Mobile health apps have features that can address older adults’ needs and expectations, contributing to enhanced cancer self-management [10-12]. Cancer apps designed for older adults have been reported to enable better communication [13], the potential for patient-reported outcome collection [14], and the feasibility of electronic rapid frailty screening [15-17]. If self- and symptom-management support for older adults with cancer is tailored to the usability and capability preferences of older adults, they can optimize the management of cancer symptoms [7,8]. However, a limited number of mobile health interventions target older adults with cancer and other conditions to support self- and symptom management [10].

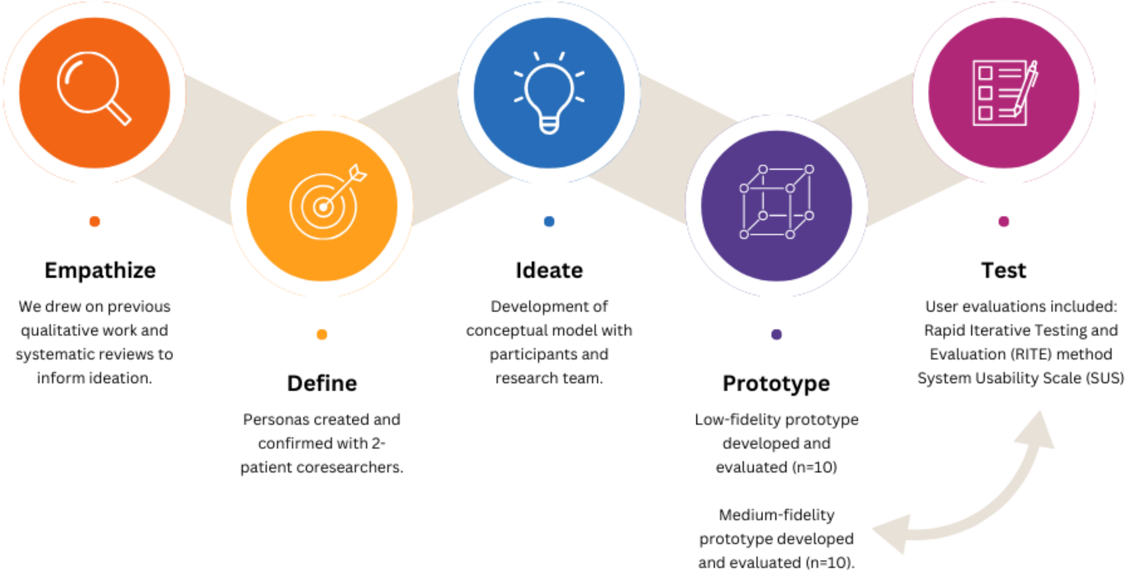
In our prior work with older adults, they described both the complex work of cancer self-management and a dearth of supports to manage the complex interplay of their cancer diagnosis with other illnesses [18,19]. Therefore, the purpose of this study was to address this critical gap, by reporting on the user evaluations of the design of a self-management app to support older adults living with cancer and multimorbidity. In this paper, we report on the process and outcomes of this iterative co-design process.

Methods

Study Design

We used the Design Thinking model [20,21], involving a user-centered approach, with engagement from patient partners as coresearchers. A Design Thinking model involves iterative rounds of developing empathy for users, defining functional and usability requirement priorities, and ideating collective perspectives to produce a final prototype [20]. We gathered participant feedback in multiple waves to ensure that the design was user-validated at every step. Figure 1 shows an overview of our methods.

Figure 1. Overview of methods. Note: empathize, define, ideate, prototype, and test are the 5 stages of design thinking. RITE: Rapid Iterative Testing and Evaluation; SUS: System Usability Scale.



Ethical Considerations

This study underwent ethical review by the harmonized research ethics review board at the University of British Columbia (BREB H21-03052). All participants completed an informed consent process and participated voluntarily. All personal data has been anonymized. All participants were provided an honorarium in the form of a gift card of their choice of $40 per design session.

Recruitment and Participants

Data collection for this study took place between 2021 and 2023 in British Columbia, Canada. We used purposive sampling to recruit older adults with cancer and caregivers. The inclusion criteria for the older adults were aged ≥ 65 years; experiencing or had previously experienced cancer; had received cancer treatment within the previous year; and had at least 1 chronic illness in addition to the cancer diagnosis that required the use of medication or treatment. They also needed to have access and be able to use an internet-connected device, such as a tablet, phone, or laptop. Participants were recruited from community centers, community meetings, support groups, and a registry of patients who had participated in prior research. Caregivers were people who identified as individuals who cared for or supported an older adult during their cancer diagnosis or treatment.

We collected demographic and medical information, health literacy (using the eHealth literacy scale [eHEALS] [22]), and fitness or frailty (using the Vulnerable Elders Survey [23]) scores on all participants, over the telephone, or in person.

We recruited a total of 18 participants comprising 15 older adults and 3 caregivers. In total, 2 older adults participated in evaluating both the low-fidelity and medium-fidelity prototypes to determine whether they perceived any improvements in the design. Thus, a total of 10 participants (8 older adults and 2 caregivers) contributed to the design of the low-fidelity prototype and 10 participants (9 older adults and 1 caregiver) evaluated the medium-fidelity prototype.

Of the 18 participants, 12 (67%) of them were women and 6 (33%) were men. The ages ranged from 40 to 88 years (only age ranges were collected; half [n=9, 50%] of the participants were between 70 and 75 years old). Most were currently married or partnered (n=7, 39%) and college or university educated (n=18, 100%), and they experienced diverse cancers. When asked, they all reported feeling comfortable using the internet.

Defining and Ideating

Using findings from previous work [18] that encapsulated the empathizing stage, we proceeded to define and ideate concepts that could help ground the prototyping phase. We broadly defined this study’s problem statement as supporting older adults’ self-management of their health to improve their quality of life. Using this definition as a prompt, as well as personas to promote empathy with the end users, the research team conducted a brainwriting exercise [24] with the target group to obtain a preliminary understanding of the key tasks that the app should support. A brainwriting exercise is an idea-generation method in human-computer interaction designed to brainstorm and generate what might be a good idea for systems design [24]. From this exercise, we shortlisted tasks that could promote users’ self-management skills according to Grey’s revised self-management theory [25] (Textbox 1). Grey’s revised self-management theory proposes that self-management for both the individual and family should be characterized as interacting with and upon a variety of proximal and distal outcomes [25]. We also highlighted tasks that promoted a more holistic and subjective understanding of users’ health, as those types of tasks could help users think about their quality of life more explicitly.

Textbox 1. Brainwriting outcomes mapped to Grey's self-management theory domains: tasks and subtasks with descriptions.

Make daily health reports

- Report symptoms: a daily report of the user's symptoms, compared to the day before.
- Report events: a daily report of events that can impact the user's symptoms, whether they are physical (taking a walk), emotional (visiting friends), or miscellaneous (weather).
- Report the day: a daily report of the day that can contextualize symptoms and events.
- Report questions and notes: a daily report of any questions or notes they may have for their health care provider.
- Report emoji: a daily report of an emoji that best represents the user's day. Emojis are effective in comprehension and utility when understanding health reports [26].

Learn weekly health trends

- Read brief weekly summaries: a textual summary of the trends of a previous week.
- View visualizations of weekly data: a graphical summary that is equivalent to the textual summary. Informatics have been shown to support holistic wellness by helping older adults with decision-making and identifying trends [27].

Schedule reminders

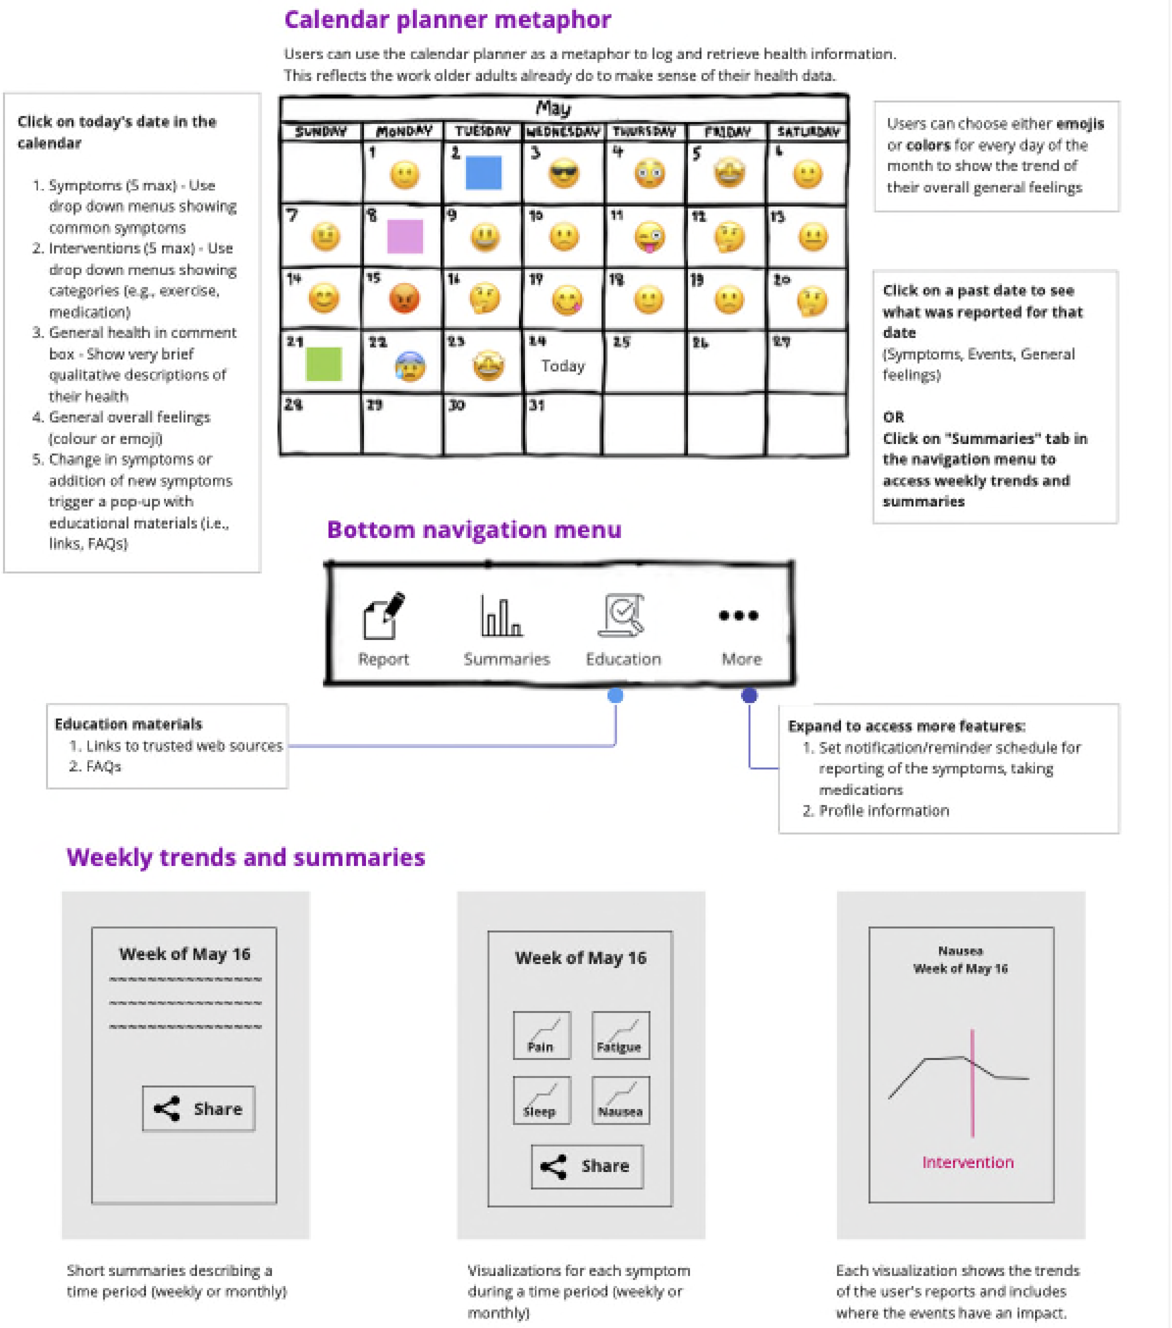
- Schedule reminders to be notified of important times (medications, health care visits, and other events) [28].

Share information

- Email trends and daily reports to health care providers and caregivers, or download them for printing.

Following the brainwriting exercises, we developed a conceptual model [24] to hypothesize, at a high level, how all the tasks should fit together (Figure 2). We leveraged the metaphor of a calendar planner that older adults frequently use to record and keep a journal of their health as a starting point for our model. To validate the usefulness of the model, and to ensure we were on the right track before prototyping, we evaluated the model with 2 participants (P1 and P2) through informal interviews held on Zoom (Zoom Video Communications, Qumu Corporation). As the model was still highly conceptual, their feedback was generally well received, but with the caveat that their positive responses may change once they saw a working prototype.

Figure 2. Conceptual model.



Users can use the calendar planner as a metaphor to log and retrieve health information. This reflects the work older adults already do to make sense of their health data.

Click on today's date in the calendar

1. Symptoms (5 max) - Use drop down menus showing common symptoms
2. Interventions (5 max) - Use drop down menus showing categories (e.g., exercise, medication)
3. General health in comment box - Show very brief qualitative descriptions of their health
4. General overall feelings (colour or emoji)
5. Change in symptoms or addition of new symptoms trigger a pop-up with educational materials (i.e., links, FAQs)

Users can choose either **emojis** or **colors** for every day of the month to show the trend of their overall general feelings

Click on a past date to see what was reported for that date
(Symptoms, Events, General feelings)

OR
Click on "Summaries" tab in the navigation menu to access weekly trends and summaries

Education materials
1. Links to trusted web sources
2. FAQs

Expand to access more features:
1. Set notification/reminder schedule for reporting of the symptoms, taking medications
2. Profile information

Short summaries describing a time period (weekly or monthly)

Visualizations for each symptom during a time period (weekly or monthly)

Each visualization shows the trends of the user's reports and includes where the events have an impact.

Development of Prototypes

We first acquainted ourselves with the basic human-computer interaction recommendations for older adults in interface design: minimal new concepts, plain language, unambiguous icons, accessible user interface, larger font and buttons, and consistent visual cues [29]. We also considered how to split information into smaller and more logical steps for more actionable tasks with less cognitive load [30]. This is especially important, as older adults often require more time to learn new computer skills, make more errors, and (generally) need more assistance than younger people [31,32].

We developed a low-fidelity prototype of a minimum viable product using Axure (Axure Software Solutions) and Sketch (Bohemian Coding Company) as our prototyping tools [33,34].

To rapidly assess where the app could be improved (and because we started this work in 2021 at a time when there were still limitations around social gatherings), we remotely evaluated the prototype on Zoom with 8 different participants. Participants showed how they would complete tasks on a browser and verbalized their thoughts, primarily to validate the usefulness of features and assess their high-level usability. We used the Rapid Iterative Testing and Evaluation (RITE) method, which is effective and efficient in identifying and fixing problems [35]. The main problem we identified was that the low-fidelity prototype needed to give more instructions and use plainer language. We also validated whether the visualizations would be easy to interpret, by having participants evaluate several versions of them to assess understandability: those who described having prior training to read graphs (6/8, 75%) highly preferred the visualizations, whereas the others preferred the textual summaries. This suggested that it would benefit users to implement both versions (text and graphs) in the app. Overall, the prototype was well received by all 8 participants.

Next, we proceeded with the development of the medium-fidelity prototype using Figma (Figma, Inc) as our prototyping tool [36] (Figure S1 in Multimedia Appendix 1). We also adopted the name *Mantra*, which draws on the terms “Managing Cancer” and “Comorbidity in Older Adults.” For the medium-fidelity prototype, we focused on the higher fidelity of both aesthetics and interaction compared to the low-fidelity version. The information architecture was determined by the high-level tasks, with more important task flows (ie, daily reports and weekly summaries) explicitly shown in the bottom navigation. Embedded in these 2 task flows was the ability to support information sharing. Scheduling of reminders was placed in the “More” menu (Figure S2 in Multimedia Appendix 1). The “More” menu shows the extent of design capabilities and contains unimplemented tasks to be considered for future iterations.

The task for making daily reports was designed to flow like a web-based questionnaire, with the subtasks taking up steps 1-5 (Figure S2 in Multimedia Appendix 1, shows a symptom report). To alleviate the burden of making daily reports, each step could be skipped and the system autosaved progress so that the user could continue where they had left off. The task for learning weekly health trends was designed so that the textual summary and the visualization for the same week were on the same page but in different tabs to show that they were equivalent (Figure S2 in Multimedia Appendix 1).

Evaluations

We designed the evaluation study to be conducted both remotely and in person, as in-person evaluation may have been too physically demanding for some participants. However, we do acknowledge that the validity of the evaluation may be compromised, as the remote participants were interacting with the prototype through a browser and not on a smartphone, which has different usability concerns. We recruited 6 older adults for remote evaluations and 4 older adults for in-person evaluations of the medium-fidelity prototype.

We had three goals for the evaluation: (1) to understand whether the participants could complete the tasks (assessed through task completion rates); (2) to understand the usability of the prototype (assessed through the System Usability Scale [SUS] [37]); and (3) to understand how the app could be integrated into participants’ existing health management practices (assessed through qualitative interviews after the evaluation of the prototype; see Multimedia Appendix 2 for sample interview questions). The data collected were both qualitative and quantitative. We audio recorded and transcribed all evaluation interviews, which on average lasted 45 (SD 3.0) minutes. Thematic analysis was completed by one of the lead authors with support from the first and final authors [38,39]. We followed the 6-stage approach, which included familiarization, generating initial codes, and searching for themes. The remaining steps related to the naming and thematic structure were refined through an iterative process with weekly meetings between the 2 first authors and the senior author.

Results

Demographic Characteristics of Participants

In total, 15 older adults and 3 caregivers (n=18) participated in this study: 10 participated (8 older adults and 2 caregivers) in the design of the low-fidelity prototype, and 10 evaluated (9 older adults and 1 caregiver) the medium-fidelity prototype (2 older adults participated in both phases). Participants emphasized the importance of tracking functions to make sense of information across physical symptoms and psychosocial aspects symptoms; a clear display; and the organization of notes and reminders to communicate with care providers. The majority of participants were women (8/10, 80%), lived alone (6/10, 60%), and lived at home (10/10, 100%; see Table 1). Only 1 participant was considered frail according to the Vulnerable Elders Survey–13. Most (8/10, 80%) had adequate eHealth literacy according to the eHEALS (mean scores 30.6, SD 9.0), with scores ranging from 8 to 40.

Table 1. Sociodemographic information for all participants: older adults (n=15) and caregivers (n=3).

Other	13 (72)

[a] Data collected only for older adults, not for caretakers; thus, 15 participants were included.

[b] Participants could select more than 1 option.

[c] COPD: chronic obstructive pulmonary disease.

Task Completion and Usability

In terms of task completion, we found that 90% (9/10) of participants who evaluated the medium-fidelity prototype were able to complete all of the tasks as scored and presented in Multimedia Appendix 3. However, 1 participant (P18) experienced initial difficulty reading the text on the screen and would not have been able to complete the "Report Symptom" feature if not for the hints we provided. Nevertheless, this high completion rate indicates that the app was sufficiently designed for older adults in our target population to accomplish the key tasks.

We also assessed the general usability of the app, by administering the SUS, and found that participants evaluated the system as very usable, with an average of 87 which is described as the "best imaginable" according to Bangor and colleagues [37]. Table 2 shows the individual scores for each participant, broken down by question. Furthermore, according to Sauro and Lewis [40], the scale can be defined by 2 dimensions, that is, learnability (questions 4 and 10) and usability (all other questions). As seen in Table 2, only P18 struggled with learnability while all others perceived the app to be easy to learn. In sum, the high SUS score from the user evaluations, reflecting high user satisfaction and usability, shows that this app has great potential to assist older adults in their self-management activities.

Table 2. System Usability Scale responses[a].

Participant	Q1[b]	Q2	Q3	Q4	Q5	Q6	Q7	Q8	Q9	Q10	Score
P3	5	1	4	1	4	2	5	1	5	1	92.5
P9	5	1	5	1	5	1	5	1	5	1	100
P11	4	2	4	2	4	2	4	1	5	2	80
P12	5	1	5	2	5	1	5	1	4	1	95
P13	4	1	5	1	5	1	4	1	4	2	90
P14	5	1	5	1	4	1	5	1	5	1	97.5
P15	5	1	5	1	4	1	5	1	5	1	97.5
P16	3	2	4	2	4	3	4	2	4	2	70
P17	4	1	3	1	5	1	5	1	5	1	92.5
P18	3	3	4	5	3	2	5	2	4	5	55

[a] Table explanation: there are 10 questions in total, ranging from strongly disagree (1 point) to strongly agree (5 points). The tone of the questions (see Multimedia Appendix 3) switches from positive (odd questions) to negative (even questions). The score for each person is calculated as follows: X = sum of the points for all odd-numbered questions – 5; Y = 25 – sum of the points for all even-numbered questions; individual SUS score = (X + Y) × 2.5. An average score of 85-100 is the best imaginable, while 52-85 is still considered excellent [37]. All participants evaluated the system as having high usability, except P18 who strongly agreed with the need for support from a technical person or additional knowledge to comfortably use the app.

[b] Q: question.

Qualitative Findings

Overview

Based on our thematic analysis, we constructed 3 global themes from the data, related to both the nature of the app and its value in supporting self-management. These themes were organized and labeled as follows: (1) app conceptual model matches users' mental model, (2) value and usefulness for self-management, and (3) confusing icons and buttons. These themes are discussed further below.

App Conceptual Model Matches Users' Mental Model

Overview

In our user testing, participants found the app interfaces easy to navigate with straightforward steps to complete tasks. They also found the text summaries and data visualizations to be visually engaging with clear health-related feedback, which contributed to the ease of use of the app. In light of these user experiences, the following subthemes were constructed from the data, related to the app structure, its usability, and its ease of use: (1) transferability; (2) intuitiveness and ease of navigation; (3) clear data visualization; and (4) simplified and comprehensive summary reports.

Transferability

In our user testing, participants found the app to have a familiar interface, with similar features to other popular health apps that they had used or were using, which reinforced a sense of transferability. For example, 1 participant stated: "I would say that the labels were very clear to me which are similar to some of the apps I've used" (P15). Participants also described the app prompts as predictable with simple steps to complete tasks and found the app's phrases and concepts to be familiar and understandable. Overall, the words and concepts used in the app followed real-world conventions which made the information appear in a logical order for participants. One of the participants said: "It was very predictable and understandable using it the first time" (P12).

Intuitiveness and Ease of Navigation

The app user interface offered a sharp, constant, and uncluttered background, which enhanced readability. Participants felt that the steps and buttons needed to complete the tasks were easy to navigate, which motivated them to use the app. They appreciated the simplicity of the app features which contributed to its intuitiveness. One participant commented: "I think even an elementary student could probably use this app quite easily" (P12). Furthermore, the simple interface and the easy task flow from the home page to completion, shaped user experiences as reflected here: "It was easy to use...the app is simple...but these other apps have a lot and it's always difficult" (P14).

For some participants, the app features felt orderly and streamlined, increasing accessibility even for users with color sensitivity. The legibility and high-contrast colors of the interface alongside the large font size were perceived as being visually engaging and readable. Some participants suggested an adjustable font size should be embedded in the app to allow customization: "Everything looks clear except that the fonts needed to be adjusted big enough. I was straining to see some things" (P9).

Overall, participants found the app easy to use regardless of their level of experience with technology and cancer type. Although older adults reported feeling comfortable using the app; some users required guidance to navigate certain icons on the app. Specifically, the remote participants had more difficulty navigating the prototype if they used a phone remotely than in-person participants. One participant stated: "I had to ask for help to identify icons on the phone" (P11). Another said: "You know, I could go through it [the app] but I needed some help" (P9).

Clear Data Visualization

Participants' most desired accurate unambiguous feedback with simple and clear data visualizations. Participants perceived the clarity and accuracy of the data visualizations as visually appealing, engaging, and readable.

While acknowledging color contrast in the charts and graphs, participants described how texts and labels highlighted important information. Participants reported that they could easily understand the visual elements, facilitating the effective abstraction of actionable insights from the data visuals. For instance, 1 participant stated: "The texts are fine with me...I can understand the data from the graphs" (P11). However, 1 participant highlighted their difficulty understanding the meanings of the different colors included in the charts. As a remedy, they suggested 1 color stream to ensure consistency. They also suggested that emojis should be used in place of graphs since emojis are considered a universal language for most users. Additionally, the text or data presented in the graphs might be difficult to understand and interpret by some non-English users of the app. As presented to participants, the app allowed for only 1 representative emoji per day. However, users suggested combining many emojis that best represent their emotions and feelings for the day. For example, users could combine 2 or more emojis to illustrate their emotions since they could have different experiences within a day—positive, neutral, and negative emotions: "I prefer more emojis, in fact a combination of them...because they tell more story about my emotions" (P9). Participants noted clear data visualization and accuracy of information displayed and affirmed the relevance of having readable and understandable trends of their health data tracked and presented to them in graphs covering either a month or week period.

Simplified and Comprehensive Summary Reports

Participants observed that the clear and comprehensive nature of the health data summaries helped to make connections between day-to-day emotions and changes over time. Some users noted the easy, actionable steps of reporting symptoms and feelings that were directly linked to the feedback. Participants found that displaying multiple types of data on 1 page was more intuitive and comprehensive and helped them make sense of their overall health:

> *Usually, what I see when I look at my blood reports [in leukaemia] is, I click on a report and I see a single trend line [in another app]. Now, with this app, I can see all different types of reports on one page. That's good. It keeps it together. Because I can see that it's helping me make connections of all the data.* [P15]

In comparing this app with other apps, participants noted that this app tends to present an integrated analysis of their health, emotions, and present health state, which made it more interesting to track and review. For example, 1 older adult stated:

> *The Apple Health app was the only one that I have used. And that tends to be reflecting sort of like a simplified quantitative analysis, not qualitative, not including emotions and things. And I think that would be an interesting thing to record and then to review. The correlation between my actual situation of cancer and how I felt about it at the time.* [P15]

Participants appreciated summary reports, although some older adults expressed a preference for monthly summary reports rather than weekly reports. They argued that cancer is a long-term condition that requires a summary of the symptoms over a longer period. Further, 1 participant said: "I would like a monthly report summary...the other apps I do it monthly...I will go over and look at the trend lines over the months. This would fit into that whole world that I'm a part of and have been now since 2015" (P3).

Value and Usefulness for Self-Management

Overview

Participants described how the app was valuable and useful in supporting them to manage their health, in the presence of a cancer diagnosis. Participants felt that the various dimensions of the app could support self-management as captured and explained in the following subthemes: (1) integration into existing self-management routines; (2) app design linked to user personal health needs; (3) recording and sharing of health information; and (4) digital health calendar.

Integration Into Existing Self-Management Routines

Our user testing demonstrated that users were ready and willing to use the app for self-management and felt the app could help them meet their health needs. App features such as the daily symptom report—which required users to report symptoms daily at a time convenient to them—were perceived as a normal daily activity that could easily be done without hassle. Participants found the app's notifications feature a useful way to engage them and remind them to report their feelings, adhere to treatments, and honor appointments with their clinicians. For example, a participant observed that the notifications could easily be synchronized with other daily tasks:

> *I could see myself spending probably half an hour a day inputting information and then reviewing the results. [With another app], every morning, I wake up and check what my sleep score was and what my resting heart rate was. And when my resting heart rate goes up, it tells me that I'm not behaving myself, or stressed. So, it's just kind of a check-in with myself almost to make sure that I'm, you know, kind of following the health path that I want to be on. Again, the reminder notification is great for reporting my emotions.* [P15]

To encourage consistent and continuous engagement of the app in daily self-management, the app was designed to prompt users to input their health report daily.

Participants expressed that reporting their symptoms and interventions daily in the app would not impact other life activities or routines and they never found tracking in the app troubling or burdensome. Further, 1 participant said:

> *For me it would be because I don't have many other obligations. I'm retired. And my wife and I live at home. We don't travel much. Not at all really. So, I mean to us, you know, this is the sort of thing that I do every day. I'm on the computer doing stuff like this* [P11]

However, some participants felt there might be user resistance during the initial stage of the app implementation particularly for those who are not technologically savvy and may also not have a family member to guide them to navigate the app. Further, 1 participant speculated about possible resistance: "I think there's going to be some resistance to adapt for those who are not good at the computer. It's doable, but it's going to be difficult for them" (P3). Overall, participants expressed high intentions of integrating the app into their daily routines for self-management.

Design Linked to User Personal Health Needs

Participants reported that the app design supported their individual health needs—symptom-monitoring, tracking, and self-managing. While the app was perceived to keep users motivated, they also felt it was designed with user needs at the forefront. Further, 1 participant, who had an adult son with autism who needed to track his diet, felt the app could be useful not only in monitoring their own treatment-related symptoms, but also for noncancer patients: "Excellent, this app could align well to my health needs and also probably work well with my son too" (P3). Older adult users could in real time monitor their unique cancer symptoms, track medication adherence, and receive reminders for appointments and other relevant health updates. Further, 1 participant stated:

> *Well, I mean I wanted to set some goals in terms of, you know, trying to fit exercise in, and it was a way for me to challenge myself, I guess, the features that I do use are here [on this app] to receive notifications and track my health.* [P9]

Recording and Sharing of Health Information

Participants reported the value of the app's capability to record and track information for later sharing with their clinicians. This act of keeping track of information in the form of note-taking was perceived as a better alternative to electronically record, share, and communicate users' health issues with their health care providers than other analogue strategies. Further, 1 older adult said:

> *It's a better way to organize notes and trends and see about trends. Just as a communication tool...maybe a better communication tool to use to talk to the different healthcare providers that we communicate with...rather than recording in so many places.* [P13]

Some participants observed that the app features mimic what older adults usually do in keeping track of events by documenting on a piece of paper their daily feelings, thoughts, and other related health issues. Some participants felt that better symptom tracking helped to gain control over symptoms and improve general well-being. Further, 1 participant stated:

> *So what this does is that you know. So, this feature imitates older adults, what they do with their own, like say journal or calendar or anything that they write things on. They keep track of their questions or note what they're feeling.* [P12]

Older adults repeatedly voiced their willingness to use the app because it offered them the ability to share their health information with their clinicians during appointment visits. Most participants felt that clinicians could deliver more tailored care when provided with additional information during consultations.

Digital Health Calendar

All necessary details regarding patients' symptom-tracking reports, treatments, and cancer education, including schedules and reminders or alerts are diarized for future reference.

Participants reported how app features particularly the “reporting” and “summaries” features provide a safe place to store more secure information in the app for reference. Further, 1 participant said:

> *It’s like an electronic diary...a good calendar to write and keep track of notes about their feelings...So you have that instant data that you can look at where you've been and where you're going.* [P14]

In addition to storing information related to a person’s cancer, the app also makes it easier for the user to edit and update information with new tasks and reschedule appointments. According to participants, the app guides users to know their current state of health and to predict their future health by simply referring to the calendar. For instance, 1 older adult stated: “I mean, one of the things you can do is to keep information here [in app]...you can schedule new appointments with your doctor. It's like I could see it having lots of benefits” (P11).

Other participants emphasized the value and usefulness of the app for older adults in keeping their health records. Participants argued that most older adults are forgetful as a consequence of aging, and this app could be a great tool to help them remember their changing health. Further, 1 participant stated:

> *I mean, one of the things is as we age, if your memory is having trouble with remembering things, that probably helps...it would help that because then you could go back and when was I really feeling so bad and you know? That’s great to know.* [P9]

For some participants, this app could also help in tracking different types of treatment and associated side effects, especially for users starting new treatments. Participants also emphasized the value of this tool early in the treatment process, given the capability to track changes over time and remind users of appointments to and schedules. A participant stated:

> *Well, what I do is I have to go through and scroll every appointment. But where this is useful for me is when, especially when I'm starting a new treatment that I've never done before. I want to track the side effects and I want to know what the trigger points are on it...the notification reminders, it’s like a reminder of things that you have to experience. Those kinds of elements that I want to be able to look at and see how that changed over six months.* [P12]

Confusing Icons and Buttons

The last theme relates to opportunities to improve the app based on evaluations. Despite the intuitiveness and ease of navigation of the prototype, some participants found the icons and buttons confusing while others could not understand some features and information displayed. These attributes impeded usability. Further, 1 participant noted:

> *Consider seeking medical care. Is this with my GP? Is this with the oncologist? Do I call for medical care for fatigue? Community health news, what does this button mean? I also wonder what that recommendation is?* [P3]

Another participant expressed their dissatisfaction with not being able to find suitable emojis to express their emotions and asked: “I don't even see happy on the list here. Where can I find happy emoji? It's rather lots of other things here” (P9). While this participant could not find suitable emojis to express their emotions, others too found the buttons too hard to tap causing frustration as they engaged with the app prototype. A participant stated:

> *...because I’m not fluent with how the technology always is depicted. I tend to tap, tap, and click, click, click fast. It’s hard...It draws, but has been crazy and often I freeze something because I’ve tried to make it all go too quickly right and I’ve not given the computer time to catch what I’m doing.* [P13]

Participants also found some icons not matching their current state. For example, participants who are used to seeing a little pencil icon indicating “write something more” were confused when it was rather meant for “edit.” A participant stated:

> *I'm accustomed to seeing...the little pencil with respect to writing something more. So I think I would have assumed I should write something about nausea as opposed to edit my answer...And it’s possible that people don’t realize [it].* [P3]

Discussion

Principal Findings

In this paper, we present the findings of an iterative co-design and evaluation study of a cancer self-management app prototype designed specifically for the needs of older adults living with cancer and multimorbidity. Our key finding was that creating a space for this population to track and interpret data related to their health, in a way that made sense to them, would support their self-management needs. The app we designed built on the concept of the calendar, a routine activity that many older adults already participate in. By drawing on this common routine we developed an app that is both useful and acceptable and was not considered burdensome. This work is novel as it acknowledges the complex health states that this population experiences and aims to address their challenges through an app that was co-designed with them, for them. Our approach was user-centered, with a research team co-led by older adults with cancer experiences and comorbidities.

Limitations

The main limitations of this study relate to the sampling. First, most of the participants were not on active treatment at the time of study participation. Future studies of the app should study usability for those with a new diagnosis using the app for the first time. Second, most participants spoke English, making usability generally easier. Third, all participants were college or university educated. Future studies should include participants with secondary education or lower to gather more broader and diverse perspectives across all levels of education and experience for the design. Finally, many of the participants regularly used technology and smartphones—however, 2 scored low on the eHEALS measure of health literacy. Nevertheless, we observe growing rates of smartphone use among older adults

[41,42] and note that views that older adults do not use technology are ageist and dated. We also acknowledge that the validity of the evaluation may be compromised, as the remote participants were interacting with the prototype through a browser and not on a smartphone, which has different usability concerns. Finally, we only included participants who had their own devices, meaning that they (may) have better technical skills than those who do not own devices, and that may overestimate the usability.

Comparison With Prior Work

This study underscores older adults' interest in proactively managing their own cancer diagnosis and other existing conditions. While older adults' interest in self-management has been reported in other studies [5,43], our study highlights the functionalities that support this work. Given that many older adults are managing distressing symptoms as a result of cancer and its treatments, alongside existing chronic illnesses, the impetus to mobilize self-management supports is critical [44]. Our app in its current state is designed for all older adults with cancer and other illnesses to self-manage their conditions, but it is most useful and valuable for older adults who have just been diagnosed with cancer.

Through our iterative co-design process, several noteworthy features were emphasized by older adults involved in this study. One of the features most valued by participants was the ability to facilitate meaningful connections across all aspects of health. A recent scoping review by Wilson and colleagues [45] found that apps that do not support older adults to make connections across functions were a key barrier to meaningful engagement with apps. The app developed in this study provides direction and guidance on how to report symptoms, events, and daily emotional states and provides an easy display to integrate these various inputs and share insights with health care providers. Unlike existing mobile apps with several views on multiple interfaces [46-48], this app provides a single view of all symptoms, events, and emotions consolidated on 1 page which aims to improve usability, efficiency, and satisfaction among users. The design also allows an effective presentation of daily reports in a comprehensive and easy-to-understand manner. Additionally, the app's design exhibits flexibility, allowing older adults—in collaboration with their health clinicians and caregivers—to prioritize specific symptoms (or variables) of focus. These features are in sharp contrast to existing apps and websites used by older adults to track health information, which often have a narrow scope, concentrating solely on particular cancers or symptoms [27,49-52]. Health apps with narrow scopes may hamper a comprehensive understanding of health and quality of life from a multidimensional perspective [27].

While other studies detail older adults reporting difficulties with limited functionalities and comprehension of visual health data [45,53], participants in this study emphasized a preference for both text and visual summaries to help them make sense of patterns in the data. Older adults also appreciated and valued different modes to view data trends. For example, notes and textual summaries served as an alternative means of conveying information for those who struggled with graphical representations. This has been reported in other studies both within cancer [54] and elsewhere [55]. For example, in a recent pilot randomized controlled trial by Lally and colleagues [54], older adults expressed a preference for information leaflets and text notes to describe the trends of their health. Our study reiterates those findings and also highlights the possibility of text summaries becoming "a voice" for older adults during consultations with their clinicians. Text summaries allow for better and more streamlined conversations with clinicians, thereby promoting shared decision-making [56,57]. It is important to note that the preferences and recommendations of our participants informed revisions of the app features and functionalities in the prototype iterations, and the current state of the app reflects the needs of its potential users. Overall, the app developed in this study represents an acceptable and usable app that is adaptable to the unique needs of older adults with cancer in monitoring changes in their health.

Conclusions

Our self-management app prototype has both content and face validity among older adults with cancer and comorbidities. At this stage, the app requires further refinements and testing to understand its efficacy and to gauge its acceptability and implementation potential within the cancer care system in Canada and beyond.

Abstract

Background: Evidence-based programs (EBPs) for health promotion were developed to reach older adults where they live, work, pray, and play. When the COVID-19 pandemic placed a disproportionate burden on older adults living with chronic conditions and the community-based organizations that support them, these in-person programs shifted to remote delivery. While EBPs have demonstrated effectiveness when delivered in person, less is known about outcomes when delivered remotely.

Objective: This study evaluated changes in remote EBP participants' health and well-being in a national mixed methods outcome evaluation in January 1, 2021, to March 31, 2022.

Methods: We used the RE-AIM (Reach, Effectiveness, Adoption, Implementation, and Maintenance) for equity framework to guide the evaluation. We purposively sampled for diverse remote EBP delivery modes and delivery organizations, staff, and traditionally underserved older adults, including people of color and rural dwellers. We included 5 EBPs for self-management, falls prevention, and physical activity: videoconferencing (Chronic Disease Self-Management Program, Diabetes Self-Management Program, and EnhanceFitness), telephone plus mailed materials (Chronic Pain Self-Management Program), and enhanced self-directed mailed materials (Walk With Ease). Participant and provider data included validated surveys, in-depth interviews, and open-ended survey questions. We used descriptive statistics to characterize the sample and the magnitude of change and paired *t* tests (2-tailed) and the Fisher exact test to test for change in outcomes between enrollment and 6-month follow-up. Thematic analysis was used to identify similarities and differences in outcomes within and across programs. Joint display tables facilitated the integration of quantitative and qualitative findings.

Results: A total of 586 older adults, 198 providers, and 37 organizations providing EBPs participated in the evaluation. Of the 586 older adults, 289 (49.3%) provided follow-up outcome data. The mean age of the EBP participants was 65.4 (SD 12.0) years. Of the 289 EBP participants, 241 (83.4%) were female, 108 (37.3%) were people of color, 113 (39.1%) lived alone, and 99 (34.3%) were experiencing financial hardship. In addition, the participants reported a mean of 2.5 (SD 1.7) chronic conditions. Overall, the remote EBP participants showed statistically significant improvements in health, energy, sleep quality, loneliness, depressive symptoms, and technology anxiety. Qualitatively, participants shared improvements in knowledge, attitudes, and skills for healthier living; reduced their social isolation and loneliness; and gained better access to programs. Three-fourths of the providers (149/198, 75.2%) felt that effectiveness was maintained when switching from in-person to remote delivery.

Conclusions: The findings suggest that participating in remote EBPs can improve health, social, and technological outcomes of interest for older adults and providers, with benefits extending to policy makers. Future policy and practice can better support remote EBP delivery as one model for health promotion, improving access for all older adults.

Introduction

Background

One in 6 adults living in the United States is an older adult (aged ≥60 y). This number is expected to double in the next 40 years [1]. While older adults possess the wisdom of experience and are often actively involved in taking care of themselves, their family members, and their communities, they also face a wide range of unique health challenges that come with aging [2]. A disproportionate number of older adults live with chronic health conditions: 85% have 1 chronic health condition, and 60% report managing at least two [3]. One in 4 older adults reports at least 1 fall every year, and falls remain a leading cause of death and injury among this age group [4]. These health issues—combined with social determinants of health such as older adults' built environment, social context, and access to medical care—put older adults at risk for premature death and poorer quality of life [5]. While only accounting for 17% of the population, older adults make up 35% of health care costs, according to 2019 Medical Expenditure Panel data [6]. Furthermore, 86 cents of every dollar of health care spending goes toward chronic conditions [7,8], and the burden of chronic disease is unevenly borne by women; older adults; people of color; and people living in poverty who experience disparities in access to, and quality of, care [9].

To address these challenges, many health promotion programs have been created based on the Chronic Care Model [10], to improve access and quality of care through community-based programs that teach knowledge, skills, and self-efficacy to enhance older adults' health and well-being in their daily lives. Among these are evidence-based programs (EBPs) that have been researched and recognized by national and federal agencies, such as the Administration for Community Living (ACL) and the Centers for Disease Control and Prevention (CDC) Arthritis Management and Well-Being Program, as being effective in promoting health outcomes through standardized interventions [11,12].

Investigating the Effectiveness of Remote EBPs

Before the COVID-19 pandemic, many of these EBPs were primarily offered in person. This was not possible during the pandemic due to safety guidelines regarding physical distancing. At the same time, there was an increased need for programs because older adults became more isolated and less physically active, and they had less access to an overtaxed medical system [13,14]. Seeing this need, EBPs quickly pivoted to remote delivery by mail, telephone, videoconferencing, or a combination of these modes. While researchers suggest that EBPs will work as intended using different forms as long as core functions are not modified [15,16], it is unknown whether program effectiveness is maintained when switching from in-person to remote delivery. To date, there have been limited studies investigating the effectiveness of remote EBPs that were originally designed to be offered in person [17-21]. As such, we conducted a longitudinal national outcome evaluation of several EBPs to assess changes in older participants' health.

Methods

Framework and Design

We used the RE-AIM (Reach, Effectiveness, Adoption, Implementation, and Maintenance) for equity framework [22] to evaluate the potential impact of remote EBPs on older adults' health and well-being. The equity lens means that in addition to evaluating impact, we looked at outcomes across programs, sampled organizations that reach older adults who are underserved, reported EBP reach, and assessed whether there were any unintended consequences. As such, we used mixed methods to "give voice to participants as well as report statistical trends" [23]. We conducted a multisite single-group pre-post evaluation. Multiple sites were selected to facilitate the generalizability of the findings, and a single-group design was chosen to make it feasible to conduct the evaluation during the COVID-19 pandemic and due to the descriptive nature of this study.

Ethical Considerations

This study was considered exempt from University of Washington Institutional Review Board review because the activities fell under category 2 with regard to quality improvement and program evaluation (STUDY00011549). Participants who completed the preprogram survey were given a US $10 gift card, and participants who completed the follow-up survey were given a US $20 gift card (we provided electronic gift cards unless participants requested a physical card). Providers who completed the survey received a US $10 electronic gift card.

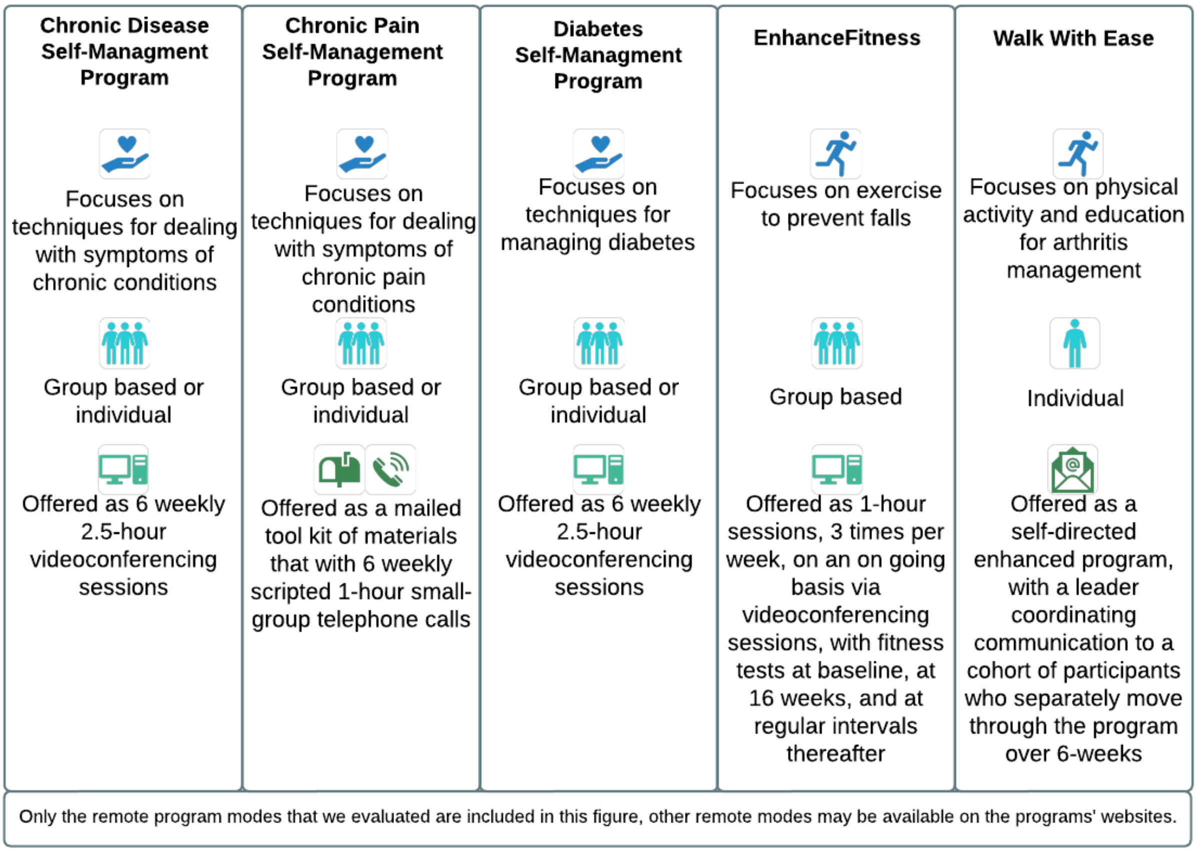
Selected EBPs

EBPs are health promotion programs that have been evaluated and proven to be effective. We included 5 EBPs in our evaluation: Chronic Disease Self-Management Program (CDSMP), Diabetes Self-Management Program (DSMP), EnhanceFitness (EF), Chronic Pain Self-Management (CPSMP), and Walk With Ease (WWE). These EBPs are all currently recognized by the national social services agency for older adults (ACL) and public health agencies (CDC) [11,12]. Before the

COVID-19 pandemic, these programs were offered in person in group formats; they were adapted as follows for remote delivery in response to the COVID-19 pandemic: videoconferencing (CDSMP, DSMP, and EF), telephone plus mailed materials (CPSMP), and self-directed mailed materials plus enhanced support (WWE).

These 5 EBPs were selected because they had sufficient program reach and represented different remote modes (telephone, videoconferencing, mail, or a combination of these modes) and health topics (chronic disease self-management, falls prevention, and physical activity). The adaptation process largely involved planned changes to modify delivery context (eg, smaller class size; adding a cofacilitator to support engagement with, and the usability of, technology; and providing telephone options for people without access to reliable internet or videoconferencing technology) as well as some unplanned changes that occurred organically during field experience in consultation with the program leads (rather than changes to program content) [24]. It should be noted that WWE had created an enhanced self-directed program before the pandemic; we included this program in the evaluation to assess different modes of remote EBP delivery, given partners', policy makers', and older adults' interest in diverse ways to engage in remote health promotion. The enhanced self-directed WWE is delivered via a cohort, with a trained leader providing web-based motivation and support to individual participants during the program period. More information about the included programs is provided below (Figure 1) and on each program's website, including guidance for remote delivery.

Figure 1. Participating remote evidence-based programs.



Chronic Disease Self-Managment Program	Chronic Pain Self-Management Program	Diabetes Self-Managment Program	EnhanceFitness	Walk With Ease
Focuses on techniques for dealing with symptoms of chronic conditions	Focuses on techniques for dealing with symptoms of chronic pain conditions	Focuses on techniques for managing diabetes	Focuses on exercise to prevent falls	Focuses on physical activity and education for arthritis management
Group based or individual	Group based or individual	Group based or individual	Group based	Individual
Offered as 6 weekly 2.5-hour videoconferencing sessions	Offered as a mailed tool kit of materials that with 6 weekly scripted 1-hour small-group telephone calls	Offered as 6 weekly 2.5-hour videoconferencing sessions	Offered as 1-hour sessions, 3 times per week, on an on going basis via videoconferencing sessions, with fitness tests at baseline, at 16 weeks, and at regular intervals thereafter	Offered as a self-directed enhanced program, with a leader coordinating communication to a cohort of participants who separately move through the program over 6-weeks

Only the remote program modes that we evaluated are included in this figure, other remote modes may be available on the programs' websites.

Recruitment

In early 2021, we recruited organizations delivering remote EBPs with a brief web-based interest survey and webinars through several networks: EBP training listserves, the CDC Arthritis Program and ACL grantees, the Evidence-Based Leadership Collaborative, and regional EBP networks. The organizations included social services, public health, and health care agencies that were largely community based, although some were located in clinical settings. We used maximum variation purposive sampling [25] to identify organizations of diverse sizes and types, varied provider characteristics, and from different geographic areas to aid the generalizability of the evaluation findings. This sampling prioritized organizations engaging older populations with low-income status with multiple chronic conditions who are vulnerable to both COVID-19 infection and poor health outcomes and care (eg, people of color, those with disabilities, and those living in rural areas). The eligibility criteria for organizations was the delivery of at least 1 of the 5 remote EBPs from January 2021 through March 2022.

We then used convenience sampling to invite all remote EBP participants to take part in the evaluation. Participant surveys were primarily conducted on the web using REDCap (Research Electronic Data Capture; Vanderbilt University) [26], with options to complete surveys by telephone or by mail.

Participants were surveyed when they enrolled in the program and again 6 months after program enrollment (regardless of when they finished the program). At both time points, a link to the survey was emailed to participants, and they received up to 3 additional reminder emails and 3 reminder calls during the month of survey eligibility. In addition, community-based organizations encouraged baseline survey completion as part of program intake and orientation.

Furthermore, all EBP providers at participating organizations were invited to take part in a 1-time survey eliciting their perspectives regarding the impact of remote EBPs on participants as well as providers. The EBP providers included leaders (people who delivered remote programs directly) and managers (people who coordinated and oversaw program delivery).

Data Collection

Quantitative

The participant outcome survey (Multimedia Appendix 1) combined several brief self-rated health measures that have been validated with older adults: single-item self-rated health [27,28], pain [29], fatigue or energy [30], loneliness (University of California Los Angeles 3-item Loneliness Scale [31]), social isolation (4-item Social Network Index [32]), depression (Patient Health Questionnaire [PHQ]-8 [33]), anxiety (Generalized Anxiety Disorder-2 [34]), physical activity (Exercise Vital Sign [35]), and social needs [36]. These cross-cutting outcomes were selected in partnership with organizations, developers or administrators, and policy makers to identify key outcomes of interest across the health promotion programs.

We also collected several program-specific outcomes [37] related to their health focus: self-efficacy for CDSMP, hypoglycemia for DSMP, and pain and the use of opioid medications for CPSMP. In addition, the preprogram survey included questions about remote EBP participant demographics: age, gender, race, ethnicity, living alone, caregiving, and chronic conditions. Rurality was defined using the participant's zip code and several federal criteria for rural funding [38]. The 6-month follow-up survey included 3 additional quantitative items: two examining the usability of and anxiety about technology using the Senior Technology Acceptance Measure [39] and the other calculating a single-item net promoter score [40,41] to assess acceptability [42].

Provider survey data included multiple-choice questions about demographics, experience delivering EBPs, and the impact of remote EBPs on both participants and providers. Response choices were created from open-ended responses to an earlier Evidence-Based Leadership Collaborative remote EBP web-based survey in 2020 (L, Steinman, personal communication, December 2020).

Qualitative

The 6-month follow-up participant survey included open-ended items about program acceptability and unintended consequences or impacts. Participants who completed the follow-up survey over the telephone were also asked 2 additional qualitative questions about participating in the evaluation. Providers were also asked an open-ended question about any additional benefits for both remote EBP participants and providers.

Data Analysis

Quantitative

Data were managed in REDCap [26] and analyzed using R software (R Foundation for Statistical Computing) [43]. Our primary aim was to evaluate changes in remote EBP participants' health and well-being (self-rated health, fatigue or energy, exercise, pain, sleep, depression, anxiety, loneliness, social isolation, and program-specific outcomes) between program enrollment and 6-month follow-up. Only participants who included both baseline and 6-month follow-up data were included in these analyses. We assessed the magnitude of the changes using descriptive statistics, percentage change, and Cohen *d* effect sizes and tested for statistical significance of the changes using paired *t* tests (2-tailed). Percentage change was reported for both people who improved—or maintained—outcomes between remote EBP enrollment and 6-month follow-up, given the importance of maintaining health in an aging population [44]. Effect sizes were calculated as mean (SD) [45]. We also used descriptive statistics to characterize the sociodemographic characteristics of remote EBP participants and providers. We chose not to use the Bonferroni correction to adjust the *P* values because we carried out tests on multiple outcomes of interest across programs without a priori hypotheses (rather than 1 primary outcome of interest) [46].

Qualitative

Audio-recorded data were transcribed into Microsoft Word documents. These text data from transcripts and open-ended survey questions were analyzed using Dedoose software (SocioCultural Research Consultants, LLC) [47]. For qualitative data, we used thematic analysis [48,49] to understand similarities and differences across and within remote EBP acceptability and benefits or unintended consequences. Two researchers (KC and LS) created a codebook to organize important text for comparison, using deductive codes from the interview guide and inductive codes from an initial read of the transcripts [50]. We conducted 2 rounds of reliability coding, adjusted the codebook codes and definitions as needed, then completed coding using 1 coder. Coded exports were then organized in interpretation memos to summarize possible explanations for what was happening, including a summary of findings, key distinctions and counterexamples, and further points for consideration [51].

Integration

We used joint display tables [52] and compared quantitative and qualitative results to see where the findings converged, diverged, or expanded [23].

Results

Participants

A total of 586 older adults participated in the evaluation over the study period, of whom 289 (49.3%) completed the 6-month follow-up survey (n=25, 8.7% completed the survey over the telephone). The primary reason for noncompletion was our inability to contact the older adults by telephone or email; only 10 (1.7%) of the 586 older adults declined to participate in the follow-up survey after being contacted.

Table 1 shows remote EBP evaluation participant demographics for those who completed both baseline and 6-month follow-up surveys. The mean age of the participants was 65.4 (SD 12.0) years. The majority were female (241/289, 83.4%) and White (184/289, 63.7%). A little more than one-third (108/289, 37.3%) identified as people of color: American Indian or Alaska Native (2/289, 0.7%), Asian (12/289, 4.2%), Black or African American (77/289, 26.6%), and Latinx (17/289, 5.9%). One in 7 (41/289, 14.2%) lived in a rural area, and 1 in 3 (99/289, 34.3%) found it “somewhat hard” or “very hard” to pay for basics such as food and housing. Of the 289 participants, 113 (39.1%) lived alone, and 58 (20.1%) were providing caregiving. The participants reported a mean of 2.5 (SD 1.7) chronic conditions, with the most common being hypertension (145/289, 50.2%), arthritis (131/289, 45.3%), diabetes (130/289, 45%), and mental health conditions (80/289, 27.7%). The prevalence of all chronic conditions is provided in Table 1, including more rare but still impactful conditions such as Crohn disease and ulcerative colitis.

Table 1. Demographics of remote evidence-based program evaluation participants.

Demographics	Total (n=289)	CDSMP[a] (n=69)	CPSMP[b] (n=47)	DSMP[c] (n=118)	EF[d] (n=12)	WWE[e] (n=40)

[a] CDSMP: Chronic Disease Self-Management Program.

[b] CPSMP: Chronic Pain Self-Management Program.

[c] DSMP: Diabetes Self-Management Program.

[d] EF: EnhanceFitness.

[e] WWE: Walk With Ease.

[f] Less than 1% of the participants reported these chronic conditions: HIV or AIDS, Crohn disease, and ulcerative colitis.

Participants who completed the 6-month follow-up survey had similar demographic characteristics and baseline health status as those who completed only the baseline survey, with a few exceptions. A larger proportion of the CDSMP and CPSMP survey completers identified as Black compared to non–survey completers (15/69, 22% vs 13/98, 13%, and 23/47, 49% vs 31/75, 41%, respectively). WWE survey completers were less likely to be living alone (18/40, 45% vs 24/41, 59%). EF survey completers were more likely to be caregivers than not (2/12, 16% vs 0/10, 0%). Finally, across all programs except EF, survey completers were less likely to be living in a rural area than non–survey completers (37/274, 13.5% vs 109/284, 38.4%).

A total of 198 remote EBP providers (n=123, 62.1% leaders; n=75, 37.9% managers) from 107 EBP organizations in 33 states participated in the evaluation. The majority of the leaders identified as female (113/120, 94.2%). Furthermore, 4.3% (5/117) identified as Asian, 12.8% (15/117) as Black or African American, 11.7% (14/120) as Latinx, and 0.9% (1/117) as biracial. One-quarter of the leaders (31/113, 27.4%) lived in rural settings, one-third (36/120, 30%) were caregivers, and one-third (37/123, 30.1%) had ≥2 chronic conditions. One-fourth (30/121, 24.7%) identified as certified health professionals and 43.3% (52/120) as community health workers, promotoras, or other lay health providers. The leaders had a range of experience in EBP delivery: a little more than half (65/123, 52.8%) had delivered both in-person and remote programs before the survey, while 36.6% (45/123) were conducting remote EBPs for the first time. In addition to completing the survey, 26 EBP administrators, managers, and leaders took part in qualitative interviews. Most of the interview participants (22/26, 85%) identified as female and worked at community or government organizations.

Outcomes (Quantitative)

Overview

Outcomes are reported by specific program and across the 5 programs included in our evaluation (Tables 2 and 3; Figure 2; Multimedia Appendix 2).

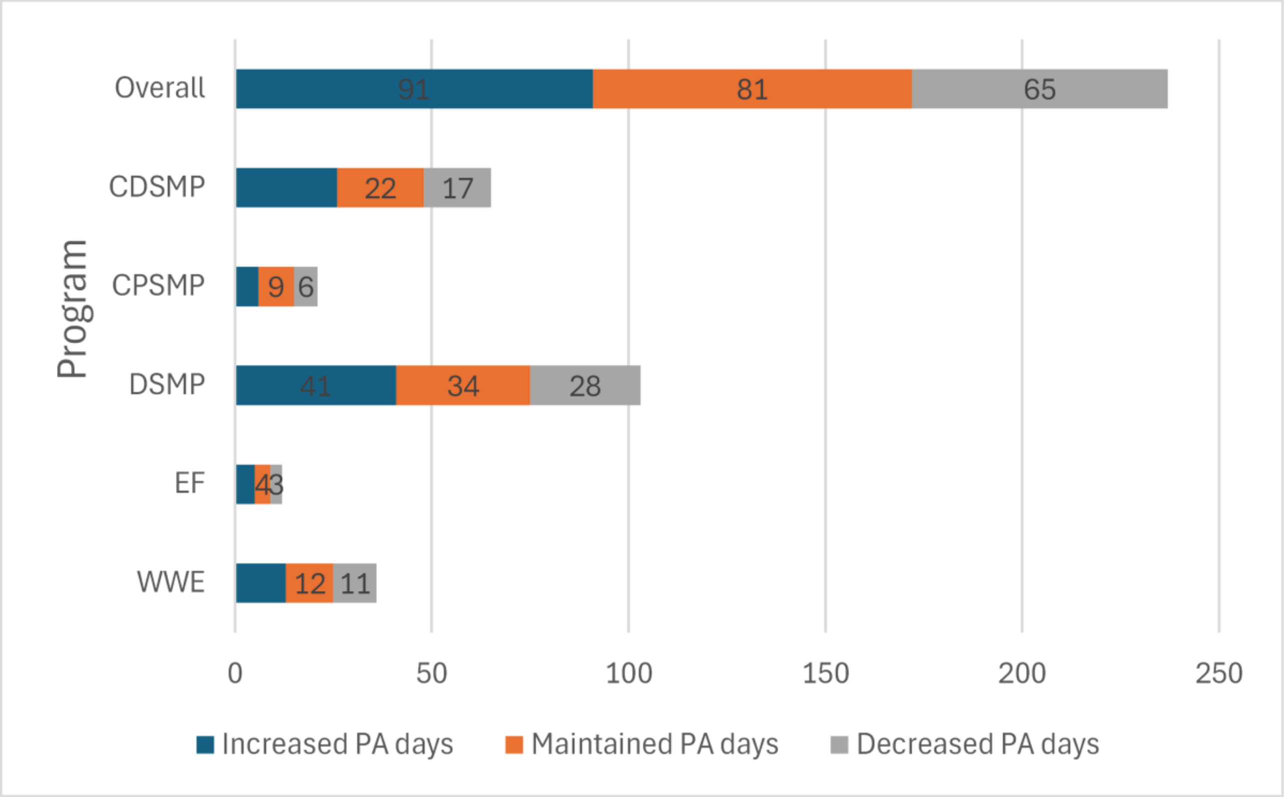
Figure 2. Change in the number of physical activity (PA) days between enrollment and 6-month follow-up for remote evidence-based program outcome evaluation participants. The participants were asked about the number of days on which they were physically active per week at both program enrollment and 6-month follow-up. The completion rates for this question, by program and overall, are as follows: Walk With Ease (WWE)=90% (36/40), EnhanceFitness (EF)=100% (12/12), Diabetes Self-Management Program (DSMP)=87.3% (103/118), Chronic Pain Self-Management Program (CPSMP)=45% (21/47), Chronic Disease Self-Management Program (CDSMP)=94% (65/69), and overall=82% (237/289).



CDSMP Participants

When testing for whether these changes over time were not due to chance, CDSMP participants showed statistically significant improvements in health (mean change 0.32, 95% CI 0.117-0.530; *P*=.003; t_{67}=3.12), energy (fatigue; mean change 0.73, 95% CI 0.061-1.408; *P*=.03; t_{63}=2.18), sleep quality (mean change 0.89, 95% CI 0.216-1.561; *P*=.01; t_{62}=2.64), and self-efficacy (mean change −0.53, 95% CI −0.970 to −0.091; *P*=.02; t_{43}=-2.49). Participants with depression at baseline (19/69, 28%; PHQ-8 score <10) also significantly reduced their depression symptom severity from mean 14.7 (SD 4.2) to mean 11.5 (SD 5.1) on the PHQ-8 (*P*=.03). Overall, 58% (40/69) of the participants improved their self-efficacy over time, with a moderate effect size of 0.38. From program enrollment to 6-month follow-up, 40% (26/65) of the participants showed improvement, and 34% (22/65) of the participants maintained the number of days on which they were physically active.

CPSMP Participants

CPSMP participants significantly improved their energy (fatigue; mean change 1.11, 95% CI 0.248-1.968; *P*=.01; t_{36}=2.61) and pain (mean change 0.97, 95% CI 0.186-1.763; *P*=.02; t_{38}=2.50). Moderate effect sizes were seen for fatigue (−0.42), pain (−0.49), anxiety (−0.36), and pain interference (−0.38). The participants with pain interference at baseline (30/289, 10.4%; PROMIS [Patient-Reported Outcomes Measurement Information System] score >6) also reduced their pain interference from mean 16.9 (SD 6.6) to mean 15.5 (SD 7.3). Only 1 (2.1%) of the 47 participants was taking opioid medications at enrollment. From program enrollment to 6-month follow-up, 29% (6/21) of the participants showed improvement, and 43% (9/21) of the participants maintained the number of days on which they were physically active.

DSMP Participants

DSMP participants demonstrated better health (mean change 0.41, 95% CI 0.259-0.552; *P*<.001; t_{110}=5.48). People with at least 1 hypoglycemia symptom at baseline (70/289, 24.2%) reduced their symptoms from mean 2.4 (SD 1.3) to mean 2.1 (SD 1.7); the effect size was low (−0.06). DSMP participants had a moderate effect size for overall improvement in health (−0.44). Participants with depression at baseline (19/118, 16.1%) also significantly reduced their depression symptom severity from mean 13.9 (SD 3.0) to mean 11.1 (SD 6.5) on the PHQ-8. From program enrollment to 6-month follow-up, 39.8% (41/103) of the participants showed improvement, and 33% (34/103) of the participants maintained the number of days on which they were physically active.

EF Participants

EF participants demonstrated better sleep quality (Fisher exact test: *P*=.001), with a large effect size of −0.66. Participants also showed strong improvements in health (effect size: −0.58) and technology usability (effect size: 0.60). From program enrollment to 6-month follow-up, 42% (5/12) of the participants showed improvement, and 33% (4/12) of the participants maintained the number of days on which they were physically active.

WWE Participants

WWE participants demonstrated better health (mean change 0.25, 95% CI 0.046-0.454; *P*=.02; t_{35}=2.49), with a moderate effect size of −0.35. Participants also had moderate effect sizes for improvements in fatigue (−0.33) and loneliness (−0.30). From program enrollment to 6-month follow-up, 36% (13/36) of the participants showed improvement, and 33% (12/36) of the participants maintained the number of days on which they were physically active.

Across Remote EBPs

Across programs, remote EBP participants showed statistically significant improvements in their health (mean change 0.33, 95% CI 0.235-0.422; *P*<.001; t_{267}=6.92), energy (mean change 0.56, 95% CI 0.264-0.853; *P*<.001; t_{264}=3.73), sleep quality (mean change 0.53, 95% CI 0.245-0.812; *P*<.001; t_{262}=3.67) loneliness (mean change 0.25, 95% CI 0.057-0.437; *P*=.01; t_{242}=2.55), depressive symptoms (mean change 0.60, 95% CI 0.111-1.091; *P*=.02; t_{212}=2.42), and technology anxiety (mean change 0.34, 95% CI 0.010-0.665; *P*=.04; t_{233}=2.03). For people living with clinically significant depressive symptoms (PHQ-8 score ≥10; 24/114, 21.1% of the sample), the overall mean change in the PHQ-8 score from enrollment to 6-month follow-up was 3.025 (95% CI 1.379-4.671; *P*<.001; t_{39}=3.717). People with clinically significant depression at baseline (52/289, 18%) also significantly reduced their depression symptom severity from mean 14.7 (SD 4.2) to mean 11.5 (SD 5.1).

The percentage change is reported in Multimedia Appendix 2. Across programs, 26.7% (66/247) to 49.8% (136/273) of the participants improved health outcomes over time, and 17.4% (41/235) to 53.8% (133/247) of the participants maintained their health. Most effect sizes (Table 3) were small (<0.3), except for change in health over time, which had an effect size of −0.37.

Outcomes (Qualitative)

Participants

Overall, participants shared that they liked and enjoyed participating in the remote EBPs and identified several ways in which the program impacted their lives. First, they reported changes in their knowledge, attitudes, and practices in promoting their health and well-being. Participating in remote EBPs helped older adults manage their chronic conditions, become more active, and feel more confident and better equipped to take care of themselves:

> *I feel as if this program literally changed the trajectory of my life. Prior to it, I was diagnosed as prediabetic and was put on medication, which made me very sick. My next option was a very expensive diabetes drug. But, through following this program, I learned about insulin resistance and what I could do to combat my descent into diabetes. I was encouraged and coached in inspiring ways. I am now barely considered even prediabetic.* [Female DSMP participant #1454; aged 66 years; living with ulcerative colitis]

> *The program helped me understand how exercise can improve my mobility, and it encouraged me to remain active.* [Male WWE participant #1346; aged 63 years; living with arthritis and asthma]

Likewise, the remote EBP participants stated that they learned a lot from the program, including from the materials, leaders, and other participants. This was true across programs: WWE participants learned about new walking spots in their communities from other walkers in their cohort, while self-management program participants learned new ways and tips for managing their condition (expanded their sense of their own options) and broadened their understanding of what life was like at different severity levels of their condition. The group-based formats of the remote EBPs helped provide accountability and motivation and also provided a variety of perspectives and ideas. For some participants, the remote program helped them accept the reality and seriousness of their condition and the changes needed to manage it. In addition, participants believed that others could benefit from the program as well.

The participants also reported social benefits from being part of the programs. Many participants felt less alone, gained a sense of comfort from talking with others struggling with the same conditions, and made friends over the course of the program. A sense of camaraderie was reported often:

> *I liked the interaction with other people, it's helpful to find out how others are going through. To know that there's other people out there with a lot of pain and they're struggling with it, made me feel not alone. Some are worse and some are better. It feels isolating a lot with pain, so that was really nice to experience, seeing others.* [Female CPSMP participant #1344; aged 74 years; living alone and managing multiple chronic conditions]

Furthermore, remote EBP participants from various programs who were grappling with new or existing chronic conditions, changes in mobility and function due to aging, and the challenges of physical distancing during the pandemic, emphasized the value of learning together and feeling less alone. Even participants in the remote WWE program (self-directed tool kit enhanced with a leader virtually supporting a cohort of participants) found social benefits:

> *I did appreciate the opportunity to meet with the group assigned to me and get the encouragement to get out and walking.* [Female WWE participant #1249; aged 65 years; living with arthritis and a mental health condition]

In addition, older adults shared how remote EBPs improved their access to the programs. The remote format made accessing these programs during the pandemic both safe and very convenient, in particular for people living with chronic pain or disabilities. Some participants would not have been able to participate if the programs had only been offered in person. That said, a few participants did not like the remote format and found it more difficult to access. For these participants, the downsides of not being able to meet and connect in person or the challenges with participating via telephone, mail, or videoconferencing outweighed the benefits of participating in class. Examples include issues with the technology itself (eg, poor internet connections that made the videoconferencing software freeze up) and discomfort with using technology (eg, unfamiliarity with navigating Zoom functions or unease using a mobile phone where they cannot see other participants). It should be noted that technology encompasses using a telephone (landline, smartphone, or other mobile phone) in addition to laptop computers, tablet devices, and PCs; dial-up or broadband internet; and videoconferencing platforms such as Zoom and Webex.

Finally, many participants shared that they wanted to take part in the remote EBP again, and some participants shared that they desired more follow-ups after the program ended. For these participants, there was a sense of having missed or forgotten some of what had been taught and wanting to refresh their knowledge. Others felt that they needed the motivation of continued check-ins to keep using what they had learned. In addition, some were not sure how to get their questions answered after the program ended, how to sign up for other programs offered by the organization, or whether they were allowed to take part in the program again. This points to opportunities for future supports and services after remote EBP engagement, such as monthly check-ins via telephone, videoconferencing, or social media to "keep the feelings of motivation and community after the program ends...[to] meet or discuss what folks are doing and what works and encourage each other to keep going" (female DSMP participant #1190; aged 61 years; living with multiple chronic conditions [arthritis, hypertension, diabetes, heart troubles, and a mental health condition]). Post-EBP supports and services could also provide a way to reinforce and deepen knowledge and skills that are learned and practiced during a relatively brief program and offer ways for family, friends, and caregivers to support the maintenance of program gains as well as widen program benefits to other people in the participants' communities.

Providers

Table 4 summarizes provider's perspectives on the impact of remote EBPs. Some of these impacts were expected; for example, 3 in 4 providers (149/198, 75.2%) reported improved health outcomes for older remote EBP participants, and reducing social isolation and loneliness emerged as the most common benefit for both participants and EBP providers (leaders and managers). In addition, half of the providers (102/198, 51.5%) noted that connections to other supports and services were a participant benefit; while this typically occurs during in-person EBP delivery, remote EBP delivery allowed for sharing timely and ever-changing information about testing for COVID-19 infection and recommended safety protocols, as well as referrals to services that may have paused or been shifted due to pandemic-related closures or physical distancing requirements.

Table 4. Perceived benefits of remote evidence-based program (EBP) delivery for participants (from providers' perspectives) and for providers (n=198).

Benefits	Survey data, n (%)		Interview data
	Leaders (n=123)	Managers (n=75)	
Benefits for participants (from providers' perspectives)			
Improved health outcomes	93 (75.6)	56 (74.7)	• Kept participants safe while also allowing them to access the benefits of these programs. • The program was still effective, and the benefit it had on participants could be seen.
Reduced social isolation and loneliness	116 (94.3)	66 (88)	• Enhanced socialization and helped with isolation, which is really needed right now. The bonds formed within the groups are really important. • Clients appreciated getting checked on; many were feeling isolated during the COVID-19 pandemic.
Improved access to technology	52 (42.3)	30 (40)	• By participating in the remote EBP, participants gained access to new or loaner technology.
Improved comfort with using technology	91 (74)	52 (69.3)	• Increased technology literacy and comfort of participants, which encourages them to explore other web-based resources. • Clients felt accomplished to have completed a class that required new technology, such as video-conferencing platforms, without help.
Enhanced access to other supports and services	67 (54.5)	35 (46.6)	• Able to educate older adults in their program about COVID-19 vaccines. • Remote program improved cross-referrals, which is good for holistically addressing health.
Improved access to EBPs	N/A[a]	N/A	• Participants can repeat the program because it is easier to access. • No concerns about driving in bad weather . • Some participants liked the virtual class and want remote options in the future.
Benefits for providers			
Improved health outcomes	58 (47.2)	27 (36)	N/A
Reduced social isolation and loneliness	61 (49.6)	39 (52)	• Able to keep working and connecting with colleagues and participants.
Improved access to technology	34 (27.6)	22 (29.3)	• Gained access to technology via work or family, friends, and neighbors. • For leaders without access, some stopped delivering the program.

[a] N/A: not applicable (either the benefit was not one of the multiple-choice answer choices in the provider survey or did not emerge during the interview data analysis).

Some of the impacts were positive but unintended; for example, providers reported improved comfort using technology as a benefit for remote EBP participants. Increasing the usability of technology and reducing anxiety about technology are not original outcomes that in-person EBPs strived to impact, but in remote EBP delivery, opportunities arose for some participants to become more comfortable using technology (telephone, videoconferencing, or tool kits) for engaging in, and receiving, other supports and services. Comfort using technology was a more prevalent impact than access to technology, which aligns with other findings that access was a challenge even when organizations provided software or hardware [53]. Other unexpected positive impacts from the providers' perspectives include that delivering EBPs remotely allowed them to continue providing the program to older adults throughout the COVID-19 pandemic, reach participants they had not reached before, connect participants to each other, learn how to use technology, and be able to continue working or volunteering during the pandemic.

We also gathered data via surveys and interviews on the unintended negative consequences of delivering EBPs remotely, an important aspect when evaluating the public health impact of these programs with an equity lens. For some leaders, teaching remotely was too difficult or disconnecting due to not being able to see people's nonverbal cues and having to work harder to teach technology, engage people, or address emotional issues such that they felt that "something was lost." Strategies for mitigating this reduced impact included reducing class sizes or duration (for both telephone and videoconferencing sessions) and requiring people attending videoconferencing sessions to have their camera on and having 2 leaders taking part so that one could focus on engagement while one managed technology.

Discussion

Principal Findings

Our evaluation found that remote EBP participants showed improvements on various outcomes from program enrollment to 6-month follow-up, including their self-rated health, energy, sleep quality, loneliness, depressive symptoms, and technology anxiety, within and across programs. Some program participants also reduced their anxiety, pain, pain interference, physical activity and self-efficacy, and enhanced their technology usability. The quantitative findings yielded mainly small effect sizes. This may be due to the heterogeneity of the participants; in particular, participants who did not enter the program as lonely or inactive would have no room to improve over time. The qualitative findings suggest that remote EBP participants improved knowledge, attitudes, and skills on how to live healthier lives; reduced social isolation and loneliness; and gained better access to programs. In addition, providers shared that they too benefited from delivering programs remotely by staying connected, having access to technology, and improving their own health and well-being.

In some cases, the findings support previous research on the effectiveness of the remote EBPs that were part of our evaluation; for example, 1 study of 213 videoconferencing CDSMP participants in rural and remote Ontario, Canada, found similar improvements in self-rated health, energy, and psychological well-being (a measure related to depressive symptoms) 4 months after their last class [54]. Another study of 97 telephone plus tool kit CPSMP participants in Cleveland, Ohio, United States, also reported better pain outcomes immediately after program completion [17]. Furthermore, a study of self-directed WWE participants (n=270) in rural and urban North Carolina, United States, who were living with arthritis found that participants also reduced fatigue at follow-up 1 year after program enrollment [21]. Our findings are also comparable to those of similar health promotion programs, such as increased physical activity and reduced depression for a remote DSMP [55].

In other cases, our findings contrast with those of previous research; for instance, 1 study of remote-delivered EF [20] found that the participants (n=15) decreased their knee pain as measured by the Knee Injury and Osteoarthritis Outcome Score; however, all study participants had symptomatic knee osteoarthritis, and the postprogram outcome was measured directly after active intervention at 12 weeks. It may be that our evaluation participants did not significantly improve pain outcomes due to their less severe baseline pain. In addition, the study of CPSMP participants mentioned previously [17] found statistically significant improvements in sleep and depression; our evaluation participants too improved their sleep quality and reduced their depressive symptom severity, but this change was not statistically significant. Our differing findings may be due to our smaller sample size (47 vs 97), which lowered our power to detect significant change, or a longer follow-up period (6 months vs 6 weeks), during which improvements may have been attenuated.

Furthermore, it should be noted that our outcome evaluation was not designed to compare in-person EBP delivery with remote EBP delivery. We used a common set of outcome measures of interest to older adults, EBP delivery organizations, and policy makers; as such, some of these measures look at similar constructs as the in-person EBP effectiveness studies but use different instruments, and some of these measures that are newly being evaluated (eg, loneliness and depression) were not evaluated in the in-person EBP research studies. In addition, we used a different time period compared to studies that evaluated the effectiveness of in-person EBP delivery: we looked at changes between program enrollment and 6-month follow-up, regardless of program duration, whereas prior effectiveness research looked at pre-post change over time based on program duration [21,56-59]. Our sample sizes were also smaller than those of previous in-person EBP research studies; therefore, the lack of statistical significance may be due to a lack of power to detect change. That said, it may be helpful to contextualize our remote EBP outcome evaluation findings with those from in-person EBP outcome evaluations. Remote CDSMP evaluation participants reported improvements in self-efficacy, health, energy (fatigue), sleep quality, physical activity, and depression, all outcomes that were also reported in previous studies of in-person CDSMP [37,60-62]. Furthermore, remote CDSMP evaluation participants did not show the significant improvements in pain outcomes that were seen in research with in-person program participants. Remote CPSMP evaluation participants reported outcome improvements similar to those of in-person CPSMP participants regarding pain and pain interference [56,63], while our evaluation added evidence for remote CPSMP participant improvements in energy (fatigue), anxiety, and physical activity; these 3 outcomes were not assessed in in-person CPSMP studies. However, remote CPSMP participants did not report significant improvements in self-efficacy, as was reported in previous in-person CPSMP studies. Looking at the DSMP, both remote and in-person delivery participants showed reduced hypoglycemia symptoms, health, and depression [57]. Earlier research with in-person program participants found improved self-efficacy as well, and remote program participants showed improvement in terms of their physical activity days. For EF, both remote and in-person program participants reported improvements in self-rated health as well as physical activity [64,65]. This evaluation adds novel findings on improved sleep quality and the usability of technology for remote program participants. In addition, in-person EF participants have reported reduced depression in other studies [64]. Looking at WWE, both in-person and remote program participants have demonstrated improvements in health, fatigue, and physical activity [21]. Remote WWE participants reduced their loneliness, which was not assessed in previous studies of in-person WWE [21]. Previous research of in-person WWE also found participant improvement in pain and self-efficacy [21].

Although EBPs shifting to remote delivery was necessitated by the pandemic-related lockdown and other restrictions [24], the findings suggest that remote delivery can improve access to quality health promotion programs outside the COVID-19 pandemic context; for example, a caregiver for a person living with dementia can join a physical activity program from home to support their own health while not having to find respite care for their loved one, an older adult living with chronic pain can join a class even if they are experiencing elevated pain levels that would make it hard to leave even their bedroom, and a program leader can deliver the program across a region in Spanish to participants who may not have access to language-specific health promotion. This is similar to other studies of remote EBPs (eg, the value for people living with cancer to be able to participate from a distance despite living with weakened immune systems [66]).

Adapting the format and channels through which an EBP is delivered [67] is considered an appropriate modifiable intervention characteristic to better align with the needs and preferences of participants, as well as organizational and geographic contexts in which a remote option improves program feasibility and sustainability [68]. Implementation science increasingly recognizes the need for adaptations [69] to improve the intervention-context fit (eg, increasing both practical and value fit [70]; increasing EBP feasibility to a given context [71]; and making sure that the EBPs can be delivered for different systems, organizations, providers, and participants than was originally studied [72]), support people living with multiple chronic conditions because comorbidity is the rule rather than the exception [73], and ensure EBP effectiveness by evaluating the intervention in different settings with varying provider and participant attributes [74]. Our complementary process evaluation found that delivering in-person EBPs remotely did not require modifications to core program components [53], suggesting that fidelity to the active ingredients of the program models was maintained. That said, some of the observed lack of improvement in health outcomes by remote EBP participants may be due to failures in implementation (eg, inadequate intervention dose due to technology issues) that negatively impacted program effectiveness [42].

Strengths and Limitations

Our evaluation comes with several strengths. First, we conducted a pragmatic evaluation across the country in partnership with policy makers and delivery organizations so that the findings would have direct implications for improving older adults' health equity. Specifically, we built upon trusting relationships and took time to foster new relationships to engage people most impacted by implementing remote EBPs; we also gathered qualitative data to put quantitative outcomes in context for future quality improvement [75]. Second, we included multiple brief, validated health outcomes across various EBPs and diverse participants and providers, centering outcomes that are important and meaningful to participants, providers, organizations, and policy makers that were not measured in previous studies [76]. These include social factors such as social isolation and loneliness and mental health factors such as depression and anxiety, which lead to premature mortality for older adults [77,78]. While measuring multiple outcomes across heterogeneous populations and programs made it harder to see large effect sizes, it better reflects how organizations work (delivering multiple programs) and how participants view health more holistically rather than as just 1 primary outcome. It may also be that small effect sizes suggest that these programs provided primary or secondary prevention to delay the onset of more impairing symptoms and conditions that was not picked up from our measures or relatively study time frame [79]. Third, collecting qualitative as well as quantitative data from the perspectives of both participants and providers provides consistent measures to compare across studies as well as stories and unanticipated outcomes to explore more broadly in future research.

Looking at limitations, first, using a single-group design with the lack of a comparison group or randomization means that we cannot attribute change in health outcomes over time to participating in the remote EBP. Second, we recognize that the lack of statistical significance when assessing for whether change was due to chance or program participation may be due to small sample sizes that lack power. This is partly why we collected qualitative data from both providers and participants: we wanted to understand the magnitude of change from their perspectives. Third, our response rate was lower than is typical in controlled research studies, with only half of the remote EBP participants (289/586, 49.3%) providing follow-up data. This was due to pandemic-related logistical and methodological challenges faced by our evaluation team, program providers, and older adult participants; conducting an evaluation during the COVID-19 pandemic has been deemed more challenging than conducting evaluations in conflict areas [80]. This suggests limitations to both internal validity through biases such as selection bias (eg, persons who liked the program or had access to a mobile phone or the internet to complete the evaluation were overrepresented) and external validity, with the COVID-19 pandemic being a unique context, because of which our findings may not be generalizable (eg, were improvements in social connection due to the high level of disconnectedness faced by everyone during the pandemic-related lockdown?). Finally, our convenience sample only included group-based programs and as such may not be applicable to one-on-one EBPs. We also did not have access to data on the entire remote EBP delivery population; therefore, we cannot comment on the representativeness of our outcome evaluation sample. Our process evaluation [24] suggests that persons who have been historically underserved by EBPs (eg, people of color, those with disabilities, and those living in rural areas) can be reached through remote delivery; however, care must be taken to ensure that remote delivery does not widen the health inequities caused by the digital divide.

Conclusions

In closing, the findings from this outcome evaluation suggest that participating in remote EBPs can improve health, social, and technology outcomes of interest for older adults, providers, and policy makers (Textbox 1). Future policy and practice can better support remote EBPs, improving access for all older adults (regardless of income, geography, and ability) and strengthening delivery organizations.

Textbox 1. Lessons learned for evidence-based program (EBP) administrators, developers, and implementers.

Key takeaways

- Delivering EBPs remotely (by telephone, videoconferencing, mail, or a combination of these modes) offers a new format for engaging older adults in quality health promotion programming.
- Outcome evaluation findings suggest that remote EBPs are effective at improving health, social, and technology outcomes for older adult participants and providers who deliver the programs, although impacts are not experienced universally across programs or outcomes.
- Interviews and surveys with remote EBP participants and providers suggest that these outcomes can be achieved because remote EBPs are acceptable; increase knowledge, skills, motivation, support, and accountability; connect people to peers and leaders; and support tech access and comfort.
- Include brief, validated pre- and postprogram surveys in your routine program delivery to understand changes in outcomes that matter to your community, organization, and funders. (The surveys may include traditional health outcomes you assessed with in-person EBPs as well as new outcomes, such as social isolation, loneliness, technology anxiety, and technology usability. Our survey measures are cited in this paper and available on request.)
- Gather data on remote EBP participant demographics to understand who is being reached and who is not being reached by remote programs to strategize engagement via other outreach strategies or in-person EBP modes.
- Remote EBP delivery may improve access to health promotion programming for people facing inequitable access to in-person programming; however, caution is needed to ensure that remote delivery does not widen the digital divide; for example, while remote delivery can support rural-dwelling older adults from areas without nearby programs or dependable transportation, the lack of reliable internet in some rural areas may necessitate a telephone or mail remote EBP delivery mode.
- Supports for remote EBPs include orienting participants to using program technology before and during the program and providing ways for program participants to connect after the program ends.

Acknowledgments

The authors thank the remote evidence-based program participants, leaders, and staff who came together during this difficult pandemic to continue health promotion from a distance. Study data were collected and managed using REDCap (Research Electronic Data Capture) tools hosted at the Institute of Translational Health Sciences and supported by the National Center for Advancing Translational Sciences of the National Institutes of Health (UL1 TR002319). This evaluation would not have been possible without generous support from the funders. This project was supported by a cooperative agreement (NU38OT000315) funded to the Society for Public Health Education by the National Center for Chronic Disease Prevention and Health Promotion (Division of Population Health, Arthritis Management and Well-Being Program) of the Centers for Disease Control and Prevention; by the Administration for Community Living (RTI contract 37-312-0214780 to Sound Generations); and by the RRF Foundation for Aging (grant 2020183 to Sound Generations). The contents are solely the responsibility of the authors and do not necessarily represent the official views of the Centers for Disease Control and Prevention, Administration for Community Living, RRF Foundation for Aging, or the Department of Health and Human Services.

Conflicts of Interest

PD and KL work for organizations that administer remote evidence-based programs. All other authors declare no other conflicts of interest.

Abstract

Background: Alzheimer disease and related dementias (ADRD) rank as the sixth leading cause of death in the United States, underlining the importance of accurate ADRD risk prediction. While recent advancements in ADRD risk prediction have primarily relied on imaging analysis, not all patients undergo medical imaging before an ADRD diagnosis. Merging machine learning with claims data can reveal additional risk factors and uncover interconnections among diverse medical codes.

Objective: The study aims to use graph neural networks (GNNs) with claim data for ADRD risk prediction. Addressing the lack of human-interpretable reasons behind these predictions, we introduce an innovative, self-explainable method to evaluate relationship importance and its influence on ADRD risk prediction.

Methods: We used a variationally regularized encoder-decoder GNN (variational GNN [VGNN]) integrated with our proposed relation importance method for estimating ADRD likelihood. This self-explainable method can provide a feature-important explanation in the context of ADRD risk prediction, leveraging relational information within a graph. Three scenarios with 1-year, 2-year, and 3-year prediction windows were created to assess the model's efficiency, respectively. Random forest (RF) and light gradient boost machine (LGBM) were used as baselines. By using this method, we further clarify the key relationships for ADRD risk prediction.

Results: In scenario 1, the VGNN model showed area under the receiver operating characteristic (AUROC) scores of 0.7272 and 0.7480 for the small subset and the matched cohort data set. It outperforms RF and LGBM by 10.6% and 9.1%, respectively, on average. In scenario 2, it achieved AUROC scores of 0.7125 and 0.7281, surpassing the other models by 10.5% and 8.9%, respectively. Similarly, in scenario 3, AUROC scores of 0.7001 and 0.7187 were obtained, exceeding 10.1% and 8.5% than the baseline models, respectively. These results clearly demonstrate the significant superiority of the graph-based approach over the tree-based models (RF and LGBM) in predicting ADRD. Furthermore, the integration of the VGNN model and our relation importance interpretation could provide valuable insight into paired factors that may contribute to or delay ADRD progression.

Conclusions: Using our innovative self-explainable method with claims data enhances ADRD risk prediction and provides insights into the impact of interconnected medical code relationships. This methodology not only enables ADRD risk modeling but also shows potential for other image analysis predictions using claims data.

Introduction

Background

Alzheimer disease and related dementias (ADRD) currently rank as the sixth leading cause of death in the United States [1]. Currently, 47 million people live with ADRD globally [2]. By the year 2050, the prevalence of dementia is expected to triple worldwide [3]. These alarming statistics emphasize the pressing need for accurately predicting ADRD risk, which holds immense significance for several reasons. First, it enables early detection and diagnosis, which can facilitate timely interventions and treatment plans that have the potential to slow down disease progression, improve patient outcomes, and enhance the quality of life for individuals affected by ADRD. Second, it also plays a crucial role in advancing research and drug development. It provides valuable insights into disease progression, risk factors, and potential therapeutic targets. By identifying individuals at high risk of developing ADRD, researchers can conduct targeted studies and clinical trials and explore preventive measures to mitigate the impact of this debilitating disease. Third, early prediction and intervention may help reduce health care costs associated with ADRD. By identifying individuals at risk and providing appropriate care, the burden on the health care system can be lessened. Nevertheless, predicting ADRD risks is an intricate task due to its nature as a long-term chronic disease with multifaceted underlying causes.

In the context of ADRD risk prediction, the conventional approach predominantly involves using machine learning (ML) models with medical imaging data as primary resources to achieve commendable success [4-6]. However, it is important to acknowledge that not all patients undergo routine clinical imaging tests during their regular visits, rendering medical imaging data less accessible for certain individuals. In contrast, claims data provide a more readily available data source for the ML predictors. Hence, the development of a valuable and easily trainable risk prediction tool necessitates the use of existing claims data as the primary input for prediction. This approach not only enhances the model's generalizability but also facilitates its adaptation to other diverse data sources.

In recent years, the emergence of graph-structured data has received significant interest within the realm of deep learning [7-11]. Graphs are composed of nodes and relationships, resulting in the representation and analysis of intricate connections and patterns within the data they encapsulate. They also offer a unique combination of topological structure and individual features, which enables a rich source of information [12,13]. To analyze and model the complex relations of interconnected graph data, graph neural networks (GNNs) have emerged as a powerful tool [14]. Unlike traditional ML models that operate on fixed-dimensional inputs, GNNs operate directly on the graph structure, which allows them to learn the representation of individuals, attributes, and relationships. In the biomedical domain, GNNs have been used for tasks such as protein function prediction, drug discovery, disease classification, and personalized medicine [15-20]. Li et al [21] proposed a multi-channel GNN for predicting drug-target interactions that combines a multi-channel graph convolutional network and graph attention network (GAT). This framework uses a topology graph for contextual representation, a feature graph for semantic representation, and a common representation of drug and protein pairs. It has demonstrated remarkable accuracy in identifying drug-target interactions, achieving an impressive area under the receiver operating characteristic (AUROC) score of 0.9665. Wang et al [22] introduced a deep learning framework, Deep Learning for Drug-Drug Synergy prediction (DeepDDS), for predicting drug-drug interactions for anticancer treatments. DeepDDS uses gene expression data from the cancer cell line and the molecular graph of the drugs as input. It leverages GAT and graph convolution transformers (GCTs) to accurately predict the synergistic effect between drug combinations. DeepDDS has achieved an AUROC score of 0.67 on an independent test set. In the task of ADRD prediction, GCT obtained an area under the precision-recall curve of 0.34 on the inpatient and outpatient electronic health record (EHR) data from NYU Langone Health (briefly called AD-EHR) [23]. Klepl et al [24] integrated functional connectivity methods with GNNs to evaluate ADRD prediction performance using electroencephalography brain data. They showed that the GNN-based approach outperformed convolutional neural network and support vector machine models and obtained an AUROC of 0.984 [24]. Zhu and Razavian [23] presented variational GNN (VGNN), a variationally regularized encoder-decoder GNN, designed specifically for EHRs. This framework showed robustness in learning graph structures by applying regularization techniques to node representations. VGNN was used for ADRD risk prediction, and it attained an area under the precision-recall curve of 0.46 when using AD-EHR.

The abovementioned GNN models [23,24] have demonstrated the potential to uncover hidden patterns, reveal biological insights, and facilitate advancements in ADRD prediction. However, because the GNN architecture is a black-box model, the absence of interpretability is harmful to both users and society [25], especially in critical applications where decisions need to be explained or understood. Even though some advanced models such as GAT, GCT, and VGNN have the ability to explain the importance of individual nodes by using attention mechanisms, they still face a limitation in their interpretability concerning the significance of underlying relationships in the prediction process. As a consequence, there is a pressing demand for research and development efforts to enhance GNNs and elucidate the influence of relationship importance in achieving more precise ADRD predictions. By addressing this interpretability issue, GNNs can become more valuable tools in advancing our understanding of ADRD and contributing to improved patient care and treatment strategies.

Objective

The first focus of this study lies in the domain of risk prediction for ADRD. In this particular context, our investigation aims to use claims data as the sole input for our GNN-based predictive model for accurate ADRD risk prediction. We enhance the predictive power of our model by incorporating advanced GNN models into a framework that enables us to effectively capture the intricate relationships and dependencies inherent in the claims data.

Second, we introduced a novel method to assess the importance of relationships within the patients' individual medical record graphs and their influence on ADRD risk prediction. Generally, an additional graph explanation technique, such as GNNExplainer [26], is used as a post hoc method to interpret the predictions made by the GNNs. However, our proposed relation importance method enables an "in-process" explanation approach that leverages the relation weights from each patient's individual graph. This method facilitates the interpretation of the GNN's predictions during the graph generation process itself. Besides that, our method aims to adequately calibrate the importance of each relationship within the graph, reflecting their true impact on prediction. Since, typically, when a relation connects to nodes that are highly prevalent in the graph, there is a risk of misdefining its significance. The frequent occurrence of these nodes can distort the perception of the relationship's importance, potentially leading to erroneous interpretations or biased conclusions. This bias can result in a skewed importance assigned to relationships, and hence potentially affecting the accuracy of ADRD risk prediction. By considering the patient groups with and without ADRD, our approach helps to mitigate the potential bias resulting from node frequency, enabling a more comprehensive and reliable interpretability of relation importance for ADRD risk prediction.

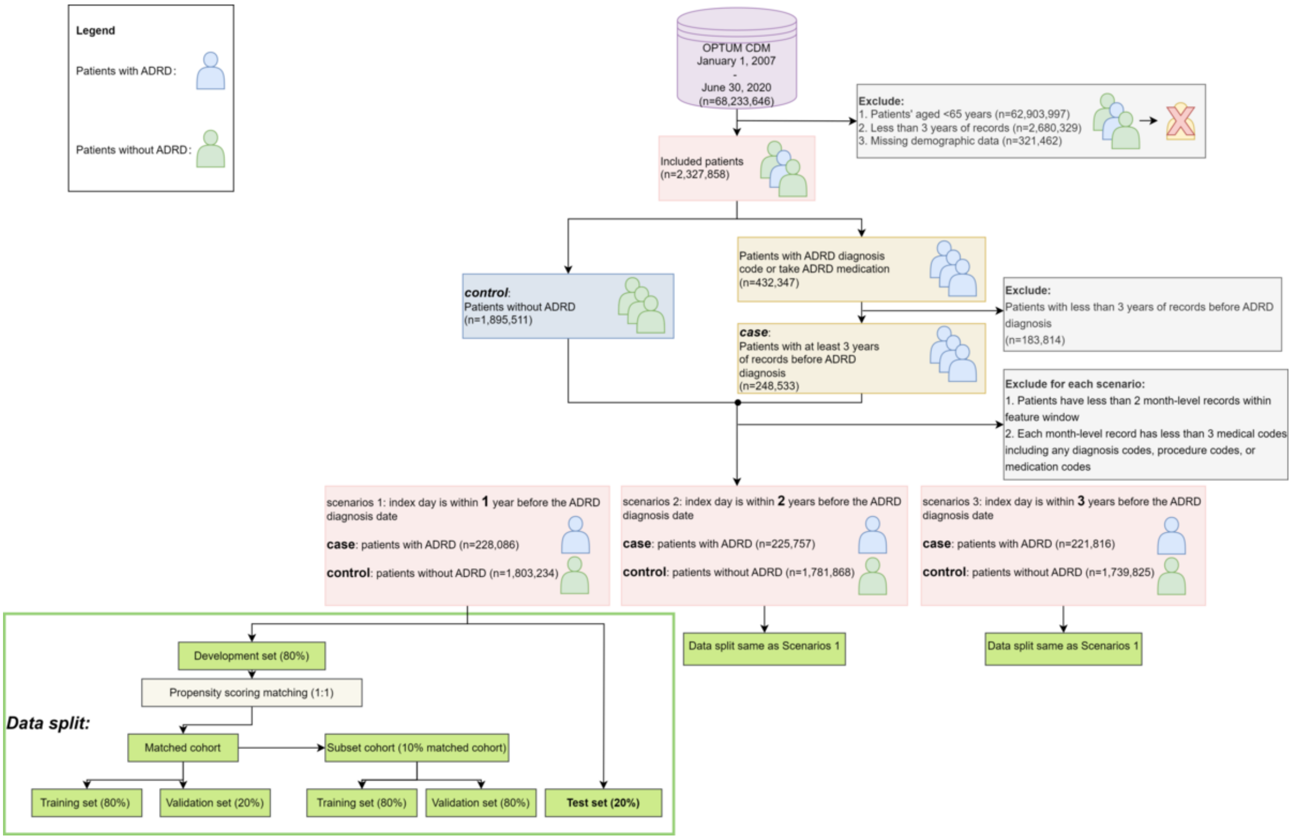
Methods

Cohort Description

We used deidentified administrative health claims data from Optum's Clinformatics Data Mart, spanning from 2007 to 2020. This data set comprises over 68 million patient-level enrollment records submitted by various health care providers, pharmacies, and other health care service organizations for reimbursement purposes. It is accessible for researchers through a subscription provided by the University of Texas Health Science Center (UTHealth) [27].

Several criteria were applied to construct the study cohort, as illustrated in Figure 1. Considering that ADRD primarily affects older individuals and is a chronic condition, we initially filtered out patients (n=62,903,997) who were younger than 65 years. To ensure a sufficient data history for tracking their medical conditions, patients (n=2,680,329) with a time span of less than 3 years between their initial and final medical records were excluded. Patients (n=321,462) who lacked demographic information were also excluded from the study. To further establish the ADRD cohort, we used the definition outlined by Kim et al [28]. Patients were classified as having ADRD if they presented specific diagnosis codes or were prescribed relevant medications. The specified diagnosis codes are Alzheimer dementia (331.0*/G30.*), vascular dementia (290.4*/F01.*), frontotemporal dementia (331.1*/G31.0*), lewy body dementia (331.82*/G31.83), senile dementia (290.0*), presenile dementia (290.1*), other specified senile psychotic (290.8*), and unspecified senile psychotic condition (290.9*), and the medication includes aricept, donepezil, razadyne, reminyl, galantamine, exelon, rivastigmine, namenda, memantine, acetylcholine, and memantine. Based on the criteria mentioned above, the resulting cohort included 432,374 patients with ADRD and 1,895,511 patients without ADRD.

Figure 1. Overview of cohort selection for 3 scenarios. ADRD: Alzheimer disease and related dementias.



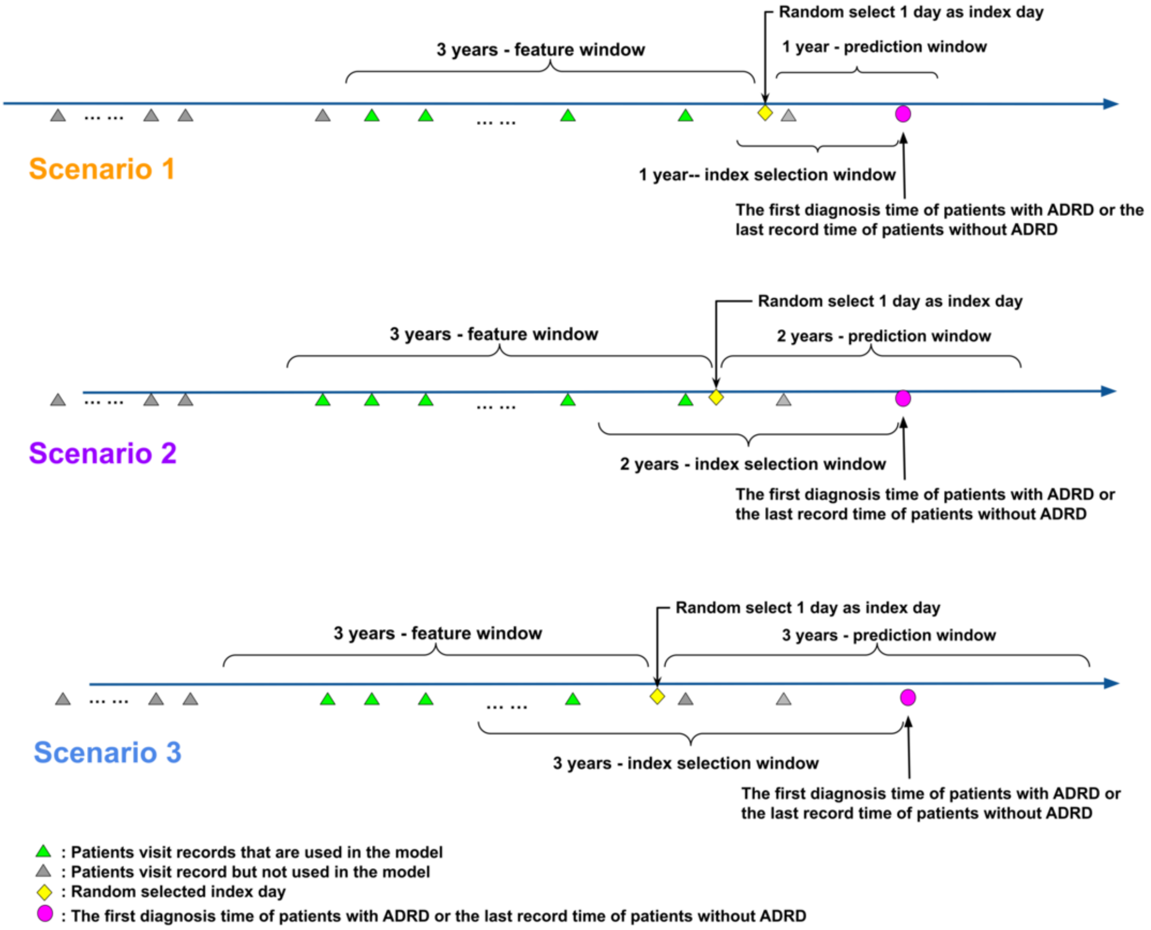
Data Preprocessing

In this study, we used a partitioning approach to categorize each patient's records into 3 time windows, such as an index selection window, a feature window, and a prediction window (shown in Figure 2). First, we designated a specific period before the initial diagnosis of patients with ADRD or the last record for patients without ADRD as the index selection window. In the real world, patients may seek consultations for their health conditions at any time. To simulate this visiting setting, we randomly select the index day within each patient's index selection window instead of using a fixed day. The 3-year period before the index day serves as the feature window for model training purposes, while a certain period after the index day is defined as the "prediction window" for ADRD risk prediction. Additionally, we designed 3 scenarios with index selection windows and prediction windows of 1, 2, and 3 years in length, respectively. By using this partitioning approach, we can comprehensively evaluate our model's predictive accuracy in dynamically predicting ADRD diagnoses. It should be noted that researchers can easily adjust the lengths of these windows to align with their specific requirements and objectives.

There are also other inclusion criteria that were applied to ensure the quality of the data and the fairness of the cohort. Specifically, within the feature window, it was required that each patient have a minimum of 2 month-level records. Furthermore, within the records in the same month, a minimum of 3 medical codes (eg, diagnosis codes, procedure codes, and medication codes) needed to be present. After applying these criteria, the resulting cohort for each scenario is presented in Figure 1. In scenario 1, the cohort consisted of a total of 2,031,320 patients, comprising 228,086 patients with ADRD and 1,803,234 patients without ADRD. For scenario 2, the cohort comprised 2,007,625 patients, including 225,757 patients with ADRD and 1,781,868 patients without ADRD. Finally, in scenario 3, the cohort encompassed 1,961,641 patients, with 221,816 patients with ADRD and 1,739,825 patients without ADRD. These cohorts provide a robust foundation for further analysis and investigation in this study.

The data used in all cohorts included claims data consisting of diagnoses encoded with both International Classification of Diseases, 9th revision (ICD-9) codes and 10th version (ICD-10) codes, the National Drug Code for pharmacy claims, current procedural terminology, and Healthcare Common Procedure Coding System codes for procedures. The inclusion of both ICD-10 and ICD-9 codes was necessary as the study period spanned the transition from ICD-9 to ICD-10 coding systems. All these different types of medical codes have been converted to a higher-level categorization scheme to achieve feature reduction, uniformity, and compatibility within the study analysis. The ICD-9 and ICD-10 codes and the current procedural terminology and Healthcare Common Procedure Coding System codes are converted to clinical classification software, which is a tool for clustering patient diagnoses and procedures into a manageable number of clinically meaningful categories developed at the Agency for Healthcare Research and Quality (formerly known as the Agency for Health Care Policy) [29]. Similarly, we are using the Pharmacologic-Therapeutic Classification System from the American Hospital Formulary Service to represent and group the drug National Drug Code in the data set [30]. It is a method of grouping drugs with similar pharmacologic, therapeutic, and chemical characteristics in a 4-tier hierarchy associated with a numeric code consisting of 2 to 8 digits. By following the conversion of these codes, the number of features was reduced from tens of thousands to hundreds. This reduction not only helps address the issue of sparsity in the model input but also improves its overall efficiency.

Figure 2. The definition of 3 scenarios. We established a time frame that includes an index selection window, a feature window, and a prediction window. The index selection window spanned a specific period before the initial diagnosis of patients with Alzheimer disease and related dementias (ADRD) or the last record for patients without ADRD. We randomly selected a day within the index selection window as the index day to simulate real-world visiting settings. The period up to 3 years before this index day was considered the feature window for training the model, while the period after the index day was used as the prediction window. We used 1 year, 2 years, and 3 years as the lengths of the index selection window and corresponding prediction window, respectively, to predict ADRD diagnosis dynamically.



Modeling

We used the VGNN in combination with patients' diagnosis, procedure, and medication codes to estimate the likelihood of patients having ADRD within a designated prediction window. VGNN consists of 4 modules, such as the encoder graph, variational regularization, decoder graph, and fully connected layer. In the encoder graph module, VGNN takes 3 types of patients' medical codes from the feature window as input and constructs a fully connected graph comprising medical codes for each patient. The representation of each node is iteratively updated through multiple graph attention layers. To address the challenges of generating node embeddings within clusters and achieving balanced attention weights, VGNN incorporates a variational regularization layer. This layer helps prevent model collapse and maintains the model's expressive capacity. The decoder graph module uses the node representations generated by the encoder graph and the variational regularization layer to compute the weighted relations between each node. These weighted relationships effectively capture the relationships among different medical codes. Finally, a linear feed-forward layer is used to calculate the probability and produce the binary classification for identifying an individual with ADRD.

We initiated the modeling process by reserving 20% of patients from the entire data set for testing purposes. Given that ADRD is more prevalent in the older population [1] and our data set exhibits a high imbalance, we used the propensity score matching method based on age and gender to mitigate potential biases associated with these factors. This matching process ensured that our model's input cohort consisted of individuals with similar age and gender distributions, reducing the potential confounding effects associated with these variables. As a result, we created a balanced cohort with a one-to-one ratio of control and case groups from the remaining 80% of the entire data set. This downsampling approach is a popular method in clinical research to create a balanced covariate distribution between treated and untreated groups, which could help significantly improve the model's ability to handle imbalanced data [31]. We named it the matched cohort and used it for the purposes of model development and validation. Additionally, we generated a smaller subset named the subset cohort, which is 10% of the matched cohort. This action allows us to evaluate the model's performance on a smaller-scale data set effectively. In order to assess the efficacy of our approach, we built models for 3 different scenarios. Moreover, we used random forest (RF) and light gradient boost machine (LGBM) as baseline models and compared their performance with that of VGNN. The overall workflow of our model pipeline is shown in Figure 3.

Figure 3. The workflow of sour study pipeline, including data preprocessing, graph modeling, and final output. The DIAG, PROC, and DRUG represent 3 types of medical codes: diagnosis, procedure, and medication, respectively. We used the variationally regularized encoder-decoder graph neural network (VGNN) to predict the likelihood of Alzheimer disease and related dementias (ADRD) using patients' medical records sourced from Optum Clinformatics. The data were input into the encoder layer of VGNN, generating a fully connected graph specific to each patient. The variational regularization layer was then applied to prevent issues like mode collapse and maintain the model's capacity to represent information effectively. Additionally, the decoder graph module used node representations to compute weighted relations between nodes, which effectively captured relationships among different medical codes. Finally, a linear feed-forward layer was used to calculate probabilities and perform binary classification.

	DIAG1	DIAG2	PROC1	PROC2	DRUG1	ADRD(y)
Patient 1	0	1	0	1	0	1
Patient 2	1	0	1	0	1	0
......	......	......	......	......	......	......
Patient n	1	1	1	0	0	1

Relation Importance

After the completion of model training, we then used the trained model to build the interconnected medical record graph for each individual patient. In order to evaluate the significance of various relationships in ADRD prediction, we extracted adjacency matrices . from the medical graphs of N patients in the training set of the matched cohort. The values within these adjacency matrices serve as indicators of the relational importance associated with predicting ADRD. Given that the generated graphs are directional, the adjacency matrices *A* are not symmetric. Therefore, we took an additional step to mitigate the influence of directionality by computing the average of the original adjacency matrix and its transposed matrix. Then, the updated adjacency matrix is:

This adjacency matrix enables us to gain insights into the intricate relationships between medical codes and their predictive power for ADRD.

However, it is crucial to consider that medical codes with higher frequencies may have received relatively larger weights compared to others, potentially introducing bias in the analysis. Given that A^+ are the adjacency matrices of patients with ADRD case group and $A^-$are the adjacency matrices of ADRD patient control group, we calculated the mean adjacency matrix of these 2 patient groups as:

By subtracting the negative mean adjacency matrix from the positive mean adjacency matrix, we eventually obtained a mean weight-difference matrix:

This mean weight-difference matrix *W* captured the relative significance of the medical code weights. A higher positive value inside *W* indicates a greater importance in predicting ADRD, while a lower negative value suggests a reduced likelihood of ADRD occurrence. A value of 0 in *W* means that the relationship does not affect a patient with ADRD.

Ethical Considerations

The approval for the use of data in this study was obtained from the UTHealth Committee for the Protection of Human Subjects, under protocol HSC-SBMI-21-0965, with a waiver of consent granted.

Results

Hyperparameter Setting

We trained the VGNN model with the following hyperparameters: a learning rate of 0.0001, a batch size of 128, and a dropout rate of 0.1. We used the Adam optimizer for gradient descent and trained the model for 200 epochs. The model consisted of 2 graph layers and 1 attention head. To balance the binary cross-entropy and Kullback-Leibler divergence losses, a parameter value of 0.002 was used. Additionally, edge information was extracted after the attention layer to facilitate future calculations of relational importance. Additionally, we used the grid search method to tune the RF and LGBM baseline models. The hyperparameters for RF and

LGBM are n_estimators=100, min_samples_split=2, and min_samples_leaf=1, and n_estimators=300, boosting_type="gbdt," num_leaves=31, and learning_rate=0.1, respectively.

Performance Evaluation

We used AUROC as a measurement to evaluate the performance of each model. As shown in Table 1, the VGNN model achieved AUROC scores of 0.7272 and 0.7480 for the subset cohort and the matched cohort, respectively, in scenario 1. It outperformed the RF and LGBM models by an average of 10.6% and 9.1% across the 2 data sets. For scenario 2, the VGNN model obtained AUROC scores of 0.7125 and 0.7281 for the subset cohort and matched cohort, respectively. It exhibited superior performance compared to the other 2 models by an average of 10.5% and 8.9% across the 2 data sets. Finally, in scenario 3, the VGNN model achieved AUROC scores of 0.7001 and 0.7187, which were surpassed by an average of 10.1% and 8.5% across the 2 data sets. The results clearly demonstrate that the GNN approach (VGNN) outperforms the tree-based models (RF and LGBM) significantly in predicting ADRD. The bar chart for the performance comparison can be found in Multimedia Appendix 1.

Furthermore, we identified the 5 most important relationships for both positive and negative predictions of ADRD in Table 2. Among the top 5 negative highest-weighted relationships, "neoplasms of unspecified nature or uncertain behavior" exhibits its influence across all relations within scenario 1, "consultation, evaluation, and preventative care" makes a total of 4 appearances within scenario 2, while "quinolone antibiotics" spans all relations in scenario 3. Within the set of the top 5 positive highest-weighted relationships, both "routine chest x-ray" and "electrocardiogram" appear 3 times each in scenario 1, "substance-related disorders" contributes to 4 relationships in scenario 2, and "substance-related disorders" emerges as the most frequently occurring medical code in scenario 3.

Table 1. The model performance (area under the receiver operating characteristic curve scores) for Alzheimer disease and related dementias risk prediction.

Scores	Random forest	Light gradient boost machine	Variational graph neural network
Matched cohort			
Scenario 1	0.6710	0.6809	0.7480
Scenario 2	0.6565	0.6658	0.7281
Scenario 3	0.6468	0.6589	0.7187
Subset cohort			
Scenario 1	0.6629	0.6720	0.7272
Scenario 2	0.6474	0.6570	0.7125
Scenario 3	0.6425	0.6490	0.7001

Table 2. Top 5 positive highest-weighted relations and top 5 negative highest-weighted relations.

Scenarios and relations	Scenario 1		Scenario 2		Scenario 3	
Top 5 negative highest-weighted relations						
1	Neoplasms of unspecified nature or uncertain behavior	Consultation, evaluation, and preventative care	Consultation, evaluation, and preventative care	Dihydropyridines	Quinolone antibiotics	Suture of skin and subcutaneous tissue
2	Neoplasms of unspecified nature or uncertain behavior	Lens and cataract procedures	Consultation, evaluation, and preventative care	Diseases of white blood cells	Quinolone antibiotics	Lens and cataract procedures
3	Neoplasms of unspecified nature or uncertain behavior	Hyperlipidemia	Consultation, evaluation, and preventative care	Upper gastrointestinal endoscopy, biopsy	Quinolone antibiotics	Essential hypertension
4	Neoplasms of unspecified nature or uncertain behavior	Diabetes mellitus with complications	Consultation, evaluation, and preventative care	Other CT scan	Quinolone antibiotics	Diagnostic ultrasound of head and neck
5	Neoplasms of unspecified nature or uncertain behavior	Diagnostic ultrasound of head and neck	Diseases of white blood cells	Dihydropyridines	Quinolone antibiotics	Psychological and psychiatric evaluation and therapy
Top 5 positive highest-weighted relations						
1	Routine chest x-ray	Electrocardiogram	Substance-related disorders	Electrocardiogram	Schizophrenia and other psychotic disorder	Substance-related disorders
2	Routine chest x-ray	Other laboratory	Substance-related disorders	Other laboratory	Schizophrenia and other psychotic disorder	Diagnostic procedures on nose, mouth, and pharynx
3	Routine chest x-ray	Heart valve disorders	Substance-related disorders	Routine chest x-ray	Diagnostic ultrasound of head and neck	Arthrocentesis
4	Electrocardiogram	Other laboratory	Electrocardiogram	Inguinal and femoral hernia repair	Diagnostic ultrasound of head and neck	Substance-related disorders
5	Electrocardiogram	Heart valve disorders	Substance-related disorders	Coronary atherosclerosis and other heart disease	Substance-related disorders	Other diagnostic radiology and related techniques

Discussion

Principal Findings

Based on this study's results, we found that some potential candidates might be relevant to ADRD risk prediction and treatment. Our self-explainable GNN prediction method reveals the underneath connections between medical codes for ADRD risk prediction. Some code pairs have been shown to accelerate ADRD progression, while others exhibit potential to slow down its development. When implementing our relation importance interpretation method, the GNN results are explainable, setting it apart from other deep learning models. Moreover, several code pairs extracted from the GNN align with findings from previous research. Those code pairs that are not proven could offer valuable insights beyond the scope of current studies, opening up avenues for further investigation and enhancing our understanding of ADRD risk prediction. Table 2 shows the top 5 positive highest-weighted relations and the top 5 negative highest-weighted relations. In the following sections, we will present examples of code pairs derived from the GNN model results and highlight their significance based on validated evidence from previous studies.

This study found that certain pairs of medical codes can be associated with a decreased likelihood of an ADRD diagnosis. For instance, the treatment of more acute conditions, such as cancer or neoplasms, may delay the diagnosis of ADRD. We hypothesize that "neoplasms of unspecified nature or uncertain behavior" may be correlated with higher health care use or more frequent physician visits, similar to the code "consultation, evaluation, and preventative care." The cooccurrence of these 2 types of coding could potentially lower the risk of ADRD. Regular health care visits could potentially reduce the risk of ADRD by improving modifiable risk factors and mitigating social isolation in older patients. Lee et al [32] revealed that cataract extraction is linked to a reduced risk of developing dementia among older adults. Cataract extraction has been associated with enhanced engagement in intellectually stimulating activities, such as reading and video consumption, as well as increased physical activity. These changes in lifestyle and cognitive engagement following cataract surgery may contribute to a delay in the onset of ADRD. Consequently, the second node pair involving “neoplasms of unspecified nature or uncertain behavior” and “lens and cataract procedures” also holds relevance and supports the observed association. In scenario 2, Peters et al [33] have indicated that the use of calcium channel blockers, specifically dihydropyridines, is associated with a lower decline in cognitive function compared to other hypertensive treatments. Thus, the presence of the “consultation, evaluation, and preventative care” and “dihydropyridines” nodes pair ranking first in importance is consistent with the reported associations. The most frequently appearing node in scenario 3 is “quinolone antibiotics.” According to the study by Pham et al [34], it is a class of medication commonly prescribed to treat various bacterial infections and is primarily used for its antimicrobial properties [34]. Additionally from a study by Gao et al [35], their review study indicates that the brain inflammation caused by microbial infections may be one of the etiologies of ADRD, and antibiotics as novel treatments may be beneficial for delaying the development of ADRD. Quinolones exhibit a distinct pharmacokinetic profile characterized by a higher cerebrospinal fluid to serum concentration ratio compared to other commonly prescribed antibiotics [36]. This unique attribute may underlie the observed robust negative correlation between quinolone administration and the development of ADRD, distinguishing its potential protective effect from that of other antibiotics. The use of quinolones likely correlates with younger age, as its use in older adults is less frequent due to the increased risk of tendon rupture. However, this is less likely to explain its negative correlation with the onset of ADRD in our age-matched cohorts. So, in other words, it can be hypothesized that “quinolone antibiotics” may potentially exhibit a slowing effect on the progression of ADRD. Combined with the aforementioned node “lens and cataract procedures,” the observed association of this node pair holds validity and is worth further investigation.

This study also found certain medical codes to be positively associated with a higher likelihood of an ADRD diagnosis. This can be explained by the fact that Alzheimer disease, to a certain degree, is a “diagnosis of exclusion.” Procedures like “routine chest x-ray” and “electrocardiogram” are commonly used as initial steps in diagnosing altered mental status, which is often the first sign of ADRD. A chest x-ray is often used to rule out any underlying pneumonia, while an electrocardiogram may be used to rule out arrhythmia [37]. Similarly, “diagnostic ultrasound of head and neck” is commonly done to rule out conditions like carotid artery clot, stenosis, or plaque in the setting of stroke workups. Once patients begin to verify these initial diagnoses of altered mental status, they are more likely to undergo comprehensive and relevant testing to exclude other potential causes of the symptoms, which may potentially lead to a timely determination of ADRD. Several studies have also found that alcohol and drug use could affect mental state and cognitive function [38]. People who abuse intoxicating substances for a considerable period may develop dementia or accelerate the neurological damage associated with Alzheimer [39].

From the modeling aspect, to the best of our knowledge, our approach offers distinct advantages in comparison to previous studies on the early diagnosis of ADRD with or without GNN methods. For instance, Li et al [40] used a gradient boost tree and logistic regression to assess ADRD risk using EHR data from the OneFlorida+ Clinical Research Consortium. They identified significant clinical and social factors through SHAP values; however, these factors were commonly known risk factors. In contrast, our findings unveil potential risk factors and explain the interaction among these factors in ADRD prediction. While VGNN demonstrates good interpretability by showcasing attention weights among features, it fails to explain how these features positively or negatively impact ADRD prediction [23]. On the other hand, our model offers interpretations of potential risk factors and illustrates their influence on outcomes. Furthermore, our proposed self-explainable framework mitigates the potential bias resulting from the prevalence of medical codes. Klepl et al [24] conducted electroencephalography-based ADRD prediction using GNN methods. As medical image data are unavailable for every patient during routine examinations, limitations arise due to the restricted user cases. Furthermore, they only assessed model performance against baseline models without providing any feature interpretation. Conversely, our method enhances interpretability by leveraging more accessible data, thereby promoting broader applicability and understanding in ADRD prediction. Overall, this is the first work that proposes a self-explainable framework, providing a feature-important explanation in the context of ADRD risk prediction leveraging relational information within a graph. Compared with other studies on ADRD risk predictions, our method can directly interpret the relationship’s importance within the training process. It does not require any additional post hoc explanation methods, such as GNNExplainer [26]. In other words, within our framework, it takes no additional time to get an explanation.

In summary, we showed that using the GNN approach for ADRD prediction has better performance compared to baseline models. Moreover, with the incorporation of our relation importance method, the model’s results become explainable, providing valuable insights into the underlying factors contributing to ADRD risk prediction.

Limitations

Our prediction does not incorporate time information into the modeling process. In this study, we aggregated 3 years of records into a single representation and treated them equally without considering their temporal sequence. In the real-world clinical setting, medical events, procedures, or medications obtained at different times should carry different levels of significance. In other words, events occurring closer in time to the prediction window are expected to have a greater impact on the disease prediction. In our future study, we could use a time series model and positional encoding method to establish connections between patients’ multiple visit records for more accurate predictions and provide more valuable insights into ADRD prediction.

On the other hand, it is important to note that certain predicted correlations may not causally assist clinicians in diagnosing ADRD. For instance, initiating tests for early detection of altered mental status might lead patients to identify ADRD through various related tests. Nonetheless, from the clinician's perspective, ordering these test results may not be helpful for early ADRD prediction. In our future work, we could try to exclude these "subjective patient-related factors" and instead focus on investigating more objective risk factors that could potentially influence the prediction of ADRD.

Conclusion

In this study, we used an advanced self-explainable GNN approach and developed a relation importance interpretation method for the ADRD risk prediction task based on claims data sources. The VGNN model's effectiveness was evaluated across 3 distinct scenarios, with comparisons made against RF and LGBM ML models. The model's performance achieved satisfactory results. In addition, we provided the interpretation for the node pairs extracted from the KG, which was generated from the VGNN model. Furthermore, we demonstrated the results' future applicability and explained the important node pairs that align with previous research findings. This work contributes to the advancement of ADRD prediction models and reinforces the importance of interpretable results for informed clinical decision-making and early detection, etc.

Acknowledgments

We thank Luyao Chen and Xiaoqian Jiang for extracting data from Optum's Clinformatics. This research was partially supported by National Institutes of Health grants under award numbers R01AG084236, R01AG083039, RF1AG072799, and R56AG074604.

Authors' Contributions

CT conceived the research project, supervised the research, and critically revised the manuscript. XH, ZS, and YN designed the pipeline and method and implemented the deep learning model of the study and the explanation method. XH, ZS, and YW prepared the manuscript. XH and YD provided the cohort selection, scenario definitions, model workflow, and model performance figures. XH and JF prepared the data. FL and EY provided suggestions on data filtering, index day selection, and model design. YW composed a clinical discussion on the principal findings. All authors proofread the paper, provided valuable suggestions, and have read and approved the final manuscript.

Conflicts of Interest

None declared.

Multimedia Appendix 1

The model performance (area under the receiver operating characteristic scores) for Alzheimer disease and related dementia risk prediction. Matched cohort: employ 1:1 propensity score match for case and control in the original training data (i.e., 80% of full data), to achieve a balanced dataset and train the models, and test the models in the hold-out 20% of full data. Subset cohort: use around 10% of the Matched cohort (i.e., 20,000 for both case and control) to train the models, and test the models in the hold-out 20% of full data.

Abstract

Background: Digital technologies can assist and optimize health care processes. This is increasingly the case in the musculoskeletal health domain, where digital platforms can be used to support the self-management of musculoskeletal conditions, as well as access to services. However, given a large proportion of the population with musculoskeletal conditions are older adults (aged ≥60 years), it is important to consider the acceptability of such platforms within this demographic.

Objective: This study aims to explore participants' opinions and perceptions on the use of digital platforms for supporting the self-management of musculoskeletal conditions within older adult (aged ≥60 years) populations and to gather their opinions on real examples.

Methods: A total of 2 focus groups (focus group 1: 6/15, 40%; focus group 2: 9/15, 60%) were conducted, in which participants answered questions about their thoughts on using digital health platforms to prevent or manage musculoskeletal conditions. Participants were further presented with 2 example scenarios, which were then discussed. Interviews were audio recorded, transcribed, and analyzed thematically. Participants were aged ≥60 years and with or without current musculoskeletal conditions. Prior experience of using smartphone apps or other digital health platforms for musculoskeletal conditions was not required. Focus groups took place virtually using the Teams (Microsoft Corp) platform.

Results: A total of 6 themes were identified across both focus groups: "experiences of digital health platforms," "preference for human contact," "barriers to accessing clinical services," "individual differences and digital literacy," "trust in technology," and "features and benefits of digital health technologies." Each theme is discussed in detail based on the interview responses. The findings revealed that most participants had some existing experience with digital health platforms for preventing or managing musculoskeletal conditions. Overall, there was a lack of trust in and low expectations of quality for digital platforms for musculoskeletal health within this age group. While there was some concern about the use of digital platforms in place of in-person health consultations, several benefits were also identified.

Conclusions: Results highlighted the need for better communication on the benefits of using digital platforms to support the self-management of musculoskeletal conditions, without the platforms replacing the role of the health care professionals. The concerns about which apps are of suitable quality and trustworthiness lead us to recommend raising public awareness around the role of organizations that verify and assess the quality of digital health platforms.

KEYWORDS

musculoskeletal; digital health platform; physiotherapy self-management; digital triaging; phone app; qualitative; focus group; mobile phone

Introduction

Background

Musculoskeletal health conditions are highly prevalent, with chronic conditions such as osteoarthritis affecting an estimated 8.5 million people in the United Kingdom. Moreover, more than half of the adults aged ≥75 have sought treatment for osteoarthritis [1]. Similarly, back pain affects 10 million adults in the United Kingdom and is the top cause of years lived with disability [2]. Physiotherapy services primarily deal with most referrals for musculoskeletal conditions. In the United Kingdom, there is an increasing burden of musculoskeletal conditions [3] and as such increasing pressure on general practitioner (GP) and physiotherapy services. This increasing burden on services has created the opportunity to develop digital health platforms (eg, a computer or remote device that can help patients manage their health remotely, such as a mobile phone app) to support patients with their physiotherapy needs. Since the COVID-19 pandemic, many digital platforms are being used in conjunction with in-person physiotherapy appointments [4]. Such digital platforms have been developed for a range of purposes, including the triaging of patients with musculoskeletal conditions (ie, assessment of patients' severity of symptoms and signposting to appropriate services) as well as the self-management of musculoskeletal conditions (eg, physiotherapy exercises [5]). Digital health platforms for musculoskeletal conditions have also been shown to improve patient outcomes (eg, in terms of reduced pain [6]) and, further, in terms of physiotherapy interventions, allow a more interactive and engaging approach to the traditional instruction leaflet, subsequently leading to better intervention adherence [7].

This Study

A large proportion of patients requiring physiotherapy who are awaiting an appointment are older adults, with age greatly increasing the likelihood of musculoskeletal conditions [8,9]. However, older adults are traditionally considered less confident with technology [10]. A recent focus group study investigated the experiences of older adults using a wide range of diabetes apps. One of the key outcomes from this study highlighted that usability was a major barrier, with participants giving an average System Usability Score [11] across all apps of just 48, equating to the lowest grade category based on the percentile classifications from a wide range of studies [12]. Similarly, an investigation into the use of digital tools in clinical research suggested that older adults are less likely to use digital technology [13]. Therefore, given the increased availability and use of digital platforms for accessing physiotherapy services and supporting the self-management of musculoskeletal conditions, it is important to consider the accessibility and acceptance of such platforms for older adults. This study uses a qualitative approach to gather older adult participants' opinions and perspectives on using technology for managing musculoskeletal conditions. The aims of the study were to (1) identify any prior experience or knowledge of digital tools to support self-management strategies for musculoskeletal problems, (2) gather opinions on the transition from seeing a health professional in person to using more technology-based support, and (3) gather and present opinions on real-world scenarios where digital platforms support access to and provide guidance on physiotherapy. The results give insights into current perceptions on the use of these technologies for managing musculoskeletal conditions in the older adult population, and we provide recommendations on how to ensure such technologies are accepted by and trustworthy to this patient group.

Methods

Participants

Participants were aged ≥60 years. We recruited participants regardless of whether they did or did not have any current musculoskeletal conditions. Similarly, we did not require participants to have any prior experience of using smartphone apps or other digital health platforms for managing musculoskeletal conditions or accessing services. This allowed us to gain a more generalized, unbiased view of using digital health technology for supporting musculoskeletal health. Participants were, however, encouraged to share their prior experiences of using technology (if appropriate).

Recruitment

The focus groups formed part of a wider study that included a trial investigating the feasibility of using smartphone sensors to objectively measure physiotherapy-related functional tests [14]. Some participants took part in both this focus group study and the trial.

The research team used a strategy to recruit from a wide range of community organizations and venues. These included community centers; local charity groups; libraries; supported living accommodations; and religious centers, such as churches and mosques. A total of 21 local organizations were contacted using the research team's professional networks along with the networks of the West Midlands Clinical Research Network [15]. Paper and digital format flyers were distributed in these locations through relevant contacts at each organization or via an in-person visit by a member of the research team.

Participants were able to register their interest by providing their name and contact details (email address or postal address) via (1) a web-based form, (2) email, or (3) a telephone voice message, details of which were provided on the flyer. The participant information leaflet and consent form were then sent to those who registered their interest (via either email or post).

Following their registration of interest, a research team member contacted each individual, offering 1 of 2 potential dates on which the focus groups were to be held. Participants registering interest in the later stages, when participation in the first focus group was not practical, were offered only the second date. Consent to participate was acknowledged via email before the focus group date (see *Procedure* section).

Ethical Considerations

This study involved human participants and was approved by the University of Warwick’s Biomedical and Scientific Research Ethics Committee (147/20-21). All participants gave informed consent, by signing a consent form after reading information about the study prior. Participants were able to withdraw from the study along with their data at any point up to 5 days after participation. The focus groups were recorded and transcribed using Microsoft Teams built-in tools. Data were pseudonymized such that any identifiable details were removed and participant quotes were identified by their first initial and focus group session. No patients or public were involved in the design, conduct, reporting, or dissemination plans of this research. All participants who attended the focus group received a £20 (US $26) gift voucher for their participation.

Procedure

A total of 2 focus groups were conducted virtually using Microsoft Teams (Microsoft Corp; on August 9 and 29, 2023). This method was chosen to remove the need for the participants, recruited across a relatively wide geographical region, to travel to a specific location for the focus group.

Before the focus group, participants were sent an invite with a clickable Microsoft Teams meeting link. Participants were also sent instructions on how to join the Microsoft Teams meeting, a study information sheet, and a consent form. Participants were instructed to read the information sheet and complete the consent form ahead of the focus group (if participants could not complete the consent form electronically, consent was accepted via email). Participants were also asked to complete a web-based demographic form. The form gathered demographic information, namely age, gender, ethnicity, and self-disclosed musculoskeletal conditions (optional), and consent to receive a £20 (US $26) voucher for participation and provided a summary of the study findings.

Each focus group lasted a total of 1 hour 15 minutes. Both focus groups were recorded and transcribed using the built-in functionality in Microsoft Teams.

Before asking any questions, the facilitator (SC) gave a brief presentation that contained a broad definition of (1) digital health platforms and (2) musculoskeletal conditions (Multimedia Appendix 1). Participants were then initially asked 3 questions covering their experiences of self-managing musculoskeletal conditions, the use of technology to manage musculoskeletal conditions, and their feelings on switching to using more technology in place of a health professional (Multimedia Appendix 1).

The initial questions were followed by participants being presented with 2 different representative scenarios based on the use of digital health apps to support musculoskeletal conditions. These scenarios were used to provide examples of real apps that were currently used in practice. This provided context to participants who were less familiar with the types of digital health apps currently in use. Scenario 1 related to physiotherapy self-referral using a clinician-developed mobile phone app (Figure 1 [16]). Scenario 2 related to support for the self-management of physiotherapy exercises through the use of a mobile phone app (Figure 2). For each scenario, participants were shown a flowchart describing the app scenario and, on a separate slide, a screenshot of each digital health platform. Alongside the flowchart and image, the facilitator described how each digital health platform worked. Participants were then asked 4 questions about each scenario (Multimedia Appendix 1). The scenarios were kept general; however, they were inspired by apps already developed and used by a UK health technology company (EQL Ltd), which was a partner in the wider project. The images used were from EQL’s apps.

Figure 1. Flowchart describing scenario 1: self-referral using a clinician-developed mobile phone app. GP: general practitioner; NHS: National Health Service.

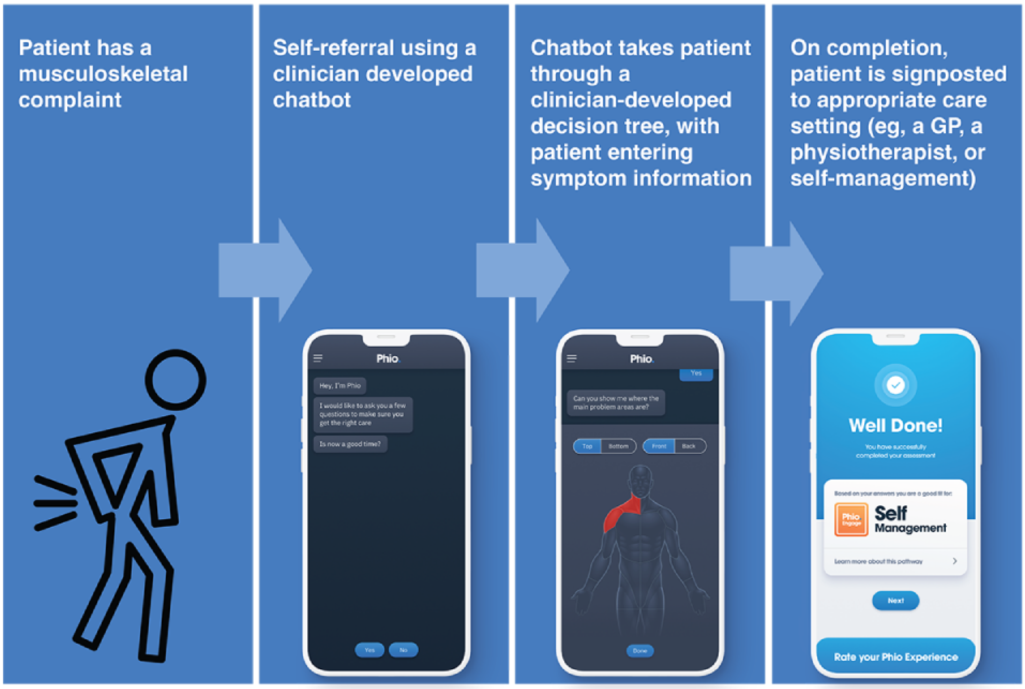

Figure 2. Flowchart describing scenario 2: self-management of physiotherapy exercises using a mobile phone app.

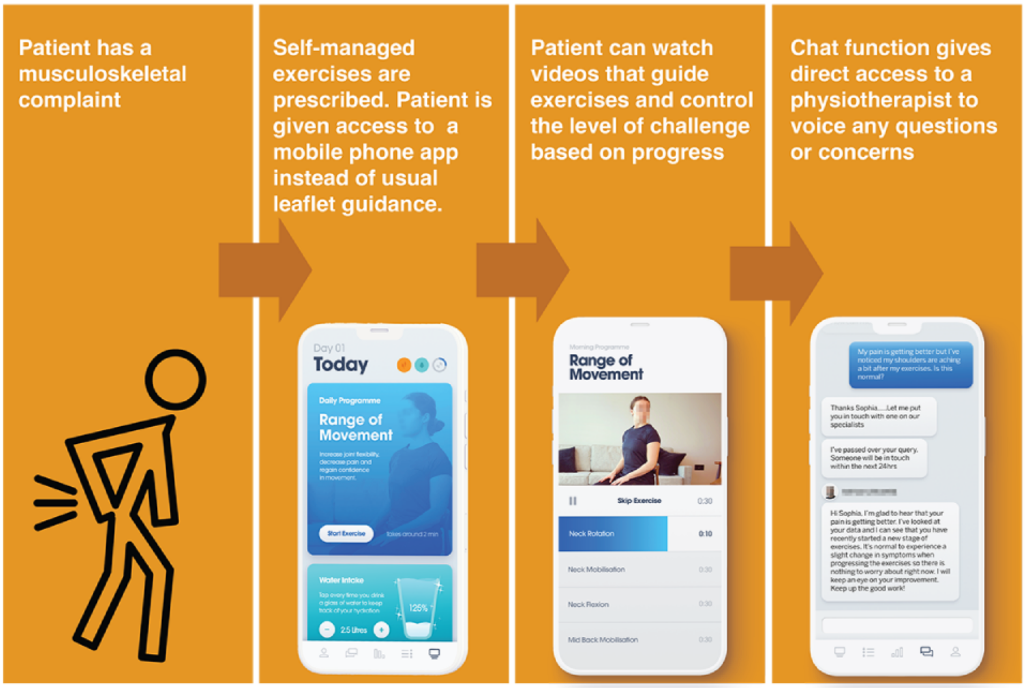

Data Analysis

Transcripts were anonymized and cross-checked for accuracy by the first author (SC) against the recordings. After each interview, the interviewer, SC, summarized key themes to inform the coding framework. Interview transcripts were then uploaded into the NVivo qualitative analysis software (version 12; QSR International). A thematic analysis was performed using an inductive approach, meaning that codes were derived from the data, and in accordance with the 6-stage model developed by Braun and Clarke [17]. To enhance validity, SC and MTE discussed the resulting coding framework, and themes were identified, reviewed, and defined iteratively. Themes and subthemes are presented and demonstrated by representative quotes.

Results

Overview

A total of 15 participants took part in 2 separate focus groups (focus group 1: n=6, 40%; focus group 2: n=9, 60%). During the second focus group, in addition to the 9 participants, a carer acted as a translator for 1 participant. A summary of participant characteristics can be found in Table 1. Of the 15 participants, 12 (80%) reported having current musculoskeletal health conditions; these are listed in Table 2, along with associated *International Statistical Classification of Diseases and Related Health Problems, 10th Revision* codes. A total of 2 (13%) participants had no or did not specifically mention experience of using digital technologies. The remaining participants (n=13, 87%) mentioned they had some experience of using digital technologies relating to musculoskeletal health. In this study, we defined digital technologies relatively broadly and included smartphone apps, smart watches, YouTube (Google LLC), and relevant website content.

Table 1. Participant characteristics (N=15).

Participant characteristic	Values
Age (y), mean (SD; range)	71 (8.4; 61-87)
Gender, n (%)	
Woman	10 (67)
Man	5 (33)
Nonbinary	0 (0)
Ethnic group, n (%)	
Asian or Asian British	2 (13)
Black, African, Caribbean, or Black British	3 (20)
White	10 (67)
Are there any current musculoskeletal conditions? n (%)	
No	3 (20)
Yes	12 (80)

Table 2. Health conditions recorded by participants on the demographic form (N=15). Participants could list multiple conditions, so total entries add up to greater than the number of participants.

Reported musculoskeletal conditions	*ICD-10*[a] mappings	Participants, n (%)
Osteoarthritis	M15.0	4 (27)
Joint pain (hip and knee)	M25.55 and M25.56	2 (13)
Back pain	M54.5 and M54.9	2 (13)
Hypothyroid	E03.9	1 (7)
Peripheral arterial disease	I73.9	1 (7)
Peripheral neuropathy	G62.9	1 (7)
Condition not stated	—[b]	2 (13)
No reported health conditions	—	3 (20)

[a] *ICD-10: International Statistical Classification of Diseases and Related Health Problems, 10th Revision*.

[b] Not applicable.

A total of 6 themes were identified across the transcripts:

- Theme 1: experiences of digital health platforms
- Theme 2: preference for human contact
- Theme 3: barriers to accessing clinical services
- Theme 4: individual differences and digital literacy
- Theme 5: trust in technology
- Theme 6: features and benefits of digital health technologies.

These themes are discussed in detail in the following sections, supported by representative quotes.

Theme 1: Experiences of Digital Health Platforms

Most participants referenced previous or current use of digital technology to help prevent or manage musculoskeletal conditions. Examples provided included smartwatches, completing physiotherapy exercises or exercise classes via YouTube or Zoom (Zoom Video Communications, Inc). They further referenced walking as an activity they engage in to either prevent or manage musculoskeletal conditions. Some participants referenced the use of digital health platforms (eg, smartwatch) while walking to count their number of steps. It appears specific features on smartwatches encouraged users to engage in more movement (eg, step count and prompt to move when sitting for a certain length of time):

> *I try to walk 7000 steps a day, I measure on my wrist. I don't always do it. I used to do 5000, but then I decided that wasn't enough. So I try to do 7000 if I can.* [M, focus group 1]
>
> *I use my smart watch a hell of a lot. Cause' it's an apple one and it has the exercise mode it has the pedometer, it has all that kind of stuff...my watch will tell me when I'm sitting down for too long, so I go and get up and just walk around. So I do utilize the fitness and the health stuff that come with my watch.* [L, focus group 2]

Apps were highlighted as beneficial when participants encountered barriers (eg, bad weather conditions) that prevented them from walking outdoors:

> *I like to go for a walk and I've got rheumatoid arthritis. So I'm sometimes a bit limited, but I have used apps and to do exercise which were appropriate for me and just, well, keep moving or keep moving anyway. But just to keep moving and you know, just to do my best cause sometimes if the weather's not good, you don't feel like going out, do you? So you can do these sort of things indoors, so I found the apps very good.* [N, focus group 1]

Theme 2: Preference for Human Contact

Participants expressed concerns when using a digital health platform for an initial musculoskeletal diagnosis or referral. There were concerns that digital health platforms (scenario 1) might fail to identify the full spectrum of a musculoskeletal condition compared to seeing a health professional in person. One of the participants expressed concerns that a more serious diagnosis might be missed if self-diagnosing via information on the internet. There was a sense that an in-person appointment would also cover the wider well-being of a person (eg, identify signals that someone is experiencing domestic abuse):

> *I mean, if you go online and you start diagnosing yourself...it always ends up to be something else less serious. I couldn't do that not unless the law changed, but not for me.* [S, focus group 2]
>
> *What you can never get from an app is the face to face, because quite often when people go to the doctor with one thing, the doctor looking at them see's something else that they hadn't sometimes realised themselves. In domestic abuse situations, someone can go in regarding something, but the doctor looking at that person can see there's more to this situation than just what she's telling me. So you just can't get that from an app. So this is why I think face to face with always remain a crucial part of the you know, welfare of human being.* [J, focus group 2]
>
> *If I was going to go down the route of asking an app about my symptoms with a chance that it might be self-management, I would have figured out where the self-management things myself first before I would start. If I've got to the stage where I'm asking for help, I want help from a person, not from an app.* [M, focus group 1]

Participants further cited concerns toward carrying out physiotherapy exercises without physical observation or input from an in-person physiotherapist. One of the participants explained how following a hospital appointment, they had been given physiotherapy exercises to complete (the exercises were described on a sheet of paper). They described how they realized they were carrying out the exercises incorrectly only after a family member had observed them:

> *I was given some exercises to do pelvic floor exercises which I must have been doing for about a month or so and thought I was getting on well. And then my midwife daughter said you're not doing those right at all. I'd been given a sheet at the hospital to follow, and I thought I was doing exactly what the sheet said. And she said, mum, what you're doing is useless now. I've been doing that for four or five weeks. There are things that you can benefit, but I didn't know I wasn't doing the exercises correctly, so I presume thousands of other people in the country who have walked away from hospital with a sheet of paper, get home and think they're doing them properly and they're not. But I don't know how to overcome that because it was only my daughter visiting me that I found out about that.* [M, focus group 2]

Participants reported further experiences of completing physiotherapy exercises incorrectly without direct observation or supervision. Consequently, some participants appeared to be wary of carrying out physiotherapy exercises alone (scenario 2):

> *My dad had online physio through his iPad and he was doing this exercise to try and strengthen his glutes. He was doing it and he was turning his whole body and a physio in person would have seen that and known that he wasn't actually doing the right exercise. So I'm not a fan of online or apps for the consultation and monitoring.* [My, focus group 2]
>
> *I think there is one issue with that, which is how the patient knows that he or she actually does the exercise in a correct way without monitoring by the presence of the physio. I think they need to look at it and then to find some ways in order to ensure that the messages delivered and the exercises are the way the GP wanted or the way their physiotherapist wants.* [H, focus group 2]

Given these concerns around the lack of person input, a hybrid approach appeared to be favored by participants in which they used digital health platforms alongside some form of face-to-face meetings with a health professional (eg, a general practitioner or physiotherapist). Participants explained a hybrid approach was preferred to ensure they are completing physiotherapy exercises correctly. It was suggested that patients could record themselves completing exercises. These recordings could be sent via the internet to physiotherapists who could track their progress ahead of a face-to-face meeting, rather than as a substitute for a meeting entirely:

> *I feel I would use it, but I would want a health professional to tell me what to do and then I would go on to technology and then be able to report back to the health professional.* [M, focus group 1]
>
> *And as long as you've had the proper consultant consultation with the physio, I don't see this taking the place of a physio appointment at all in anyway, but in terms of monitoring and feeding back your progress to your physio in advance of the next meeting, because one of the things that I would look for in that like this is to be accountable and to get to the end of the week and say yes I did do that. Yeah, I did that three times a day all. But for the whole week and to have that recorded and for the physio to have access to that.* [M, focus group 2]

Another participant suggested patients could complete exercises in a group (even virtually, using a platform such as Microsoft Teams), which could help increase their confidence:

> *So, if you do it with support possibly even with for example a group. Some get together where you like you are now. And you can see us all individually doing the therapies. You can then say oh excuse me you're doing that incorrectly or something like that. So we get that input in a better way.* [L, focus group 2]

It was observed that using technology would depend on a patient's circumstances:

> *So last time I saw a physiotherapist when I had a blood test from the doctor beforehand to check it wasn't some biological problem. It was mechanical and then the physiotherapist was a mixture of exercises and also ultrasound treatment. I obviously can't do that at home and don't have the skill to apply the ultrasonic probe in the correct manner, so I think it depends on the injury and what the best treatment is, whether you can go a hybrid mode or whether its technology or just physio.* [M, focus group 1]

Theme 3: Barriers to Accessing Clinical Services

While expressing a preference for human contact, participants recognized the role of technology when there are barriers to accessing services. Participants referenced seeking help from medical professionals (eg, occupational health practitioners, general practitioners, and physiotherapists) for musculoskeletal conditions and explained how they decided to use technology while waiting to hear back from a health professional. One of the participants described how they had been assigned self-management exercises by their physician but did not receive the exercises. As a result, they sourced their own self-management exercises on the United Kingdom's National Health Service (NHS) website. A second participant felt it was not always clear which health professional they needed to see (ie, a physiotherapist or a chiropractor) and had experienced a long wait to get a physiotherapy appointment. Due to this long wait, they had engaged in self-management by trying to move their body regularly and using apps:

> *I had just sciatica not so long ago and it got diagnosed by the doctor. And he said he'd give me some exercises to do, but he never actually did. So when I went on the web and went on the NHS website and found some site, sciatica specific exercises, which I then started doing on a regular basis.* [J, focus group 2]
>
> *I've had to wait six months on the NHS to get a physio appointment. I wasn't sure whether to go to a chiropractor or a physio. And so just thought I'll just follow the doctor's advice and wait. And it was a long wait we didn't go privately and I'm not being seen. I like to go for a walk and I've got rheumatoid arthritis so I'm sometimes a bit limited, but I have used apps to do exercises which were appropriate for me and just, well, keep moving.* [N, focus group 1]

The availability and accessibility of resources were raised by participants. It appears some participants may have access to health professionals more readily. According to one of the participants, patients can access health professionals with greater ease if they pay for their appointments privately. Despite this perceived benefit, another participant noted it was very difficult to obtain a private physiotherapist's appointment due to long waiting times:

> *If you're privileged enough to be able to pay privately, then there will be a few, a lot fewer barriers.* [My, focus group 1]
>
> *I will say at the moment it's very difficult to see people privately at, whereas at one time you rang and you saw them the next day. I've had to wait two months for appointments, even privately.* [B, focus group 1]

Considering scenario 1 and in light of current waiting lists, a participant saw the benefits of a referral app:

> *I was just going to say if you've sprained knee or have a hand sprain, for example you go to the GP. You're not going to see the same GP that you've seen last time. And if you get referred for Physio, you'll be lucky to see a physiotherapist for six months. So an app would be more useful because you would have some advice if you like online immediately.* [S, focus group 2]

In terms of accessing support for self-management via digital means, participants mentioned accessing useful resources on YouTube. One of the participants described how they had found trained physiotherapists on YouTube to follow a program of physiotherapy exercises and stretches:

> *I found Bob and Brad on YouTube and that really good, really entertaining.* [J, focus group 2]

A participant described how they already had an experience of scenario 1. However, they noted It was only certain physicians or healthcare organizations that offered the digital services, suggesting not all members of the public can access this service:

> *It's already out there. So as far as I'm concerned, I've done it. It's ok, it's only experimental in certain surgeries and things, but it's out there.* [L, focus group 2]

Theme 4: Individual Differences and Digital Literacy

The topic of inclusivity arose from the focus groups (ie, can individuals aged >60 years successfully access and use digital technology to manage their health?). Participants acknowledged there may be a range of individual differences when it comes to using digital health platforms. There was acknowledgment that users may differ on a variety of characteristics; for example, age and several elements of apps were highlighted as challenging for users. One of the participants expressed concerns toward people in an older age group (aged ≥75 years) using a referral app (scenario 1). They believed this group of people may prefer to speak with a health professional in person. They explained that chatbots can be difficult to use (eg, a chatbot might not recognize certain phrases or words):

> *I think the older people, older generation, probably people 75-80 don't feel ready for it. Even just the telephone conversations with doctors. I like to go in person to see my doctor. Whereas when I talk to my children, they think telephone triage is brilliant, so I think it and that's not to say I mean there's a lot of very technical people in the older group, but the vast majority, like people have said either or, not, or are distrusting of it. I just think they much on the whole, much prefer seeing someone, even the telephone, does mean you are talking to your doctor, even if you're not seeing them face to face. Even though you can do video calls with your doctor, I just think that while it's good I don't get on with chat bot, I never put the right words in. You've got to know what words to use to make the thing effective.* [F, focus group 2]

Another participant also raised the issue of accessing digital health platforms. It was implied some people may find it more challenging:

> *I went into hospital and I had to have physio afterwards and that was given as a YouTube thing with the nurse. My only problem with it, I did most of the exercises and things that were required and requested. The only thing I found was I kept losing the YouTube and trying to find the link to it because they sent it as a link. Because you're not feeling 100%, I didn't secure it, so I forgot where I put it and so I stopped doing it so probably didn't complete the course... because at that point I wasn't feeling physically fit and I wasn't very well and probably wasn't thinking the way I would normally think. Apps need to be absolutely simple and as somebody else said, idiot proof.* [F, focus group 2]

Theme 5: Trust in Technology

Issues around the legitimacy of some health apps were highlighted. Participants expressed concerns about not knowing whether apps are real or fake:

> *It's not beyond the bounds of possibility that you get on to the wrong sort of website and you get the wrong sort of information. You would need to know that what you've accessed is in fact a genuine one.* [B, focus group 1]

Several suggestions were made to help to instill confidence in users. One of the participants suggested that they would feel more comfortable if information or link for a digital health platform came straight from health care professionals rather than an unknown source:

> *Nowadays we are bombarded with a lot of information. So if there is a direct communication between the people who supply this app and the clinic itself or the hospital, which means that I received the information from the clinic or from the hospital that gives me confidence and that's giving me trust that I can trust the source of this information. Rather than it is, it is independent from the hospital or from the clinic, which makes me think is this genuine? Is it the same people?* [H, focus group 1]

There was also the proposal that app developers might wish to include some form of legitimacy mark (eg, kite mark) to help users know that the app has been verified and delivers accurate health care advice:

> *It needs a sort of kite mark, if you remember what they are, but I don't know how you do that.* [B, focus group 1]

Training was also suggested as a method to encourage greater uptake and use of such apps:

> *I think the issue is not with using them. I think the main issue is we need more training on how to implement, how to use these apps and how to become familiar with them. This is very important if the training is not available then I think it will create some frustration and with the users and users may refuse or may not like to use them.* [H, focus group 2]
>
> *I think until people can be trained to use it a lot better than. You know, it's people gonna still find it difficult to use. If you feel you've pulled a muscle and you're in pain, you don't wanna be fiddling about with technology at that time.* [L, focus group 1]

In the context of scenario 1, a participant suggested that case studies of worked examples would be useful to instill trust in the referral app:

> *I guess what we really want is case examples, so a worked example where a patient that goes through what the questions are ends up with self-management. Then a different patient, different symptoms ends up with consult your GP. So examples of how it actually works in practise. But what would what they would be looking for to validate it.* [M, focus group 1]

One of the participants described how they had recently trialed new technology after being invited by their local hospital. They stated that technology needs to become the norm, which will encourage people to try it:

> *So you know the technology is out there. It's just you've gotta have people who are prepared to try it. And to make it become the norm. Once it's the norm, then the fear disappears and so on. But at present a lot of this stuff is new, and it's scary for a lot of people. You take the fear out and then it's fine.* [L, focus group 2]

Theme 6: Features and Benefits of Digital Health Technologies

In the context of scenario 2, participants stated a number of positive views toward the use of videos demonstrating physiotherapy exercises. Using an app to perform physiotherapy exercises was compared to using a piece of paper with static poses on it. One of the main perceived benefits of videos was the ability to stop and start the video according to the individual's own pace. Participants also compared watching videos to meeting with a medical professional, who may not always have time to demonstrate exercises, or alternatively, appointments are rushed, and patients are unable to clarify what is correct:

> *Having the videos online...you can see how your body should be positioned, you can see from one position to the next where your body should be. Where sometimes we just get the instructions or guidance on the flat sheet of paper, you're unsure how to move next or how your body should be positioned so having the video of the graphics or whatever it is online I think would definitely be beneficial for someone who's going down that route. Also online you can do exercises at your own pace. Whereas sometimes medical professionals are on a clock, so ok do this, do this and then they're off. Whereas if you're online, you've got time to go how did that one go again? And you can see it again, slow it down, pause it, look again.* [J, focus group 2]

> *If you watch an app, it's easier to understand what you meant to be doing than looking at a sheet cause I find that if you have followed the exercises from you're trying to, even if you're lying down, you're trying to hold the sheet of the air to check that you're doing the exercise correctly. I found an app quite good really for showing you how to do them.* [N, focus group 2]

Other benefits of using apps included reducing the need to travel to a physical location for an appointment, saving patients' time:

> *I think it is a good idea because it saves time for a patient to travel from his or her home to the clinic or to the hospital.* [H, focus group 2]

> *Well, going to the doctor or physician or therapist, it takes more time... the technology is much better for me at my own pace, at my own time.* [S, focus group 1]

Participants considered a number of benefits of using the chatbot referral app (scenario 1) compared to going directly to a health professional. These benefits included reducing wait times for patients as well as freeing up time for health professionals:

> *It's the way forward, 'cos it means you're freeing up GP time, you're freeing up hospital time. So the people who are more needy can actually get that support. You are getting your support is a slightly easier and slightly less cumbersome way I suppose.* [L, focus group 2]

> *I was just going to say if you've sprained your knee or have a hand sprain, for example you go to the GP. You're not going to see the same GP that you've seen last time. And if you get referred for Physio, you'll be lucky to see a physiotherapist for six months. So an app would be more useful because you would have some advice if you like online immediately.* [S, focus group 2]

Participants spoke of adapting digital health platforms to suit their needs. For example, one of the participants described adapting app exercises to suit their own abilities and pain level:

> *It started off quite gently and that used every part of your body and something that I had to adapt because I've also had an operation on my thought and I am a replacement hips, so I'll just adapt whatever, but yeah. I just think. That's what you know most of the things you try to do your best, don't you try to do them and but just adapt them...Yeah, some exercises are found too fast for me and some too slow. I think the pace of exercise is sometimes very helpful. And also whether you can follow it or not.* [N, focus group 1]

Suggestions were made for future adaptations to apps. There was a desire for information on the timings of each exercise to be specific. Participants expressed a concern that sometimes it is not clear how long they need to hold a certain position for; as a result, they suggested embedding a countdown or timer into the app:

> *Sometimes it doesn't say how long you're to hold a position for.* [N, focus group 1]

> *Like how many times should you do an exercise within a minute or like a time scale so that you're not doing it too quickly or too slowly? You can then try to keep some sort of balance.* [N, focus group 1]

Another participant described adapting a phone app from its original use of sending medication reminders. The participant described how they instead used the function on the app to remind them to do specific physiotherapy exercises at specific points in the day. This insight suggests that reminders for physiotherapy exercises could be inbuilt into existing physiotherapy apps (scenario 2):

> *One thing I've found quite useful when I was doing my post-surgery exercises was there's an app...it tells you when to take pills so it reminds you when it's time to take your medication, but rather than entering medication, I entered each of the exercise and then I've got a record of when I done the exercises and it reminded me to do, it reminded me to take the pink tablet, but I've actually got that it was leg raises or whatever and I haven't been able to find something like that, that is for exercise, rather than just adapting*

> *the medication one but that was good cause you have records and you could sort of see progress.* [My, focus group 1]

Discussion

Principal Findings

This study aimed to explore older adults' opinions and perceptions on the use of digital platforms for supporting the self-management of musculoskeletal conditions. Using a focus group approach, we found that most participants had some knowledge or experience of using digital tools for supporting musculoskeletal problems, although this could be something as simple as YouTube guidance videos. As health care organizations are increasingly focusing on the delivery of digital services (eg, the NHS Long Term Plan in the United Kingdom [18]), we further wanted to gather opinions from participants around potentially using technology-based support as an alternative or a complement to traditional face-to-face services. In the initial stages of discussions, participants were skeptical of this and highlighted a lack of trust in the quality and scope of digital services. However, we further included real-world examples of physiotherapy-related digital health technologies into our focus group discussions. By moving away from theoretical perceptions to specific examples, we found participants subsequently recognized the potential advantages of such platforms and how they could provide relevant support to self-managing musculoskeletal health conditions. In the following sections, we discuss the main findings in more detail.

Experiences of Using Digital Tools for Self-Managing Musculoskeletal Conditions

In this study, we purposefully aimed to recruit participants for the focus group without explicitly requiring them to either have current musculoskeletal conditions or experience of using technology for managing musculoskeletal health. Despite these broad inclusion criteria and recruitment across a diverse set of community groups, we found that most participants (12/15, 80%) had some type of current musculoskeletal condition. Furthermore, most participants had used a form of technology to help self-manage their condition. Around 60% of adults aged >65 years live with a musculoskeletal condition in the United Kingdom [3]. Therefore, it was expected that a significant proportion of our participants would have current musculoskeletal conditions, as observed. It was less expected to find that most of our participants had some experience of using technology to support the management of their musculoskeletal conditions. However, this included the use of exercise and guidance videos on YouTube, a medium that is accessed by 52% of older adults (aged >65 years) in the United Kingdom [19]. A study investigating the quality of physiotherapy videos for older adults on YouTube [20] found that the content was rated as poor or lower when assessed according to DISCERN [21] and Journal of American Medical Association scoring methods. This highlights the need for high-quality digital tools and resources that are easily accessible for older adults to avoid the default option of using nonregulated or low-quality resources.

Quality and Expectation

There was some dismissiveness around the ability of a digital health platform to diagnose conditions fully or correctly, highlighting a low expectation for the accuracy or quality of a digital service. However, these comments emphasize the disparities between the perspectives of what the technology is trying to do and the scope of what it is actually doing. For example, in scenario 1, the scope of the chatbot tool covers triaging and signposting the most appropriate service. To achieve this, it does not need to diagnose the condition per se (as inferred by a participant) but rather assess the risk and urgency based on the patient's symptoms and direct to the most relevant service. One of the participants notably raised the need for education on such technologies. Understanding the aim and scope of a platform, along with its limitations, is important. This sets expectations and ensures there is clarity on what functions the platform will and will not perform, particularly in the context of any traditional (eg, human interaction) functions it will replace [22].

A previous study of diabetes apps with older adults highlighted that usability is the main concern [12]. Here, the use of a chatbot raised usability issues, with participants highlighting that chatbots often fail to function correctly unless exactly the correct wording or phrasing is used to describe their condition. This highlights issues with earlier technologies and limitations in health-based chatbots [23]. The recent advent of large language models has created a step change in the interaction with chatbots, creating significantly increased flexibility in the conversational style in terms of inputs and responses [24]. This is likely to make chatbots more practical and, importantly, accessible in the future. For example, chatbots are likely to be able to quickly switch between different languages for conversations [25], without requiring complex remapping of decision trees or separate database content. However, this broader scope of chat ability comes with challenges around maintaining boundaries within which conversations must remain (ie, forcing the chatbot to discuss content outside the scope of the health conditions it is designed for) [24].

Trust

Participants raised several issues around trusting the use of technology for self-managing their health. Notably, this was in response to the initial questions before specific scenarios were introduced and highlights a general distrust around health technologies and digital tools for health, with a concern that this is reducing the quality of the health care patients receive. Once the specific scenarios were presented (which contained details about the functionality of digital health tools), then positives were identified. An example of this was when scenario 2 demonstrated the use of videos to provide guidance on exercises, rather than the leaflets with photographs or diagrams that participants would normally receive. Participants immediately recognized the advantages of being able to watch and pause the video to gain more detailed guidance. It has further been shown that people can accurately follow the movements of an avatar [26] or video-based movements for physiotherapy [27], confirming the advantages of animated or video-based guidance. However, additional annotation of videos maybe required, with guidance on the timing of an exercise requested for specific details on how long a position should be held, for example. The advantages of using video-based guidance through an app also included being able to do exercises at one's own pace and being able to repeat and retry exercises without the pressure of a physiotherapist observing. The patient-therapist relationship can be complex, with the physiotherapist often seen as an educator [28]. These comments from participants demonstrate a flip side to in-person consultations, where a health professional can create anxiety rather than reassurance in some cases, possibly due to an expectation that the patient must perform the exercises correctly while under observation.

Issues in trust also arose around how to determine whether a digital health platform is genuine. One of the participants referred to using a scheme similar to a "kitemark," referring to the British Standard Institution Kitemark symbol used on products to show it is approved by the British Standard Institution [29]. In fact, in the United Kingdom, the Organisation for the Review of Care and Health Apps (ORCHA [30]) assesses and provides quality assurance to digital health and care platforms. At a more regulatory level, the evidence standards framework for digital health technologies [31] has been developed by the UK National Institute for Health and Care Excellence to provide standardized guidance on the levels of evidence needed for the clinical and economic evaluation of digital health technologies. However, these are aimed more toward delivering guidance to developers and commissioners. It could be argued that a more consumer (ie, patient)-focused communication campaign could raise the awareness of ORCHA and hence allow potential users of the apps to quickly check whether they have been reviewed and rated.

Balancing Face-to-Face Consultations With Technology

It was clear that during the initial questions, participants were highly reluctant to reduce or replace face-to-face time with a health professional for a digital health platform. Participants highlighted that one of the advantages of in-person consultations was around the more comprehensive and wide-ranging assessments, with participants mentioning that clinicians are more likely to diagnose more complex issues or other unrelated health conditions during a consultation for a musculoskeletal health issue. This further extended to a patient safety aspect, with the opportunity for health care professionals to spot cases of domestic abuse during face-to-face consultations. While in-person consultations were clearly important to participants, it was acknowledged that waiting times to see a physiotherapist and other health professionals are continuing to increase [32], and it was highlighted by one of the participants that this is also increasingly the case with accessing private practitioners as well as NHS in the United Kingdom.

Given this, the advantages of a hybrid approach were recognized, keeping in-person consultations but using digital platforms in-between appointments. In reality, this is the most likely use case in the future, but more evidence is required on how this can be optimized [4]. Digital platforms can deliver a way to provide continuous guidance and support during the long periods between in-person consultations [33] and potentially increase adherence to the physiotherapy program [7]. In some cases, apps have built-in communication functions to allow chat or video call with a physiotherapist, further bridging the gap between in-person sessions (eg, [34]). This approach can help reduce the demand for in-person consultations and thus offer the opportunity for optimally timed regular face-to-face sessions complementing self-management using digital platforms [33].

Strengths and Limitations of This Study

This study has gathered opinions from a diverse sample of older adults. Although ethnicity was not formally recorded, we recruited participants through a mixture of supported living complexes. We purposely aimed for broad inclusion criteria, where participants were not required to have a current musculoskeletal condition or an experience of using technologies to manage musculoskeletal conditions to participate. While this aimed to get a broad range of opinions, we found most participants did have current musculoskeletal conditions and experience of using technologies. Therefore, a more targeted recruitment approach may have helped balance the sample. A limitation of this study is that it may have attracted participants who already used digital health platforms or had an interest in digital health technology. In particular, our requirement to access the focus group via a web-based platform could have excluded certain individuals with less technical literacy. In contrast, however, a web-based platform can make access easier for some groups (eg, those with mobility problems) [13].

Future research could further explore opinions of health professionals toward these digital platforms, thus providing perspectives from both the patient and health professional sides.

Conclusions

In conclusion, it is promising that digital health platforms for musculoskeletal conditions appear to be used and normalized within this age group. However, to enhance trust in these technologies, there needs to be clear communication around how digital platforms can support and assist with the self-management of musculoskeletal conditions and that their role is to complement rather than reduce or replace the role of the health care professional. In addition, we recommend raising public awareness around the role of organizations (such as ORCHA) that verify and assess the quality of digital health platforms to further enhance trust in the use of these technologies.

Acknowledgments

This study was funded by Medical Research Council (MR/W003775/1) and National Institutes of Health Research (NIHR205809). MTE, PG, and KR obtained funding and conceptualized the research.

Authors' Contributions

MTE and SC drafted initial qualitative interview questions. SC, MTE, PG, and KR reviewed the draft survey and qualitative questions. SC, MTE, and CK were directly involved in activities relating to participant recruitment. SC tidied the qualitative interview transcripts and analyzed qualitative data. SC and MTE conducted data analysis and drafted the manuscript. All authors reviewed the final manuscript.

Conflicts of Interest

KR and PG are employed by EQL Ltd. This study is part of a wider project that KR and PG helped conceptualize with MTE. MTE is in receipt of Medical Research Council funding covering his time on secondment with EQL Ltd for 1 day per week. All other authors declare no other conflicts of interest.

Abstract

Background: Chronic noncancer pain (CNCP) is a major health issue among the older population, affecting multiple aspects of individual functioning. Recently, the use of eHealth solutions has been proposed in supporting chronic pain self-management even among older adults, although some barriers have emerged. Few qualitative studies, with none conducted in Mediterranean countries, have explored older people's experiences and perceptions regarding the types of strategies used to cope with chronic pain and eHealth tools for chronic pain management.

Objective: This study's objectives were to explore the perspectives and experiences of older adults regarding the coping strategies used to manage chronic pain, the use of digital technologies in everyday life, and the potentiality and barriers in using those technologies for health and pain management.

Methods: A multimethod approach (ie, self-report questionnaires and a semistructured interview) has been adopted targeting older adults (ie, those who are aged 65 to 80 years and presenting different types of CNCP) who are attending a pain therapy center in Italy. Qualitative answers were analyzed using thematic analysis.

Results: Overall, participants reported using a variety of pain coping strategies; however, they showed an attitude of resignation to their CNCP condition. Nearly 70% (12/18) of the interviewees referred to using digital technologies for purposes related to health and pain management, mostly involving very basic management activities. The participants' opinions on the useful functions that need to be incorporated in eHealth tools for chronic pain management have been categorized into four themes: (1) *specific pain self-management skills*, (2) *support in organizing various health-related aspects*, (3) *sharing experiences with other*s, and (4) *increasing pain-related personal knowledge*. Conversely, the following potential barriers to adopting eHealth tools emerged: (1) *computer illiteracy*, (2) *negative effects or risks*, (3) *impersonal interaction*, and (4) *physical limitations*.

Conclusions: The use of eHealth solutions still seems low, often being accompanied by a perceived lack of digital skills or attitude among a sample of older adults from Italy with CNCP. Before introducing innovative eHealth solutions, it would be of primary importance to take action to enhance, on the one hand, self-efficacy in pain management and, on the other, the digital literacy level among older people.

Introduction

Background

Chronic pain (ie, pain lasting for >3 months) [1] is a major global health issue, affecting approximately 20% of people worldwide [2]. The prevalence of chronic pain generally increases with age, and it is estimated to be higher in adults aged ≥65 years, with a substantial negative impact on their physical, psychological, and social functioning [3-5]. Because of the several physiological age-related changes and frequent pathological comorbidities, effective treatment of chronic pain can be challenging in the older population [6]. Furthermore, in addition to the reluctance of older people to seek or accept medical help, the common belief among older adults and health care providers that pain is a normal part of aging may partially explain why chronic pain is often underestimated and underreported [7]. In this regard, a few studies showed that older adults tend to adopt a stoic attitude while experiencing pain, most often preferring to use self-reliance–based coping strategies, although they are not always effective [7,8]. Several studies have explored the life experiences and needs of older adults with chronic pain as well as the strategies they use to cope with it [9-11]. These studies also aim to promote more effective and tailored pain self-management interventions [8,11,12].

In recent years, particularly in the wake of the COVID-19 pandemic, there has been a massive increase in the adoption of eHealth solutions to ensure the continuity and accessibility of care [13]. Preliminary evidence supports the potential of these solutions in pain assessment, diagnosis, and treatment [14]. However, older adults, especially subgroups aged 75 to 84 years and ≥85 years, still seem to be underrepresented in this field of research [15]. There is, indeed, evidence that older people are more likely to experience digital exclusion, even in research settings, due to age-related negative stereotypes that depict them as a homogeneous group of technologically illiterate users [16-18]. This often results in a lack of consideration of their needs and preferences from the earliest stages of the eHealth solutions design process, with the risk that the proposed tools do not fully match the real needs of end users and are thereby weak in terms of feasibility and acceptability for older people [19-22].

Although it represents a growing area of interest, to date, to the best of our knowledge, only a few qualitative studies have explored the specific experiences and perspectives of older adults on the use of eHealth solutions in the context of coping with chronic pain. Among the recent studies, Bhattarai et al [23] carried out a qualitative study aimed at evaluating older people's views and experiences of using a smartphone app, with the sole focus on chronic arthritic pain management. In addition, O'Reilly et al [20] identified barriers and specific needs of both middle-aged and older adults (mean age of 61.3, SD 7.7 y) regarding the use of eHealth solutions for chronic pain self-management. Further qualitative approaches have been introduced with the specific aim of developing eHealth tools and often targeting a specific population of patients with chronic pain (those with osteoarthritis [24], older adults with obesity and experiencing chronic pain [25], those with chronic back pain [26], those with chronic pain in comorbidity with cognitive decline [27], and those with chronic musculoskeletal pain [28]).

To the best of our knowledge, none of the aforementioned studies were carried out in a Mediterranean country, such as Italy.

It should be indeed considered that values; norms; and, in general, the cultural framework can significantly affect people's life experiences and health-related issues, including the ways in which pain is perceived and managed [11,29]. For example, older adults living in Mediterranean countries seem to value and rely more strongly on close family support in managing well-being, compared with those living in Nordic countries, for whom values such as autonomy and a tendency to rely on formal caregivers outside the immediate family entourage prevail [30]. Concurrently, the use of technology may vary according to the sociocultural context [31]. Interestingly, as shown in recent qualitative research about internet use among people aged ≥65 years during the COVID-19 pandemic [32], many Italian older people tended to seek technological help from close family members such as children or grandchildren. This propensity to ask for help or to totally delegate the execution of activities using technological devices, for example, may at least partly impact the degree to which older people are motivated and willing to enhance their digital skills for independent use of such devices.

Objectives

This study aims to integrate previous research by exploring perspectives and experiences regarding eHealth solutions for coping with chronic pain among older adults with different types of chronic noncancer pain (CNCP) in the context of an Italian center for pain management. Specifically, this paper aims to explore the perspectives of this population regarding (1) the types of strategies used by older adults to cope with chronic pain and the related perceived effectiveness, (2) the types of digital technologies adopted in everyday life and the purposes of their use, (3) the use of digital solutions for health and pain management and older adults' experience with those solutions, and (4) the potential useful functions to be included in eHealth solutions for chronic pain self-management and the barriers to use such tools.

Methods

Ethical Considerations

The study was approved by the local clinical research committee of the Verona University Hospital (Registro del Dolore protocol, ID 1751CESC) and was conducted in accordance with the principles of the Declaration of Helsinki. Written informed consent was obtained from all participants. The participants did not receive any form of compensation. The collected data have been anonymized to safeguard participants information.

Study Design

This study used a multimethod approach: self-report questionnaires and semistructured interviews.

Participants and Setting

A purposive sample of community-dwelling older adults living with chronic pain was recruited from the pain therapy unit of the Verona University Hospital, Italy. This highly specialized center offers clinical activities for the diagnosis and pharmacological and nonpharmacological treatment of all forms of pain (eg, low back and osteomuscular pain, fibromyalgia syndrome, maxillofacial complex pain forms, headaches, neuropathic pain, complex regional pain syndromes, and district pain). It is mainly attended by people whose pain is difficult to manage in primary care settings and who often undergo several types of treatments unsuccessfully.

Self-report questionnaires and a semistructured interview were administered to all patients evaluated at the outpatient center who met the following inclusion criteria: age range between 65 and 80 years; having a clinical diagnosis of CNCP (lasting for at least 3 months), as defined by the referring physicians according to the clinical records; being an Italian speaker; and being able to answer interviews and questionnaires as established by the referring physicians.

Available patients were approached from the end of September to the beginning of December 2023 at the pain therapy unit, and recruitment continued until data saturation in the interviews was reached [33].

Measures

Sociodemographic (ie, sex, age, educational level, and civil status) and clinical data (ie, type of CNCP diagnosis, pain intensity, and duration) were collected immediately before starting the administration of the questionnaires and interviews. The specific diagnosis of CNCP was made by the referring physicians based on the widely accepted temporal criterion by which persistent pain is any pain lasting >3 months [34]. Pain intensity on average over the last week was measured by verbally asking participants to rate their pain on a scale from 0 (ie, no pain) to 10 (ie, the worst pain imaginable).

Participants were asked to fill out the following self-reported questionnaires: the Psychological Well-Being Questionnaire (Ben-SSC [35]) and the Chronic Pain Coping Inventory-Italian version (CPCI-I [36]).

The Ben-SSC [35] is a validated 37-item questionnaire specifically constructed to assess psychological well-being in both the adult and older Italian populations. It is inspired by the eudaimonic perspective of well-being [37], covering 3 different dimensions: personal life satisfaction, sense of autonomy and self-efficacy, and emotion-regulating skills. The participants are asked to indicate their degree of agreement with each item on a 4-point Likert scale, ranging between 1 (not at all) and 4 (always). The Ben-SSC provides a total well-being score, obtained by summing the score for each of the 37 items, where higher scores indicate higher levels of psychological well-being. The 3 subscale scores are calculated by dividing the sum of the items' scores by the number of items in that subscale. The Ben-SSC demonstrated good reliability (Cronbach α=0.91) [35].

The Italian version of the 42-item CPCI-I [36] is a self-report questionnaire that focuses on asking the users to rate the frequency of use of cognitive and behavioral pain coping strategies during the previous week. The strategies are categorized into the following 8 subscales: guarding (avoiding or restricting the use of a body part or movement or specific activities), resting (eg, sitting and laying), asking for assistance (asking someone for help with a task), relaxation (engaging in specific relaxation exercises to reduce muscle tension, eg, slow, deep breathing), task persistence (eg, ignoring pain and carrying out an activity despite the pain), exercise or stretch (doing specific muscle-strengthening or stretching exercises), seeking social support (talking with a significant person to receive support when one experiences pain), and coping self-statements (encouraging oneself through positive thoughts about the painful condition). Each item is scored on a 0 to 8 points scale, where higher scores indicate a greater use of coping strategies. Subscale scores are obtained by dividing the sum of the items' scores by the number of items in that subscale. The CPCI-I proved to have a good factorial structure and psychometric properties similar to the original and adapted versions [36].

The face-to-face semistructured interviews were conducted by ADL at the pain therapy unit. Interviews were based on an interview guide developed by the multidisciplinary research team (Multimedia Appendix 1). The included questions mainly explored the following aspects: the pain coping strategies perceived as most effective among those indicated in the CPCI-I and potential additional helpful coping strategies (ie, not included in the CPCI-I coping categories), the type of digital technologies used and their purposes of use, the experiences regarding health-related purposes of use for digital technologies, and the potential useful functions and barriers to use eHealth solutions for chronic pain management.

Data Analysis

Descriptive statistics were used to summarize the sociodemographic and clinical characteristics of the sample and questionnaire scores.

For data collected qualitatively (ie, semistructured interview), for each theme, we reported examples (the participant ID code to which the quote corresponds is provided in brackets) and the number of quotes related to that theme. All interviews were transcribed "verbatim" in real time and anonymized by alphanumeric codes. A reflexive thematic analysis was used to identify and analyze patterns within the collected qualitative data following the 6 steps proposed by Braun and Clarke [38-40]. More specifically, an inductive and epistemologically constructionist approach to understanding the data was adopted to better capture the meaning and meaningfulness attributed by the participants. Consequently, apart from the recurrence of certain themes within the data set, major importance in the coding process was placed on the significance or relevance of potential themes to the research questions. After familiarizing ourselves with the data by reading the transcripts several times and noting down initial ideas (step 1), the data were initially coded (step 2) and then sorted into potential themes and subthemes (step 3). Next, these preliminary themes were compared and refined repeatedly (step 4) until coherent and meaningful patterns were obtained both at the level of individual themes and of the data set as a whole (step 5). Finally, a concise, coherent, and nonrepetitive story of the data was provided, and representative quotes were provided to exemplify the themes selected (step 6). Data analysis was performed by 2 researchers (ADL and IP) independently, and a third researcher was involved in the discussion when disagreement emerged (VD).

Diverse steps have been used to guarantee the rigor of qualitative methods [41]. More specifically, credibility was ensured by investing an adequate period in the research setting and interacting with the participants (ie, prolonged engagement) and using investigator triangulation. The triangulation, along with the involvement of a researcher not directly engaged in the data analysis and collection (LDP), allowed us to ensure consistency, repeatability, and confirmability of the methods.

Results

Sociodemographic and Clinical Characteristics of the Sample

A total of 23 participants were considered eligible according to the inclusion criteria and approached during the recruitment period. Of these 23 participants, 3 (13%) refused to participate in the study, 1 (4%) discontinued completing the questionnaires due to time constraints, and 1 (4%) was excluded because of substantial hearing impairment that prevented an accurate understanding of the interview questions. However, data saturation (ie, recurrence of themes when no new information emerged) was achieved after interviews with 18 participants, thus not proceeding with the recruitment. The numerosity results are in line with the sample sizes reported in previously published qualitative exploratory research [10,11,42].

On average, the completion of the questionnaires and interviews took about 40 minutes, ranging from 30 to 50 minutes. All questions included in the questionnaires and the interviews were answered by the participants.

Table 1 describes the participants' sociodemographic and clinical characteristics. The average age of the participants was 72.7 (SD 5.2; range 65-79) years. Most of them were female (14/18, 78%) and married (12/18, 67%), with a primary or middle school level of education (14/18, 78%).

Table 1. Participants' sociodemographic and clinical characteristics.

ID	Sex	Age (years)	Educational level	Civil status	Chronic pain condition	Pain intensity (0-10)	Pain duration
1	Female	79	Primary school	Married	L5 radiculopathy (persistent canalar stenosis) on the right side	10	7 to 8 years
2	Female	75	Primary school	Married	Fibromyalgia	8	Lifelong
3	Female	75	Middle school	Married	Low back pain on the right side	5.5	4 to 5 years
4	Male	78	Primary school	Married	Postherpetic neuralgia	10	3 years and 7 months
5	Female	66	Middle school	Married	Low back pain	7	About 8 months
6	Male	74	Middle school	Married	Low back pain	5	Pain for several years that has worsened for about 20 days
7	Female	73	Middle school	Married	Radiculopathy and rheumatoid arthritis	8	18 years
8	Female	79	Primary school	Widower	Neck pain	8	A few years
9	Male	75	Middle school	Married	Postherpetic neuralgia	3	1 year
10	Female	65	University	Married	Fibromyalgia and Sjögren syndrome	4.5	10-year diagnosis but lifelong pain
11	Female	65	High school	Married	Postherpetic neuralgia	10	4 years
12	Female	75	Middle school	Married	Low back pain	10	36 years
13	Male	75	Primary school	Celibate	Neuropathic pain	10	33 years
14	Female	74	Primary school	Divorced	Low back pain	10	20 years
15	Female	79	Primary school	Widower	Fibromyalgia	9	Lifelong
16	Female	70	University	Widower	Fibromyalgia	8	Diagnosed in 2018 but pain for almost 20 years
17	Female	66	High school	Divorced	Chronic migraine	7	46 years
18	Female	65	Middle school	Married	Lumbosciatalgia and neck pain	7	8.5 years

Participants reported a wide range of CNCP conditions, among which the most frequent were low back pain, fibromyalgia, and postherpetic neuralgia, with an average pain intensity level of 8.1 (0 to 10 scale). The duration of pain ranged between 8 months and "lifelong," with 50% (9/18) of participants experiencing pain for >20 years.

Psychological Well-Being

The total mean score of the Ben-SSC was 109.2 (SD 17.2), indicating a medium level of perceived psychological well-being. The mean scores obtained in each subscale of the Ben-SCC also reflect a medium level regarding the specific constructs of personal satisfaction (mean 32.3, SD 8.1; possible range 11-44), perceived self-efficacy and sense of autonomy (mean 25.7, SD 5.2; possible range 9-36), and emotion regulation skills (mean 30.8, SD 3.6; possible range 10-40).

Coping Strategies to Manage Chronic Pain

The most adopted strategies to cope with pain, as assessed by the CPCI-I, were coping self-statements (mean 4.3, SD 1.6), resting (mean 4, SD 1.9), task persistence (mean 3.9, SD 1.6), and guarding (mean 3.7, SD 1.9). The least used strategies were relaxation (mean 2, SD 1.4) and exercise or stretch (mean 2.3, SD 1.7; Table 2).

Table 2. Total sample mean scores for each of the Chronic Pain Coping Inventory-Italian version subscales (score range for each subscale: 0-8).

Coping strategies	Score, mean (SD)
Coping self-statements	4.3 (1.6)
Resting	4 (1.9)
Task persistence	3.9 (1.6)
Guarding	3.7 (1.9)
Seeking social support	3.3 (2)
Asking for assistance	3.2 (1.7)
Exercise or stretch	2.3 (1.7)
Relaxation	2 (1.4)

On the basis of the participants' responses to the interview questions, among the strategies indicated in the CPCI-I, those perceived to be most effective were resting (6/18, 33%), followed by exercise or stretch (3/18, 17%), task persistence (2/18, 11%), guarding (2/18, 11%), relaxation (1/18, 6%), and seeking social support (1/18, 6%). Of the 18 participants, 1 (6%) participant indicated >1 strategy as the most effective, and 4 (22%) participants reported that none of these strategies were effective. The average perceived efficacy level in terms of pain reduction of the referred strategies was 5.9 (SD 3.4; 0 to 10 scale). As for the scores assigned to each CPCI-I strategy, the values ranged from 7 to 10 for exercise or stretch, 1 to 10 for resting, while the remaining strategies—mentioned less frequently as being effective—were assigned the following scores: 3 and 5.5. for task persistence, 4 and 7 for guarding, 3 for relaxation and 6 for seeking social support.

Additional coping strategies (ie, not evaluated through the CPCI-I) have been reported by participants during the interview. Quotes regarding the additional coping strategies were grouped into the following categories:

1. Body treatments with home remedies: some participants (n=6 quotes) reported resorting to home-based informal strategies to relieve pain, including massages, warm or cold modalities, and salt and water baths, such as in the following case:

> *I take a bath with water and salt. Also, I warm my leg with my phono, and I have to warm it slowly or it hurts even more.* [ID 13]

2. Medications: for 4 participants (n=4 quotes), taking medications, for example, anti-inflammatory drugs, have been described as an effective, and sometimes as the only possible, strategy:

> *Besides resting, there is no other strategy, only anti-inflammatories.* [ID 2]

3. Spirituality, such as prayer: 2 respondents (n=2 quotes) declared that they seek hope and comfort in faith:

> *I pray a lot; prayer calms me down... in addition to reciting the formulas, I speak within myself freely, from the heart.* [ID 7]

4. Adjusting daily rhythms to pain: this strategy reflects the tendency to perceive pain as unavoidable and the consequent need to change certain lifestyle habits to continue one's daily activities to the best of one's capabilities. Specifically, to best pursue his professional activity, a participant said the following:

> *I adopted a system, I sleep from 8 p.m. to midnight, the pain is not so intense... afterward I take the pills and sleep maybe half an hour until morning... I totally changed my routine, but I had to do it.* [ID 6]

5. Resignation: an attitude of distrust of health services emerged from 1 participant, indicating a reduction in expectations regarding the actual help provided by the health care system for the treatment of pain:

> *I feel little help from institutions, doctors, professionals, there is no listening. We are numbers, when I come to a new institution my motto is don't expect anything.* [ID 10]

Type of Digital Technologies Used by the Participants and Purposes of Use

All the interviewees (18/18, 100%) reported owning a mobile phone and using it independently, while only 3 (17%) of them referred to using other technological devices, such as computers, tablets, and smartwatches.

As for the general purposes of use in daily life, all participants indicated that they use digital technology tools *to keep up connections with others* (n=18 quotes), and more than half of them also use these tools *for leisure activities* (n=14 quotes):

> *The mobile phone for me is essential for communicating with my daughters and grandchildren who don't live very close to my home... either with calls or messages or even video calls.* [ID 14]
>
> *I usually use my mobile phone to play cards to while away the time....* [ID 4]
>
> *I like visiting websites of catechesis and prayer, listening, watching videos...* [ID 11]

Of the 18 participants, 6 (33%) declared *other daily life uses* of digital solutions, such as web banking and shopping. (n=7 quotes):

> *Other things that I do are for example accessing my bank account, making payments and bank transfers....* [ID 14]

Only 1 (6%) of the 18 participant spontaneously reported engaging in health-related activities, specifically searching the internet for information related to one's medical condition or any new pharmacological therapies being undertaken (ID 12).

Experiences of Using Technological Solutions for Health-Related and Pain-Related Purposes

When participants were explicitly asked whether they use such devices for purposes related to health management (including pain conditions), nearly 70% (12/18) of the interviewees answered affirmative, while the other participants declared that they do not directly use eHealth solutions (even if in some of these cases, they delegate the use of these tools to informal caregivers).

The quotes reported by affirmative responders have been categorized into the following themes:

1. *Booking medical visits or tests* (n=11 quotes):

> *I often book medical examinations on the internet or call the medical service directly.* [ID 18]

2. *Searching health information* (n=8 quotes):

> *When I am prescribed new drugs, I go and look online to find out what it is.* [ID 12]

3. *Managing pharmaceutical prescriptions* (n=6 quotes):

> *Sometimes I use this app of the National Health System, that allows you to receive and manage medical prescriptions.* [ID 11]

4. *Accessing the personal electronic health record* (n=4 quotes):

> *I always use the Electronic Health Record, for example, I check if the doctors have uploaded the reports, I keep track of all the medical examinations...* [ID 16]

5. *Purchasing medicines on the web*: Of 18 participants, 2 (11%) stated ordering and purchasing medications on the web (n=2 quotes):

> *I find it good to order medication on the internet, it is a fast method, the medicines arrive directly at home in no time.* [ID 18]

As for the participants' current use experiences of digital devices for health-related purposes, the reported quotes have been categorized into 3 themes, with 1 concerning the quantity and 2 regarding the quality (respectively, positive or negative) of such experiences.

1. *Limited to few activities*: for 5 (28%) of the 18 participants, the use of digital technologies (mainly mobile phones) is limited to a few activities related to their health management (eg, booking medical visits and tests and downloading clinical reports) or is not very frequent (n=5 quotes):

> *I don't know many things, but I am able to do the things that are essential to me [for healthcare].* [ID 8]

2. *Positive and helpful experience* refers to fulfilling experiences related to the use of digital technologies in health care, as reported by 4 (22%) of the 18 participants, with the following example being 1 of the 4 quotes:

> *Technology is a great help and support in managing several aspects of my health and my painful condition.* [ID 10]

3. *Negative experience*, which was reported by 3 (17%) of the 18 participants, included answers related to "external support/delegating to others" (n=2 quotes) and "unsatisfactory" in relation to malfunctions (n=1 quote):

> *There are some things that I can't do, for example checking emails, and therefore I ask my neighbor, a very nice lady, to do these things for me.* [ID 15]
>
> *Some systems, such as the Electronic Health Record, are potentially useful, but they must work properly! But it rarely happens, there is always a problem.* [ID 16]

Specifically, for the first subtheme, despite the independent use of digital devices for some basic health-related activities (eg, making a phone call to book a medical visit), a few of the interviewees (3/12, 25%) highlighted the need for assistance or to delegate the execution of more complex operations to others.

Potential Useful Functions of eHealth Tools for Chronic Pain Self-Management

According to 10 (56%) of the 18 interviewees, adopting eHealth tools specifically designed for pain management might be useful.

Regarding the potential useful functions of possible new eHealth tools for pain management, we identified the following four themes: (1) *specific pain self-management skills* (n=7 quotes), (2) *support in organizing various health-related aspects* (n=2 quotes), (3) *sharing experiences with others* (n=2 quotes), and (4) *increasing pain-related personal knowledge* (n=2 quotes). Of the 18 participants, 3 (17%) reported having no specific ideas about possible functions to be included in such tools, although they expressed themselves favorably about the usefulness of possible eHealth solutions.

The first theme includes several strategies that participants find helpful for achieving better self-management of pain to be delivered, for example, through text, audio, or video files explaining good practices, physical exercises or stretching, and relaxation or meditation practices. Indeed, just over half of the interviewees (6/10, 60%) expressed the need to strengthen their pain self-management skills through targeted content relating to both the physical or biological and psychological or educational fields. For example, a participant said the following:

> *Looking for an alternative to medication... for example, when I wake up in the morning, I feel the need to stretch my muscles... so an alternative might be videos showing specific exercises or relaxing therapies.* [ID 12]

In addition, some participants argued for the usefulness of providing professionals with different backgrounds and the possibility to select the proposed activities according to one's interests. This is to emphasize the necessity of interacting with a range of experts and choosing content that is not "standard" and applicable to all but rather unique depending on the specific requirements of everyone:

> *It would be helpful to include the names of experts with different backgrounds, not only health care, but also theologians or meditation teachers to have moments of reflection.* [ID 11]
>
> *I would include both "random" and "user-selected" activities, because I would be interested, for example, in videos of professionals with a spiritual background but others might prefer a more medical approach.* [ID 15]

The second theme focused on the support provided by digital tools in organizing various health-related aspects. Some participants stated it could be helpful to receive automatic notifications on their smartphones to prevent forgetfulness regarding scheduled appointments, as explained in the following case:

> *First of all, a reminder if I have to do something, for example, appointment reminders... for example, the day before the visit it comes up on my cell phone screen that tomorrow I have to undergo that medical examination.* [ID 1]

Furthermore, the need for digital systems that allow medical appointments to be booked quickly and easily was highlighted:

> *A program that allows me to quickly book visits.* [ID 5]

The third theme addresses the need for social support and the desire to share experiences with others facing similar circumstances, as explained by the following participant:

> *It would be important to share my experience with other people who may be experiencing the same issues, this would be helpful and allow to exercise one's skills of listening to the other.* [ID 11]

The fourth theme highlights the need to increase one's knowledge about their medical condition, obtain reliable information about chronic pain and treatment options, and directly consult experts in the field. The following are 2 exemplary quotes on this theme:

> *Since these are unknown diseases, there are no effective drugs, only supplements, it would be helpful to have a source of up-to-date information.* [ID 7]
>
> *An app where you can contact experts to ask for information, to receive support.* [ID 10]

Potential Barriers to the Use of eHealth Tools

Finally, with regard to the potential barriers to using eHealth tools, the following four themes were identified: (1) *computer illiteracy* (n=7 quotes), (2) *negative effects or risks* (n=3 quotes), (3) *impersonal interaction* (n=2 quotes), and (4) *physical limitations* (n=2 quotes).

In general, the first theme concerns the perceived lack of technological skills or attitude and the reduced interest in learning how to use new technologies, sometimes citing advanced age or the belief that such digital devices are substantially useless in the treatment of pain as reasons. The following are some examples of quotes to support this theme:

> *I find technology difficult, I'm not capable, I never did bother to learn it.* [ID 7]
>
> *I'm not really into technology, it has never been my strong suit.* [ID 14]
>
> *Honestly, I'm not interested in learning to use technology... And then at my age...* [ID 4]
>
> *I'm not someone who believes in these fancy things. If you feel pain and it doesn't go away, you keep it and that's it.* [ID 6]

The second theme addresses concerns of older adults regarding potential risks or negative effects arising from the use of eHealth tools. On the one hand, these concerns pertain to the risk of developing technology addiction, as pointed out by the following interviewee:

> *Then you get used to it, you always look for more... you get addicted to that too.* [ID 8]

On the other hand, these risks might involve potential adverse effects. For example, 1 participant stated the following:

> *When you search for information on the internet, for example, sometimes it seems like you have more pain, you start to fantasize about having a serious pathology...* [ID 3]

The third theme explains the idea that interaction with a device cannot be considered as satisfactory as that with a real person (eg, health care professional), which is, instead, considered essential. In this regard, 1 participant stated the following:

> *I need to hear from someone, not technology... not for human issues like health care.* [ID 9]

In this sense, several participants considered the eHealth tools to be inadequate substitutes for in-person interaction, also expressing a clear preference for the latter:

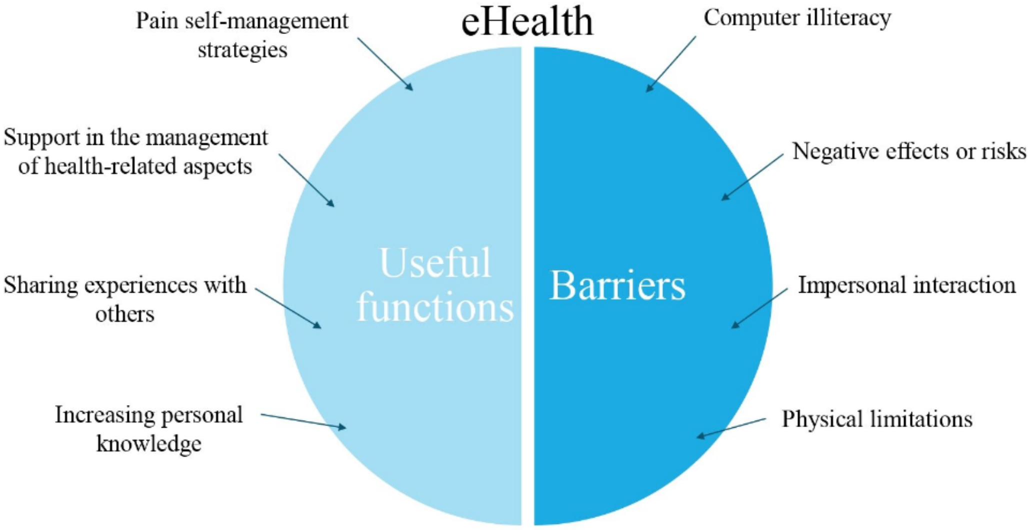
> *I think talking to a person, to a doctor, is more helpful than looking at your cell phone. I prefer it...* [ID 3]

The fourth theme concerns physical limitations that could prevent the use of the technology, such as visual and hearing impairments, as reported by a participant:

> *I don't even watch television, my hearing is bad, I understand little of what I hear, I get about 40% of what I listen to.* [ID 13]

Figure 1 shows an overview of the themes related to the potential useful functions and the barriers to the use of eHealth solutions in the context of CNCP management.

Figure 1. Potential useful functions and barriers to the use of eHealth solutions in the context of chronic noncancer pain management.



Discussion

Principal Findings

This study aimed to explore perspectives and experiences of older adults (aged 65 to 80 years) with any type of CNCP regarding the strategies used to cope with chronic pain and the related perceived effectiveness; the types of digital technologies adopted in everyday life and the purposes of their use, including those related to health and pain management; the potential useful functions to be included in any eHealth solutions; and the potential barriers to use such tools in the context of chronic pain self-management. To the best of our knowledge, this is the first qualitative study to investigate the abovementioned aspects in a population of older adults with CNCP without focusing on a specific pain-related diagnosis but in the general context of a pain therapy outpatient center. Moreover, looking at the previous literature, the main research in this field has not been conducted in a Mediterranean country, such as Italy. This study thus enables insight into the specific features and needs of the Italian older population with chronic pain. This is of particular relevance considering that, as reported in the *Background* section, sociocultural factors may significantly affect how people perceive and manage well-being and health-related aspects, including the experience of chronic pain [11,29,43], along with the degree to which technology is accepted and used [31].

Regarding the first aim, the most frequently declared strategies to cope with chronic pain were coping self-statements, resting, task persistence, and guarding, while the least used strategies were relaxation and exercise or stretch. These findings are consistent with those found in 2 previous research carried out in the United States, targeting older adults with chronic pain, in facilities homes and community-based settings [44,45]. Interestingly, compared to those studies, we found greater use of resting as a strategy for managing pain, which was also qualitatively described as the most effective in terms of perceived pain reduction by the study sample. It must be noted that although a certain strategy was designated as the most effective, some participants were assigned a minimal score in terms of effectiveness in reducing pain. Similarly, although some strategies (eg, task persistence) were among the most widely used, they have been reported as effective by only a few participants. Overall, the results seem to show that in this study sample, the use of a specific strategy is not aimed at achieving a significant pain reduction but rather at obtaining some relief to be able to maintain their daily activities, often under the belief that pain will always be a part of their lives. As for this emerging attitude, the findings are consistent with the passive acceptance attitude that was found in older people with long-term pain conditions [8]. In this regard, it should be noted that this disposition may also have been influenced by the very long duration of chronic pain in our sample and by having experienced numerous medical treatments that were nevertheless unresolved. When faced with this sort of scenario, which often underlies a belief of total ineffectiveness and uselessness of any interventions, it is, therefore, of primary relevance to foster a more proactive attitude and simultaneously an increased self-efficacy to promote better chronic pain management, including the use of eHealth solutions.

Regarding the type of digital technologies used, all participants reported owning a mobile phone and using it independently, while only a few other digital tools were considered. This result is in line with international statistics indicating that the number of people aged >65 years who smartphones is increasing considerably, while for other modern technological devices (eg, tablets, computers, and smartwatches), there seems to still be a larger gap with younger age groups [46]. Especially following the acceleration induced by the COVID-19 pandemic, there has been an increasingly widespread use of technology, which also involved the older population. Indeed, some evidence showed higher levels of digital device adoption in daily life (eg, for entertainment, socialization, and health needs) by older adults already in the first stages of the COVID-19 pandemic [42,47,48]. Even in the Italian context, the frequency of use of digital technologies by the older population appears to have risen between 2019 and 2022 [49]. For example, the percentage of individuals who reported using a smartphone “often” or “always” increased by 16.3% (ie, from 37.7% in 2019 to 54% in 2022). This tendency is also supported by statistics from the European Commission, indicating that the percentage of Italian older people aged 65 to 74 years who have used the internet in the past 12 months increased from 44.6% in 2019 to 62.3% in 2023 [50]. Our results concerning the purposes of use in everyday life (eg, keeping in touch with others and leisure activities) also seem to point out in this direction. Despite this increase, it has to be considered that to date, a digital divide still remains with some northern European countries, where this percentage is significantly higher (eg, 97% in the Netherlands, 96.6% in Denmark and Luxembourg, and 94% in Sweden) [50].

Notably, none of the participants spontaneously indicated activities related in any way to health management, except for one who referred to using the internet to seek information about one's medical condition or newly prescribed medications. Concerning the use of digital devices for health-related purposes, it is interesting to note that in our sample, these mostly involved very basic organizational activities (eg, booking medical visits and managing pharmaceutical prescriptions), and none of the participants reported the use of digital technologies for treatment purposes (eg, telemedicine) with respect to either their general health or CNCP condition. Although telemedicine interventions have also been implemented in Italy in the wake of the COVID-19 pandemic–induced acceleration [51], significant disparities remain in the country, with the telemedicine approaches (eg, televisiting, teleconsulting, and telemonitoring) offered to patients across the different Italian regions, varying in number from 1 (ie, telereferencing and televisiting in Basilicata Region and Autonomous Province of Bolzano, respectively) to 66 typologies (Lombardia Region) [52]. Moreover, according to the results of recent studies, a large proportion of Italian citizens are unaware of the availability of such digital health solutions [53], and especially among older adults living in remote areas of Italy, a digital health gap exists due to both infrastructural deficiencies and a lack of digital skills [54]. In light of the potential benefits offered by the digitization of the health care field, it would, therefore, be important to implement more large-scale initiatives aimed at raising awareness of the potentialities of digital technologies on a broad scale, involving both health care professionals as well as patients and their caregivers.

Consistent with the framework outlined here, several participants in our study described the experience of using eHealth tools as limited in terms of the number of activities performed or frequency. In addition, some older adults reported needing external assistance from informal caregivers in using digital devices or completely delegating to them the execution of health-related management activities, citing as the main explanation the lack of familiarity with the technology in general. This attitude may, to some extent, disincentive them from experiencing the use of eHealth tools on their own.

Nevertheless, in other cases, the experience of using such tools was defined as positive or helpful with respect to one's purposes. Indeed, more than half of the respondents (10/18, 56%) were favorable about the potential usefulness of any eHealth tools specifically designed for chronic pain self-management, suggesting several potential useful functions to be included in such digital health solutions. More specifically, consistent with the findings of previous research [20,23], participants in this study highlighted the need to obtain updated and reliable information regarding their medical condition and available treatment options, including the option of contacting experts directly for questions or advice. In addition, there was a desire to improve pain self-management skills by learning new physical and psychological strategies. This highlights the need for targeted and diverse content to accommodate individual preferences. As observed in other studies [20,55], the inclusion in any eHealth solutions of features that allow remote interaction and sharing of experiences with others experimenting with a similar condition has been described as potentially helpful by several participants. This may also be beneficial in countering social isolation as a risk factor for poor well-being in older adults [56], which, especially in Mediterranean countries, seems to be one of the main factors affecting the psychological well-being older people aged 80 years and above [30].

Among the possible barriers to the use of eHealth solutions, just under half of the study participants (7/18, 40%) reported a lack of digital skills or technological attitude, resulting in a reduced sense of familiarity and trust in the potential of these tools for CNCP self-management. This is coherent with the evidence that older adults are less digitally literate than younger cohorts [57,58]. Even in previous research, this represents one of the main obstacles to the adoption of digital devices for health-related purposes [20,42]. Looking at the specific Italian sociocultural context, according to the Digital Economy and Society Index report of 2022 [59], Italy ranks 18th out of 27 European Union member states, and, to date, more than half of the Italian population does not have at least basic digital skills. If the analysis is extended to different age groups, the disparities widen even further: the percentage of Italian people who have at least basic digital skills stands at 42.2% in those aged 55 to 59 years and drops to 19.3% among those aged 65 to 74 years compared to 61.7% among young people aged 20 to 24 years [60]. Interestingly, according to a recent study that explored the digital divide of older adults living in peripherical areas of Italy, those with higher levels of education are more likely to use new digital technologies [54], and this could partly support our results because almost 80% (14/18) of our sample has a primary or middle school education level.

Among the potential barriers to the use of digital health tools, concerns about possible risks and negative effects were highlighted, such as the risk of developing a technological addiction or worsening one's chronic pain condition. As previously mentioned, because these concerns may arise at least in part from misinformation, it might be useful to propose educational initiatives also aimed at promoting more accurate knowledge and thus greater awareness regarding the potential and the correct use of these tools in the health care context [61]. Regarding the physical limitations (eg, visual and hearing impairments) that could prevent the adoption of digital health devices, as pointed out in previous studies [20,23], it is crucial to attentively address design aspects to tailor the features of these tools to the age-related psychophysical needs of the older population (eg, provide adequate font size and screen brightness and the ability to select visual and auditory aids).

Finally, the lack of human interaction and the preference for an in-person relationship (ie, with health care providers) emerged in this study as possible deterrents to the adoption of eHealth solutions. This seems to be in line with previous evidence both internationally [62] and pertaining to the Italian population [53], which suggested a favorability for traditional visits over remote visiting modalities. In this regard, as pointed out by Bhattarai et al [23], it might be useful to support older people in the use of such tools by providing for the direct involvement of physicians and health care professionals and thus promoting such innovative modalities to be better integrated into the care process.

Strengths and Limitations

This study has several strengths and limitations. The first strength is that it involved a diversified sample of Italian older adults, that is, including older people in the age range of 65 to 80 years experiencing a wide range of CNCP conditions, mainly of high-medium intensity and long-term duration, and referring to a clinical center for pain management. Although the upper age limit of the participants has been set to 80 years due to clinical and practical reasons (ie, physical and mental discomfort due to the time-consuming medical examination that preceded the evaluation), we have broadened the target population generally involved in these typologies of studies by including not only those aged 65 to 74 years but also a subgroup of people aged 75 to 80 years. This is noteworthy considering that people aged 75 to 80 years have traditionally been underrepresented in clinical research, despite the high comorbidity and presence of chronic pain [63].

In addition, a high percentage (18/23, 78%) of older individuals who visited the center during the recruitment period participated in the study, which helped reduce selection bias. As an additional strength, this is the only study conducted in Italy to have considered the older population with chronic pain. Considering the differences in the digital skills and pain perception across the culture and context, this represents a strength. The findings could inform the future development of eHealth solutions tailored to the specific needs and characteristics of the older Italian population with CNCP.

However, other limitations should be considered. First, we recruited a small sample size, although this was in line with other qualitative studies, and data saturation was achieved. This also precludes further considerations regarding the attitudes that emerged toward eHealth in relation to gender, age subgroups, or type of chronic pain. Therefore, future studies could focus on these aspects. Second, we enrolled participants among those already accessing health care services for pain management while not reaching out to individuals who might benefit and need eHealth solutions even more due to residing in geographically distant, poorly connected, or isolated areas.

Conclusions

To conclude, this study contributed to integrating and extending the current literature on the potentiality and barriers of eHealth for chronic pain management among older adults with different types of CNCP. Being aware of the differences in pain perception and management and the level of digital skills according to the sociocultural contexts, the results of this study allowed us to explore perspectives and experiences about the eHealth solutions for coping with chronic pain in a sample of older adults in the context of an Italian pain therapy center.

Results have been discussed considering how health care services can be directed to promote the use of these solutions and improve the management of chronic pain in older people.

Overall, participants showed an attitude of resignation to their chronic pain condition. Moreover, the use of digital solutions for health and pain management purposes is still scarce, even considering the perception of a lack of digital skills or technological attitude, resulting in a reduced sense of familiarity and trust in the potential of these tools for CNCP self-management. However, older adults are able to identify potential in the adoption of such tools.

The findings of this study may inform the development of new digital health tools specifically targeted at the characteristics of the Italian older population with CNCP. They also provide insights into how these tools should be proposed for them to be useful and feasible, emphasizing, in this regard, the importance of enhancing self-efficacy in pain management and digital literacy among older adults.

To summarize, the need to foster educational initiatives on the actual potential and purposes of eHealth solutions emerged, addressing the specific needs and challenges encountered by older adults and eventually involving their formal and informal caregivers. At the same time, it is of paramount importance to increase public welfare policies aimed at enhancing the older population's digital skills and consequently reducing the existing digital divide before introducing innovative eHealth solutions.

Acknowledgments

This publication was produced during ADL's attendance at the PhD program in Neuroscience, Psychological and Psychiatric Sciences, and Movement Sciences at the University of Verona, cycle XXXVIII, with the support of a scholarship financed by the Ministerial Decree no. 351 of April 9, 2022, based on the National Recovery and Resilience Plan (PNRR) funded by the European Union, NextGenerationEU, mission 4 (Education and Research), component 1 (Enhancement of the offer of educational services: from nurseries to universities), investment 3.4 (Teaching and advanced academic skills) and investment 4.1 (Extension of the number of research doctorates and innovative doctorates for public administration and cultural heritage), project M4C1, investment 3.4, CUP B31I22000190006 and project M4C1, investment 4.1, CUP 31I22000200006.

Authors' Contributions

VD and CP were involved in the conceptualization of the study. ADL, VD, and CP were involved in the data curation and writing of the original draft. EP, LDP, SV, and IP were involved in reviewing and editing of the paper. All authors have read and agreed to the published version of the manuscript.

Abstract

Background: The co-occurrence of chronic illnesses and substance use presents complex challenges for health care systems. Understanding the interplay between these factors, compounded by the context of the COVID-19 pandemic, is essential for effective intervention strategies.

Objective: This study aims to investigate the relationships among chronic illness, substance use, and COVID-19 infection in adults aged 50 years and older.

Methods: Participants were 1196 adults aged 50 years and older. Descriptive statistics were used to describe demographic information. Logistic regressions and multiple regression analyses were used to determine associations between chronic illnesses, substance use, and COVID-19 infection. Mediation analysis was used to determine the effect of chronic illness mediators in the association between COVID-19 concerns and substance use.

Results: The mean age was 68 (SD 10.3) years, with 58.6% (701/1196) being women. Adjusted analysis revealed that age and sex (women) significantly predicted a lower level of substance use ($P<.05$). However, marital status (separated or widowed) and chronic illness significantly predicted a higher level of substance use ($P<.05$). Furthermore, having dementia, arthritis, and high cholesterol significantly predicted a higher level of concern about the COVID-19 pandemic ($P<.05$). Logistic regression analysis indicated that individuals with hypertension (odds ratio [OR] 1.91, 95% CI 1.37-2.66; $P<.001$), lung disease (OR 2.42, 95% CI 1.23-4.75; $P=.01$), heart condition (OR 1.99, 95% CI 1.28-3.10; $P=.002$), stroke (OR 2.35, 95% CI 1.07-5.16; $P=.03$), and arthritis (OR 1.72, 95% CI 1.25-2.37; $P=.001$) were more likely to have their work affected by the COVID-19 pandemic. The mediation analysis showed a significant effect of COVID-19 concern on substance use through the mediation of chronic illness, with a 95% CI of –0.02 to –0.01 and an indirect effect of –0.01.

Conclusions: Our study reveals complex associations among chronic illnesses, substance use, and COVID-19 infection among adults aged 50 years and older. It underscores the impact of demographics and specific chronic conditions on substance use behaviors and COVID-19 concerns. In addition, certain chronic illnesses were linked to heightened vulnerability in employment status during the pandemic. These findings emphasize the need for targeted interventions addressing physical health and substance use in this population during the COVID-19 pandemic.

Introduction

Background

Chronic illnesses are persistent health conditions requiring long-term management [1]. Common examples include diabetes [2], cardiovascular diseases [3], and respiratory infections [4], which contribute significantly to the increasing burden of chronic conditions among adults aged 50 years and older [5,6]. The high prevalence of these conditions highlights the importance of examining the factors that influence health trajectories in this age group [7]. While managing chronic illnesses is critical, it is also important to consider other health issues that can compound the challenges faced by this demographic. Among these, substance use problems stand out as a significant concern. Substance use, which includes excessive alcohol and drug consumption, not only jeopardizes mental and physical health but also complicates the management of chronic illnesses [8,9]. The relationship between chronic illnesses and substance use is intricate, with substance use potentially exacerbating chronic conditions and vice versa. A study using electronic health records from the United States found that 48.3% (102,324/211,880) of individuals were diagnosed with at least 1 chronic disease [10]. Furthermore, those with at least 1 substance use disorder had higher odds of having a chronic disease [10]. Another retrospective study explored the association between chronic disease and substance use among older adults and found that marijuana use and smoking were significantly associated with chronic disease, while alcohol use was not [11]. This interplay highlights the need for a comprehensive approach that addresses both chronic conditions and substance use, ensuring that health care strategies are well-rounded and effective in managing the multifaceted health needs of older adults.

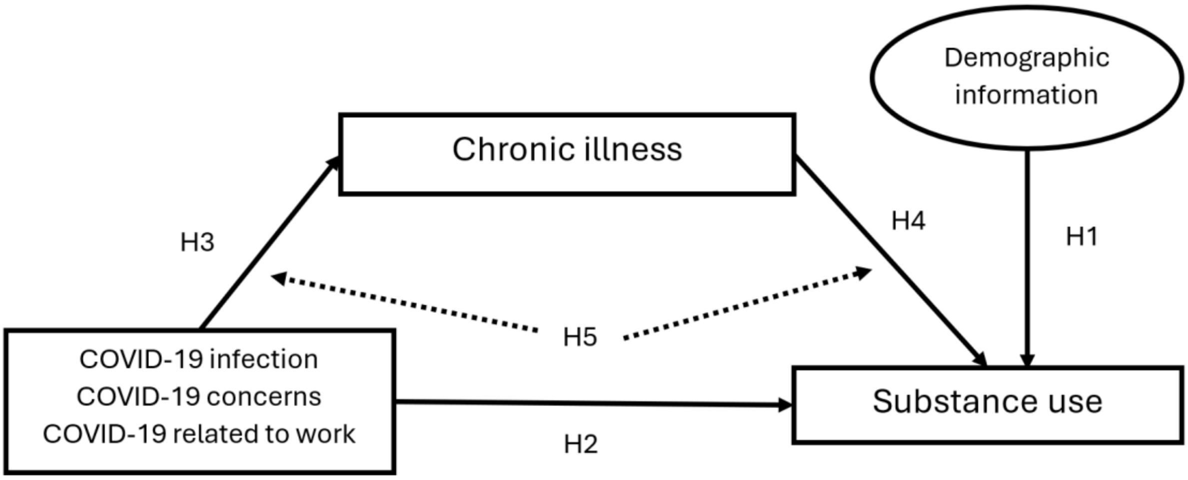
As the COVID-19 pandemic continues to reshape the health care landscape, the interplay between chronic illnesses and substance use has grown increasingly complex. Beyond the direct impact of the virus, the pandemic has introduced additional stressors and challenges, influenced health behaviors, and exacerbated preexisting health conditions [12-14]. In particular, the pandemic has intensified the prevalence and severity of chronic illnesses, while also disrupting health care access and support systems. A study shows that the COVID-19 pandemic has worsened chronic illnesses by increasing their severity and risk. Patients with conditions such as cardiovascular diseases and diabetes experience more severe outcomes due to factors such as elevated angiotensin-converting enzyme 2 levels and cytokine storms. In addition, the COVID-19 pandemic can also induce new chronic conditions, highlighting the need for targeted management strategies [15]. The pandemic's impact on substance use patterns is of particular interest. Factors such as isolation, economic uncertainties, and disruptions in health care access may contribute to shifts in how individuals cope with stress, potentially affecting substance use trends [16,17]. Amid this complex backdrop, the relationship between substance use and chronic illnesses takes on heightened significance [10]. While research has explored these factors individually, a comprehensive understanding of their interconnection—particularly within the unique context of COVID-19 pandemic—is lacking. It is plausible that both the effects of COVID-19 pandemic and chronic illness are related to substance use. Therefore, chronic illnesses could serve as a mediating variable in the relationship between COVID-19 infection and substance use. This study addresses this gap by conducting secondary data analysis on the HRS (Health and Retirement Study) 2020, a retrospective cohort study. The HRS 2020 represents American adults aged 50 years and older, investigating characteristics, health behaviors, and the unique context of the COVID-19 pandemic.

This research holds practical implications that extend beyond theoretical contributions. By identifying and elucidating the pathways through which chronic illness impacts substance use, our mediation analysis can inform public health strategies. This investigation aims to contribute to a comprehensive understanding of the multifaceted challenges faced by adults aged 50 years and older, ultimately enhancing the effectiveness of health care interventions and care for these vulnerable groups.

Study Aims

This study aims to investigate the relationships among chronic illness, substance use, and COVID-19 infection in adults aged 50 years and older. We hypothesized that the undesirable demographic factors of adults aged 50 years and older (ie, lower number of years in school, being separated or divorced or widowed) would be positively associated with substance use (hypothesis 1). Furthermore, we anticipated that higher odds of COVID-19 components, including COVID-19 infection, COVID-19–related concerns, and its relationship to work (hereinafter "COVID-19 related to work"), would increase the likelihood of substance use (hypothesis 2). In addition, we hypothesized that the odds of all COVID-19 components would be associated with a number of chronic illnesses (hypothesis 3) and a higher number of chronic illnesses would be positively linked with the likelihood of substance use (hypothesis 4). Finally, we expected that the direct effect of all COVID-19 components would be mitigated and the indirect effect through chronic illness would be significant among adults aged 50 years and older, thus revealing a mediating role of chronic illness (hypothesis 5; Figure 1).

Figure 1. Hypothesis model. H: hypothesis.



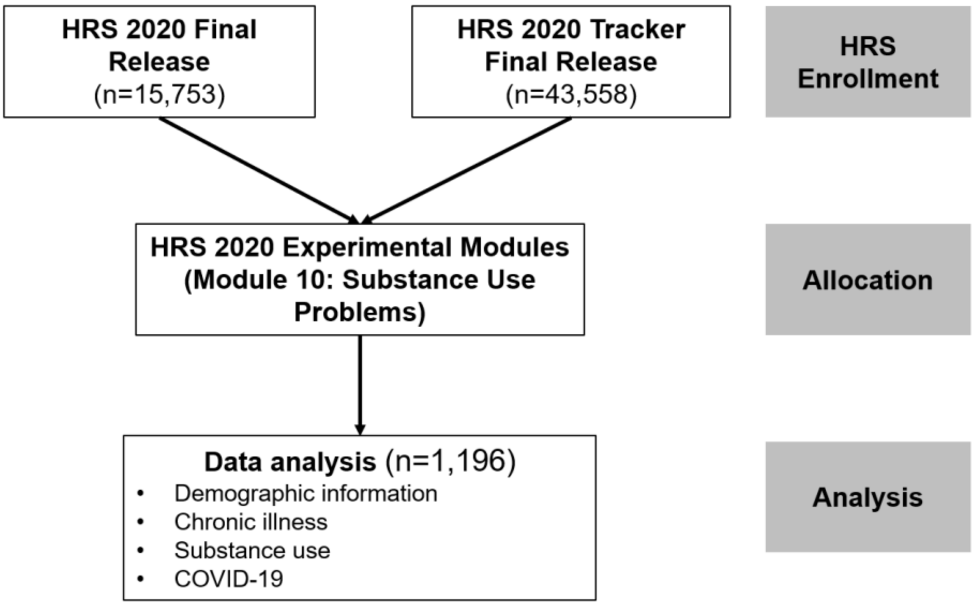
Methods

Study Design and Data Collection

The research was carried out following the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for cross-sectional studies (Multimedia Appendix 1). In this retrospective cross-sectional study, we used public data from the HRS, an ongoing longitudinal panel survey [18]. The HRS sample follows a multistage, stratified study design conducted every 2 years since 1992, interviewing approximately 20,000 Americans aged 50 years and older [19]. This study used the HRS 2020 Final Release, HRS 2020 Tracker Final Release, and HRS 2020 Experimental Modules (specifically, Module 10: Substance Use Problems). In every wave, HRS incorporates numerous experimental modules (eg, Module 10: Substance Use Problems), which are conducted following the core interview. These modules, typically lasting 2-3 minutes, are deliberately crafted to address various topics, including both new subjects and those that augment the core information. While sample sizes may vary, they generally constitute approximately 10% of a random sample drawn from the core. Importantly, each respondent is assigned only 1 experimental module per wave.

For this study, 15,753 participants were recruited from the HRS 2020 final release, and 43,558 people were included from the HRS 2020 Tracker final release. After including only those who participated in Module 10: Substance Use in Experimental Modules, 1196 participants were eligible and will be included in the final analysis (Figure 2).

Figure 2. Study flowchart. HRS: Health and Retirement Study.



Measures

Demographic Information

In this study, demographic information included age (in years), sex (“men” or “women”), race or ethnicity (“White/Caucasian,” “Black/African American,” or “Other”), number of school years (“no formal education” [0 years], “grades” [1-11 years], “high school” [12 years], “some college” [13-15 years], “college graduate” [16 years], or “post college” [17 years or more]), and marital status (“married,” “separated or divorced,” “widowed,” or “never married”). Demographic data were extracted from the HRS 2020 Final Release and HRS 2020 Tracker Final Release to facilitate consistent use of HRS data across waves.

Chronic Illness

Chronic illnesses, as defined by the Centers for Disease Control and Prevention (CDC), are conditions that persist for 1 year or more and require ongoing medical attention or limit daily activities [1]. In this study, we examined 9 chronic conditions: hypertension, diabetes mellitus, lung disease, heart conditions, stroke, depression, dementia, arthritis, and high cholesterol. Participants were asked whether they had ever been diagnosed with each condition, with responses coded as binary: “No” was coded as 0, and “Yes” as 1. The total number of chronic conditions was summed to create a “Chronic Illness” variable, ranging from 0 to 9, where a higher score indicates a greater number of chronic illnesses. Data were extracted from the HRS 2020 Final Release, and recoding was performed as necessary to facilitate analysis.

COVID-19

COVID-19 variables consisted of 6 measures, which can be categorized into three categories: (1) COVID-19 Concern (assessed on a scale from 1 to 10, where 1 indicated the least concern and 10 the most); (2) COVID-19 Infection: Self-report (Had you had or did you then have COVID-19, the disease caused by the novel coronavirus?) and Test-based (Did any tests indicate that you had the virus?); and (3) COVID-19 Related to Work: Working Affected by COVID-19 (Was your work affected because of the coronavirus pandemic?) and Stop Working (Did you have to stop work entirely because of COVID-19?). The responses to the questions COVID-19 Self-report, COVID-19 Test-based, Working Affected by COVID-19, and Stop Working were “No = 0” and “Yes = 1.” All variables were extracted from the HRS 2020 Final Release. Original response categories for each variable were combined and recoded as necessary to facilitate data analysis.

Substance Use

Module 10 in HRS 2020 Experimental Modules [20] focused on issues related to substances, encompassing medications, other substances, tobacco, and alcohol that HRS participants might have encountered. Developed by the National Institutes of Health, these questions, now commonly posed in various medical settings such as doctors’ offices and hospitals, aimed to address concerns regarding substance use among Americans. The module prompted respondents to indicate how frequently they had used various substances over the past few months to a year.

In this study, we analyzed variables associated with the use of alcohol, tobacco, cannabis, prescription medications for nonmedical purposes, illegal substances, cocaine, stimulants, methamphetamines, inhalants, sleeping pills, hallucinogens, street opioids, and prescription opioids. Responses to these questions were coded as “Never = 1” and “At least 1 time (including once or twice, monthly, weekly, daily, or almost daily) = 0.” Substance use was then coded such that a higher total score indicated less frequent use, with scores ranging from 0 to 13, where 0 represented the most frequent use.

Statistical Analysis

In this study, we combined the HRS 2020 Final Release, the HRS 2020 Tracker Final Release, and the HRS 2020 Experimental Modules’ respondent-level analytic weights and used the combined weight in the analyses. Listwise deletion, which means deleting cases with missing data, was used to deal with the missing data [21]. Analyses were conducted using SPSS Statistics (version 20.0; IBM Corp). In our study, demographic information of participants was assessed using descriptive statistics such as percentages or means as appropriate. Logistic regressions and multiple linear regression analysis were used for associations where the outcome variable was categorical (binary) and continuous, respectively. For logistic regression, odds ratio (OR), 95% CI, and *P* value (significance level<.05) were reported as appropriate. For multiple linear regression, R^2, adjusted R^2, unstandardized and standardized b, SE, and *P* value were reported. The mediation analysis, the “PROCESS” Procedure for the SPSS (version 3.3), written by Hayes [22], was used. A total of 5000 bootstraps were applied to estimate 95% CI and evaluate the significance of indirect effects. Strategies proposed by Preacher and Hayes [23] were adapted to evaluate the pathway, and 4 necessary steps were followed to assess mediation. Step 1: association between the predictor and outcome (path $c = X \rightarrow Y$; total effect or the sum of the direct and indirect effects); step 2: association between the predictor and mediators (path $a = X \rightarrow M$); step 3: association between mediators and outcome (path $b = M \rightarrow Y$); and step 4: association between the predictor and outcome after controlling for mediators (path c’ = direct effect). The indirect effect was the coefficient of the “a” path multiplied by the coefficient of the “b” path, representing the effect of X on Y through M.

Ethical Considerations

The University of Michigan’s institutional review board (IRB) approved the HRS survey. The HRS provides financial payments as tokens of appreciation to respondents for their participation in various aspects of the study, rather than as compensation. For all regular study components involving enrolled participants, these payments are typically issued via check, included in advance letters informing them of upcoming participation requests. The primary exception is for baseline interviews with new participants, for whom there is no prior information available to issue checks in advance. In these cases, compensation is provided in cash at the time of the interview. Since 2016, the payment schedule for research activities has been structured as follows: US $100 for the baseline core interview, US $80 for the core panel interview, US $20 for the leave-behind after the core, US $25 for mail surveys, and US $50 for in-home venous phlebotomy. Moreover, informed consent is not required in this study as the original consent was obtained in the original HRS study. The data used in this study have been publicly released and deidentified, and are available from the HRS website. Therefore, it did not require ethical approval (project no. MU-MOU-IRB-NS 2024/13.2901 exemption approved by the IRB, Faculty of Nursing, Mahidol University).

Results

Sample Characteristics

Table 1 shows the characteristics of adult and older adult participants. Overall, 1196 participants were included. The mean age was 68 (SD 10.3) years, and most of them were women (701/1196, 58.6%), White individuals (765/1196, 64%), had completed high school (363/1196, 30.4%), and were married (631/1196, 52.8%). In terms of chronic illnesses, the mean number of chronic illnesses was 2.54 (SD 1.6). Also, 64.2% (768/1196) of participants had hypertension, 27.6% (330/1196) had diabetes mellitus, 11.1% (133/1196) had lung disease, 24.2% (289/1196) had a heart condition, 8.2% (98/1196) had a stroke, 26.7% (319/1196) had depression, 1.7% (20/1196) had dementia, 38.7% (463/1196) had arthritis, and 29.2% (349/1196) had high cholesterol. Regarding COVID-19 infection, the average concern score about the virus was 7.89 (SD 2.7). Only 3.3% (39/1196) of respondents reported contracting COVID-19 infection, while 2.2% (26/1196) tested positive for the virus. Concerning employment, 20.5% (245/1196) of participants indicated that COVID-19 infection had an impact on their work, with 9.4% (113/1196) of individuals halting work entirely due to the pandemic. As for substance use, the mean score was 11.37 (SD 0.85), ranging from 0 to 13; a higher score reflects lower levels of substance use.

Table 1. Characteristics of participants (adults aged 50 years and older).

Characteristics of participants[a]	Values
Age (years), mean (SD; range)	68 (10.3; 50-99)
Gender, n (%)	
Men	495 (41.4)
Women	701 (58.6)

Working affected by COVID-19, n (%)	245 (20.5)
Stop working, n (%)	113 (9.4)
Substance use	
Substance use[e], mean (SD; range)	11.37 (0.85; 0-13)

[a] Listwise deletion, which entails deleting cases with missing data, was used to handle missing data.

[b] The sum of chronic illnesses includes hypertension, diabetes mellitus, lung disease, heart condition, stroke, depression, dementia, arthritis, and high cholesterol (score range between 0 and 9; a higher score indicates a higher number of chronic illnesses).

[c] This encompasses chronic bronchitis or emphysema.

[d] This encompasses heart attack, coronary heart disease, angina, congestive heart failure, or other heart problems.

[e] Substance use (score range between 0 and 13; a higher score indicates a lower level of substance use, including drinking alcohol, tobacco use, cannabis use, prescription drugs for nonmedical reasons, illegal drugs, cocaine, stimulants, methamphetamines, inhalants, sleeping pills, hallucinogens, street opioids, and prescription opioids).

Association Between the Characteristics of Adults Aged 50 Years and Older and Substance Use

The association between the characteristics of adults aged 50 years and older and substance use is shown in Table 2. In model 1, where characteristics of participants including age, sex, race or ethnicity, number of years in school, marital status, and chronic illnesses are independent variables, and substance use is the dependent variable, a significant equation was found ($F_{6,589}$=13.55; P<.001), with an R^2 of 0.12 and adjusted R^2=0.11. The results show that age (B=0.03; P<.001) and being women (B=0.18; P=.007) significantly predict a lower level of substance use. However, marital status (separate or widow; B=–0.11; P=.001) and chronic illnesses (B=–0.11; P<.001) significantly predict a higher level of substance use. After excluding race or ethnicity and number of years in school in model 1 as they are insignificant, age, sex, marital status, and chronic illnesses remain significant predictors of substance use (model 2).

Table 2. The association between the characteristics of adults aged 50 years and older and substance use[a].

Characteristics	Unstandardized coefficients		Standardized coefficients	*t* test (*df*)	*P* value[c]
	B [b]	SE	*b*		
Model 1 (n=596)					
Constant	9.84	0.329	—[d]	29.87 (6,589)	<.001
Age (years)	0.03	0.004	.29	7.07 (6,589)	*<.001*
Sex (reference group: women)	0.18	0.066	.11	2.69 (6,589)	*.007*
Race/ethnicity (reference group: White)	0.06	0.052	.05	1.21 (6,589)	.23

[e] The sum of chronic illnesses includes hypertension, diabetes mellitus, lung disease, heart condition, stroke, depression, dementia, arthritis, and high cholesterol (score range between 0 and 9; a higher score indicates a higher number of chronic illnesses).

The Association Between Chronic Illness in Adults Aged 50 Years and Older and COVID-19 Concern

Table 3 shows the association between chronic illnesses in adults aged 50 years and older and concern about the COVID-19 pandemic. After adjusting for age, sex, race or ethnicity, number of years in school, and marital status in model 1, a significant equation was found ($F_{14,861}$=5.81; P<.001), with an R^2 of 0.09 and adjusted R^2=0.07. The results indicate that having dementia (B=1.60; P=.02), arthritis (B=0.69; P=.001), and high cholesterol (B=0.49; P=.02) significantly predict a higher level of concern about the COVID-19 pandemic. In model 2, adjusting for sex and race or ethnicity, dementia, arthritis, and high cholesterol remain significant predictors of COVID-19 concern with slightly changed significance values.

The Adjusted OR of COVID-19 Infection and COVID-19 Related to Work in Adults Aged 50 Years and Older With Chronic Illness

The adjusted (sex and race or ethnicity) association between chronic illnesses and various COVID-19 components, including COVID-19 infection and COVID-19 related to work, was determined (Table 4). In model 1, the independent variables are chronic illnesses, and the outcome variable is work affected by COVID-19 pandemic (Was your work affected because of the coronavirus pandemic?). The results indicate that for individuals with hypertension (OR 1.91, 95% CI 1.37-2.66; *P*<.001), lung disease (OR 2.42, 95% CI 1.23-4.75; *P*=.01), heart condition (OR 1.99, 95% CI 1.28-3.10; *P*=.002), stroke (OR 2.35, 95% CI 1.07-5.16; *P*=.03), and arthritis (OR 1.72, 95% CI 1.25-2.37; *P*=.001), their work is more likely to be affected because of the COVID-19 pandemic. Moreover, model 2 shows the association between chronic illnesses and stopping work as an outcome (Did you have to stop working entirely because of COVID-19?). The results reveal that individuals with diabetes mellitus are 49% as likely to stop working entirely because of the COVID-19 pandemic compared with those with no diabetes mellitus (OR 0.49, 95% CI 0.25-0.95; *P*=.04). No significance was found in the model in which COVID-19 infections (both self-report and test-based) are dependent outcome variables, so they are not shown in Table 4 but can be found in Multimedia Appendix 2.

Table 4. The association between chronic illness of adults aged 50 years and older and COVID-19 infection and COVID-19 related to work[a].

Chronic illness	COVID-19–related factors					
	Model 1[b]: working affected by COVID-19[c] (n=876)			Model 2[b]: stop working[d] (n=245)		
	P value	OR[e]	95% CI	*P* value	OR	95% CI
Hypertension	*<.001*	*1.91*	*1.37-2.66*	.48	0.82	0.47-1.44
Diabetes mellitus	.20	1.29	0.87-1.89	*.04*	*0.49*	*0.25-0.95*
Lung disease	*.01*	*2.42*	*1.23-4.75*	.23	0.43	0.11-1.68
Heart condition	*.002*	*1.99*	*1.28-3.10*	.67	1.21	0.52-2.81
Stroke	*.03*	*2.35*	*1.07-5.16*	.36	2.29	0.40-13.26
Depression	.50	0.88	0.60-1.20	.51	1.24	0.66-2.37
Dementia	.73	1.26	0.33-4.86	.45	0.33	0.02-5.77
Arthritis	*.001*	*1.72*	*1.25-2.37*	.95	0.98	0.57-1.71
High cholesterol	.93	0.99	0.68-1.42	.66	1.15	0.62-2.14

[a] No significance was found in the model in which COVID-19 self-report and COVID-19 test-based are dependent outcome variables; therefore, it was not shown in Table 4. The reference group consists of the respondents who did not report having any chronic illnesses. *P* values in italics indicate statistically significant results (*P*<.05).

[b] Adjusted for sex and race or ethnicity.

[c] Working affected by COVID-19: Was your work affected because of the coronavirus pandemic?

[d] Stop working: Did you have to stop working entirely because of COVID-19?

[e] OR: odds ratio.

Examining the Role of Chronic Illness as a Mediator in the Relationship Between COVID-19 Concern and Substance Use

The effect of COVID-19 concern (X) on substance use (Y) through the mediator of chronic illness (M) was examined. The path from COVID-19 concern to chronic illness exhibited a significant positive relationship (*b*=0.12, SE=0.03; *P*<.001).

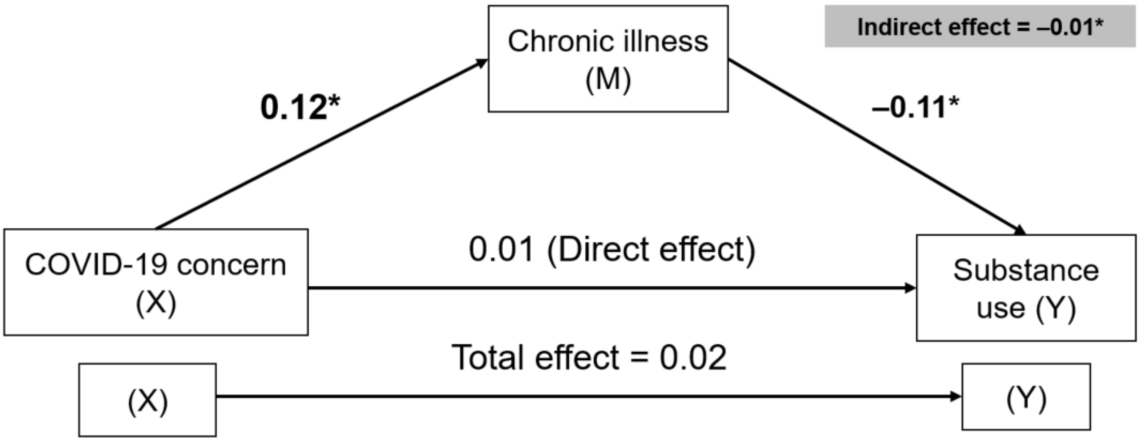
The path from the chronic illness mediator to substance use exhibited a significant negative relationship (*b*=–0.11, SE=0.02; *P*<.001), suggesting that individuals with higher numbers of chronic illnesses were more likely to demonstrate a higher level of substance use. The direct effect of COVID-19 concern on substance use was positive and insignificant (*b*=0.01, SE=0.02; *P*=.57). The indirect effect was assessed using nonparametric 5000 bootstrapping. The 95% CI for the indirect effect (–0.01) was –0.02 to –0.01, indicating a significant effect of COVID-19 concern on substance use through the mediation of chronic illness (Table 5 and Figure 3).

Table 5. The effect of chronic illness mediators (M) in the association between COVID-19 concern (X) and substance use (Y).[a]

	COVID-19 concern (X) (n=460)										
Chronic illness (M)	X→M (a)			M→Y (b)			X→Y (c’)			Indirect effect (a×b)	
	a	SE	*P* value	*b*	SE	*P* value	c’	SE	*P* value	a×b	95% CI
	0.12	0.03	<.001	–0.11	0.02	<.001	0.01	0.02	.57	–0.01	–0.02 to –0.01

[a] Dependent variable: substance use (score range between 0 and 13; a higher score indicates a lower level of substance use, including drinking alcohol, tobacco use, cannabis use, prescription drugs for nonmedical reasons, illegal drugs, cocaine, stimulants, methamphetamines, inhalants, sleeping pills, hallucinogens, street opioids, and prescription opioids). Total effect (X→Y): effect 0.02 (95% CI –0.03 to 0.03).

Figure 3. The mediation analysis model of the effect of chronic illness mediators (M) in the association between COVID-19 concern (X) and substance use (Y). *Statistically significant at *P*<.05.



Discussion

Characteristics of Adults Aged 50 Years and Older and Substance Use

Focusing upon adults aged 50 years and older, prior studies revealed that substance use is increasing in comparison with younger adults, and this trend has been well documented [24,25]. In our research, when considering characteristics of substance use in this demographic, we found that age, sex, race or ethnicity, number of years in school, marital status, and chronic illnesses explained 12.0% of substance use behaviors. However, only age, sex, marital status (being widowed or separated), and chronic illnesses added statistically significantly to the prediction of substance use. Our findings showed that women aged 50 years and older used fewer substances than men in the same age group. However, widowed or separated individuals and those dealing with chronic illnesses were more likely to engage in substance use. These findings align with prior studies, which showed that more than half of older adults (ranging from 54.5% to 57.8%) engaged in substance use, with higher rates observed among those aged 65 years and older [26,27]. However, substance usage among older women and men varies based on the particular types of substances. Older women are more likely to use sedatives, weight loss medications, and pain relievers, while older men are more likely to consume alcohol [24,28,29]. In terms of chronic illnesses, Ahuja et al [11] found similar results to our findings, indicating a correlation between chronic illnesses and various substance use among the older adults. Specifically, this earlier work highlighted that reporting 2 or more chronic illnesses is linked to a higher probability of substance use, such as marijuana [11]. Regarding marital status, our results correspond with those of Johar et al [30]. Their research suggests that the experience of being widowed or separated is frequently tied to emotions of loneliness, social isolation, or lifestyle changes, which could impact substance use behavior [30]. Based on our findings, it is unclear whether the specific substances used among older women present an opportunity to delve into why substance use is relatively low in this group. Moreover, taking into account specific conditions such as dementia, arthritis, and high cholesterol may influence substance use to alleviate chronic illnesses; therefore, screening and assessment are important to identify the factors affecting substance use.

Chronic Illness, COVID-19 Concerns, and Adults Aged 50 Years and Older

Individuals with dementia experience a loss of cognitive functioning, including rationality, memory, and logical thinking. This condition is recognized as one of the significant causes of dependency among adults aged 50 years and older [31]. The COVID-19 pandemic has raised concerns for individuals with dementia, who are at high risk of severe COVID-19 infection [32]. Those with dementia may face challenges in following safeguarding procedures, such as maintaining social distancing, wearing masks, and practicing hand hygiene, which all leave them more vulnerable to COVID-19 infection [33] and encounter difficulty communicating their health concerns and face barriers to accessing health care services during the COVID-19 pandemic [31]. The impact of the COVID-19 pandemic on adults aged 50 years and older with dementia has been reported, including worsening mental health while receiving live-in home health care [34] and poor health outcomes from COVID-19 hospitalization [35,36]. Individuals with arthritis may have significant concerns as they are at risk of COVID-19 infection. A recent study found that individuals with arthritis have a significantly higher risk of contracting COVID-19 infection [37]. This increased risk may be attributed to factors such as receiving treatment involving immunosuppressant medications, which can predispose them to COVID-19 infection and severe illness, potentially leading to hospitalization or death when compared with those with no arthritis [37,38]. In addition, the literature indicates that individuals with arthritis face an elevated risk of experiencing severe COVID-19 symptoms, particularly those associated with interstitial lung disease [39]. These findings may heighten concerns among individuals with arthritis about navigating the COVID-19 pandemic. Social isolation stemming from the COVID-19 pandemic poses a significant concern for individuals' lifestyles, particularly those with high cholesterol. Managing high cholesterol necessitates lifestyle modifications such as adopting a healthy diet, engaging in regular physical activity, and reducing stress to mitigate cholesterol levels and delay-associated mortality [40]. However, adhering to these recommendations has been challenging during the pandemic, with individuals facing limited access to healthy food options, disrupted eating patterns, reduced physical activity, heightened stress levels, and compromised sleep quality [41]. These factors can impede efforts to control cholesterol levels and elevate the risk of progression to comorbidities such as metabolic syndrome and cardiovascular disease [42]. Furthermore, research indicates a correlation between cholesterol levels, higher body mass index, and susceptibility to COVID-19 infection, as well as the severity of COVID-19 illness [43-45]. These findings underscore the heightened concerns surrounding COVID-19 infection for individuals managing high cholesterol.

The Impact of COVID-19 Pandemic on Employment in Adults Aged 50 Years and Older With Chronic Illness

Our findings indicate the effect of the COVID-19 pandemic on work among individuals with hypertension, lung disease, heart condition, stroke, or arthritis. According to the CDC, individuals with chronic illnesses are at higher risk for poor health outcomes and developing more serious complications from COVID-19 infection [46]. The Occupational Safety and Health Administration launched general guidance for employees and employers based on the CDC's statement on recognizing personal health risk factors and helping facilitate their work [47]. For example, people with chronic illnesses are allowed to work from home every day to reduce contact with other coworkers. Moreover, employees with chronic illnesses reported higher levels of COVID-19 fear than employees with no chronic illnesses, which may affect how they work [48]. However, our findings indicate that the effect of the COVID-19 pandemic on work is not correlated with individuals with diabetes, depression, dementia, or high cholesterol, despite being listed in the CDC's statement. These findings remain inconclusive in previous studies. Regarding the association between the effect of the COVID-19 pandemic and leaving the workforce entirely, our findings reported the significance of diabetes mellitus, while other chronic illnesses are not significant. Individuals with diabetes mellitus may have to maintain their financial stability in managing their diabetes treatment, especially oral medications and insulin regimens. On the other hand, other chronic illnesses may have a lower cost of health care than diabetes mellitus. A study conducted in Tanzania reported that the financial burden relative to household income in individuals with diabetes mellitus increased by 32.1% [49]. As a result, individuals with diabetes mellitus may have to continue working during the COVID-19 pandemic.

Chronic Illness as a Mediator in the Relationship Between COVID-19 Concerns and Substance Use

Based on our analysis, chronic illnesses act as a mediator in the relationship between COVID-19 concerns and substance use. There are 2 main postulations drawn from the results. First, individuals with chronic illnesses face a higher risk of COVID-19 infection, leading to increased stress and anxiety, which may prompt them to use substances as a coping strategy. This could be due to concerns about visiting hospitals amid the pandemic, driving them toward substance use to manage their heightened emotions, fears, and health conditions. Second, individuals may turn to substances as a means of self-medication to alleviate the psychological distress caused by both their chronic illnesses and the added anxiety from the pandemic. However, it is important to note that the cross-sectional nature of the study limits our ability to establish the temporal relationship conclusively. Nevertheless, evidence suggests an uptick in substance use among adults aged 50 years and older with chronic conditions during the COVID-19 period. Studies, such as one conducted in Chicago, observed a surge in alcohol consumption among adults aged 50 years and older with chronic conditions at the onset of the pandemic, which then declined by late summer 2021 with the expiration of stay-at-home orders [50]. This indicates a possible impact of lockdown measures on substance use [50]. This effect could be especially pronounced among adults aged 50 years and older with chronic illnesses who were significantly affected by lockdown policies and harbored heightened concerns about the pandemic, potentially leading them toward substance use. Moreover, a network analysis involving 3075 adults from the United States and Canada found strong links among COVID-19 stress syndrome, COVID-19 disregard syndrome, and substance use [51]. Symptoms of traumatic stress and disregard for social distancing were particularly associated with alcohol and drug abuse [51]. Interestingly, concerns about the severity of the COVID-19 pandemic emerged as a central factor in the network, suggesting that targeting this concern could help reduce substance abuse [51]. Another study also proposed a pathway linking COVID-19 concerns to substance use among underserved populations such as patients with chronic illness [52]. It suggested that COVID-19 concerns and social isolation could impact health care access and worsen economic statuses, potentially driving individuals toward self-medication with substances such as opiates [52]. The relationship among COVID-19 concerns, chronic illnesses, and substance use is undoubtedly complex. However, it provides valuable insights and a framework for future efforts to mitigate substance use.

Moving forward, proactive measures are crucial to support adults with chronic conditions during pandemics. By addressing pandemic-related stress and improving health care access, we can help prevent reliance on substance use as a coping mechanism. This proactive approach is vital not only for individual well-being but also for the broader public health landscape. In addition, this call for health care providers to play a pivotal role in intensifying screening efforts for stress and substance use concerns, particularly among the older adults, may require enhanced training to address mental health issues effectively.

Limitations

Several limitations are noteworthy. First, the exclusion of psychological illness, which is prevalent among older adults, might fail to fully grasp the correlation between psychological illness and substance use. Hence, future studies should incorporate psychological illness to foster a more comprehensive understanding of the subject. Second, self-reported substance use may underestimate actual prevalence due to social desirability bias. Therefore, future studies should integrate self-reported data with objective measures such as prescription records or biological markers to enhance accuracy in estimating substance use among older adults. Third, using a cross-sectional study design might fail to establish the relationship between COVID-19 concern and substance use. Therefore, future studies should consider a longitudinal approach to track substance use patterns among older adults over time, facilitating a clearer understanding of the temporal relationship between pandemic-related concerns and substance use. Finally, there is a modest R^2 change between model 1 (adjusted for age, sex, race or ethnicity, number of years in school, and marital status) and model 2 (adjusted for sex and race or ethnicity) of 2 associations: (1) the association between characteristics of adults aged 50 years and older on substance use and (2) the association of chronic illness in adults aged 50 years and older and COVID-19 concern. Therefore, the findings should be interpreted with caution and future studies should include a larger sample to strengthen statistical analysis and result findings.

Conclusions

Our study highlights the intricate relationship between chronic illnesses, COVID-19 infection, and substance use among adults aged 50 years and older. We found that age, sex, marital status, and chronic illnesses significantly influence substance use behaviors in this demographic. Older adults with certain chronic conditions exhibited heightened COVID-19 concerns, which, in turn, mediated their substance use. These findings underscore the importance of proactive support for older adults with chronic conditions during pandemics and the need for further research to elucidate these complex dynamics.

Abstract

Background: In the United States, over 60% of adults aged 65 years or older have multiple chronic health conditions, with consequences that include reduced quality of life, increasingly complex but less person-centered treatment, and higher health care costs. A previous trial of ElderTree, an eHealth intervention for older adults, found socioemotional benefits for those with high rates of primary care use.

Objective: This study tested the effectiveness of an ElderTree intervention designed specifically for older patients with multiple chronic conditions to determine whether combining it with primary care improved socioemotional and physical outcomes.

Methods: In a nonblinded randomized controlled trial, 346 participants recruited from primary care clinics were assigned 1:1 to the ElderTree intervention or an attention control and were followed for 12 months. All participants were aged 65 years or older and had electronic health record diagnoses of at least three of 11 chronic conditions. Primary outcomes were mental and physical quality of life, psychological well-being (feelings of competence, connectedness, meaningfulness, and optimism), and loneliness. Tested mediators of the effects of the study arm (ElderTree vs active control) on changes in primary outcomes over time were 6-month changes in health coping, motivation, feelings of relatedness, depression, and anxiety. Tested moderators were sex, scheduled health care use, and number of chronic conditions. Data sources were surveys at baseline and 6 and 12 months comprising validated scales, and continuously collected ElderTree usage.

Results: At 12 months, 76.1% (134/176) of ElderTree participants were still using the intervention. There was a significant effect of ElderTree (vs control) on improvements over 12 months in mental quality of life (arm × timepoint interaction: b=0.76, 95% CI 0.14-1.37; *P*=.02; 12-month Δd=0.15) but no such effect on the other primary outcomes of physical quality of life, psychological well-being, or loneliness. Sex moderated the effects of the study arm over time on mental quality of life (b=1.33, 95% CI 0.09-2.58; *P*=.04) and psychological well-being (b=1.13, 95% CI 0.13-2.12; *P*=.03), with stronger effects for women than men. The effect of the study arm on mental quality of life was mediated by 6-month improvements in relatedness (α=1.25, *P*=.04; *b*=0.31, *P*<.001). Analyses of secondary and exploratory outcomes showed minimal effects of ElderTree.

Conclusions: Consistent with the previous iteration of ElderTree, the current iteration designed for older patients with multiple chronic conditions showed signs of improving socioemotional outcomes but no impact on physical outcomes. This may reflect the choice of chronic conditions for inclusion, which need not have impinged on patients' physical quality of life. Two ongoing trials are testing more specific versions of ElderTree targeting older patients coping with (1) chronic pain and (2) greater debilitation owing to at least 5 chronic conditions.

Introduction

Background

Global data indicate that among adults with a chronic disease, more than half have multiple diagnosable conditions [1]. Although the consequences of multimorbidity vary by the particular array of conditions, research often indicates a compounding effect on the complexity of medical treatment [2-4], a reduction in patient-centered care as clinicians respond to the most pressing medical needs [5], and markedly increased medical costs [6-8]. For patients, multiple chronic conditions (MCCs) heighten the treatment burden [9] and the risk of adverse outcomes such as prolonged hospitalization and mortality [10]. Research also suggests that patients with MCCs tend to experience reduced quality of life (QOL) [11,12] as well as greater depression [13,14] and loneliness [15].

The prevalence of multimorbidity increases with age and low-income status. Assessments of United States data from 2018 found diagnoses of MCCs among more than 60% of those aged 65 years or older (vs 27.2% of the total adult population) and among 76.9% of older adults who qualified for low-income medical care (ie, “dual eligible” for Medicare and Medicaid) [16]. As such, the burden of MCCs often falls on those patients who may have fewer resources to navigate the complexities of their conditions.

One of the core challenges of MCCs is that the specific combination of conditions experienced by a given patient can vary widely. Clinical practice guidelines and recommendations for self-management tend to be based on specific diseases or conditions, and adjusting those guidelines and recommendations becomes more difficult as the number of comorbid conditions rises [17,18]. As various authors have noted, the risk of polypharmacy and the difficulty of self-management escalate with the number of comorbid conditions [19,20]. Given these challenges, the National Institutes of Health called for researchers to develop and test behavioral interventions that could be implemented in primary care and that would offer one broadly applicable and effective tool to help manage a wide array of combinations of chronic conditions [21]. This project was funded by the National Institutes of Health and responds to that call.

A recent review and meta-analysis of 16 randomized controlled trials (RCTs) of interventions to address multimorbidity in primary care and community settings was not encouraging [22]. Interventions were broadly grouped into those focused on medication management, self-management support, or care coordination plus self-management support. Most were designed to enhance patients’ interactions with their primary care team by coaching or informational sessions and materials. Across the 4753 participants, with most of them being older adults with 3 or more chronic conditions, there was “little or no evidence” of effects (relative to usual care [UC]) on health-related QOL or mental health, or on an array of secondary outcomes, including health care use, medication adherence, and self-efficacy. Notably, only 2 of the 16 interventions (both relatively brief, at 6 weeks in length) offered peer support in the form of weekly meetings [23,24], and none provided online resources for communicating with clinicians or peers.

A second meta-analysis, focusing on “digital telemedicine interventions” for patients with at least 2 comorbid chronic conditions [25], found somewhat more encouraging results, though the authors noted the prevalence of low-quality study designs, small sample sizes, and short durations (2-6 months with limited follow-up). The interventions were typically multifaceted, offering services such as telemonitoring (eg, online tracking of blood glucose, blood pressure, or weight, to be reviewed by the medical team), telecare (eg, online feedback or appointments with clinicians based on health-tracking scores and online yoga classes), or automated reminders (eg, for exercise or medications). The results across 2 or 3 studies for each outcome indicated moderate decreases in systolic blood pressure and cholesterol and small to moderate decreases in hemoglobin A_{1c}. In contrast, the effects on patient-centered outcomes, such as QOL, perceived health status, and depression, were largely nonsignificant. Again, it was notable that no interventions involved peer support, and most focused on tracking specific health indicators rather than patient well-being.

The current RCT was designed to build on this prior work but to avoid key limitations, including small sample size, short intervention duration, and limited or no opportunity for communicating with clinicians or peers. It presents a relatively novel and rigorous approach to multimorbidity, testing a 12-month eHealth intervention designed to improve QOL, socioemotional outcomes, and health-related outcomes among older adults with 3 or more chronic conditions. The intervention, ElderTree (ET), is an information and support platform developed by our Center of Excellence in Active Aging, which was funded by the Agency for Healthcare Research and Quality, and is one of a collection of eHealth systems known as CHESS (Comprehensive Health Enhancement Support System) [26,27].

All CHESS systems, including ET, are built on the principles of continuing care and self-management, including long duration

[28]; assertive outreach [29]; tracking [30]; prompts [31]; problem solving [32]; and peer, family, or clinical support [33]. In addition, CHESS systems are consistent with Self-Determination Theory, which asserts that satisfying the fundamental psychological needs of competence (feeling effective), relatedness (feeling connected to others), and autonomy (feeling internally motivated rather than coerced) contributes to adaptive functioning [34]. In randomized trials, our interventions significantly improved asthma control [35]; QOL and cost of care in HIV patients [36]; QOL and self-efficacy in breast cancer patients [37-39]; risky drinking [40]; and caregiver burden, symptom distress, and median length of survival in lung cancer patients [41].

ET was previously tested in an RCT involving 390 adults aged 65 years or older with at least one health risk factor (eg, recent fall, depression, or emergency room visit) in 3 Wisconsin communities (urban, suburban, and rural), who were followed for an intervention period of 12 months [27]. There were no significant effects in the sample as a whole, but subgroup analyses indicated that among participants who had 3 or more primary care visits in the 6 months prior to baseline, those in the ET group performed significantly better than those in the control group on measures of mental QOL, social support, and depression.

The results suggested that (1) ET may be more effective for patients who are dealing with multiple chronic conditions (MCCs), given that primary care use is relatively high among such patients, and (2) a system such as ET may be most effective if integrated into primary care. Building on those findings, this study examined the effects of an enhanced version of ET specifically for patients with MCCs rather than a general older population, focusing on not only QOL and socioemotional outcomes but also health measures and health care use.

Study Objectives

The overall goal of the study was to assess the effects of ET versus attention control in older patients with MCCs. Our primary objective was to determine whether, and to what extent, supplementing patients' UC with ET would lead to improvements in 4 primary outcomes. Like other interventions for chronic conditions (eg, those reviewed above), we assessed physical and mental QOL. Additionally, given the focus of our intervention on the core constructs of Self-Determination Theory (ie, motivation, competence, and autonomy), we assessed psychological well-being, using a measure that focused on feelings of competence, connectedness, meaningfulness, and optimism [42]. Finally, given the evidence about the bidirectional causal impact of loneliness on the progression of chronic conditions in older adults [43,44], we assessed participants' loneliness. We also tested whether the effects of the study arm on these primary outcomes were mediated by 6-month changes in health-related coping strategies and motivation, social relatedness, anxiety, and depressive symptoms and whether effects were moderated by sex, scheduled health care use, and the number of chronic conditions.

As prespecified in the trial protocol [26], we tested the effects of the study arm (ET vs active control) on changes over time in a number of health-related secondary and exploratory outcomes: pain, number and severity of falls, symptom distress, medication adherence, use of crisis health care and long-term care, diet, alcohol use, cigarette use, and pain medication issues. To restrict the paper length, we only briefly summarize the results for these nonprimary outcomes. Complete descriptions and analyses of these variables are reported in Multimedia Appendix 1.

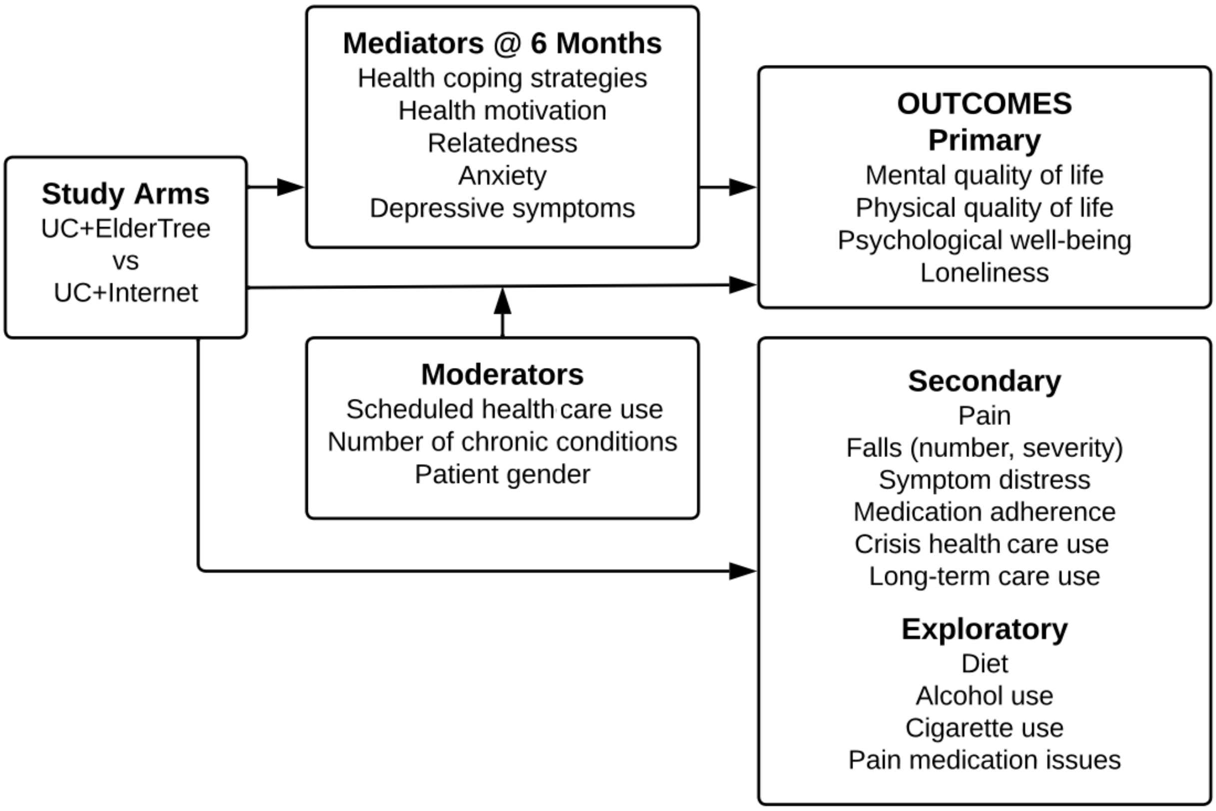
Lastly, the COVID-19 pandemic, which began mid-way through the study, overlapped with some portion of the 12-month intervention period for nearly half of the participants. As a result, we conducted post-hoc analyses, examining the months of overlap with the pandemic as a possible unanticipated moderator of the effects of the study arm.

Methods

Trial Design

The trial was a nonblinded, randomized controlled design with 1:1 allocation to the intervention arm or an attention control for a period of 12 months. Assessments were conducted at baseline, 6 months, and 12 months. We originally planned an 18-month follow-up assessment (ie, 6 months after the end of the intervention). However, with the start of the pandemic and lock-down, as we considered the role that ET played in connecting participants to each other and to their primary care team, we (the study investigators) made an ethical decision to offer continued access to ET to those participants who were approaching months 13-18. This did not change the study design for the 12 months of the intervention, but it meant that the 18-month follow-up comparison between study arms was compromised: Participants in the ET arm varied in their access to the intervention during their final 6 months of the study, depending on whether that period coincided with the pandemic. We continued to gather the 18-month data to offer participants closure, but we no longer planned to analyze and did not reach out to participants in cases of incomplete or ambiguous data. As such, we did not analyze and do not report the 18-month results. Figure 1 shows the study design.

Figure 1. Study design. UC: usual care.



Participants

Older adult patients with at least three chronic conditions were recruited from primary care clinics within the UW Health Department of Family Medicine and General Internal Medicine at the University of Wisconsin–Madison (UW Health). Eligible patients (1) were aged 65 years or older; (2) had been treated in the clinic for the previous 18 months or longer with no plans to leave during the study period; and (3) had diagnoses of 3 or more of the following 11 chronic conditions: hypertension, hyperlipidemia, diabetes, arthritis, BMI ≥30, chronic kidney disease, chronic pain, chronic obstructive pulmonary disease (COPD), congestive heart failure, arrhythmia/atrial fibrillation, and pulmonary heart disease. We originally planned to recruit participants based on self-reports of the first 5 conditions (4 of them related to metabolic syndrome). Before recruitment began, we changed our criterion to 3 or more of any of the 11 conditions listed above. We did so both to increase the pool of eligible patients and to provide a more expansive test of the effectiveness of ET in addressing a wide array of comorbid conditions prevalent among older adults.

Prior to recruitment, we also decided to use documented diagnoses from electronic health records (EHRs) as inclusion criteria, rather than relying on participant self-report (including possible self-diagnosis). This not only provided a more standardized assessment of chronic conditions but also allowed clinics to identify eligible participants and send them a recruitment letter describing the study.

Further eligibility criteria were as follows: (4) no current psychotic disorder that would prevent participation; (5) no acute medical problem requiring immediate hospitalization; (6) no visual or motor impairment preventing the use of a computer; (7) ability to read and sign the consent form in English; (8) agreement to share health-related study data (eg, lab scores and health care utilization); (9) permission to share information with the patient's primary care physician; and (10) no moderate or advanced dementia.

Interventions

Patients in both conditions continued with their UC provided by primary care and internal medicine clinics in the University of Wisconsin–Madison system and received their assigned intervention.

Control Condition

In addition to their UC, patients in the control condition received internet service and a laptop computer for 12 months. Shortcuts to 4 general health information websites, vetted for quality by our research team, were placed on the computer desktop for easy access: the Cleveland Clinic [45], National Institute on Aging [46], the American Academy of Family Physicians [47], and Mayo Clinic [48]. We expected this UC+internet intervention to be relatively ineffective because information alone is unlikely to have much impact on health behaviors [39,49-51]. Instead, access to the device, the internet, and the sites functioned as a form of attention control versus pure control comparison and as a way to isolate the specific effects of access to ET. In an attention control group, participants receive the same amount of interaction and "attention" from the research team as the intervention group, but that interaction does not contain the hypothesized therapeutic content [52]. In our case, control participants could go online and interact with others but did not do so in the context of ET.

Experimental Condition

Patients in the experimental condition received UC plus ET access and a laptop computer, along with internet for 12 months. This UC+ET group did not receive the health information websites placed on computers for control patients, although they could have sought them out independently.

ET System Overview

As described previously [26], ET provides tools, motivation, and social support to help patients manage their chronic conditions, communicate with peers and research staff, and improve communication with clinicians. The system was developed specifically for older adults with extensive input from advisory and focus groups of older adults. It featured large fonts, few options, and uncluttered screens for easy comprehension, navigation, and usability. Areas of the site were Community (with chatroom-like discussion groups, email-like private messaging, and a bulletin board of local events); Well-Being (offering relaxation and meditation videos and journaling with positive psychology prompts); and My Health (a collection of health information resources). The content was continuously refreshed. While the design and navigation were based on the original ET and principles established in our earlier testing [27,53], we enhanced the system for this study as described below. A sample of the home screen is shown in Figure S1 in Multimedia Appendix 2.

ET Enhancements

We made 3 major enhancements to the original ET. First, we expanded a basic health-tracking feature in the original ET to create a weekly survey with feedback. Patients were prompted to complete weekly check-ins regarding 10 general health indicators: sleep, nutrition, physical activity, cognition, balance, falls, mood, pain management, medication adherence, and quality of social interactions. As soon as the survey was completed, ET feedback commended any improvements. If survey results showed mild reductions in any of the health indicators, ET feedback directed the patient to relevant articles in the ET My Health library. If the algorithm detected a sudden or steep negative change in any of the indicators or a problem that was not improving over several weeks, ET recommended that the patient contact their clinic. ET also generated a graph charting the patient's responses for each indicator over the last 3 months to facilitate self-monitoring (Figure S2 in Multimedia Appendix 2).

Second, we used the survey-generated graph as the basis for a clinician report that was shared with the patient's primary care clinic. We used a similar report in a lung cancer trial comparing a CHESS system alone to a CHESS system combined with a clinician report [54] and found that the addition improved symptom distress by more than 100% (26.2% improvement with CHESS alone vs 53% with CHESS+clinician report; n=71 vs 68, respectively; *P*<.001). The clinician report was designed to offer specific benefits in health care delivery for patients with MCCs. While MCCs can lead to rapid declines in health [55], care for such patients usually consists of periodic onsite contact with primary care clinicians, who may be unaware of such changes or cannot respond as promptly as may be warranted. The report, sent the week before a patient's scheduled visit, shared timely information on health indicators and helped both patients and clinicians make the most of these visits. As a single-page graphic summary of health-tracking data, the report could be viewed and understood at a glance, avoiding a time burden for clinicians while allowing them to provide responsive and appropriate treatment. A hard copy of the report was also mailed directly to the participant to take to the appointment.

When the COVID-19 lockdown began and clinics transitioned to telehealth and fewer in-person visits, we altered our strategy for the clinician report. Every 2 months, the study project manager prepared a clinician report summary providing an overview for all participants at each clinic. The goal was to help clinicians identify patients who were reporting issues such as missed medications or mood changes between appointments, particularly as patients continued to isolate due to COVID-19. This summary was emailed to clinic managers to share with individual clinicians (Figure S3 in Multimedia Appendix 2).

Third, because our original trial of ET identified the greatest improvements in mental QOL, social support, and depression, we tried to strengthen these effects still further by adding an interactive Fun & Games area (light-hearted polls, quizzes, videos, and games) and a weekly Lifestyle article (topics included travel, mind and body, etc). Both features were designed to increase participants' enjoyment of the site and engagement with others via asynchronous comment threads.

Measures

Participants were assessed for all study variables at baseline, 6 months, and 12 months, as described below. To assess system use, time-stamped usage data from ET participants were continuously captured in our database, including specific services used; date and time the system was accessed; and text entered into discussions, comment threads, and message features.

Primary Outcomes

Mental and physical QOL were assessed using the 8-item PROMIS (Patient-Reported Outcomes Measurement Information System) Global Health measure [56,57], with 4 items for mental QOL (eg, "How would you rate your mental health, including your mood and your ability to think?") and 4 for physical QOL (eg, "To what extent are you able to carry out your everyday physical activities such as walking, climbing stairs, carrying groceries, or moving a chair?"). Scoring of individual items varies and is calculated by the scale's developers; the total possible ranges are 21.2-67.6 for mental QOL and 16.2-67.7 for physical QOL, with higher values indicating better QOL [58]. For consistency with other primary outcome measures, the timeframe was modified to the past 2 weeks.

Psychological well-being was assessed with the 8-item Psychological Flourishing Scale (eg, "My social relationships are supportive" and "I lead a meaningful life") [42]. Each item is scored on a 5-point scale, for a total possible range of 8-40, with higher scores indicating greater flourishing.

Loneliness was measured with 8 items from the UCLA Loneliness Scale that showed the highest factor loadings among elderly adults in prior work (eg, “How often do you feel part of a group of friends?”) [59]. Each item is scored on a 5-point scale, for a total possible range of 8-40, with higher scores indicating increasing loneliness.

Mediators

We measured 5 possible mediators. Health coping strategies were assessed with 10 items from the Ways of Coping Scale (eg, “Made a plan of action and followed it” and “Accepted the situation”) [60]. Each item is assessed on a 5-point scale, for a possible range of 10-50, with higher scores indicating better coping.

Motivations were assessed with four 5-point items from the Treatment Self-Regulation Questionnaire [61]; 2 items assessed autonomous motivation (eg, “I try to manage my health conditions because I want to take responsibility for my own health”) and 2 assessed external regulation (eg, “I try to manage my health conditions because I feel pressure from others to do so”). The total possible range for each motivation subscale is 2-10, with higher scores indicating greater autonomous and external motivation.

Relatedness was assessed with the 6-item McTavish Bonding Scale [62] plus 3 items from the short form of the PROMIS emotional support scale [63]. For all items, patients indicated on a 5-point scale the frequency of the type of support (eg, “Someone you can count on to listen when you need to talk” and “Someone to love and make you feel wanted”). The total possible range is 9-45, with higher scores reflecting more support.

Anxiety and depressive symptoms were assessed with the 7-item Generalized Anxiety Disorder scale [64] and the 8-item version of the Patient Health Questionnaire Depression scale [65], respectively. The response option in both 4-point scales was the frequency of a symptom (eg, “Trouble relaxing” and “Poor appetite or overeating”) in the past 2 weeks. Higher scores indicate more anxiety or depression symptoms.

Moderators

We investigated whether the effects of the study arm on change from baseline to endpoint in primary outcomes were moderated by sex, health care use, and number of chronic conditions. Participants indicated their sex (male or female) at baseline. On all assessments, they reported scheduled visits in the preceding 3 months to primary care, specialists, physical and occupational therapists, chiropractors, and counseling. For the number of chronic conditions, we used EHR data obtained during enrollment for each participant, and the range was 3-11.

Potential Covariates

Potential covariates included comfort or familiarity with technology, physical challenges using technology, and life stressors. Patients rated on a 6-point scale their comfort with 6 communication technologies: computer, smartphone, tablet, smart speaker, email, and Facebook. The total possible range is 0-30, with higher scores indicating greater comfort. For physical challenges, participants reported vision, hearing, hand pain or tremors, memory, “other,” or no limitations for both a computer/tablet and a smartphone, checking all that applied. To gauge life stressors, they reported on 14 possible stressors from the Social Readjustment Rating Scale (eg, “Death of a very close friend or family member” and “Change in financial status”) [66], checking all that applied (possible range is 0-14). Participants also reported sociodemographic variables of race and ethnicity, education, income, health insurance, whether they had a significant other, housing type, and whether they lived alone or with others. We planned to control for these if they varied by study arm.

Sample Size Determination and Power

We focused on the effect of Cohen d=0.50 on the primary outcome of patients’ perceptions of their QOL, given recommendations that this is the minimally important difference for QOL measures in clinical trials [67]. For our other primary outcomes (psychological well-being and loneliness), effect sizes tend to be smaller. For example, a prior web-based intervention for rural women with chronic diseases showed an effect of Cohen d=0.29 on loneliness among those who scored above the median on baseline levels of loneliness, depression, and stress [68]. Given that our intervention was substantially longer (12 months vs 22 weeks) and had more components specifically designed to address social connectedness, we expected somewhat larger effects but did not expect to reach Cohen d=0.50. Balancing the need to be adequately powered with the need to focus on meaningful impacts, the study was powered to detect a main effect of Cohen d=0.35 for our primary outcomes. Adequate power to detect a between-subjects effect of Cohen d=0.35 ($1-\beta=0.80$; $\alpha=.05$) with repeated measures on the outcome required a final sample of 262 patients (130 per arm). On the basis of our prior trial of ET, we assumed 20.5% attrition and thus arrived at a recruitment goal of 330 patients (165 per arm).

Recruitment

The UW–Madison Clinical Research Data Service examined UW Health Clinic EHRs to identify patients who met the eligibility criteria, including chronic conditions. Potential participants then received an opt-in letter from the university’s Office of Clinical Trials. The letter described the study and included a postage-paid return invitation for further contact from the study team.

After a patient returned the invitation, study staff called and provided a detailed trial overview, including benefits and potential risks of participation. If interested, patients were screened on all eligibility criteria. Those who verbally confirmed they wanted to participate and met the criteria were mailed the baseline survey and received a home visit from a member of the research team, at which time written consent was obtained, baseline data were collected, and randomization was determined.

Randomization

The project manager used a computer-generated allocation sequence to randomize patients in a 1:1 ratio to the experimental (UC+ET) or control (UC+internet) group, stratified by sex, clinic site, and number of chronic conditions (3-5 vs. ≥6). The block size was 10. When baseline assessment and consent were complete, the research staff person opened the numbered, sealed, opaque envelope revealing group assignment, and then conducted equipment setup and training for either the intervention (including all the services and how to use them) or control device. Once the assignment was made, participants could not be blind to their condition, given that those in the experimental arm were asked to use ET, while those in the control arm were not. The training researcher also could not be blind to the condition after the assignment was revealed.

Statistical Methods

From the list of our prespecified potential covariates, we selected covariates to include in analyses by examining whether they were moderately correlated (0.30 or higher) with at least one of the primary outcomes [69]. Only life stressors met the correlation benchmark (mental QOL: r=–0.35; physical QOL: r=–0.34).

In addition, given that participants varied in the extent of overlap between the COVID-19 pandemic and the 12-month intervention period (range=0.02 to 6.33 months), we included this variable (defined as participant's number of months during the pandemic prior to each survey timepoint) in our analyses at each timepoint as a covariate. Of note, pandemic months significantly influenced mental QOL (*P*=.03) but none of the other primary outcomes (all *P*>.31). Ultimately, life stressors and pandemic months were the only covariates included in the models.

Normality, linearity, and homoscedasticity/homogeneity of variance for outcome data were assessed using descriptive statistics and graphical representations. Outcomes were analyzed with mixed-effects models, using (g)lmer() from the lme4 package, implemented in the R statistical software environment. These models account for correlated measurements within participants, use all available data (allowing for intention-to-treat rather than only complete-case analysis), and provide unbiased estimates when data are missing at random [70]. Each model included a random effect for participant, as well as fixed effects for survey timepoint, study arm, and arm-by-timepoint interaction. The survey timepoint was entered as a continuous variable with 3 timepoints (baseline, 6 months, and 12 months).

Ethical Considerations

This study received ethical approval from the University of Wisconsin Health Sciences Institutional Review Board (reference number: 2017-0849) and has been registered at ClinicalTrials.gov (NCT03387735).

Results

Participants

A total of 346 participants were randomized, and 344 received either the assigned intervention or control device and were included in the analyses (Figure 2). Of the 344 receiving an intervention, 321 (93.3%) completed the 6-month survey and 309 (89.8%) completed the 12-month survey. As data were analyzed with mixed-effects models, which use all available data rather than only complete cases, 318 (92.4%) were included in the analyses. Recruitment began in February 2018 and ended in December 2019. The intervention period concluded in December 2020 (Figure 2). The CONSORT (Consolidated Standards of Reporting Trials) checklist is presented in Multimedia Appendix 3.

Participant characteristics at baseline are presented in Table 1. Most participants identified as white (317/344, 92.2%) and female (209/344, 60.8%), and the average age was 74 years 9 months. The average number of chronic conditions was 5.28. For a detailed breakdown of chronic conditions by group, see Multimedia Appendix 4.

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) flow diagram of participants through the study. Data were analyzed with mixed-effects models, which use all available data rather than only complete cases.

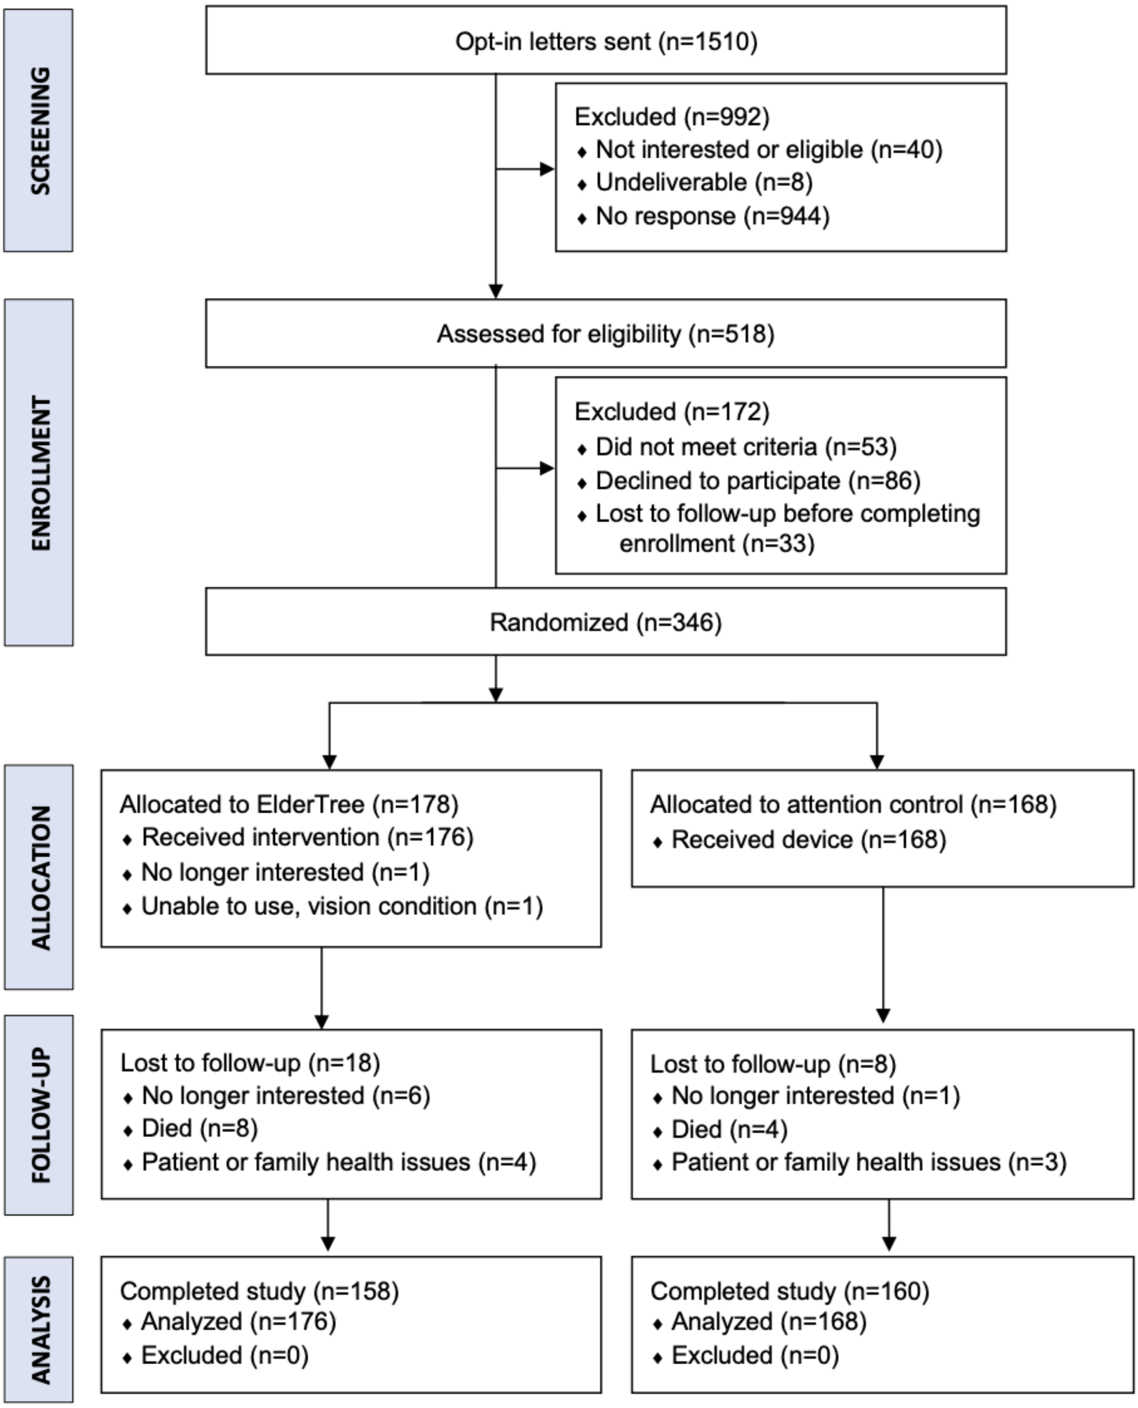


Table 1. Participant characteristics by study arm at baseline.

Characteristic	UC[a]+internet (N=168)	UC+ElderTree (N=176)
Female, n (%)	103 (61.3)	106 (60.2)
Number of chronic conditions at enrollment (from EHRs[b]), n (%)		
3-5 chronic conditions	104 (61.9)	108 (61.4)
6-11 chronic conditions	64 (38.1)	68 (38.6)
Race, n (%)		
American Indian, White	1 (0.6)	2 (1.1)
Black	14 (8.3)	8 (4.6)
Jewish	0 (0.0)	1 (0.6)
Unspecified mixed race	0 (0.0)	1 (0.6)
White	153 (91.1)	164 (93.2)
Ethnicity Hispanic or Latino, n (%)	1 (0.6)	0 (0.0)
Highest level of completed education, n (%)		
Middle school	2 (1.2)	1 (0.6)
High school	40 (23.8)	30 (17.1)
Vocational or technical school	19 (11.3)	26 (14.8)
Some college	38 (22.6)	49 (27.8)
College graduate	30 (17.9)	35 (19.9)
Postgraduate or professional	39 (23.2)	35 (19.9)
Annual income, n (%)		
Less than US $12,000	5 (3.0)	7 (4.0)
US $12,000-24,999	34 (20.2)	32 (18.2)
US $25,000-49,999	44 (26.2)	41 (23.3)
US $50,000-74,999	30 (17.9)	34 (19.3)
US $75,000 or above	41 (24.4)	43 (24.4)
Did not report	14 (8.3)	19 (10.8)
Had significant other, n (%)	105 (62.5)	110 (62.5)
Housing, n (%)		
Nursing home	1 (0.6)	0 (0.0)
Own	114 (67.9)	134 (76.1)
Rent	33 (19.6)	27 (15.3)
Assisted living facility	3 (1.8)	1 (0.6)
With family or friends	11 (6.6)	11 (6.3)
Live alone, n (%)	118 (70.2)	124 (70.5)
Age (years), mean (SD)	74.54 (6.45)	74.88 (6.11)
Comfort using technology (range 0-5)[c], mean (SD)	2.81 (1.30)	2.79 (1.34)
Physical issues with technology (range 0-10)[d], mean (SD)	0.46 (1.19)	0.38 (0.87)
Life stressors (range 0-14)[e], mean (SD)	1.11 (1.46)	1.01 (1.36)

[a] UC: usual care.

[b] EHRs: electronic health records.

[c] Higher values indicate greater comfort.

[d] Higher values indicate more physical issues.

[e] Higher values indicate more stressors.

ET Use

We defined “use” as accessing any service or feature beyond the home screen at least once during a given time period. Of the 176 participants randomized to UC+ET, 166 (94.3%) had used ET in their first month, 164 (93.2%) used it in months 2-6, 137 (77.8%) used it in months 7-11, and 134 (76.1%) used it in the final month of the study.

Number of days of use (ie, accessing any ET service in a 24-hour period) also indicated sustained use. In the first 6 months (180 days), participants accessed ET for a mean of 48.95 days (SD 35.16 days; 27.2% of days; range 0-179 days). During months 7-12, participants used the intervention for a mean of 31.40 days (SD 32.07 days; 17.44% of days; range 0-167 days). These means include participants with no days of use (scored 0).

Participants made the most use of ET services that facilitated social interaction. Of the 6 main areas on the site, Community was the most active. During their year on the intervention, 172 of the 176 UC+ET participants used this area a mean of 42.78 days (SD 59.66 days; range 1-305 days). Discussion Groups, an activity within the Community area, was the most heavily used single service on the system. During their intervention year, a total of 162 participants used it for a mean of 34.82 days (SD 57.48 days; range 1-295 days). Of the other main areas, Fun & Games was the second most visited (n=163 participants; mean 32.74 days, SD 57.50 days; range 1-311 days), followed by Lifestyle (n=163; mean 15.34 days, SD 23.81 days; range 1-214 days), both of which allowed for asynchronous interaction via comments. The nonsocial areas were used somewhat less often: My Health informational resources were used by 169 participants for a mean of 24.89 days (SD 21.66 days; range 1-135 days), and Well-Being was used by 158 participants for a mean of 15.32 days (SD 35.14 days; range 1-290 days).

Regarding the weekly health-tracking feature, 162 of the 176 UC+ET participants (92.0%) used the tracker during their first 6 months in the study, and 134 (76.1%) were still using it in the 12th month. Prior to the 6-month survey, participants used the tracker for a mean of 20.16 weeks (SD 7.11 weeks; range 0-30 weeks). Between the 6- and 12-month surveys, participants used it for a mean of 16.99 weeks (SD 8.21 weeks; range 0-26 weeks). These means include participants with no weekly tracker use (scored 0).

Use of the Clinician Report and Summaries

We had planned to conduct study-end quantitative assessments and qualitative interviews with clinicians about their uses and perceptions of the clinician report. Because of the pandemic, clinicians were unavailable to provide feedback on either the prepandemic individual reports or the clinic summaries we pivoted to once the pandemic started. We had anecdotal feedback from staff members that the clinic summaries were helpful in highlighting patients who might need outreach, but we had no way of assessing the extent to which clinicians used the reports or summaries and which aspects they found helpful or cumbersome. We did not measure patients’ uses and perceptions of the clinician reports, but some participants volunteered instances in which the clinician report sparked a conversation with their doctor (eg, about sleep).

Effects of the Study Arm on Changes Over Time in Primary Outcomes

Primary outcomes were physical and mental QOL, psychological well-being, and loneliness. We conceptualized these as distinct though related variables. In fact, the 3 socioemotional outcomes (mental QOL, psychological well-being, and loneliness) were more strongly correlated than we had anticipated (Table 2).

Table 2. Correlations between primary outcomes.

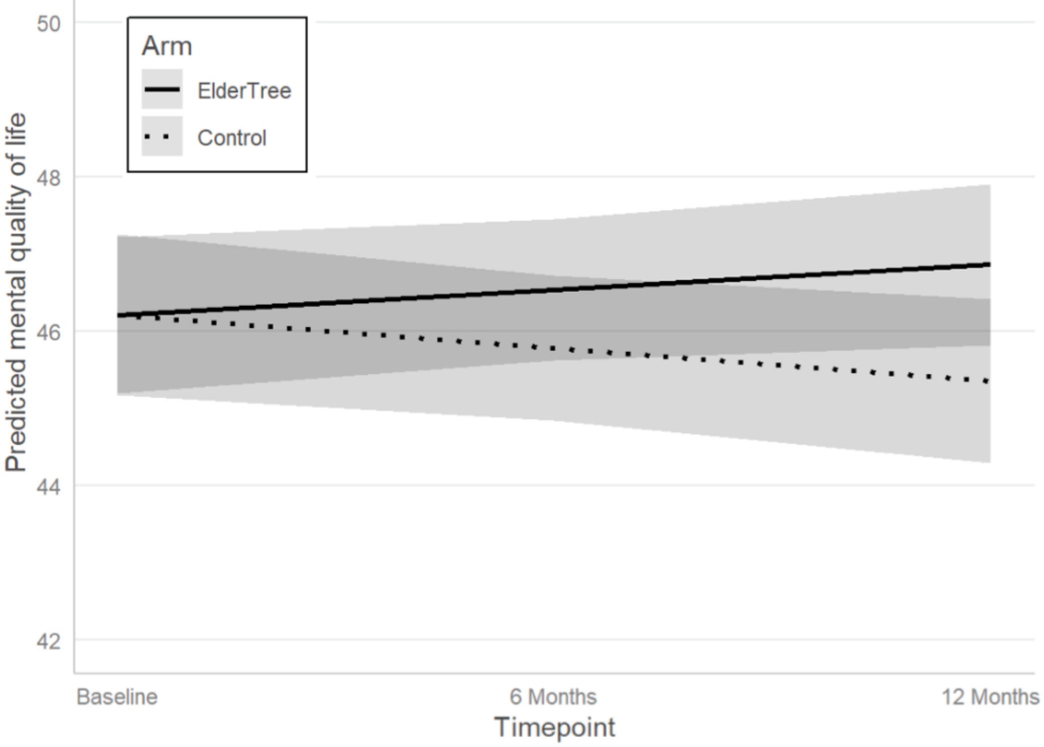
Variable	Data		Correlation			
	Number	Mean (SD)	Mental quality of life	Physical quality of life	Psychological well-being	Loneliness
Mental quality of life	344	46.25 (7.28)	—[a]	0.50[b]	0.61[b]	–0.56[b]
Physical quality of life	344	42.39 (6.23)	0.50[b]	—	0.37[b]	–0.17[b]
Psychological well-being	344	31.33 (5.23)	0.61[b]	0.37[b]	—	–0.68[b]
Loneliness	344	16.59 (5.93)	–0.56[b]	–0.17[b]	–0.68[b]	—

[a] Not applicable.

[b] *P*<.05.

Controlling for life stressors and pandemic months, we found a significant difference between the ET and control arms in the extent of change in mental QOL over time from baseline to 12 months (arm × timepoint interaction: b=0.76, 95% CI 0.14-1.37; *P*=.02). Specifically, as shown in Figure 3, the ET arm showed an increase in mental QOL and the control arm showed a decrease, for a total difference of 1.5 T-score points (PROMIS measures are standardized so that scores have a mean of 50 and SD of 10. Thus, the T-score difference can be interpreted as Cohen d divided by 10, that is, 1.5 points can be read as Cohen d=0.15). Although this difference in means between the 2 groups at 12 months was statistically significant (*P*=.04), PROMIS scoring guidelines [71,72] state that a difference is considered meaningful at 3 or more T-score points when comparing groups.

Figure 3. Predicted mean values of mental quality of life over time. Possible range is 21.2-67.6, with higher values indicating better mental quality of life. Shaded areas represent 95% CIs.



We did not find significant differences between groups in changes over time for physical QOL (b=0.10, 95% CI –0.44 to 0.64; *P*=.71), psychological well-being (b=0.23, 95% CI –0.26 to 0.72; *P*=.36), or loneliness (b=–0.25, 95% CI –0.73 to 0.22; *P*=.29).

ET System Use as a Predictor of Primary Outcomes

As the overall goal of the study was to assess the effects of ET, we examined whether the amount of use of the ET system would predict changes in our primary outcomes, as specified in our protocol [26]. For these analyses, the amount of ET use was measured as days of any use. If a participant in the intervention arm did not use the system after training, they were assigned a value of 0 days. Both arms (control and intervention) were included in these analyses, with all control participants assigned values of 0 days.

With regard to mental QOL, controlling for baseline scores, days of ET use significantly predicted improvement over the 12 months of the intervention (b=0.02, 95% CI 0.00-0.03; *P*=.046), and the magnitude of this effect did not change over time (b=0.00, 95% CI –0.02 to 0.02; *P*=.72). The model predicted that those using ET every day within a 6-month time span (180 days) would show a 3.23-point increase in mental QOL compared to those not using the system. A clinically meaningful difference of 3 points would thus be seen at 167 days within a 180-day span or 92.7% of days.

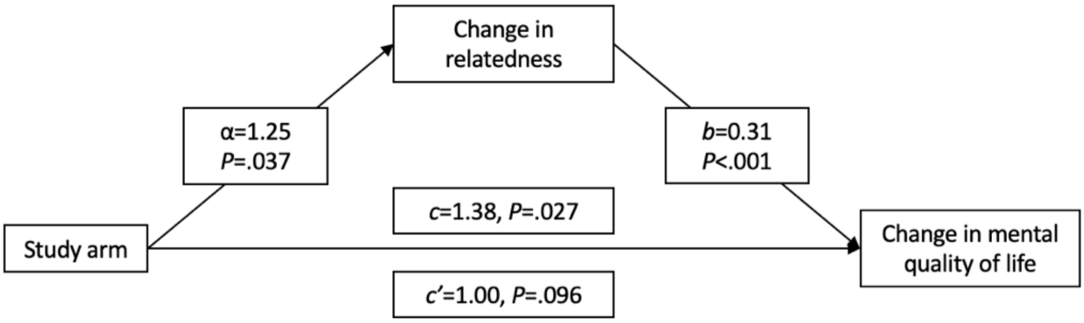
Days of ET use did not statistically predict a difference in the other primary outcomes: physical QOL (b=–0.00, 95% CI –0.02 to 0.01; *P*=.90), psychological well-being (b=0.01, 95% CI –0.01 to 0.02; *P*=.26), or loneliness (b=–0.01, 95% CI –0.02 to 0.00; *P*=.20).

Mediation of the Effects of the Study Arm

As proposed, we investigated whether the effects of the study arm on changes in primary outcomes over time would be mediated by 6-month changes in health coping strategies, health-related motivation, feelings of relatedness, depression symptoms, and anxiety symptoms. Controlling for baseline, the study arm did not significantly predict coping (b=–0.69, 95% CI –2.14 to 0.75; *P*=.34), motivation (b=0.04, 95% CI –0.56 to 0.64; *P*=.88), depression (b=0.05, 95% CI –0.53 to 0.64; *P*=.86), or anxiety (b=0.12, 95% CI –0.48 to 0.71; *P*=.70) at 6 months (simple test of path α). However, the study arm did significantly predict feelings of relatedness (b=1.35, 95% CI 0.13-2.57; *P*=.03) at 6 months. Given this, we tested a simple mediation model of the effect of the study arm on the change from baseline to 12 months in our primary outcome mental QOL, mediated by the change from baseline to 6 months in relatedness. We did not test mediation for our other 3 primary outcomes because the arm-by-time analyses were nonsignificant.

The mediation analysis showed that the study arm was significantly associated with changes in mental QOL from baseline to 12 months (path *c*=1.38; *P*=.03), as was demonstrated by our main primary outcome analyses. The inclusion of relatedness in the model resulted in significant associations between the study arm and relatedness (path α=1.25; *P*=.04) and between relatedness and mental QOL (path *b*=0.31; *P*<.001). The association between the study arm and changes in mental QOL (direct effect) was not significant (path *c′*=1.00; *P*=.10), indicating complete mediation. See Figure 4 for a diagram of this mediation model.

Figure 4. Diagram of the study arm mediational model.

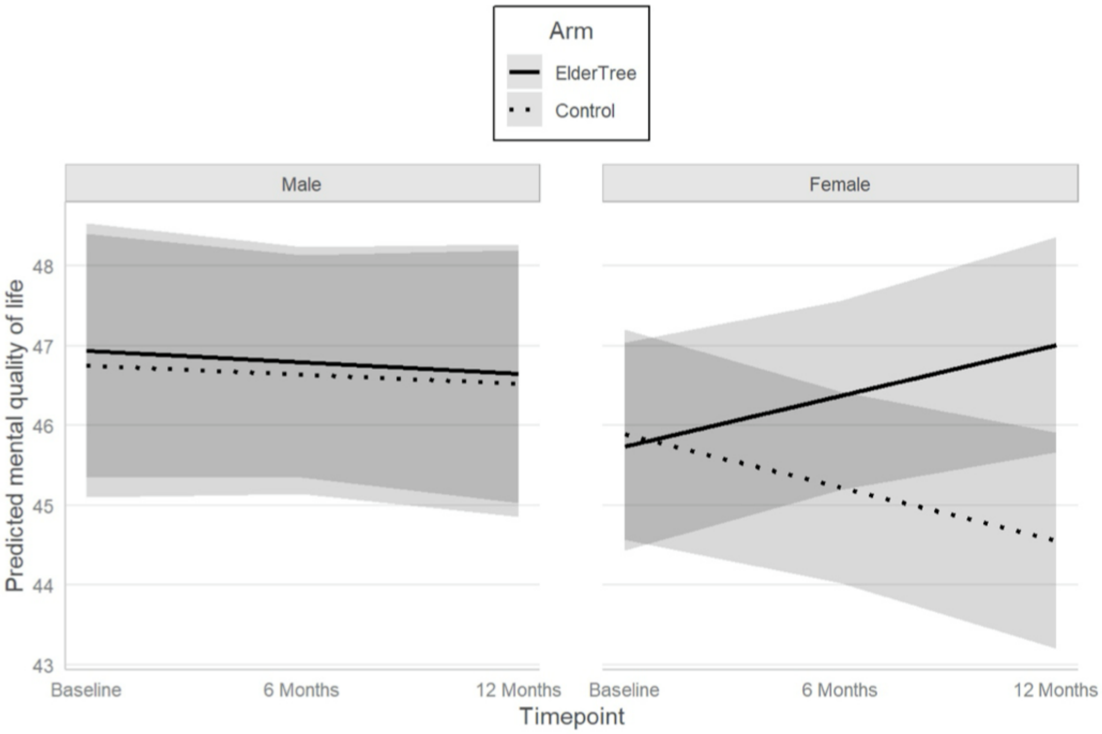


Moderation of the Effects of the Study Arm

We examined whether the effects of the study arm on changes over time in the primary outcomes were moderated by sex, amount of scheduled health care use, and number of chronic conditions.

Sex moderated the effect of the study arm over time on mental QOL (sex × arm × time interaction: b=1.33, 95% CI 0.09-2.58; *P*=.04). To understand this 3-way interaction, we looked at the simple effects of time for the 4 combinations of sex and arm. For female participants, the ET arm showed an increase in mental QOL over time, while the control arm showed a decrease. By 12 months, the difference in means was statistically significant (mean difference=2.60; *P*=.002) for females, although it did not exceed the benchmark of 3.0 considered meaningful. For male participants, no difference in means was seen between groups over time (12-month mean difference=–0.06; *P*=.95). Data are presented in Figure 5.

Figure 5. Predicted mean values of mental quality of life by sex over time. Possible range is 21.2-67.6, with higher values indicating better mental quality of life. Shaded areas represent 95% CIs.



Sex also moderated the effect of the study arm over time for psychological well-being (sex × arm × time interaction: b=1.13, 95% CI 0.13-2.12; *P*=.03). To understand this 3-way interaction, we looked at the simple effects of time for the 4 combinations of sex and arm. For female participants, the ET arm showed an increase in well-being over time and the control arm showed a decrease. By 12 months, the difference in means was statistically significant (mean difference=1.38; *P*=.04; Cohen d=0.28). For male participants, the ET arm remained steady while the control group showed an increase in psychological well-being over time. However, at 12 months, the difference in means was not statistically significant (12-month mean difference=0.88; *P*=.28; Cohen d=0.18). Data are presented in Figure 6.

No other moderation of the effect of the study arm over time was found. Inferential statistics for all moderation analyses are presented in Table 3.

Figure 6. Predicted mean values of psychological well-being by sex over time. The possible range is 8-40, with higher values indicating greater psychological well-being. Shaded areas represent 95% CIs.

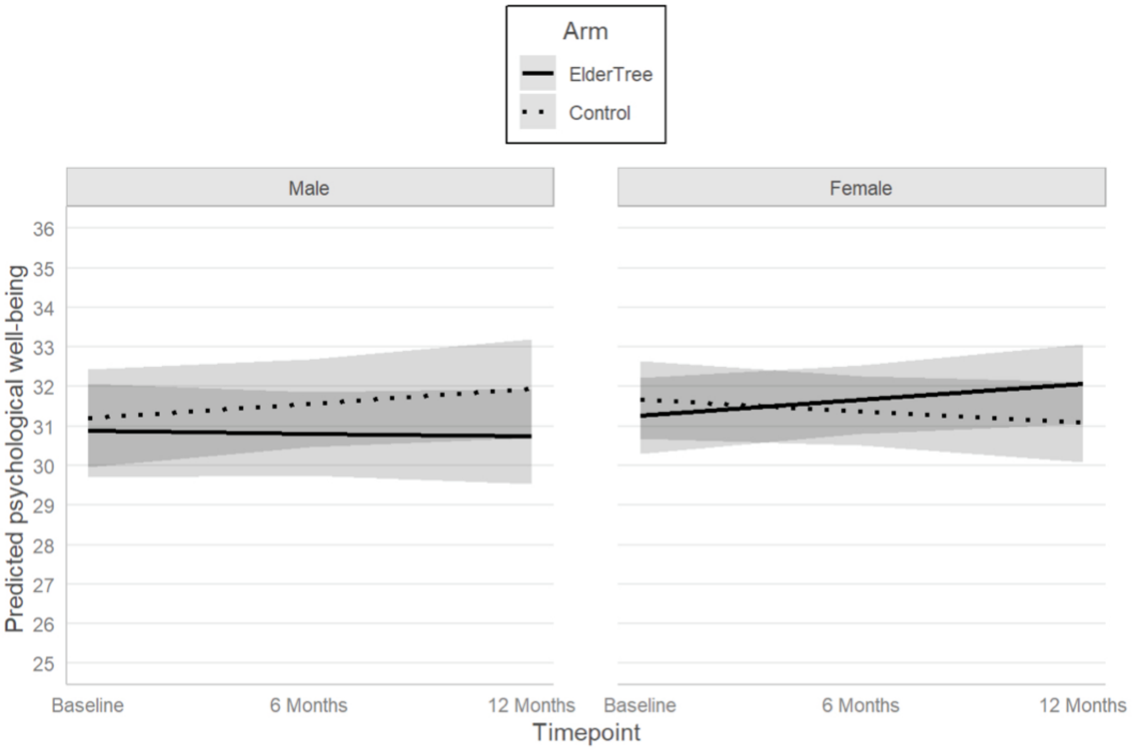


Table 3. Inferential statistics for the moderators of the study arm regarding primary outcomes.

Moderator and outcome	Inferential statistics for moderator × arm × timepoint		
	b	95% CI	*P* value
Sex			
Mental quality of life	1.33	0.09 to 2.58	.04
Physical quality of life	0.08	–1.02 to 1.18	.88
Psychological well-being	1.13	0.13 to 2.12	.03
Loneliness	0.51	–0.45 to 1.48	.30
Number of scheduled health care visits			
Mental quality of life	–0.06	–0.17 to 0.04	.26
Physical quality of life	0.00	–0.09 to 0.10	.92
Psychological well-being	–0.05	–0.13 to 0.04	.28
Loneliness	–0.00	–0.09 to 0.08	.91
Number of chronic conditions from EHRs[a]			
Mental quality of life	–0.02	–0.49 to 0.45	.94
Physical quality of life	–0.01	–0.42 to 0.41	.97
Psychological well-being	–0.02	–0.40 to 0.35	.91
Loneliness	–0.01	–0.38 to 0.35	.94

[a] EHRs: electronic health records.

Post Hoc Probing of Sex Moderation

To probe the finding that the effects of the study arm on mental QOL and psychological well-being were stronger for women than for men, we began by examining whether there were sex differences in variables that might explain this pattern: other demographic or background variables that we had considered as covariates, baseline levels of relatedness and primary outcomes, days of ET use, and (more specifically) days of ET discussion group use. There were only 2 significant differences. For education (4=some college, 5=college graduate, 6=postgraduate or professional degree), men (mean 5.37, SD

1.36) had higher levels than women (mean 4.85, SD 1.46; *P*<.001). For the likelihood of having a partner, men (n=112, 83%) had a higher likelihood than women (n=103, 49%; *P*<.001). However, adding education and the presence of a partner as covariates to the moderation analyses for mental QOL and psychological well-being did not alter the significance of the study arm × time × sex interactions or the magnitude or direction of the coefficients for the study arm (b=1.35, 95% CI 0.10-2.60; *P*=.03 for mental QOL; b=1.14, 95% CI 0.15-2.14; *P*=.025 for psychological well-being). See Table 3 for values without education and partner. Further exploratory analyses examining possible moderated mediation are reported in Multimedia Appendix 1.

Post Hoc Moderation Analysis: Effect of COVID-19 on the Study Arm for Primary Outcomes

Because our outcomes seemed likely to be impacted by the extended isolation of lockdowns, which began in March 2020, and because our older health-compromised population was among the most vulnerable to the illness [73,74], we conducted post hoc analyses. Specifically, to understand how the pandemic may have affected primary outcomes, we tested pandemic months as a moderator.

The pandemic overlapped with some portion of the 12-month intervention period for 158 (45.9%) of the 344 participants who received an intervention. A total of 77 (43.8%) ET and 81 (48.2%) control participants completed the 12-month survey during the pandemic, and of these, 3 (1.7%) ET and 6 (3.6%) control participants also completed the 6-month survey during this period. The 81 control participants experienced a mean overlap of 3.11 months (SD 2.03 months; range 0.02-6.33 months), while the mean overlap for the 77 ET participants was 3.02 months (SD 1.94 months; range 0.20-6.10 months). Given this, we examined months of overlap with the pandemic as a possible unanticipated moderator (rather than covariate) of the effects of the study arm.

The pandemic did not appear to impact the effects of the study arm on the primary outcomes. Controlling for baseline, we found that months during COVID-19 did not moderate the effect of the study arm for mental QOL (b=–0.98, 95% CI –4.03 to 2.08; *P*=.53), physical QOL (b=–0.13, 95% CI –2.91 to 2.64; *P*=.93), psychological well-being (b=–1.73, 95% CI –4.16 to 0.71; *P*=.16), or loneliness (b=1.15, 95% CI –1.27 to 3.57; *P*=.35).

Secondary and Exploratory Outcomes

Results for secondary and exploratory outcomes are presented and discussed in Multimedia Appendix 1. To summarize, we found a significant effect of the study arm on changes over time in the level of pain, such that the ET arm showed a slight increase in pain over time, while the control arm showed a slight decrease, resulting in a significant difference between study arms at 12 months. We did not find significant effects of ET versus control on changes over time in falls, symptom distress, medication adherence, use of crisis health care, pain medication issues, alcohol use problems, or diet. We were unable to test cigarette use due to a lack of participants who smoked at any point during the study.

Discussion

Summary and Interpretation

Given the need for broadly applicable behavioral interventions that could be implemented in primary care to help manage patients' varied combinations of chronic conditions [20,21], this study was designed to test the effectiveness of an online intervention, ET. Given that prior interventions for multimorbidity have been critiqued for low-quality assessments [25], this study was designed to be a high-quality clinical trial featuring a large sample of older adults with 3 or more of 11 chronic conditions randomized to the ET intervention or an attention control group for a full year. The goals of the intervention were to help older adults manage their chronic conditions (in part by providing their primary care team with insights about their ongoing health status) and to connect them with peers for social support. A previous iteration of ET yielded positive effects on socioemotional outcomes of mental QOL, social support, and depression among those with high levels of primary care use [27]. The current iteration leaned into this finding, with system enhancements designed to connect participants with their primary care team and to strengthen peer interactions and pleasurable aspects of the site.

Consistent with the findings for the earlier version of ET, the current ET version showed signs of improving socioemotional outcomes. There was a significant effect of ET (vs control) on improvements over the 12-month intervention period regarding the primary outcome of mental QOL, as well as a significant study arm × sex interaction, indicating stronger effects for women than men. There was a significant moderated effect of ET on improvements over the 12-month intervention period in the primary outcome of psychological well-being, again indicating stronger effects for women than men. There was a significant effect on improvements over 6 months in relatedness, which was our hypothesized mediator variable that assessed feelings of social support, love, and connectedness.

As such, even though we did not find the predicted effects on the primary outcome of loneliness, ET relative to an attention control group showed socioemotional benefits for older adults with MCCs. We acknowledge that the 3 socioemotional primary outcome variables (mental QOL, psychological well-being, and loneliness) were more strongly correlated than we initially anticipated. Given that we had preregistered the analyses in our protocol paper and given that we continue to believe these are important and conceptually distinct variables, we have treated them as separate variables. However, it is important to note that doing so inflates the risk of type 1 errors across the set of outcomes, and therefore, the identified effects should be considered preliminary until replicated.

It is also important to acknowledge that the difference between study arms for mental QOL at 12 months was smaller than the benchmark for a clinically meaningful effect (benchmark = T-score difference of 3.0), both in the overall sample (difference=1.5) and for women (difference=2.6). Our analyses examining days of ET use predicted that the benchmark difference between study arms would occur with at least 167 days of app use over 6 months (or at least 93% of days), suggesting that while clinically meaningful effects for mental QOL may be possible, substantial engagement with ET would be needed. Possible strategies to foster sustained high levels of engagement are being examined in our subsequent ongoing RCT of ET. Our current iteration of ET is now being tested on smart displays as well as laptops, the content library is much larger, and we now have weekly video-chat "meet-ups." These meet-ups not only allow participants to interact with each other and build social connections but also provide opportunities for a trained moderator to highlight key aspects of ET and their uses.

Although participants' engagement with ET was markedly lower than our analyses suggest would be needed for clinically meaningful effects on mental QOL, it is noteworthy that the percentage of participants who were still using ET at the end of the year-long intervention (76.14%) was far higher than is typical for mental health apps. A 2019 review of 93 apps targeting emotional well-being, anxiety, or depression found median 30-day retention rates of 3.3%, with somewhat higher rates for 2 apps offering peer support (8.9%) [75]. A 2022 review of 56 mental health apps found that retention 7 days after download varied from 5.5% to 19% [76]. Although ET use was undoubtedly higher because participants were aware of being in a study, they were not required to use the app. The fact that they showed the most use of the tools for social engagement suggests that these forms of contact continued to have meaning and value for them across the year of the study.

In contrast to the effects on a subset of socioemotional outcomes, we found no significant effects of ET on any of our physical health outcomes. Due to insufficient EHR data, as described in Multimedia Appendix 1, we were unable to conduct planned analyses for participants' lab scores. However, there were no significant effects of ET on participants' physical QOL or the secondary outcome of "symptom distress" (eg, shortness of breath, bowel problems, cough, and weakness) or scheduled health care use. This lack of effects on physical outcomes is consistent with the weak mostly null effects yielded in a meta-analysis of 16 RCTs of in-person primary care interventions for multimorbidity [22] and is in contrast to the moderate effects on lab scores observed in a meta-analysis of digital telemedicine interventions [25], perhaps reflecting the fact that the latter interventions tended to engage medical care more directly and specifically (eg, via online tracking of blood pressure). On the other hand, those interventions found scant effects on patients' QOL.

Our expanded inclusion criteria meant that participants could have varied combinations of 11 chronic conditions. This was arguably a strength of the study, in that such diverse arrays are a key challenge of treating patients with multimorbid conditions. On the other hand, this design decision may also have contributed to the lack of effects on physical outcomes and the relatively weak effects on mental QOL, in that some patients' chronic conditions need not have been particularly onerous. A patient could have high blood pressure, high cholesterol, and a BMI over 30 without feeling much incentive to engage with the health-related aspects of the intervention and without much impact on their ability to engage in social activities. Although, as shown in Multimedia Appendix 1, the majority of participants in both study arms had EHR diagnoses of chronic pain or arthritis, there were signs that patients did not see themselves as incapacitated and that many had active social lives. In exit interviews, participants made comments such as, "If I had more medical problems, this could be more helpful. But I am pretty healthy" and "I don't have any chronic aches or pains, nothing constant that bothers me. I think this doesn't apply to me." Others made comments about their high levels of social engagement as a reason for not needing the interactions offered by ET (eg, "I'm not a shut-in. We're very active, do lots of things with family, don't need interaction with other people that much"). In our current RCT of a subsequent iteration of ET, we are focused on older adults with at least 5 (rather than 3) chronic conditions to probe whether there are indeed stronger effects for patients with more complex sets of conditions.

It is also possible that the effects of ET were reduced by the overlap of the study with the pandemic. A key component of ET was the health tracking survey and the ensuing clinician report. The goals of the clinician report were to not only flag potential issues for health care providers (eg, recent falls could signal important health risks) but also open conversations during appointments about issues, such as sleep, diet, or mood, that may not be primary concerns for clinicians in the context of more urgent medical indicators but that may affect patients' physical and socioemotional QOL. As clinic visits ceased and clinical staff were triaging the crises of the pandemic, the potential for such expansive conversations decreased, even though we adapted to send clinics a summary of their patients' health tracker responses. However, despite the intuitive appeal of the pandemic as a potential limiting factor, we found no indication that days of overlap with the pandemic moderated the effects of the study arm for either physical or socioemotional outcomes. Approximately half of the sample who completed the 12-month intervention period prior to the pandemic did not appear to respond differently than those who overlapped with the pandemic.

It is also worth noting that these analyses leave the pattern of stronger effects for women (vs men) unexplained. One possibility is that there were sex differences in the types of messages posted and received on ET and that this had implications for participants' socioemotional outcomes. A 2020 meta-analysis found that women were more likely than men to give social support in online communities (eg, social networking sites) and were also slightly more likely than men to receive social support [77]. This pattern of sex differences was also observed in a CHESS intervention for alcohol use disorder [78]. Moreover, giving and receiving social support via the discussion groups in CHESS interventions was previously found to predict more positive outcomes: improved mental well-being in a CHESS intervention for women with breast cancer [79] and reduced drinking in a CHESS intervention for alcohol use disorder [80]. Further work is needed with the current data set to code the types of online interactions that took place on ET and to assess how they may have contributed to socioemotional outcomes.

Limitations

We have already alluded to several limitations, including the issues of multiple primary outcomes potentially inflating type 1 error and the lack of EHR lab data. The latter issue means that this is a study of the effects of ET on older adults' perceptions of their physical status, rather than a study of whether the intervention could induce sufficient behavioral changes to be reflected in participants' physical health indicators. While our focus was more on participants' QOL than lab scores, as evidenced by our choice of primary versus secondary outcomes, this nonetheless leaves an important question about physical effects to be answered by further work.

As noted in the Methods section, we lost the 18-month follow-up timepoint, given our ethics-based decision to allow participants during the pandemic to continue their use of ET beyond the 12-month study period. The goal of the follow-up period is, of course, to assess whether any effects observed during the intervention period endure even after the intervention ends. While we acknowledge the loss of these insights, we also note that they may be less critical than for other types of interventions. Unlike interventions that are highly burdensome for clinicians or that involve biomedical procedures, the online accessibility of ET resources could potentially be an ongoing open-ended opportunity for patients, rather than coming to an end once a "dose" is completed.

Perhaps a more substantive limitation was the lack of data about the clinician report. We originally intended to gather both quantitative and qualitative data from primary care clinicians to gain insights into the ways they did (or did not) engage with patients' health tracking data. Given the effort involved in making sure that clinicians received the relevant report in a timely manner before a patient's appointment, it would have been useful to understand the results of those efforts. This was intended to be an intervention implemented within primary care. It is possible that the benefits could be observed even in the absence of engaging directly with clinics, simply by encouraging participants to reflect on their health tracking data and to use their EHRs or clinic visits to flag changes over time that mattered to them. The relatively high sustained rates of engagement with the tracker suggested that participants found some utility, but we did not obtain their ratings of the helpfulness of the tracker or the associated clinician report. Measures of patient perceptions of the intervention or the 6- and 12-month participant surveys would have helped us assess the value of the feature and determine possible improvements for future interventions.

Finally, it is important to highlight that participants were all located in Wisconsin and were mainly white (92.2%), with at least some education beyond high school (78.8%), limiting the generalizability of the results. This limitation reflected our focus on implementing ET into primary care and our goal of using EHR data to assess physical outcomes. The complexity of engaging with clinics and accessing EHR data limited the number of clinics that participated and restricted us to 1 health care organization. A possible solution is to prioritize the accessibility of ET over the as-yet-unknown benefits of trying to implement ET within specific primary care clinics. In our ongoing RCT, we have made that trade-off by recruiting participants via television and social media rather than through specific clinics, allowing us to recruit a more diverse sample.

Conclusions

This study extends our prior findings by focusing exclusively on the growing complex population of older adults coping with MCCs. The current findings continue to support the value of ET for patients' socioemotional outcomes, with less impact on physical outcomes. Subsequent RCTs of ET are underway with (1) older adults experiencing chronic pain and (2) older adults with 5 or more chronic conditions for whom there may indeed be greater decrements to physical and mental QOL, with content more explicitly focused on addressing their serious health-related needs.

Acknowledgments

This study was funded by the National Heart Lung and Blood Institute, National Institutes of Health, United States Department of Health and Human Services (grant number 1R01HL134146). Support included the use of the UW Institute for Clinical and Translation Research (ICTR) Data Monitoring Committee (DMC) and Clinical Research Data Service. The project was also supported by the Clinical and Translational Science Award (CTSA) program through the NIH National Center for Advancing Translational Sciences (NCATS) (grant UL1TR002373). Abstract

Background: We live in a digital age where social media has become an essential part of people's lives. It is also one of the leading platforms responsible for spreading health-related falsehoods. This study explores who adults of different age groups perceive as responsible for reducing health-related falsehoods on social media.

Objective: Despite growing concern over older adults' exposure to false health information on social media, little research examines their beliefs on how to address the problem. This study examines how the age of US adults is associated with their reported experiences with health-related falsehoods on social media and their beliefs about who should be tasked with reducing such falsehoods.

Methods: This study is a secondary analysis of data from the 2022 Health Information National Trends Survey, a nationally representative survey of US adults (18 years and older). Multivariable logistic regressions estimated how a respondent's age was associated with their self-reported social media use, their difficulty to detect health-related falsehoods on social media, their discussion of health information found on social media with medical providers, and their beliefs regarding who should be responsible for reducing health-related falsehoods on social media. Regression estimates were adjusted for respondents' sociodemographic and health characteristics.

Results: Daily social media use decreased with respondents' age. Respondents aged 50 - 64 years (*b*=0.515, *P*=.01) and 65 - 74 years (*b*=0.697, *P*=.002) were more likely than respondents aged 18 - 34 years to report they strongly agree that it is difficult for them to detect health-related falsehoods on social media. Compared to younger adults, older adults (65 - 74 years: *b*=0.818, *P*=.002; 75 years and older: *b*=1.058, *P*<.001) were more likely to believe medical providers should be responsible for reducing online falsehoods.

Conclusions: In addition to ongoing efforts by social media platforms to detect and remove falsehoods, the findings suggest medical providers should be tasked with discrediting health-related falsehoods on social media for older adults. However, time during the clinical visit is limited. Future research is needed to discover new approaches and tools tailored to older adults to assist with filtering and discrediting health-related falsehoods on social media.

KEYWORDS

social media; health misinformation; gray digital divide; United States; older adults; aging; health information; false information; falsehoods

Introduction

The COVID-19 pandemic heightened attention to concerns about the prevalence of false health-related information circulating on social media [1,2]. Of particular concern is exposure to falsehoods among older adults (≥65 years old), who generally have less experience with social media than younger adults [3]. Older adults are more inclined to interact with false information [4,5], perhaps due to their longer experience managing truths from both digital and nondigital news sources [6]. Compared to younger adults, older adults exhibit less confidence in discerning false information [7]. Altogether, this suggests older adults are more susceptible to harms stemming from health-related falsehoods on social media.

To reduce online falsehoods, various entities have adopted several measures, including the use of algorithms by social media companies to automatically detect falsehoods, but these are neither built nor deployed with older adults in mind [8,9]. Few studies examine the perspectives of older adults regarding their beliefs about the best ways to address falsehoods online. An exception is a Pew Research Center survey from 2021, in which older adults were the least likely to prefer social media platforms address online falsehoods [10]. However, it is unknown what older adults would prefer, especially given the COVID-19 pandemic potentially altering their adoption and use of information and communication technologies. To address this gap, we analyzed data collected in 2022 from a national sample of US adults to understand how respondents' age is associated with their social media experiences and their beliefs about the best way to address health-related falsehoods online. We discuss how the findings could be used to shape the policy-making process and to design interventions to assist older adults in filtering out falsehoods.

Methods

Sample

We derived data from the 2022 Health Information National Trends Survey (HINTS), a cross-sectional survey by the National Cancer Institute to document how noninstitutionalized US adults (≥18 years old) access and process health information. Complete survey design details are available elsewhere [11]. Briefly, the survey was fielded from March to November 2022 and included 6242 respondents, with a final weighted response rate of 28.1%.

The outcomes of interest, which broadly assessed experiences with and beliefs about falsehoods on social media, were asked only of respondents who reported social media use (n=4415). Among these respondents, most missing values were for the item asking respondents their race and ethnicity (n=439), which we accounted for by including an indicator for those with a missing response. Respondents with missing values on other measures were dropped from the analysis. The final analytic sample comprised 3941 respondents.

Measures

We analyzed three survey items to characterize respondents' experiences with social media and falsehoods. Daily social media users were identified as those who reported they visited a social media site "Almost every day." Self-reported difficulty to detect health-related falsehoods was measured using their level of agreement with the item, "I find it hard to tell whether health information on social media is true or false." Discussion of social media with medical providers was determined based on their level of agreement with the item, "I use information from social media in discussions with my health care provider." The latter two items were ordinal variables with four response options each. Because the proportional odds assumption was violated, to simplify the table summaries, we present results in the main text that compare those selecting the modal response option (assessment: strongly agree; discussion: strongly disagree) to all others (assessment: somewhat agree, somewhat disagree, strongly disagree; discussion: somewhat disagree, somewhat agree, strongly agree). Multimedia Appendix 1 includes full results using partial proportional odds models to analyze the outcomes in their original ordinal form. Conclusions about older adults from the simplified models shown in the text are the same as those drawn from analyses that address the violation via estimating partial proportional odds models.

A fourth item determined respondents' beliefs regarding who should reduce health-related falsehoods on social media. The question posed was, "Who do you think has the main responsibility for reducing the amount of false or misleading health information on social media?" The five response options included news media, social media platforms, government, individual users, and medical providers. The respondents were limited to select only one option.

Respondents' age was measured using categories (18 - 34, 35 - 49, 50 - 64, 65 - 74, and ≥75 years). We adjusted estimates based on respondents' sociodemographic and health background. These were measures of respondents' sex (male, female), race and ethnicity (Black, Latino, White, other, missing), education (high school or less, some college, college graduate, and postgraduate), relationship status (single, divorced/widowed/separated, and married/cohabitating), and self-rated health (excellent, very good, good, fair, poor).

Statistical Analyses

After characterizing the sample by examining frequencies and proportions, we estimated eight binary logit regressions to understand how respondents' age was associated with the outcomes of interest. The first three logit regressions estimated responses to items assessing participants' experiences with social media and health-related falsehoods. Because self-reported difficulty to detect falsehoods and discussion of social media information with providers may be less likely among more frequent social media users, we included being a daily social media user as a covariate for these regressions. The next five regressions estimated responses to the item assessing participants' beliefs about who should be responsible for reducing health-related falsehoods on social media. The item had five possible options, and thus each regression estimated the likelihood of selecting a given option. Because one possible option was social media companies, we included being a daily social media user as a covariate for these regressions. All regressions adjusted estimates based on covariates. All analyses were weighted (except for the calculation of frequencies) with survey weights provided by the HINTS methodologists to approximate the US adult population, which accounted for the sampling design and nonresponses. Analyses were performed with Stata 18. Statistical significance is defined as $P<.05$, determined by a 2-tailed t test.

Ethical Considerations

Ethics review for this study was waived because it is a secondary analysis of deidentified survey data.

Results

Sample Characteristics

Table 1 summarizes sample characteristics. Approximately 14.7% of the sample comprised older adults (≥65 years old). The majority of the sample (73.1%) reported daily usage of social media. Around 58.3% of the respondents reported they strongly disagree that they discuss social media with their health care provider, and around 28.8% of the respondents reported they strongly agree that it is difficult for them to detect health-related falsehoods on social media. When considering responsibility for addressing health-related falsehoods on social media, approximately 13.1% of the sample believed the news media should take responsibility, 34% felt social media platforms were responsible, around 15.5% assigned the responsibility to the government, 22.5% believed individual users of social media should take action, and 14.8% believed it should be medical providers.

Table . Sample characteristics.

Characteristic	Frequency, n (weighted %)[a]
Respondents reported they strongly agree that it is difficult for them to detect health-related falsehoods on social media	1338 (28.8)
Respondents reported they use social media daily	2771 (73.1)
Respondents reported they strongly disagree that they discuss social media information with health care practitioners	2312 (58.3)
Who should reduce falsehoods	
News media	473 (13.1)
Social media platforms	1452 (34)
Government	578 (15.5)
Individual users	843 (22.5)
Medical providers	595 (14.8)
Sex	
Female	2474 (53.2)
Male	2176 (46.8)
Age (years)	
18 - 34	747 (29)
35 - 49	966 (29)
50 - 64	1181 (27.3)
65 - 74	728 (10)
≥75	319 (4.7)
Education	
High school or less	782 (25.1)
Some college	1157 (39.6)
College graduate	1175 (20.3)

Latino	704 (17.3)
Other	348 (10.5)
Missing	103 (1.8)
Self-rated health is excellent, very good, or good	3295 (84.4)
Relationship status	
Single	821 (32.4)
Divorced, widowed, or separated	951 (10.1)
Married or cohabitating	2169 (57.5)

[a] Weighted frequencies were calculated using the weighted averages provided by the Health Information National Trends Survey.

Logit Regressions

The binary logit regressions estimating how respondents’ age was associated with their experiences with social media and health-related falsehoods are shown in Table 2. Older adults were significantly less likely to use social media daily than 18-34 year olds (65-74 year olds: b=−1.603, P<.001; ≥75 year olds: b=−1.427, P<.001). Adults aged 35-49 years were significantly more likely than those aged 50 to ≥75 years to strongly disagree they discuss social media with their health care provider (b=0.309, P=.04). Adults aged 50-74 years old were significantly more likely than 18-34 year olds to strongly agree that it is difficult for them to detect health-related falsehoods on social media (50-64 years olds: b=0.515, P=.01; 65-74 years olds: b=0.697, P=.002).

Table . Binary logit regression predicting experiences with social media and falsehoods online.

	Respondents who reported they use social media daily			Respondents who reported they strongly disagree that they discuss social media information with health care practitioners			Respondents who reported they strongly agree that it is difficult for them to detect health-related falsehoods on social media

[a] *b*: sample regression coefficient.

[b] As being a daily social media user was a covariate and the regression was between daily social media users against daily social media users, this did not generate any values.

Table 2 also shows that, compared to respondents with high school or less education, postgraduates were less likely to strongly agree that it is difficult to detect health-related falsehoods on social media (b=−0.418, P=.04), while those with some college education were more likely to agree (b=0.358, P=.03). This pattern does not hold in the supplemental analyses in Multimedia Appendix 1.

Table 3 summarizes binary logit regressions estimating how respondents’ age was associated with their beliefs about who should be responsible for reducing health-related falsehoods on social media. Respondents aged 75 years and older were significantly less likely than 18‐34 year olds to believe individual users are responsible for reducing online falsehoods (*b*=−0.888, *P*<.001). Compared to 18‐34 year olds, older adults were significantly more likely to believe medical providers were responsible (65‐74 year olds: *b*=0.818, *P*=.002; ≥75 year olds: *b*=1.058, *P*<.001). Respondents' ages were unrelated to the likelihood of selecting any of the other three entities (news media, social media platforms, government) as responsible.

Table . Binary logit regressions predicting beliefs about who should reduce falsehoods online.

[a]b: sample regression coefficient.

Table 3 shows additional demographic patterns that were unrelated to our focus on age, but warrant detailing. Among these include educational differences. Specifically, college graduates (b=−0.670, P=.006) and postgraduates (b=−0.766, P=.007) were less likely than those with high school degree or less to feel that news media should be held responsible. Individuals reporting some college (b=0.575, P=.006), college graduate (b=0.650, P=.005), and postgraduate (b=0.687, P=.001), were more likely than people with high school or less education to believe that individual users should be held responsible for reducing health-related falsehoods online.

Discussion

From the results, we see that adults aged 50 years or older reported that they strongly agree that it is difficult for them to detect health-related falsehoods on social media. Compared to younger adults (18-34 years old), older adults (≥65 years old) were more likely to believe medical providers should be responsible for reducing online falsehoods. Despite heightened scrutiny of the veracity of health information on social media during the COVID-19 pandemic, little research has examined the public's perspective on who should be held responsible for reducing the prevalence of falsehoods. In particular, such information would be useful from older adults because, compared to younger adults, they are both more likely to engage with falsehoods on social media and are less confident in deciphering its veracity [1,4-7,9]. We discuss implications stemming from our findings regarding the development of interventions to assist older adults with interpreting the health-related information they find on social media.

Consistent with other research [8,12], we found an age divide for who is likely to use social media. We found older adults were less likely to report using social media daily than younger adults. While the COVID-19 pandemic may have encouraged older adults to turn to social media for pandemic-related information [13-15], the age divide remains among US adults in 2022. This may be due to continued barriers faced among older adults to learn new information and communication technologies [15].

Despite the age divide in social media use, we found that some experiences with health-related information on social media were comparable between older and younger adults. We found older adults were just as likely as younger adults (18 - 34 years old) to discuss information they found on social media with health care providers. Overall, only 58% of the respondents reported they strongly disagree that they discuss health information found on social media with medical providers, likely due to concerns about feeling embarrassed or receiving disapproval from the provider [16]. Where we found differences was in the reported difficulty in detecting falsehoods. Specifically, older adults were more likely than younger adults to report they strongly agree that it is difficult for them to detect health-related falsehoods on social media. This is concerning, especially given other research showing older adults are the most likely to be exposed to falsehoods online [5]. Thus, although older adults are less frequent users of social media than younger adults, they tend to be exposed to more falsehoods and are also less confident in their ability to detect them. Such a concentration of falsehood exposure and difficulty detecting falsehoods warrants seeking interventions tailored to this population.

To begin to identify how to tailor interventions, we turn to our final set of findings. Regarding beliefs in who should be responsible for reducing health-related falsehoods on social media, we found older adults were more likely than younger adults to choose medical providers. The differences may be due to older adults exhibiting higher levels of trust in medical providers [17]. Older adults are also more likely to turn to medical providers for health information than their younger counterparts [18]. We also found adults who were aged 75 years and older were less likely than younger adults to believe individual users should be responsible for reducing online falsehoods. This may be due to age differences in confidence in detecting falsehoods, as well as the differences in digital and health literacy skills necessary to curate one's own social media experience [19]. We found no other associations between the respondents' age and the selection of any of the other three entities (news media, government, social media platforms). Altogether, these patterns suggest that, while the emphasis within the United States has been for social media platforms to reduce health-related falsehoods, medical providers may be key for designing interventions to assist older adults in identifying and debunking falsehoods.

Besides age, we found additional demographic variables were related to the outcomes studied. Results show that respondents with postgraduate, college graduate, and some college education are more likely than respondents with high school or less education to feel that individual users should be held responsible for reducing health-related falsehoods on social media. This could be in part because individuals who pursue higher education are more likely to exhibit prosocial behavior, which can be understood as an individual's responsibility to contribute to the social good [20]. We also see that college graduates and individuals with postgraduate education are less likely to feel that news media should be held responsible for removing health-related falsehoods online than respondents with a high school education or less. This could be due to people with a higher level of educational reporting they support freedom of the press, even if that means falsehoods can be published [21].

This study has a few limitations. Because this is a secondary analysis of survey data, and we are limited in the questions available, we cannot evaluate the mechanisms underlying why older adults prefer medical providers as being responsible for reducing falsehoods online. The questions of interest were only asked of those who are current social media users, and thus we cannot tell what the preferences are among those who do not currently use social media but may use it in the future. The analysis also relies on self-reported data, which may be subject to biases. Because the data are cross-sectional, we cannot distinguish age effects from cohort effects. Age effects refer to how a person's age can biologically influence their physical, cognitive, emotional, and social experiences, while cohort effects refer to how the era in which a group of individuals is born can influence their experiences, behaviors, and attitudes. From the results, we see that adults aged 50‐64 years and 65‐74 years were more likely than younger adults to report they strongly agree that it is difficult for them to detect health-related falsehoods on social media. This finding could be explained by an age effect, perhaps due to age-related cognitive and physical challenges, or a cohort effect because older adults are from a generation that grew up with no internet and no social media [22]. Lastly, the survey was only available in English and Spanish, thereby missing the preferences of those who speak other languages.

Despite these limitations, this study's findings shed light on targeted interventions for assisting older adults in filtering falsehoods from the health-related information they encounter on social media. Social media platforms have sought to combat falsehoods by implementing algorithms, moderation teams, and options for users to report posts, but falsehoods persist. Only 58% of respondents reported discussing what they found on social media with their medical providers, suggesting an opportunity to spend more time with the small percentage of older adults on social media to discuss the health-related information they encounter. However, time during the clinic visit is limited. Other research has explored how medical providers can present themselves on social media to appear credible and combat falsehoods by sharing their own advice [23], but this still requires time on behalf of the provider. New technological tools may be needed [24], such as a mobile app endorsed by medical providers for older adults to confirm the accuracy of the health information they encounter online. Future research is needed to identify how best to build on our findings to develop and test targeted interventions for older adults that identify and discredit online falsehoods.

Abstract

Background: Over the last decade, many organizations dedicated to serving the needs and interests of older adults have turned to social media platforms, such as Twitter, subsequently rebranded X, to improve the visibility of age-related issues. However, notwithstanding their growing digital presence and participation, minimal attention has been paid to the use of social media among these advocacy groups. To achieve policy change, advocacy organizations must first be able to engage and mobilize audiences.

Objective: Our study aims to elucidate how different tweet features affect the time it takes for posts uploaded by age advocacy organizations to reach peak engagement.

Methods: We collated 204,905 tweets from 53 age advocacy organizations posted over a 12-year period. The engagement score of each tweet was calculated by combining well-established metrics, namely likes, retweets, quote tweets, and replies. We ran Cox models with tweet features as predictors and time-to-peak engagement as the outcome. “Peak engagement” (event) refers to engagement scores above the 75th percentile, and “time” refers to months taken to reach peak engagement per tweet.

Results: Approximately 1 in 2 tweets (n=103,068, 50.3%) had either no hashtags or just 1 hashtag. Around two-thirds (n=131,220, 64%) of the tweets included a URL. Visual information was highly underused, with most tweets not including GIFs (n=204,202, 99.7%), videos (n=199,800, 97.5%), or photos (n=143,844, 70.2%). Roughly half (n=101,470, 49.5%) of the tweets contained mentions and 9.3% (n=19,009) of tweets were replies. Only 4.5% (n=9285) of tweets were quote tweets. Most tweets were uploaded in the afternoon (n=86,004, 42%) and on a weekday (n=180,499, 88.1%). As hypothesized, features associated with peak engagement were the inclusion of visual elements like photos, which increased peak engagement by 3 times ($P<.001$), and the use of 3 or more hashtags ($P<.001$). Quote tweets increased engagement by 3 times ($P<.001$), as compared to regular tweets, controlling for account-level covariates. Tweets from organizations with a higher tweet volume were 40% less likely to reach peak engagement ($P<.001$).

Conclusions: Social media as a networked platform has the potential to reach users on a global scale and at an exponential speed. Having uncovered the features that are more likely to reach peak engagement on Twitter, our study serves as an invaluable resource for age advocacy organizations in their movement to create a more age-inclusive world.

Introduction

Over the last decade, many organizations dedicated to serving the needs and interests of older adults have turned to social media platforms, such as Twitter, consequently rebranded as X, to improve the visibility of age-related issues. However, notwithstanding their growing digital presence and participation, minimal attention has been paid to the use of social media among these advocacy groups. To achieve policy change, advocacy organizations must first be able to engage and mobilize audiences. Our study elucidates how different tweet features affect the time it takes for posts uploaded by age advocacy organizations to reach peak engagement. We define “age advocacy” as the act of supporting or championing initiatives that address the needs of older adults.

The advent of social media has been profitable to advocacy groups for multiple reasons. First, although the visibility of a social movement was formerly determined by its ability to make headlines [1], social media has democratized the process of activism, allowing social actors to bypass the lack of attention received by a particular issue [2]. Second, the exchange of information via social media channels is not constrained by geographical barriers, thus enabling the rapid diffusion of information worldwide [1]. Third, social media platforms are a cost-effective means through which information can be transmitted and awareness of social issues heightened. Fourth, social media facilitates interaction between organizations and the public, thereby fostering sociopolitical discussion and participation [3].

When using social media, organizations typically set out to engage followers by uploading content that resonates with audiences [4] especially in view of the constant influx of information on the internet [5,6]. A well-engaged audience is essentially proof that a particular account has content which audiences find valuable and meaningful. Over the years, this concept of engagement has gained popularity across myriad disciplines, including marketing, psychology, communication, public relations, and organizational studies [3].

Twitter is a microblogging service home to over 300 million active users monthly [7]. Although originally viewed as an avenue for personal communication, the social media platform has since been used by academics, policy makers, and advocacy groups to access, share, and disseminate information [8]. Given the growing presence of age advocacy organizations on Twitter, this study looks at how different tweet features affect the time taken to reach peak engagement for posts uploaded by these organizations.

Both marketing experts and academics have conducted research on the features that promote user engagement on Twitter [9-15]. Although it is clear that adding photos and videos improves engagement [10,14], it remains a scholarly crux when the best time to post is [9,10,14,15], what the ideal number of hashtags to include is [11,12,14], and whether quote tweets drive engagement. There is, therefore, a need to ascertain which tweet features are linked to greater user engagement for content uploaded by age advocacy organizations specifically.

To date, only 1 study has explored the concept of engagement in relation to tweets uploaded by age advocacy organizations [16]. However, this study did not consider the time taken to reach peak engagement, which is important for several reasons. First, the time taken to hit peak engagement may be viewed by potential funders as a key performance indicator, which is a signal of the ability of an organization to retain the interest of its user base and consequently be eligible for further funding. Second, being able to reach peak engagement within a short period of time is vital if age advocacy organizations happen to be posting about time-sensitive issues.

From a conceptual angle, this study is significant in that it is one of the first to develop a framework that age advocacy organizations can use to optimize their social media posts for increased engagement. Existing studies have traced the origins of age advocacy in the United States [17] and have covered the need to advocate for older persons [18-24]. Research on web-based age advocacy, however, remains conspicuously absent, with most social media analyses in the gerontological field analyzing attitudes toward older persons [25-32]. From a practical angle, this study provides organizations with a road map to raise consciousness of age-related matters, which is especially pressing given the increasing proportion of older adults in populations worldwide [33]. By successfully engaging audiences, age advocacy organizations will be able to spur collective action and create policy change.

The tweet features examined in this study include the number of hashtags, URLs, and mentions present in the tweet; whether the tweet contains a GIF, photo, or video; whether the tweet is a “quote tweet”—a retweet with a comment added by the account—or a “reply”; the time of day the tweet was uploaded; and whether the tweet was uploaded on a weekday or the weekend.

We sought to test 4 hypotheses. First, in light of past findings that the inclusion of hashtags predicts the likelihood of a post to get retweeted [9,10,12], we hypothesized that tweets with more hashtags would be quicker to reach peak engagement (hypothesis 1). Second, in line with evidence that visual information is usually more stimulating than textual information [34,35], we hypothesized that tweets with GIFs, photos, or videos would be quicker to reach peak engagement than those without (hypothesis 2). Third, since followers of age advocacy organizations are likely to include scholars and policy makers who may value dialogue, input, or commentary [9,12,36,37], we hypothesized that quote tweets would be quicker to reach peak engagement (hypothesis 3). Finally, consistent with prior research, which finds higher tweet counts to be associated with negative engagement [9], we hypothesized that tweets uploaded by accounts with a higher tweet count would be slower to reach peak engagement (hypothesis 4).

Methods

Data Set

As few studies have looked at age advocacy organizations on Twitter, we first consolidated a list of organizations by referring to various sources [38-40]. Next, we checked whether these accounts had a presence on Twitter. To build a more comprehensive list of accounts, we looked through the list of followers of these accounts and identified other organizational accounts with large followings using a snowball sampling method. The organizations were eventually chosen based on the following inclusion criteria: (1) the organization was based in North America; (2) the organization was dedicated to serving the needs and interests of older persons specifically; and (3) the organization had at least 1000 followers. In total, there were 53 accounts (Multimedia Appendix 1).

We retrieved the data using the Twitter application programming interface (API) v2, which was accessed through Twitter’s Academic Research Product Track [41]. The v2 full-archive search allows for the programmatic access of public tweets from the complete archive dating back to the first tweet in March 2006, when the application was created. Relative to what was achievable with the standard v1.1 API, the v2 API grants users a higher monthly tweet cap and access to more precise filters [42].

Tweets collected (n=403,426) covered a period of 12 years, from July 17, 2009, to October 8, 2021, with the start date as the earliest date a particular tweet from any of the sampled accounts was uploaded and the end date a week after October 1, 2021, which was designated by the United Nations as the

International Day of Older Persons [43]. “Retweets” (n=118,454) were excluded since they are not original content. Similarly, tweets with zero engagement (n=80,065) were excluded, as our focus was to observe the time taken to reach peak engagement. Finally, due to glitches with the API during the period of data collection—there were inaccuracies in the number of “likes” received by certain tweets—a few posts (n=2) were excluded. The final data set comprised 204,905 tweets.

Tweet Features (Predictors and Covariates)

Similar to earlier work [9], we divided the tweet features into 2 categories: tweet-level (predictors) and account-level (covariates) features. The tweet-level features include the number of hashtags, URLs, and mentions present in the tweet; whether the tweet contains a GIF, photo or video; whether the tweet is a “quote tweet” or a “reply”; the time of day the tweet was uploaded; and the day—weekday or weekend—the tweet was uploaded. Following past literature [14], we divided the time of day based on CST into the following periods: morning (6 AM to 11:59 PM), afternoon (noon to 16:59 PM), evening (5 PM to 8:59 PM), and night (9 PM to 5:59 AM).

Account-level features, which served as covariates in our modeling, were consistent across all tweets belonging to a given account. These covariates included the number of followers, the number of accounts followed, the total number of tweets, and whether the account was “verified.” Except for the last variable, all skewed account-level variables were log transformed. Multimedia Appendix 2 contains a list of definitions of terms used on Twitter.

Time-to-Peak Engagement (Outcome)

Following Twitter’s data dictionary [44], we used “likes” (ie, the number of times a particular tweet has been liked by other Twitter users), “retweets” (ie, the number of times a particular tweet has been retweeted), “quote tweets” (ie, the number of times a particular tweet has been quoted by other Twitter users) and “replies” (ie, the number of times a particular tweet has been replied to) as a proxy for user engagement. Our measurement of engagement aligns with that of previous studies [9,10,12-14]. To model the temporal aspects of engagement, we applied methods from survival analysis [45,46], which involved operationalizing engagement as a time-to-event variable. “Peak engagement” (event) refers to engagement scores above the 75th percentile, and “time” refers to months taken to reach peak engagement per tweet.

Analytic Strategy

First, we performed Kaplan-Meier analyses to assess differences in engagement between categorical features—type of tweet and presence or absence of visual elements, such as photos, GIFs, videos, hashtags, URLs, and mentions. Respective curves were compared using the log-rank statistic. Second, we ran Cox regression models to identify the tweet features significantly associated with time-to-peak engagement, controlling for account-level variables. Since tweets from the same account contained identical account-level information, the independent assumption did not hold. To achieve a more robust variance, we set different user IDs as clusters [47]. Model 1 consisted of tweet-level features. Model 2 contained tweet-level features, controlling for account-level variables as covariates.

Ethical Considerations

Ethical approval was not deemed necessary, as all the data used were publicly available and anonymized.

Results

Descriptive Statistics

Approximately 1 in 2 tweets (n=103,068, 50.3%) had either no hashtags or just 1 hashtag. Around two-thirds (n=131,220, 64%) of the tweets included a URL. Visual information was highly underused, with most tweets not including GIFs (n=204,202, 99.7%), videos (n=199,800, 97.5%), or photos (n=143,844, 70.2%). Roughly half (n=101,470, 49.5%) of the tweets contained mentions, and 9.3% (n=19,009) of the tweets were replies. Only 4.5% (n=9285) of the tweets were quote tweets. Most tweets were uploaded in the afternoon (n=86,004, 42%) and on a weekday (n=180,499, 88.1%). Table 1 summarizes the descriptive statistics. With regard to engagement, the lowest score was 1, and the highest score was 18,558. The engagement score at the 75th percentile was 8. Of the 204,905 tweets, 48,103 received an engagement score above 8.

[c] P values are for the ANOVA test.

Kaplan-Meier Analysis: Differences in Engagement Across Tweet Features

We performed Kaplan-Meier analyses to examine differences in engagement across tweet features for 204,905 tweets posted over 146 months. Quote tweets achieved median engagement twice (log-rank test: χ^2=3820; P<.0001) as fast as regular tweets (Figure 1). Specifically, there was an engagement advantage of 65 months, meaning that on average, quote tweets achieved peak engagement 65 months faster than regular tweets. Regarding visual elements, tweets with photos reached 75th percentile engagement 2.5 times faster than tweets without photos (log-rank test: χ^2=1070; P<.0001), having an engagement advantage of 80 months (Figure 2). Similar results were observed for tweets containing GIFs (log-rank test: χ^2=1070; *P*<.0001) and videos (log-rank test: χ^2=8069; *P*<.0001) as compared to tweets without the respective features. Tweets with 3 or more hashtags had an engagement advantage of 14 months as compared to those with 2 hashtags (log-rank test: χ^2=2700; *P*<.0001). Similar patterns emerged for URLs and mentions. Tweets with 2 or more URLs achieved an engagement advantage of 14 months compared to tweets with 1 URL (log-rank test: χ^2=514; *P*<.0001). Conversely, tweets without mentions had greater engagement advantage than tweets with at least 1 mention (log-rank test: χ^2=850; *P*<.0001).

Figure 1. Engagement trajectories for 204,905 quote tweets, regular tweets, and replies posted over 12 years.

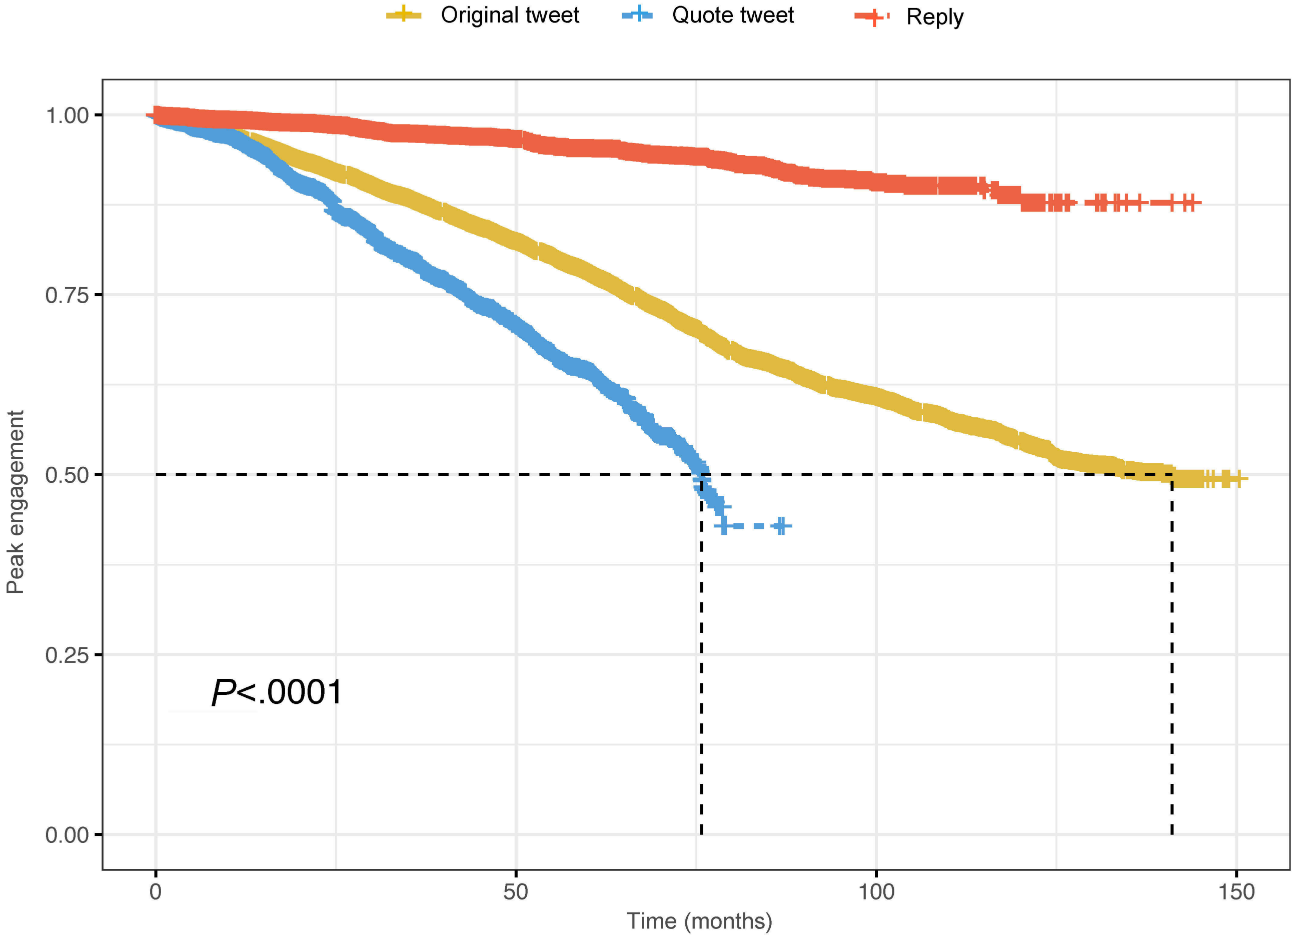

Figure 2. Engagement trajectories for 204,905 tweets with and without photos posted over 12 years.

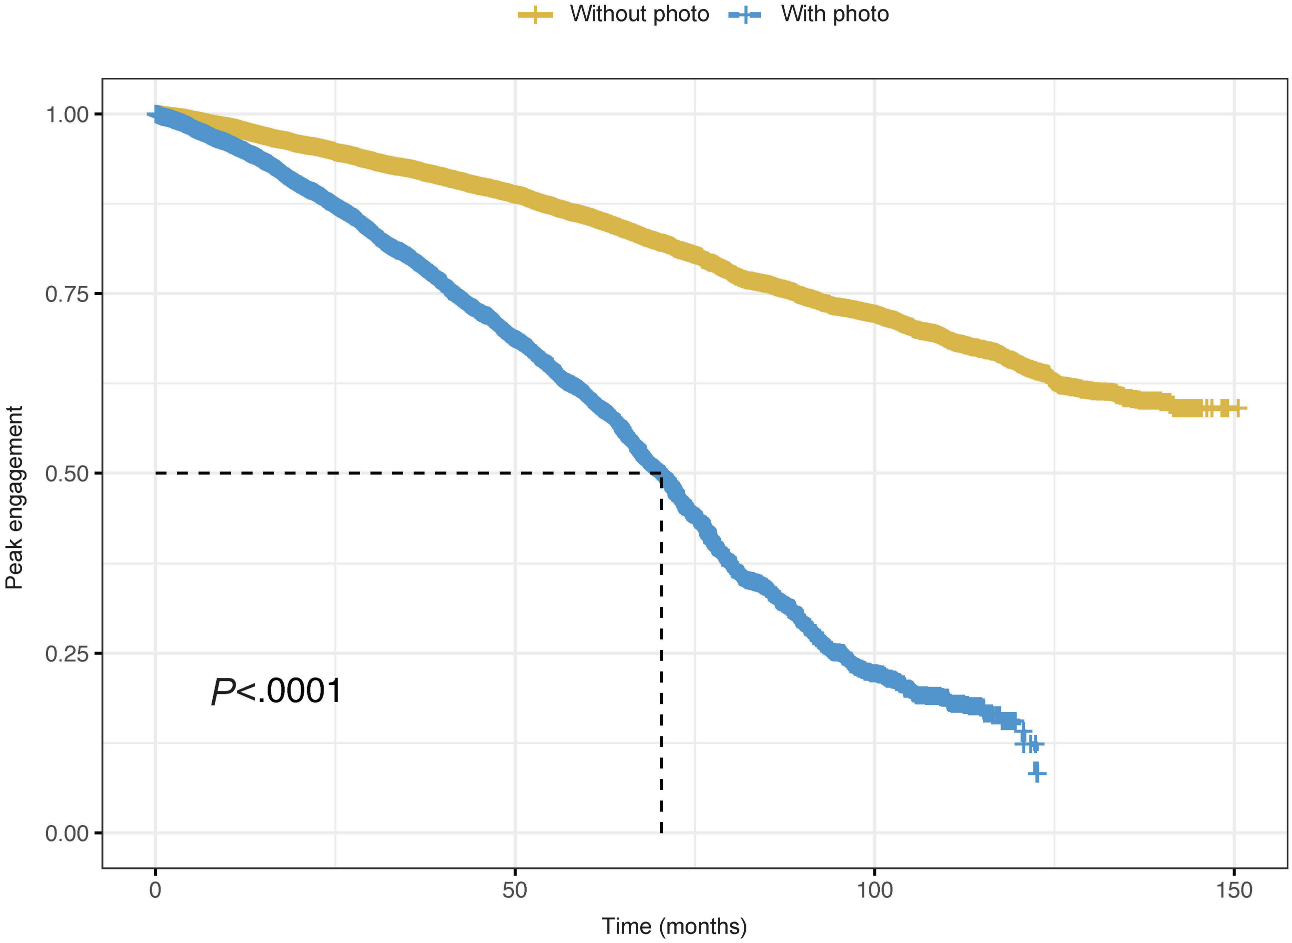

Multivariable Cox Regression: Tweet Features Associated With Time-to-Peak-Engagement

Tweets with 3 or more hashtags were 75% more likely to reach peak engagement than those with 1 or no hashtags (hazard ratio 1.75; *P*<.001), supporting hypothesis 1. Visual elements were particularly effective in nudging tweets toward peak engagement, being 4.25 times more effective for tweets with photos (*P*<.001), 6.38 times more effective for tweets with GIFs (*P*<.001), and 9.97 times more effective for tweets with videos (*P*<.001). This provided support for hypothesis 2. Consistent with hypothesis 3, quote tweets were 3.15 times more likely to achieve peak engagement (*P*<.001), as compared to regular tweets, controlling for account-level variables, such as the number of followers, the number of people followed, the number of tweets, and verified status. Meanwhile, at the account level, tweets posted by organizations with a higher tweet count were 40% less likely to reach peak engagement (hazard ratio 0.60; *P*<.001) as compared to those with a lower tweet count, providing support for hypothesis 4. The regression results are presented in Table 2. Coefficients reached significance at *P*<.05 after correcting for multiple comparisons using the Bonferroni method [48].

Table . Multivariable Cox models of tweet-level and account-level predictors of time-to-peak engagement for tweets (n=204,905) posted by age advocacy organizations over 12 years. Variables were log transformed.

Discussion

Principal Findings

Although the technological era has ushered in numerous opportunities for advocacy organizations, scant attention has been devoted to examining the use of social media as a tool for age advocacy. As social media can be instrumental in fostering policy change, we sought to fill this gap by examining how different tweet features influence engagement for tweets uploaded by age advocacy organizations. Findings indicate that tweets that are more likely to reach peak engagement are those that include 3 or more hashtags, contain visual elements, or are quote tweets. In contrast, tweets posted by organizations with a higher tweet count are less likely to reach peak engagement as compared to those with a lower tweet count.

Unsurprisingly, tweets with hashtags are more likely to achieve peak engagement. Arguably the most iconic feature of Twitter, the hashtag is an organizational device that connects users to a broader community of individuals who use the same hashtag [1]. Although movements concerning race- or gender-related matters are notably associated with hashtags, such as #BlackLivesMatter and #MeToo, hashtags related to age have not garnered the same level of success. Nevertheless, several age advocacy groups have rolled out their own hashtag campaigns in recent years. For example, the American Association of Retired Persons started the hashtag #DisruptAging as a way to spark conversations on what it means to grow older [49]. Age Platform Europe, a network lobbying for the rights of older adults, began the #AgeingEqual campaign in 2018 to raise awareness of ageism [50]. More recently, the World Health Organization started the hashtag #AWorld4AllAges in a bid to encourage individuals to build a more age-inclusive world [51]. Moving forward, age advocacy organizations could consider embedding their tweets with more hashtags to improve the visibility of their content.

Peak engagement is also achieved when visual elements, such as GIFs, photos, or videos, are included in a tweet. That the brain absorbs and synthesizes visual information faster than textual information is an insight from past research [34,35]. Our results reveal that GIFs, photos, and videos are all piteously underused in content uploaded by age advocacy organizations. These organizations should therefore strive to include visual elements in their tweets to bolster their chances of capturing the attention of followers. Importantly, these elements should be carefully selected to avoid perpetuating visual ageism [52]. Organizations could consider selecting images from the newly launched Age-Positive Image Library, which houses images that portray old age more realistically [53].

Quote tweets reach peak engagement faster than original tweets. Whereas the retweet function enables users to repost a tweet verbatim, quote tweets give users the option of adding their own comments to the tweet being reposted and is often used by individuals who wish to express their opinions in the context of the original tweet [54]. Given how a large subset of those following age advocacy organizations likely comprises academics and policy makers—people who may rely on Twitter for sharing knowledge or participating in intellectual discussions [9,12]—it makes sense that quote tweets take less time to reach peak engagement. With less than 5% of the tweets collected being quote tweets, age advocacy organizations should consider using the quote tweet function more regularly to establish a dialogic relationship with the public.

As expected, having a high follower count lessens the time needed to reach peak engagement. Both older and newer accounts should therefore make concerted efforts to amass as many followers as possible. In particular, age advocacy organizations with little or no digital presence should prioritize crafting strategies to increase their follower count before attempting to bolster engagement.

Not spamming audiences with content is considered by marketing experts to be a basic rule of Twitter etiquette [55]. By posting too often, organizations risk losing public interest or frustrating followers [9]. In seeking to forge a connection with the public, organizations must exercise prudence with regard to how frequently they post to prevent inundating followers' feeds. There are no hard and fast rules about how often to tweet, but social media managers of age advocacy organizations could monitor levels of engagement using the platform's "Tweet Activity Dashboard" [55]. By tracking the level of engagement of each tweet, organizations will be able to gain insight into the optimal frequency for tweeting.

As age advocacy organizations curate their content with the goal of maximizing engagement, it is imperative that these organizations extend their outreach beyond researchers and policy makers to the larger society. This is especially critical since age-related issues have yet to gain widespread awareness among the public. Moreover, age advocacy organizations could involve older adults in the cocreation of initiatives, such as by collaborating with older influencers [56,57]. In addition, amid the prevalence of intergenerational tension in the digital sphere [29,30], there is a need to create opportunities for older and younger generations to interact. Hashtag campaigns could be used to encourage both generations to engage in meaningful dialogues.

Limitations

This study has a number of limitations. First, the period that the tweets were posted is likely to have been a confounder in our analysis. It was only in 2014 that GIFs could be shared on Twitter. Likewise, the quote tweet feature was introduced only in 2015. However, tweets uploaded from 2009 onwards were included in our data set. The fact that there are now many more users on Twitter also means that posts that were uploaded before the platform was popular were less likely to be well engaged with. Second, considering that our objective was to look specifically at organizations, we could not offer insight into the level of engagement of tweets belonging to influential activists who champion the rights of older persons. Third, age advocacy organizations that are newer to Twitter were not included in the study since they did not fulfill the inclusion criterion of having at least 1000 followers at the time of analysis. Fourth, it is important to highlight that some tweets may have been uploaded solely for the purpose of informing or educating the public, rather than with the goal of engagement [9]. Finally, whether or not digital engagement actually inspires real-world action remains a moot point. Future analyses could adopt survey-based techniques [58,59] to understand activists' perceptions of digital activism and how it compares to traditional offline activism.

Despite these limitations, our study contributes to the field of gerontology by developing some practical guidelines for improving age advocacy efforts on Twitter. With research on this topic still at the outset, directions for future research are plentiful. Foremost among them is the need to construct a theoretical framework outlining the concept of age advocacy. Subsequent research could also explore how levels of engagement vary across organizations specializing in areas like retirement, housing, or health care. Additionally, it would be worthwhile to dissect the profile of followers of age advocacy organizations. This could include an analysis of the distribution of followers based on characteristics such as age, gender, and occupation.

Conclusions

Social media as a networked platform has the potential to reach users on a global scale and at an exponential speed. Having uncovered the features that are more likely to reach peak engagement on Twitter, our study serves as an invaluable resource for age advocacy organizations in their movement to create a more age-inclusive world.

Abstract

Background: Informal dementia caregivers are those who care for a person living with dementia and do not receive payment (eg, family members, friends, or other unpaid caregivers). These informal caregivers are subject to substantial mental, physical, and financial burdens. Online communities enable these caregivers to exchange caregiving strategies and communicate experiences with other caregivers whom they generally do not know in real life. Research has demonstrated the benefits of peer support in online communities, but this research is limited, focusing merely on caregivers who are already online community users.

Objective: We aimed to investigate the perceptions and utilization of online peer support through a survey.

Methods: Following the Andersen and Newman Framework of Health Services Utilization and using REDCap (Research Electronic Data Capture), we designed and administered a survey to investigate the perceptions and utilization of online peer support among informal dementia caregivers. Specifically, we collected types of information that influence whether an informal dementia caregiver accesses online peer support: predisposing factors, which refer to the sociocultural characteristics of caregivers, relationships between caregivers and people living with dementia, and belief in the value of online peer support; enabling factors, which refer to the logistic aspects of accessing online peer support (eg, eHealth literacy and access to high-speed internet); and need factors, which are the most immediate causes of seeking online peer support. We also collected data on caregivers’ experiences with accessing online communities. We distributed the survey link on November 14, 2022, within two online locations: the Alzheimer’s Association website (as an advertisement) and ALZConnected (an online community organized by the Alzheimer’s Association). We collected all responses on February 23, 2023, and conducted a regression analysis to identifyn factors that were associated with accessing online peer support.

Results: We collected responses from 172 dementia caregivers. Of these participants, 140 (81.4%) completed the entire survey. These caregivers were aged 19 to 87 (mean 54, SD 13.5) years, and a majority were female (123/140, 87.9%) and White (126/140, 90%). Our findings show that the behavior of accessing any online community was significantly associated with participants’ belief in the value of online peer support (P=.006). Moreover, of the 40 non–online community caregivers, 33 (83%) had a belief score above 24—the score that was assigned when a neutral option was selected for each belief question. The most common reasons for not accessing any online community were having no time to do so (14/140, 10%) and having insufficient online information–searching skills (9/140, 6.4%).

Conclusions: Our findings suggest that online peer support is valuable, but practical strategies are needed to assist informal dementia caregivers who have limited time or online information–searching skills.

informal dementia caregiver; online health community; social support; survey; online peer support; caregiving challenges

Introduction

Alzheimer disease—the most common cause of dementia—is a brain disorder that affects the thinking, comprehension, and learning capacity of more than 6 million Americans and is the seventh leading cause of death in the United States [1]. An estimated 80% of people living with Alzheimer disease or related dementia are cared for by unpaid informal caregivers (eg, family members, friends, or other unpaid caregivers) [2]. In 2021, over 11 million informal dementia caregivers provided 16 billion hours of care to people living with dementia [1]. Although this care was valued at nearly US $271.6 billion, it imposed substantial physical, financial, and mental burdens on these informal caregivers [3]. Additionally, 30% of informal dementia caregivers are aged ≥65 years [1]. They are likely to experience reduced social engagement due to caring for people living with dementia, which increases their risk of developing Alzheimer disease or some other dementia [4-6] and their risk of early death [7,8]. To ensure sufficient support for both informal caregivers and care recipients, it is essential for society to develop effective support mechanisms for the needs of informal dementia caregivers [9].

Research on how to best support informal dementia caregivers has focused primarily on assistance from credentialed professionals [10-12]. This type of assistance can improve a caregiver’s emotional well-being and caring skills, but maintaining this assistance over time can be difficult to achieve on a large scale. This is due, in part, to an insufficiently sized workforce, limited financial support [13,14], the stigma of asking for help, and difficulties encountered when leaving individuals with dementia [15,16]. In addition, if they lack a shared experience, it may be difficult for health care professionals or other family members to respond to the specific needs of informal caregivers. The perception that “they simply do not understand” [17] can contribute to feelings of loneliness [18], which were found to be negatively associated with the health and well-being of these caregivers [19].

The integration of the internet into daily life has enabled many people, including informal caregivers, to discuss health-related topics on online social media platforms [20,21]. For example, ALZConnected [22], which is organized by the Alzheimer’s Association, is the largest online community for people living with Alzheimer disease or related dementia and their caregivers in North America. ALZConnected has accumulated tens of thousands of online community users to discuss a broad range of topics regarding dementia caregiving and disease management [23]. Through online communities, informal dementia caregivers seek support and are willing to share experiences and practical information that they believe will assist other caregivers [24]. A study that analyzed an Alzheimer caregiver group on Facebook found that online peer social support had decreased the caregivers’ burdens while increasing their emotional and informational well-being [3]. Similarly, a survey found that increased online activity among caregivers was associated with lower levels of depression and loneliness [25]. In addition, many online communities provide added benefits, such as anonymity, asynchronous participation, and connection to numerous caregivers without physical location and time constraints [26], which provide cost-effective and convenient ways for informal dementia caregivers to gain support and access resources.

Based on internet utilization, informal dementia caregivers can be categorized as (1) *non-internet caregivers*, who never use the internet; (2) *non–online community caregivers*, who use the internet but do not participate in online communities; and (3) *online community caregivers*, who both use the internet and participate in online communities. Current social media–based dementia caregiving research primarily focuses on online community caregivers [25-27]. Although improving the online experiences of these caregivers is important [28], understanding how non–online community caregivers perceive the value of online peer support is significant as well. This would inform the development of interventions for non–online community caregivers to use and benefit from online peer support, thereby helping to mitigate the potential digital divide and decreasing existing health disparities in accessing online peer support [29].

The primary objective of this research was to gain insight into the perceptions and utilization of online community support among informal dementia caregivers, specifically non–online community caregivers and online community caregivers. To do so, we designed and administered a survey based on the Andersen and Newman Framework of Health Services Utilization (ANFHSU) [30]. The ANFHSU is a classical model for identifying and describing the factors that may affect a person’s access to and utilization of health services. Within this framework, we can analyze the various factors gathered through a survey questionnaire to determine an informal dementia caregiver’s access to or utilization of online peer support. Our findings suggest that online peer support is valuable, but practical strategies are needed to assist caregivers with limited time or online information–searching skills. This investigation marks the initial step toward addressing a long-term research objective, aiming to comprehensively elucidate the intricate mechanisms underlying online social support in dementia caregiving.

Methods

Online Peer Support

We begin this section with the definition of *online peer support*. Although peer support groups can be organized in an online format (eg, via Zoom meetings), the online peer support in this paper refers to the communications among informal dementia caregivers who may not know each other in real life but connect in online communities, forums, or websites (eg, Twitter, Facebook, Reddit, or ALZConnected). More broadly, since reading online caregiving discussions from other caregivers can serve as a way to obtain information and resources or learn caregiving skills, we also treated reading online posts as an online peer support–seeking behavior.

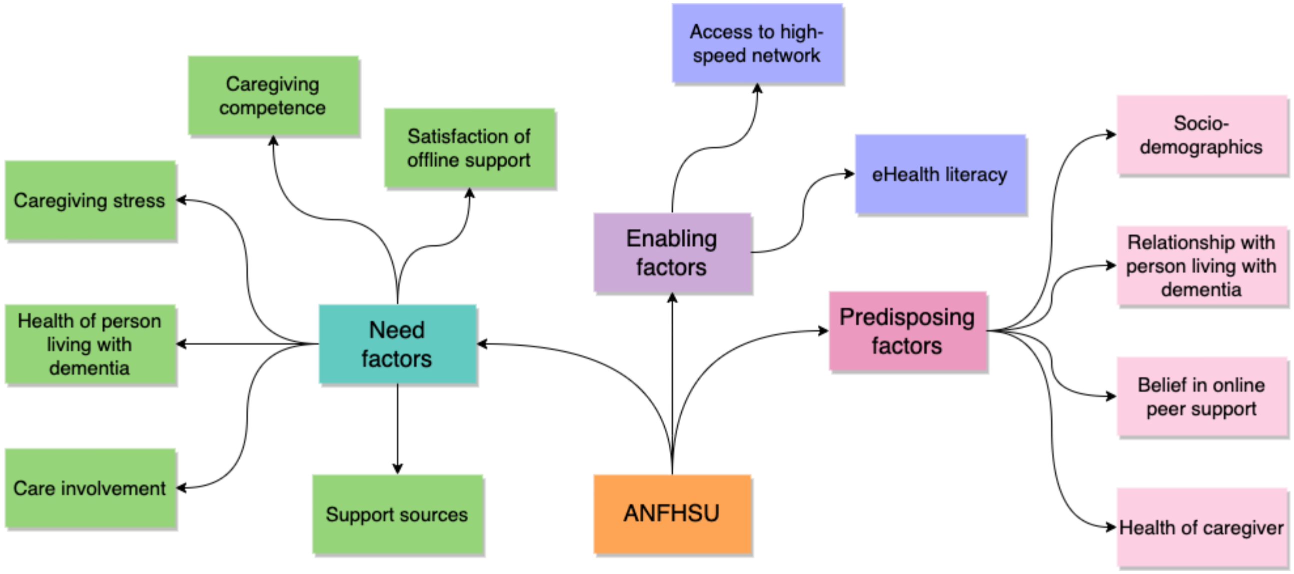
Ethical Considerations

This study was reviewed and deemed as non-human subjects research by the Vanderbilt University Medical Center Institutional Review Board (IRB 221732). Each survey participant was asked to confirm that they were unpaid informal dementia caregivers and that they were voluntarily participating in this survey in an information sheet. The sheet also included the definitions of *informal Alzheimer disease and related dementia caregivers* and *online communities*; the research purpose; a notice that the data would be collected, processed, and used; the methods applied to protect participant privacy; and a contact number for the Institutional Review Board.

Questionnaire Design

Social support is valuable in improving personal health [31]. In this study, we designed the survey based on the ANFHSU, whereby an informal dementia caregiver's access to or utilization of online peer support was considered to be a function of 3 characteristics (Figure 1).

Figure 1. The predisposing, enabling, and need factors in the ANFHSU. ANFHSU: Andersen and Newman Framework of Health Services Utilization.



Predisposing factors were the sociocultural characteristics of individuals or other factors that existed before these individuals became dementia caregivers. Specifically, we included the following predisposing factors:

- Sociodemographics: these included age, biological sex, education level, race, ethnicity, occupational status, and income; we also inquired about the number of children being cared for (if applicable), acknowledging the significant challenges in life balance experienced by caregivers in the "sandwich generation" [23].
- Relationship between the caregiver and a person living with dementia: this was included because caregivers who have different relationships with a person living with dementia face different caregiving challenges and burdens.
- Belief in the value of online peer support: we asked the following seven 7-point Likert scale (ranging from "Strongly disagree" to "Strongly agree") questions: "Do you believe that reading online discussions from, or directly writing posts to discuss with, other caregivers whom you do not know in the real world will help a) find caregiving resources that you need, b) increase caregiving knowledge, c) increase understanding of the disease and patient, d) improve caregiving skills, e) increase confidence in caregiving, f) reduce caregiving stress or g) reduce the feeling of loneliness as a caregiver?"
- Health of the caregiver: we collected data on this factor through the following 7-point Likert scale (ranging from "Extremely disagree" to "Extremely agree") item: "I feel healthy and do not have any major diseases that affect my daily life."

Enabling factors referred to the logistic aspects of accessing online peer support. The following enabling factors were included:

- Access to a high-speed network, which is an important contributor to the digital divide [32].
- eHealth literacy: this was measured through the eHealth Literacy Scale (eHEALS) [33] to evaluate if a caregiver could process online health-related information.

Need factors referred to the most immediate causes of seeking online peer support. The following need factors were included:

- Health of the person living with dementia: for simplicity, caregivers reported the dementia stage for people living with dementia as "early," "middle," or "late."
- Care involvement: this was measured through two questions ("How long have you been taking care of the PLWD (caregiving duration)?" and "How frequently do you care for the PLWD per week (caregiving workload)?"), and this design was based on the facts that dementia caregiving is a long-term dynamic process and that the weekly caregiving workload would affect the need for online peer support.
- Caregiving challenges: data on these were obtained via an open-ended question that requested caregivers to indicate the most challenging issues that they have faced when caring for a person living with dementia.
- Offline support sources: we also asked caregivers to describe (in a textbox) where to obtain support in the real world to handle the aforementioned challenges.
- Satisfaction with any support received in offline environments (7-point Likert scale).
- Caregiving stress: improving psychological well-being is a key focus of many interventions. The intuition is that

higher levels of stress in caregivers often drive them to seek support. We measured this factor by using the Zarit Burden Interview (12-item) scale [34].

- Caregiver competence: this factor referred to one's self-evaluation of their capacity to care for a person living with dementia and was measured by using the CARERS (Coaching, Advocacy, Respite, Education, Relationship, and Simulation) Interview (4-item) scale [35].

The rationale of the design of the survey was that if an informal dementia caregiver finds offline support to be insufficient in solving their caregiving challenges, they may turn to online environments for peer support. In addition to the ANFHSU factors, we surveyed each participant's experiences with using online peer support in the past 3 months (ie, their behavior). For the survey participants who were already online community users, we asked the following questions: (1) "Which online platforms have you visited in the past three months?" (2) "How frequently did you visit those online communities?" (3) "Will you intend to revisit these online communities in the next three months (intention)?" (4) "If the answer to question 3) is yes, what are your motivations for revisiting these online communities?" For participants who were not online community users, we asked them an open-ended question regarding why they did not seek online peer support in the past 3 months.

Implementation and Dissemination

We implemented the survey questionnaire in REDCap (Research Electronic Data Capture; Vanderbilt University) [36]—a secure web application for building and managing online surveys. We distributed the survey link within 2 online locations. The first was ALZConnected, where we posted the survey link at the top of the thread board in the community's two major caregiver forums: (1) *Caregivers Forum* and (2) *Spouse or Partner Caregiver Forum*. The second was the Alzheimer's Association website [37], where an advertisement for this survey was created to allow any person who visited the website to have a chance to access the survey link. Given that this website is a popular source of information for patients with dementia and dementia caregivers, we expected to obtain survey responses from caregivers who were not part of online communities.

Analysis

We performed three types of analyses. First, we summarized the answers to the multiple-choice questions by illustrating the respondent distribution for each choice. This was done to paint a broad picture of who the responding caregivers were and their perceptions and utilization of online peer support.

Second, we summarized the answers to the open-ended questions through manual annotation. This was not a trivial task because the responses were written as free text, and there were no predefined categories before the annotation. To address these issues, two authors (CN and QS) read the responses and annotated the categories for each open-ended question independently. Next, both annotators compared and discussed their summarized categories to create the final categories, including category names and definitions. Both annotators then independently modified their annotations with the agreed upon categories. For each response, we adopted a conservative approach and only reported the interactions of the categories summarized by the two annotators.

Finally, we fitted a logistic regression model (R v4.2.2; R Foundation for Statistical Computing) to analyze how the proposed ANFHSU factors were associated with using online peer support. Due to the small sample size, we converted some categorical variables into binary ones. Specifically, we encoded *gender* as "female/non-female," *race* as "white/non-white," *education level* as "4-year college degree or above/below 4-year college degree," *access to high-speed network* as "yes/no," *relationship* as "spouse/non-spouse," and all the other categorical variables (eg, *annual income*, *dementia stage*, *caregiving duration*, and *caregiving workload*) as ordinal variables (eg, numerical values with equal distance). A 2-sided P value of <.05 was considered to be statistically significant.

Results

Survey Overview

We distributed the survey link on November 14, 2022, leaving it open for over 3 months until February 23, 2023. During this time period, we collected responses from 172 dementia caregivers. Of these participants, 140 (81.4%) completed the entire survey.

Characteristics of Caregivers and People Living With Dementia

Table 1 summarizes the sociodemographic and caregiving characteristics of the 140 caregivers who completed the survey. These caregivers were aged 19 to 87 (mean 54, SD 13.5) years, and a majority were female (123/140, 87.9%) and White (126/140, 90%). Over 60% (89/140, 63.6%) of these caregivers had a 4-year college degree or higher, whereas 36.4% (51/140) had a below–4-year college education level. A majority of the caregivers were the adult children of the people living with dementia (71/140, 50.7%), followed by spouses or partners (41/140, 29.3%) and other relatives (19/140, 13.6%). Only 40.7% (57/140) of these caregivers were employed full-time, and 28.6% (40/140) took care of the person living with dementia and at least one child simultaneously. Further, 17.9% (25/140) and 32.1% (45/140) of the respondents reported taking care of the person living with dementia for <1 year and >4 years, respectively, and 66.4% (93/140) provided daily care. The caregivers' annual income was approximately uniformly distributed across incomes of less than US $25,000 to incomes ranging between US $100,000 and US $149,999. Only 7.9% (11/140) of these caregivers earned more than US $149,999.

Table 2 presents the characteristics of the people living with dementia reported by 140 survey participants. The ages of the people living with dementia ranged from 46 to 97 (mean 76, SD 9.5) years, and 65% (91/140) were female. Over 60% (86/140, 61.4%) of the people living with dementia were at the middle stage of dementia, 21.4% (30/140) were at the late stage, and 17.1% (24/140) were at the early stage.

Table . Summary of the sociodemographics and caregiving characteristics of the 140 survey caregiver participants.

Characteristic		Caregivers (N=140)
Age (y), mean (SD; range)		54 (13.5; 19-87)
Gender, n (%)		
	Female	123 (87.9)
	Male	16 (11.4)
	Undifferentiated	1 (0.7)
Race, n (%)		
	White	126 (90)
	Asian	8 (5.7)
	Black or African American	5 (3.6)

	75,000-99,999	21 (15)
	100,000-149,999	28 (20)
	≥150,000 or more	11 (7.9)

Table . Characteristics of the people living with dementia reported by survey participants.

Characteristic		People living with dementia (N=140)
Age (y), mean (SD; range)		76 (9.5; 46-97)
Gender, n (%)		
	Female	91 (65)
	Male	49 (35)
Dementia stage, n (%)		
	Early stage	24 (17.1)
	Middle stage	86 (61.4)
	Late stage	30 (21.4)

Caregiving Challenges and Support Sources

Table 3 summarizes reported caregiving challenges and the sources where caregivers sought support. The main caregiving challenges included dealing with the memory issues of a person living with dementia (40/140, 28.6%), supporting a person living with dementia in their daily life (such as showering and transportation; 30/140, 21.4%), and maintaining a balanced life (24/140, 17.1%). It should be noted that life balancing included the ability to (1) balance taking care of one’s children and a person living with dementia, (2) balance work and caregiving, and (3) balance one’s social life and caregiving. Dealing with the emotional fluctuations of the person living with dementia (21/140, 15%) and dealing with financial issues (14/140, 10%) were also major caregiving challenges. Some caregivers expressed concerns about the dementia treatment (11/140, 7.9%) for people living with dementia and their own mental health issues (10/140, 7.1%).

Table . Summary of caregiving challenges and specific support sources.[a]

		Caregivers (N=140), n (%)
Challenge		
	Legal issue	1 (0.7)
	Physical health	1 (0.7)
	Other health issue	2 (1.4)
	Mental health (caregiver)	10 (7.1)
	Treatment concern	11 (7.9)
	Family conflict	13 (9.3)
	Financial issue	14 (10)
	Emotion change	21 (15)
	Life balancing	24 (17.1)
	Daily caregiving	30 (21.4)
	Memory issue	40 (28.6)
Support source		
	Self-learning (book)	4 (2.9)
	Dementia caregivers (offline)	7 (5)
	Self-learning (online search)	8 (5.7)
	Local support group	23 (16.4)
	Friend	35 (25)
	Dementia caregivers (online community)	35 (25)
	Health care provider	38 (27.1)
	Family member	66 (47.1)

[a] Caregivers could report multiple challenges and support sources, which is why the total of the percentages for each section exceed 100%.

Satisfaction With Support and Network Access

Table 4 depicts the distribution of caregivers by satisfaction with the support they sought and by their access to a high-speed network. Of the 140 caregivers, 69 (49.3%) reported an "agree" or above response (which included "Slightly agree," "Quite agree," and "Extremely agree") for their satisfaction with the sought support. Among the 56 (40%) caregivers who reported negative experiences, 12 (8.6%) reported "Extremely disagree," indicating the challenging situations faced by these caregivers. Only 6 caregivers reported that they could not access a high-speed network.

Table . Distribution of caregivers by satisfaction with support that was sought and by access to a high-speed network.

Items and responses		Caregivers, n
Satisfaction with the sought support		
	Extremely disagree	12
	Quite disagree	29
	Slightly disagree	15
	Neither	15
	Slightly agree	37
	Quite agree	31
	Extremely agree	1
Access to a high-speed network		
	Extremely disagree	1
	Quite disagree	2
	Slightly disagree	3
	Slightly agree	11
	Quite agree	38
	Extremely agree	85

Measures of Caregiving Stress and Competence, eHEALS, and Belief

Figure 2 illustrates the distribution of the scores associated with caregiving stress, caregiving competence, eHealth literacy, and a caregiver's belief in the value of peer support from an online environment. The Cronbach α—a measure of the internal consistency of a questionnaire or survey (the higher, the better)—of these measures was 0.86 (95% CI 0.82-0.89), 0.83 (95% CI 0.78-0.87), 0.87 (95% CI 0.84-0.90), and 0.87 (95% CI 0.83-0.89), respectively. These indicated very good internal consistency. Specifically, of the 140 caregivers, 121 (86.4%) had a stress score above 30 (the score when "neutral" was selected for all the questions; the same cutoffs were used for each measure), 67 (47.9%) had a competence score above 12, 138 (98.6%) had an eHealth literacy score above 20, and 125 (89.3%) had a belief score above 24. These results suggested that most of the caregivers were in stressful caregiving experiences, had high eHealth literacy, and believed in the value of online peer support. However, over half (73/140, 52.1%) of these caregivers were not confident in their caregiving skills.

Figure 3 provides a detailed illustration (in the form of heat maps) of the responses for each belief category and the correlations in the responses. It shows that obtaining the needed resources, increasing one's understanding of the patient and the disease, and improving caregiving skills and confidence were the top "believed" values of online peer support. In contrast, reducing caregiving stress and the loneliness of being a caregiver was slightly more challenging. However, both categories received more "likely" responses than "unlikely" responses, with 57.1% (80/140) and 65% (91/140) of caregivers selecting "likely" responses, respectively. There were also several interesting observations made. First, reducing loneliness as a caregiver was highly correlated with reducing stress. Second, improving caregiving skills was highly correlated with increasing caregiving confidence. Third, reducing stress was correlated with improving caregiving skills and increasing caregiving confidence. Although correlation does not necessarily imply causation, these results suggested that improving caregiving skills and reducing loneliness may help to reduce caregiving stress.

Figure 2. Distribution of scores for the four measures. The red vertical lines in the "Caregiving stress," "eHealth literacy," and "Belief" in online peer support graphs correspond to the scores when "neutral" or "undecided" was selected for all the questions in each measure. The red vertical line in the "Caregiving competence" graph corresponds to the score when the "fairly" option was selected for all the questions.

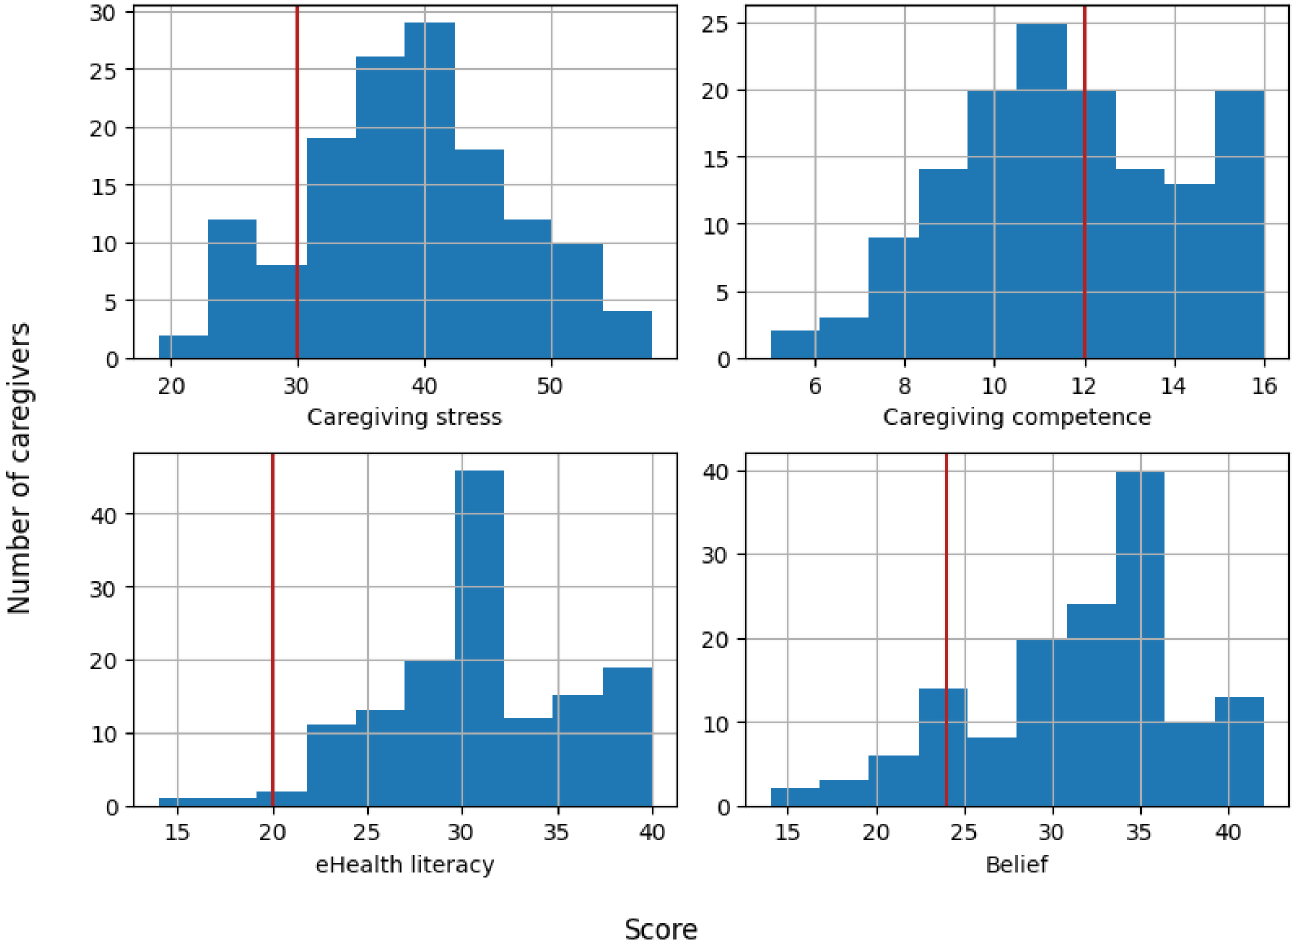

Figure 3. Heat maps of the number of survey participants in each belief category and scale pair (left) and the correlations in the responses (right). *Resources*: obtain the needed resources; *Understanding*: understanding patients or the disease; *Skill*: improve caregiving skills; *Confidence*: increase caregiving confidence or competence; *Stress*: reduce caregiving stress; *Loneliness*: reduce the feeling of loneliness as a caregiver.

	Extremely Unlikely	Quite Unlikely	Slightly Unlikely	Neither	Slightly Likely	Quite Likely	Extremely Likely
Resources	2	1	5	8	39	70	15
Understanding	0	1	3	3	36	64	33
Skill	0	2	7	9	42	56	24
Confidence	1	2	8	12	46	51	20
Stress	6	12	22	20	39	24	17
Loneliness	6	12	12	19	28	34	29

	Resources	Understanding	Skill	Confidence	Stress	Loneliness
Resources	1	0.54	0.61	0.59	0.46	0.51
Understanding	0.54	1	0.58	0.49	0.37	0.29
Skill	0.61	0.58	1	0.79	0.62	0.51
Confidence	0.59	0.49	0.79	1	0.61	0.56
Stress	0.46	0.37	0.62	0.61	1	0.7
Loneliness	0.51	0.29	0.51	0.56	0.7	1

Utilization of Online Peer Support

Of the 140 survey participants, 40 (28.6%) reported never using any online community to either read online caregiving discussions or discuss caregiving issues with other online peers in the past 3 months. The regression analysis showed that only the belief score was statistically significantly associated with the utilization of online peer support (β: 0.11, SD 0.041; *P*=.006). All the other factors, including sociodemographics, care duration and workload, dementia stage, access to a high-speed network, eHealth literacy, stress score, and competence score, did not have statistically significant effects (all *P* values were >.10). Additionally, of the 40 non–online community caregivers, 33 (83%) had a belief score above 24—the score when “neutral” was selected for all the questions. The reasons for not using any online community to access online peer support included having no time for online activities due to the intensive caregiving workload (14/140, 10%), having a lack of searching skills (9/140, 6.4%), having belief in unreliable online information (6/140, 4.3%), and having security and privacy concerns (2/140, 1.4%). Further, 4 (2.9%) caregivers reported not wanting to spend time online after working on a computer during the daytime. Interestingly, 99 of the 100 online community caregivers reported an intention to revisit online communities in the following 3 months. The only caregiver who did not do so said that too many sad stories in online communities made her worry about her father’s future.

Discussion

Principal Results

When comparing with *2022 Alzheimer’s Disease Facts and Figures* (AFF) [1], we observed that our survey recruited a similar proportion of caregivers who were Hispanic caregivers (our survey: 10/140, 7.1%; AFF: 8%) and Asian caregivers (our survey: 8/140, 5.7%; AFF: 5%). However, the proportion of Black or African American caregivers we recruited was far below that reported in AFF (our survey: 5/140, 3.6%; AFF: 10%), which suggests that Asian and Hispanic caregivers are more likely to participate in research studies when compared to Black caregivers [38]. To gain greater insight into the situation, we reviewed the responses of the five caregivers who reported their race as Black. We found that two of the caregivers accessed online communities in the past 3 months, with one (age: 49 y; education level: college degree; stress score: 51) reporting this at least once per week and the other (age: 50 y; education level: more than a 4-y college degree; stress score: 19) reporting doing this when she had a caregiving question that needed an answer. Among the three remaining caregivers who reported their race as Black and did not access any online community in the past 3 months, one (age: 60 y; education level: 4-y college degree; stress score: 55) said, “I have used books and I think some information on the internet can be misinterpreted”; another one (age: 29 y; education level: some college or 2-y degree; stress score: 55) said, “In [*sic*] recently started looking for online communities”; and the third (age: 30 y; education level: some college or 2-y degree; stress score: 52) said that they were “unaware.” However, all their belief scores were above 24 and ranged from 25 to 42, which suggests that these three caregivers believed in the value of online peer support, but they may not have known how to search online communities for peer support. Notably, the caregiver who relied on books for information seeking exhibited the lowest belief score (ie, a score of 25), indicating the survey results’ reliability.

Our study shows that the most prevalent challenges faced by these informal caregivers were (1) handling the memory issues of a person living with dementia, (2) daily caregiving, (3) life balance, and (4) emotional fluctuations. Caregivers facing such challenges can, at times, receive guidance from their peers who have shared the same firsthand experiences. This suggests that online communities, such as ALZConnected, that provide an online platform for caregivers to discuss their challenges and experiences can be a valuable resource for those seeking informational or emotional peer support. This implication is further supported by our observation that a large proportion of the surveyed caregivers indicated a belief in the value of online peer support. Still, given that some caregivers did not access online environments for peer support, it is evident that online environments alone are not a comprehensive solution and that caregivers need other types of support. Moreover, there are various caregiving challenges that are more likely to be addressed by professionals rather than peers, such as clinical questions about treatment, legal issues, and financial concerns. Given that 50.7% (71/140) of the survey participants were not satisfied with their received support, it is essential to diversify the support source portfolio to assist a broad range of caregivers. As such, the use of online environments can serve as one of a collection of strategies that, in concert with one another, provide a support structure for informal caregivers.

Another main result of this study is that whether an informal dementia caregiver accessed online health communities in the past 3 months depended upon their belief in the value of peer support obtained from online health communities but not upon their sociodemographics or any other ANFHSU factors. For example, one caregiver said, “I don’t find comfort from strangers on the internet. I would love to, and I am willing to go to an in-person meeting of a support group, but I don’t have anyone to watch my mother so that I could attend,” and they exhibited a belief score of 14, which is logical based on their reason for not accessing any online communities. This further highlights the dilemma that there is limited time to attend local support groups because of intensive caregiving [15]. Another caregiver, who had a belief score of 14, indicated that their health insurance could only cover 40 days of at-home nursing support in 1 year, which made their family feel so “helpless and alone.” Despite various reasons for not using online health communities in the past 3 months, 89.3% (125/140) of respondents exhibited a belief score above 24. This suggests that online peer support was valuable to them, but an effective strategy for bridging their needs and the desired online peer support is needed. Finally, the correlation of the survey responses to the six value aspects implied that an intervention designed around peer learning can effectively enhance a caregiver’s caregiving competence and reduce feelings of loneliness.

Limitations

There are, however, several limitations to this study that can serve as a basis for future research. First, since we distributed our survey link in the ALZConnected online community and the Alzheimer’s Association’s website, our results may be biased toward online community users. A less biased approach may be designed to collect data that reflect the perceptions and utilization of online peer support in the dementia caregiver population. Making online peer support beneficial to noninternet caregivers is equally essential, but determining how to address the internet access issue is a priority and is beyond the scope of this study. Second, only a small percentage of the participants were caregivers who reported their race as Black. Increasing participation in this group would increase the understanding of their perceptions and utilization of online peer support. Third, the analysis relied on 140 completed responses, indicating limited statistical power. Although statistically significant findings emerged, larger sample sizes are necessary for a more precise examination of this research. Fourth, in an open-ended question, we inquired about the types of offline support caregivers received to address their caregiving challenges. Some caregivers mentioned online peer support in their responses, leading to misalignment between their answers and the original research design, particularly regarding satisfaction with offline support. Future investigations should clarify this question or convert this question to a multiple-choice version. Finally, it is essential to study how to help caregivers without time or sufficient online information–searching skills screen the online caregiving discussions they need.

Conclusions

This study reported on an online survey about the perceptions and utilization of online peer support among informal dementia caregivers. Belief in the value of online peer support was statistically significantly associated with accessing online communities (*P*=.006). Moreover, there were a number of caregivers who were not using online peer support but held belief in the value of such support. As such, there is clearly an opportunity to build tools that help caregivers who are existing online community users and caregivers who intend to seek online information find reliable, matched online peer support.

Acknowledgments

ZY and L Stratton designed the survey questionnaire. L Song provided the theoretical support for the survey design. L Song and PC revised the survey questionnaire. QS implemented the questionnaire with REDCap (Research Electronic Data Capture). L Stratton disseminated the questionnaires. CN conducted the regression analysis. QS collected and cleaned the survey responses. ZY drafted the first version of the manuscript. All the other authors edited and approved the manuscript.

Abstract

Background: Social media platforms have been effective in raising awareness of the underassessment and undertreatment of pain in dementia.

Objective: After a successful pilot campaign, we aimed to scale our pain-in-dementia knowledge mobilization pilot initiative (ie, #SeePainMoreClearly) to several social media platforms with the aid of a digital media partner. The goal of the initiative was to increase awareness of the challenges in the assessment and management of pain among people with dementia. A variety of metrics were implemented to evaluate the effort. Through this work, we endeavored to highlight key differences between our pilot initiative (which was a grassroots initiative), focusing largely on Twitter and YouTube, and the current science-media partnership. We also aimed to generate recommendations suitable for other social media campaigns related to health or aging.

Methods: Evidence-based information about pain in dementia was summarized into engaging content (eg, videos) tailored to the needs of various knowledge users (eg, health professionals, families, and policy makers). We disseminated information using Facebook (Meta Platforms), Twitter (X Corp), YouTube (Alphabet Inc), Instagram (Meta Platforms), and LinkedIn (LinkedIn Corp) and measured the success of the initiative over a 12-month period (2020 to 2021). The evaluation methods focused on web analytics and questionnaires related to social media content. Knowledge users' web responses about the initiative and semistructured interviews were analyzed using thematic analysis.

Results: During the course of the campaign, >700 posts were shared across all platforms. Web analytics showed that we drew >60,000 users from 82 countries to our resource website. Of the social media platforms used, Facebook was the most effective in reaching knowledge users (ie, over 1,300,000 users). Questionnaire responses from users were favorable; interview responses indicated that the information shared throughout the initiative increased awareness of the problem of pain in dementia and influenced respondent behavior.

Conclusions: In this investigation, we demonstrated success in directing knowledge users to a resource website with practical information that health professionals could use in patient care along with pain assessment and management information for caregivers and people living with dementia. The evaluation metrics suggested no considerable differences between our pilot campaign and broader initiative when accounting for the length of time of each initiative. The limitations of large-scale health campaigns were noted, and recommendations were outlined for other researchers aiming to leverage social media as a knowledge mobilization tool.

Introduction

Background

Social media platforms play an important role in academic dissemination and have untapped potential as knowledge mobilization (KM) tools that can allow researchers to interact directly with the public worldwide [1]. KM encompasses activities involved in the synthesis and dissemination of research information; this process includes knowledge synthesis, dissemination, transfer, exchange, and cocreation by researchers and knowledge users [2]. Knowledge users, such as older adults and their families, are increasingly turning to web-based platforms (eg, Twitter [subsequently rebranded as X] and Facebook) to share and obtain information [3,4]. Health-related initiatives on social media networks have successfully raised awareness about a host of topics (eg, mental health, breastfeeding, and cancer) [5]. For example, a nationwide HIV prevention campaign (#PrEP4Love) garnered >40 million views across various social media platforms [6].

Researchers have supplemented social media KM initiatives with other web-based KM methods (eg, web-based repositories, educational videos, and community groups) [7,8]. Despite the innovation of this approach, the sustainability of social media health campaigns is contingent upon different factors (eg, continued content generation and ongoing funding) [9]. As such, there is a growing need for partnerships with digital media experts to aid in health KM. A notable example of this is the work by Chambers [10], who mobilized knowledge about pediatric pain within the context of a science-media partnership through her #ItDoesntHavetoHurt campaign. The initiative demonstrated worldwide impact and great success in producing and disseminating digital evidence–based content tailored to the needs of parents and health professionals, obtaining 1.3 million Twitter impressions, 5.5 million hashtag mentions, and >250,000 views of her YouTube video [10]. Impact was also demonstrated through indices of adoption and changed practices [10].

Although researchers have attempted to track the reach and impact of social media for KM through web metrics and the use of social listening software [11,12], very little research has been conducted using social media for KM in older adults with dementia. To address limitations in the reach of traditional KM campaigns and a gap in the literature, we launched and evaluated the pilot #SeePainMoreClearly (phase I) social media KM campaign with messages that reached >2,376,853 unique individuals on Twitter [9]. The goal of the pilot initiative was to increase awareness of the challenges in the assessment and management of pain among people with moderate to severe dementia with limited ability to communicate [13,14]. Moreover, we aimed to disseminate information on evidence-based approaches to effectively assess and manage pain in this population (eg, [15-18]). To maximize uptake, we created a web-based repository of pain assessment and management information [19]. We also prepared an engaging 2-minute YouTube video with evidence-based information about pain in dementia [20].

The script for the video was created and modified with input from health professionals, caregiver partners, researchers, and knowledge user organizations. The pilot campaign was evaluated by tracking social media and web metrics and by conducting qualitative analyses of social media posts in response to the #SeePainMoreClearly campaign over a 5-month period. #SeePainMoreClearly demonstrated substantial reach with >5,000,000 hashtag impressions on Twitter. The short video was viewed >50,000 times, and our web-based repository was visited by people in >55 countries. Moreover, the content analysis of social media posts (ie, tweets) from users who used the hashtag or responded to our messaging and content posted on Twitter were favorable. Many users expressed support for the initiative and increased advocacy for improved pain care for people living with dementia.

Our findings showed the effectiveness of web-based KM methods in reaching very broad international audiences quickly. Perhaps most importantly, without counting the posts that were produced by members of our team, the initiative doubled the number of posts made on the topic of pain dementia on Twitter during the campaign period as compared with a control period of the previous year [9]. It is important to note that the #SeePainMoreClearly pilot campaign took place in 2019, before the COVID-19 pandemic. The pilot #SeePainMoreClearly was a grassroots initiative in which a small number of researchers prepared engaging materials and disseminated them on their own with support from several knowledge user organizations that agreed to help disseminate the message. A lesson from the pilot #SeePainMoreClearly experience was that although KM grassroots campaigns can be very successful, lengthier social media campaigns (run solely by researchers) would not be sustainable, as involvement can be very time-consuming for researchers who generally must attend to multiple other obligations. A partner with digital media expertise and time to dedicate resources is necessary for a sustainable large-scale KM campaign. Hence, we sought and obtained funding to support such a partnership.

Objectives

The primary purpose of this study was to launch and evaluate a longer (12 months instead of 5 months) #SeePainMoreClearly campaign with expanded social media platform coverage (eg, Twitter, Instagram, Facebook, and LinkedIn as opposed to just Twitter) with the following additional objectives:

1. Track the reach of a larger social media KM campaign over a 12-month period on various platforms (eg, Facebook, Twitter, Instagram, and LinkedIn)
2. Evaluate the impact of the campaign on knowledge users' (eg, patient, caregiver, health professional, and policy maker) knowledge
3. Evaluate the impact of a science-media partnership on our pilot campaign in meeting knowledge users' needs
4. Outline recommendations to develop and scale social media KM initiatives.

We expected the results to demonstrate a large scope and breadth of our campaign, resulting in a large number of visits to our resource website [19]. Moreover, we predicted that our results would demonstrate the value of a science-media partnership as a strategy for improving KM in the area of pain in dementia. We contrast the experiences of the digital media partnership campaign with the pilot #SeePainMoreClearly campaign. The findings from this project can inform subsequent evaluations of social media as a KM tool.

Methods

Ethical Considerations

The evaluation process involving contact with human participants (eg, questionnaires and semistructured interviews) was approved by the University of Regina Research Ethics Board (#REB 2020-036).

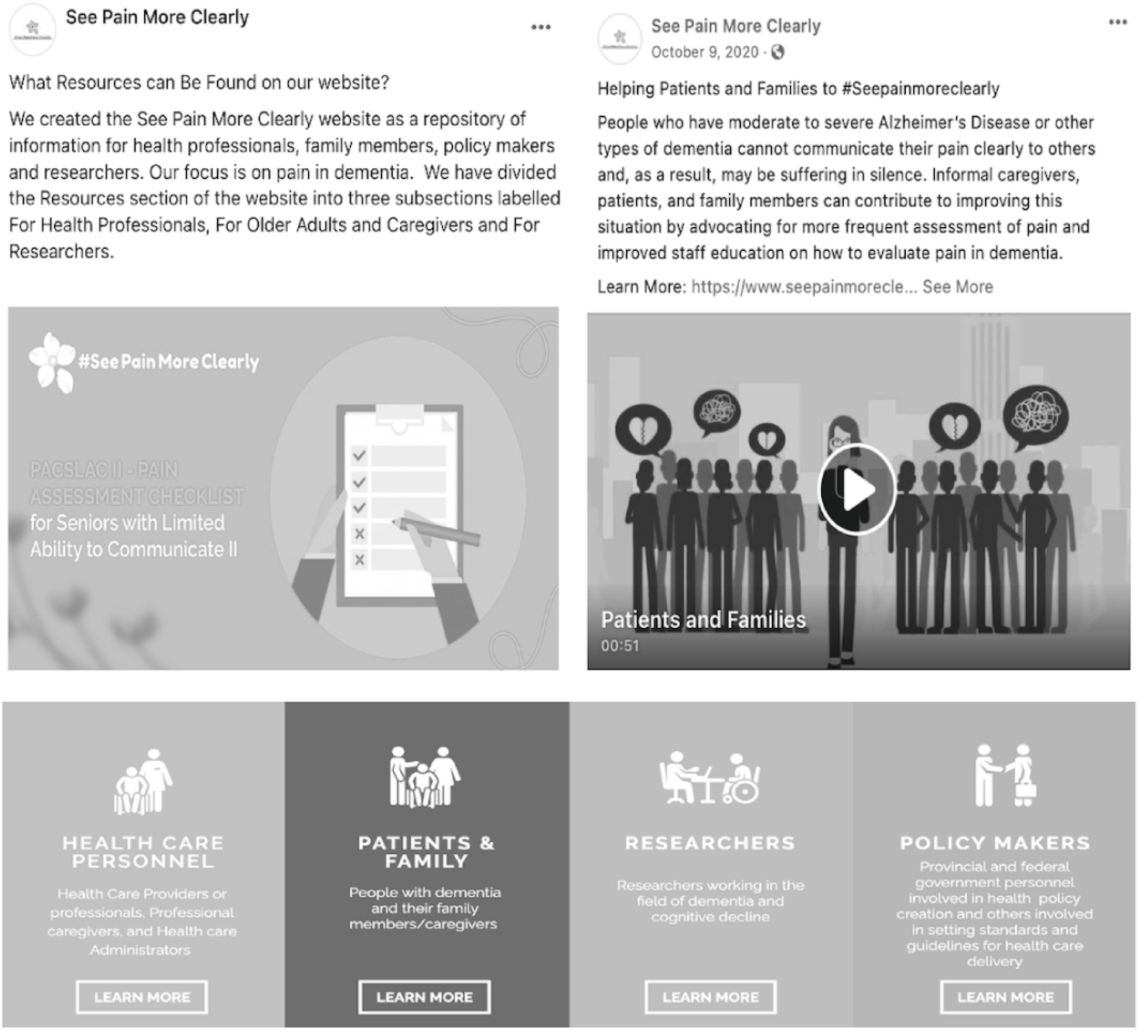
Identification and Engagement of Digital Media Partner

Given the nature of our funding, we were restricted to identify a digital media partner within our home province. As such, a web search was conducted to identify potential locally based digital media partners that listed social media promotion as part of their services. We then communicated with 2 of the firms that, based on their websites, seemed highly experienced with social media marketing and described the nature of our work to confirm that they understood the needs of our project and that they were interested in partnering with us for the campaign. Our institution required us to subject the project to an open competitive bidding process before awarding the contract. This process allows qualified bidders to submit proposals and budgets. The 2 firms with which we had communicated were invited to submit their proposals. On the basis of this process, the best qualified bidder who offered competitive pricing was selected from a total of 3 bidders.

Development of Content and the Campaign

We worked with the selected digital media partner to develop the campaign content and KM strategy as well as to collect social media analytics in response to our campaign. An iterative process was implemented with team collaborators (eg, caregiver partners, researchers with knowledge of the content area, media experts, and health care professionals) with the aim of developing lay summaries of evidence-based information about pain in dementia. Specifically, a series of web-based meetings with members of the team were coordinated to identify pertinent information about pain assessment and management among older adults with dementia, which served as the basis of the campaign's content. Accordingly, the general topics agreed upon by the team were as follows: (1) the feasibility of regular pain assessments, (2) available guidelines for pain assessment, (3) resources for informal caregivers, (4) effects of psychotropic medication in long-term care (LTC), (5) validated pain assessment tools, (6) implementing regular pain care in LTC, (7) gaps in education for health professionals and ways to address this challenge, (8) effects of untreated pain in dementia, (9) pain care during the COVID-19 pandemic, (10) cost of untreated pain for the health care system, (11) benefits of regular pain assessments, and (12) effective ways to assess pain in dementia. Once the general topics were identified, information was gathered that corresponded to established guidelines (eg, [17,18,21,22]) or was supported by published research in leading peer-reviewed journals. Specific evidence-based information was selected by our team, which included content experts and caregivers with lived experience. Next, the team developed lay summaries (eg, 200-300 words) of the evidence present in the literature covering each aforementioned topic (eg, [17,18,21,22]). Several rounds of refinement were conducted by team members. Following this, the team developed 8 cross-cutting messages and key points (Multimedia Appendix 1) divided by the target group (eg, health professionals, policy makers, and public or families). These messages were then relayed to the digital media team as the basis for the messaging developed for the campaign. The digital marketing team developed a series of images and posts for each target group. Moreover, a short animated (ie, 2-minute long) video was created for each target group (eg, family, health care professionals, researchers, and policy makers). The animated videos were posted on the web page and on social media platforms. Examples of the content and posts are shown in Figure 1. Blog posts written by team members and people with lived experiences related to the topics outlined in this section were shared throughout the initiative. A total of 42 blog posts [23] were created and posted on the web page of this project.

Figure 1. Digital content samples shared throughout the initiative.



See Pain More Clearly

What Resources can Be Found on our website?

We created the See Pain More Clearly website as a repository of information for health professionals, family members, policy makers and researchers. Our focus is on pain in dementia. We have divided the Resources section of the website into three subsections labelled For Health Professionals, For Older Adults and Caregivers and For Researchers.

See Pain More Clearly
October 9, 2020 ·

Helping Patients and Families to #Seepainmoreclearly

People who have moderate to severe Alzheimer's Disease or other types of dementia cannot communicate their pain clearly to others and, as a result, may be suffering in silence. Informal caregivers, patients, and family members can contribute to improving this situation by advocating for more frequent assessment of pain and improved staff education on how to evaluate pain in dementia.

Dissemination Strategy

Unlike the pilot campaign [9], which focused on Twitter and YouTube, information was disseminated on 5 social media platforms used for the campaign: Facebook (Meta Platforms), Twitter (X Corp), YouTube (Alphabet Inc), Instagram (Meta Platforms), and LinkedIn (LinkedIn Corp).

A total of 756 posts were shared across Facebook, Twitter, Instagram, and LinkedIn, and 5 videos were posted on YouTube over a 12-month period (ie, October 1, 2020, to September 30, 2021). A key goal of the dissemination strategy was to direct knowledge users to the web-based repository to share further information and resources about pain in dementia [19]. We designed the content (eg, social media posts, images, and short animated videos) to be of interest to our target groups. Moreover, we developed social media posts to gain the attention of specific target groups (eg, by including an image with the statement *Resources for researchers* prominently displayed). As with the pilot initiative, the #SeePainMoreClearly hashtag was used to maximize the reach of the content and information. We leveraged events (eg, the International Day of Older Persons in October, World Alzheimer Awareness Month in September, and Alzheimer Awareness Month in January) to develop tailored content. The total amount of money spent on post promotion and advertisements was CAD $29,793.86 (US $22,133.06); the vast majority of this amount was spent on Facebook and Instagram, CAD $26,384 (US $19,599.96), Twitter, CAD $3045 (US $2262.05), and LinkedIn, CAD $364.86 (US $271.04).

Evaluation of the Campaign

Engagement and Reach of the Initiative

Web Analytics

A longitudinal data collection strategy was used to obtain web and social media metrics over a 12-month campaign period (ie, October 1, 2020, to September 30, 2021). For the website, the number of content viewers and pages views were tracked using Google Analytics [24]. For our analysis, we reported a descriptive count (eg, count of total engagement, reach, and impressions) of all web and social media analytics. Google Analytics was used to collect data from the website. To clarify how Google Analytics works, each time a user visits a web page, a tracking code by Google Analytics collects information on how that user interacted with the page [25]. Google Analytics then aggregates and organizes this information in the Google Analytics portal as a report detailing different metrics (eg, the count of web page visits and the number of pages viewed). Similarly, the social media metrics were aggregated by each social media platform. This information was accessed through the social media platform’s website (eg, Facebook Analytics). Web and social media analytics were exported and reported.

Social Media Analytics

The reach, scope, and engagement of the initiative and web-based repository were monitored through social media metrics (eg, web analytics, hashtag analytics, and social media analytics). Similar metrics have been used in previous research to quantify the impact of social media initiatives [10,12]. The number of impressions (ie, the number of times users have seen the web-based content), reach (ie, the number of unique users who have seen the web-based content), and engagement (ie, the number of comments, retweets, “likes,” and shares) were extracted using the analytics provided by each platform. Not all analytics were available for each social media platform (eg, reach was not available for LinkedIn). Analytics were summarized based on three sources of information: (1) analytics of only paid posts provided by the social media platform, (2) analytics of the total number of posts (ie, paid and unpaid) provided by the social media platform, and (3) third-party social media analytics manager (eg, CloudCampaign) provided by the digital marketing team. Moreover, our digital media partner could only obtain data for specific periods (eg, year-long data could not always be obtained) for some platforms owing to limitations in the sources of information. Nevertheless, attempts were made to encompass the entire evaluation period. Depending on the data source, data were provided from (1) October 1, 2020, to September 3, 2021; (2) October 1, 2020, to November 2, 2020; or (3) November 3, 2020, to September 30, 2021. Thus, the reported numbers varied as a function of the period. The Keyhole social media monitoring (also known as social listening) software [26] was used to collect the metrics and analytics for the #SeePainMoreClearly hashtag on Twitter.

Knowledge Users’ Responses to the Initiative

Semistructured Interviews With Knowledge Users

Individuals who viewed and engaged with the content (eg, responded to social media posts or added their own commentary when reposting content shared throughout the initiative) on social media were invited to participate (ie, research personnel commented back to users who responded to social media posts and invited them to participate in interview) in semistructured interviews with a researcher to gain an understanding of their perceptions about the initiative. Moreover, invitations (ie, through social media posts or recruitment posters) to participate in the interview were circulated across social media platforms. All participants recruited through social media posts were asked to contact the research team to indicate their interest. The interviews were conducted over Zoom (Zoom Video Communications Inc) audio-only and covered the following topics: perceptions about the initiative, quality of information and messages disseminated, and impact of the initiative on knowledge and behavior (Multimedia Appendix 2). Zoom’s automated transcription feature was used to facilitate the transcription of the interviews. The transcription was then reviewed with the interview audio recording to ensure accuracy. NVivo (version 12; Lumivero) software [27] was used to facilitate the coding reliability thematic analysis [28]. Two independent researchers initially organized a subset of data into clusters based on commonalities and recurring ideas to develop a coding book [28]. Consistent with a coding reliability thematic analysis approach, themes were developed inductively and aligned with the data collection questions of the study [28]. Themes that emerge from this analysis can be viewed as a summary of the participant responses. Codes were developed after data familiarization, while keeping the data collection questions in mind. Two coders individually coded a subset (3/13, 20%) of the data to develop a coding book. They grouped each line of text into clusters and then into higher-level codes (ie, themes). The coders then met to discuss and finalize the coding book. Discrepancies between the coding researchers and decisions to merge or split categories were discussed throughout the process until a consensus was reached. The developed coding book was applied to the remaining data to identify the prevalent categories and obtain a frequency count of the identified themes. To ensure rigor in our analysis, we conducted consistency checks on the coded themes and categories (eg, discussing discrepancies between coders) and maintained ongoing communication among coders throughout the process to establish consensus. Moreover, a randomly selected subset of data was coded to assess intercoder agreement. Triangulation was considered through the different perspectives (eg, health professionals, caregivers, and people with dementia) obtained in this study and the use of a mixed methods approach (ie, use of interview and numeric questionnaire data). A primary coder coded the entire data set, and a secondary coder coded a subset of the data to establish intercoder agreement. The second coder coded a randomly selected 20% (3/13) of the participant data. NVivo calculates a κ coefficient to evaluate agreement as follows: total units of agreement between the 2 coders minus the expected frequency of the agreement occurring by chance, divided by the total units within the source minus the expected frequency of the agreement occurring by chance [29].

Social Media Comments About the Campaign

Social media analytics do not provide information about the content of the comments in response to our initiative (ie, whether users liked or disliked the content). As such, we analyzed the responses to the initiative to better understand users’ perception of our campaign. To assess the perception of a wider sample of knowledge users, comments by web users in response to the posts made during the campaign across Facebook, Twitter, Instagram, and LinkedIn were collected manually and subjected to a coding reliability thematic analysis, consistent with the method outlined in the *Semistructured Interviews With Knowledge Users* section. The aim was to understand the type of comment (ie, opinion, personal experiences, and information) in response to the content shared to determine prevalent themes.

Overview of Evaluation Questionnaires

A brief survey was circulated across the campaign’s social media platforms to receive feedback about users’ perception of the content and information shared during the initiative. The participants were recruited via invitations on social media platforms. For example, social media posts were created to encourage participants to provide their input on the initiative by clicking on the link that directed users to the questionnaires. The link to the questionnaire was also available on the website for this project. Individuals who accessed the surveys were asked to indicate the group they belonged to (1) caregiver, family member, or friend of a person with dementia, (2) person living with dementia, (3) public, (4) health professional, or (5) policy maker. Demographic information questions about participant age, gender, country, relationship with the person living with dementia, and type of health care provider (ie, for individuals who identified as a health care professional) were collected and outlined using descriptive and frequency statistics.

Pain in Dementia Evaluation Questionnaire

A short questionnaire, used in the pilot campaign evaluation [9], was used to solicit anonymous responses from various knowledge users. The survey included both general and specific questions for the general public, health professionals, and caregivers and family of people with dementia. Most responses were provided along 7-point Likert scales (eg, 1=not very likely to 7=very likely) and focused on viewers' opinions about the initiative, content, and likelihood of using the information provided. Descriptive statistics were calculated for the Likert scale items in the evaluation questionnaire.

Information Assessment Method for All

Users' perception of the content and potential benefit of the information were assessed using the IAM4all (Information Assessment Method for All) [30]. The IAM4all consists of 6 general questions assessing information relevance and use, with nested follow-up questions depending on participant responses. Accordingly, the IAM4all is a 28-item self-report questionnaire designed to measure 4 levels of outcomes associated with receiving or seeking web-based information: situational relevance, cognitive impact, information use, and health benefits. Each item is rated based on agreement to a question (ie, yes, no, or possibly). Content validity of the IAM4all has been substantiated through a review of the theories of information science and feedback from knowledge users (eg, laypersons, health professionals, and experts) [30]. Descriptive and frequency statistics were used to calculate the means and SDs for the items in the questionnaire.

Web-Based Discussions About Pain in Dementia

The level of web-based discussions about pain in dementia was determined by examining the number of posts on Twitter and Facebook. Three periods of comparison were established: (1) a precampaign period (ie, a 7-month period following the end of the pilot campaign and before the start of #SeePainMoreClearly phase II, March 1, 2020, to September 30, 2020); (2) a campaign period (October 1, 2020, to September 30, 2021); and (3) a postcampaign period (ie, a corresponding 7-month period following the end of #SeePainMoreClearly phase II, October 1, 2021, to April 30, 2022). Searches for unique (ie, not retweets or reposts) tweets on Twitter containing the hashtags "#pain #dementia" AND/OR key words "pain dementia" were conducted for all 3 periods using the Keyhole software. A catalog of all the tweets during the specified periods was collated on a spreadsheet by Keyhole. A similar method could not be used to obtain Facebook posts on Keyhole (ie, this feature was not available on Keyhole for Facebook posts); hence, a manual search using the aforementioned keywords was conducted for all 3 periods. That is, the specific keywords were typed in the search bar on Facebook, and the period (eg, precampaign period, campaign period, and postcampaign period) was specified in the search filter. Posts for each platform across the 3 periods were cataloged. The following types of posts were excluded: (1) pertaining to pain as a metaphor (ie, using "pain" as a metaphor for psychological distress, such as in the context of grief "I feel your pain"), (2) unrelated to the problem of pain in dementia, (3) shared by our own research group, and (4) not in the English language.

Results

Engagement and Reach of the Initiative

Web Analytics

Over 60,000 users from 82 countries viewed the web-based repository website, which resulted in 83,247 page views over the 12-month period (ie, October 1, 2020, to September 30, 2021). In examining the manner (ie, how people found the website) in which users were directed to the website, a majority of users (ie, 51,693 users) were directed to the website through links (ie, posts including a link to the website) from social media platforms. Other users directly typed the website link (ie, 6927 users) or searched the website link (ie, 2152). A small number of website users (ie, 116 users) were referred by other sites (ie, partnering organizations linking the web-based repository website on their web page). The blog web pages were viewed 59,919 times. Of the blogs posted during the project, the article written (on the request of our team) by an acclaimed author, Louise Penny, in which she relayed her experiences caring for her husband who lived with dementia [31], garnered most of the views (ie, received 33,226 views).

Social Media Analytics

The analytics are summarized in Table 1 based on the 3 sources of information and data periods described in the *Methods* section. The advertisements that were initiated on Facebook could also be posted on Instagram based on advertisement specifications. To maximize reach, the digital media team specified advertisements on Facebook and Instagram to be displayed on all available placements and to the specified targeted audiences. This includes Facebook and Instagram feeds (ie, advertisements displayed on the user's feed), in-stream advertisements for videos, search results, and external apps and sites (ie, advertisements displayed to audiences on additional websites and mobile apps, such as newspaper websites). That is, advertisements initiated on Facebook could be displayed on Facebook, Instagram, or to external websites or apps connected to Facebook, resulting in increased impression and reach than organically derived engagement. The advertisements analytics (eg, impression and reach) on Facebook and Instagram differs from Twitter and LinkedIn as a function of the data source (ie, paid impression or reach on Facebook and Instagram are higher because they capture not just impression or reach derived on Facebook and Instagram but also on third-party websites such as newspaper websites; Table 1).

Table 1. Summary of the social media analytics for the #SeePainMoreClearly campaign.

Period, metric, and source of information[a]	Facebook, n	Twitter, n	Instagram, n	LinkedIn, n
Period 1[b]

[a] Some analytics could not be obtained for specific platforms because they were not available. Moreover, the digital marketing team could only obtain data for specific periods (eg, year-long data could not be obtained) for some platforms owing to limitations in the sources of information. Nonetheless, efforts were made to capture the entire period.

[b] Period 1=October 1, 2020, to September 30, 2021.

[c] "Facebook overall analytics"=generated from paid and unpaid impressions on Facebook and third-party websites such as newspaper websites that are part of the Facebook advertising display network across Canada.

[d] Data for this period or metric were not applicable or not available.

[e] "Twitter/Instagram/LinkedIn only analytics"=analytics based on unpaid posts circulated only on Twitter, Instagram, or LinkedIn.

[f] On Instagram, the period 1 impressions only include impressions for unpaid posts posted on Instagram. It does not include paid posts that were posted on Facebook but reached Instagram audiences.

[g] "Twitter/LinkedIn advertisement analytics"=analytics based on paid posts circulated on Twitter and LinkedIn.

[h] "Instagram advertisement analytics"=the analytics are based on paid posts that were posted on Facebook but reached Instagram audiences based on specified target audiences.

[i] "Facebook only analytics"=based on paid and unpaid posts that were circulated only on Facebook.

[j] CloudCampaign (ie, third-party social media monitoring software): these analytics are based on unpaid posts circulated individually on Twitter, LinkedIn, and Instagram. The Cloud Campaign analytics from Facebook includes analytics of paid and unpaid posts circulated only within Facebook.

[k] Period 2=October 1,2020, to November 2, 2020.

[l]Period 3=November 3,2020, to September 30, 2021.

For a graphical illustration of the analytics, refer to Multimedia Appendix 3. Social media analytics indicated that 1,313,485 people were reached by the content shared on the Facebook page created for this project (Table 1). The #SeePainMoreClearly hashtag on Twitter (eg, obtained by Keyhole) was used by 540 users, resulting in 2835 posts. Moreover, the hashtag reached 1,691,440 users and gained 8,592,929 impressions and 8696 engagements. The 4 animated videos developed during the initiative were viewed over 257,000 times across the web page and social media platforms. The views for each video were as follows: 106,055 (family), 102,407 (health care professionals), 42,731 (policy makers), and 5911 (researchers). The pilot campaign video was also disseminated during phase II of the campaign across social media platforms and received 45,637 views (ie, 43,870 views on Facebook, 1043 on Twitter, 709 views on YouTube, and 15 views on Instagram).

Knowledge Users' Responses to the Initiative

Semistructured Interviews

Overview

A total of 13 knowledge users who interacted with the initiative's posts participated in semistructured interviews. All participants provided informed consent. Participants had varied perspectives: 1 participant had lived experience of dementia, 4 participants had family members living with dementia and were health professionals, 4 participants were caregivers, and 4 were clinicians. A thematic analysis was conducted by 2 separate coders to establish an intercoder agreement. A randomly selected 20% (3/13) subset was coded by a second coder to assess for agreement. Overall agreement was excellent (k=0.81). Five themes emerged from the data: (1) increased awareness about the problem of pain in dementia, (2) perceived barriers to pain management, (3) increased knowledge and changes in behavior, (4) value of social media as a method of scientific dissemination, and (5) suggestions for improvement.

Increased Awareness About the Problem of Pain in Dementia

A majority of participants expressed positive views about the initiative, particularly about the manner in which the content was shared throughout the initiative and the resulting increased awareness about the problem of pain in dementia. One participant noted the importance of the information shared during the initiative:

> *Overall as a whole, I really liked it. I like the messaging that comes out of it, and I think it's something really important to continue doing...I don't think there's a real understanding about pain and older adults. I like the messaging and I think it's something that's really important for us, as well as a society to promote.*

Participants also expressed that the information shared during the initiative highlighted the experiences of older adults with dementia and pain. A person indicated that they thought the initiative was "great" because "the more information that can get out to caregivers, the better it will be for the residents [and] the people that have loved ones at home." Furthermore, the initiative brought awareness to an underdiscussed problem of pain in dementia. For example, one participant stated:

> *Oh it's good thing to put out here, something that people haven't really thought about even the health care system and [pain in dementia] is a huge problem...so to bring it to the forefront is good, it needs to be brought to the forefront.*

Overall, participant responses described a lack of prior understanding related to the experience of pain in dementia and the need for increased awareness about this topic.

Some individuals commented on the significance of the specific messages shared throughout the campaign in raising awareness about pain in dementia. For example, a participant noted the following:

> *I love what you're doing. It's a concern that everybody has, and why I call you a niche [because] it is a subject that people haven't traditionally thought of.*

Similarly, one participant expressed that the messaging on the videos were informational. This participant noted the following:

> *I guess one thing that stood out to me so much was the video of the man who seemed very angry. And so, I think back of all the people who've been labeled as the "angry person" could be the person in pain. And I think that message really hit me the most on pain.*

Several participants expressed that the messaging shared during the initiative changed their perception about the problem of pain in people with dementia. A person commented on the videos:

> *You know one thing I did really like is the video with the gentleman that they thought was being kind of aggressive...I thought that video was really good but then on the other side [you] have the gentleman communicating how he is feeling. That was really good because that was really eye-opening.*

Perceived Barriers to Pain Management

Knowledge users described various barriers that they have experienced in managing pain in their clinical practice or as a family member caring for a person living with dementia. The barriers encountered by knowledge users centered on inadequate pain assessments conducted in their practice or of their family member and relative living with dementia. For example, a health care professional reported the inadequate frequency of pain assessment in their facility:

> *You know, often in Ontario anyway, where I live, assessments in long-term care are done quarterly on clients and that's, you know, that'll be an all-encompassing assessment but certainly pain is part of that evaluation and, I mean, four times a year is not even close to being adequate to properly address and intervene if someone is living with pain.*

In light of inadequate pain assessment practices, caregivers are often left to advocate for their family member or relative living with dementia. A caregiver in the study expressed the importance of families in advocating for assessment for their loved one:

> *I realized I don't know if [my mother] might have tooth decay in her teeth [or if it] would be hurting her, and I don't know how to figure that out. And I don't think anyone else is checking. Yeah, because I think the lesson of my story here is that I am more likely to assess pain in my mom than her* [care providers]

Participants described lack of continuing education and awareness as significant barriers to improving practices in LTC settings. For instance, a participant indicated the following:

> *I think there's certainly a lack of understanding and education by many health care professionals who are working with older adults who live with dementia, so I think a barrier is getting that education, well, I mean, it's an opportunity for people to have more education but a barrier is kind of reaching the people.*

Participants also indicated that the lack of education of the public at large was a significant barrier to improving current practices:

> *I think the barrier is the lack of education, the lack of knowledge that people with dementia can have pain and express it in a different way. So, I think that the lack of education of health care workers, but the public in general.*

Insufficient education about the topic means that health professionals or caregivers of persons with dementia may not be aware of the signs and symptoms that can indicate pain. A caregiver in the study reflected on this notion and shared their lack of knowledge about the signs of pain in her mother living with dementia:

> *I mean I can think back to my mother who had two strokes. And after the second one, she used to scream all the time. She used to scream. And she never spoke to anyone, but she screamed. And when I questioned the doctor, if could she be in pain, he was so sure that she was not. It doesn't manifest that way. And so, I think back like, "was she in pain all the time?" When she screamed louder when we came, was it a plea for help. I think lot about that.*

Increased Knowledge and Changes in Behavior

Participants described the positive impact of the information on their knowledge and behavior. Some participants noted that the information shared during the initiative influenced their awareness and advocacy in their personal life or in clinical practice. Health professionals indicated that they found gaps in their own practice as a result of viewing the content shared in this initiative. A participant said the following:

> *It made me more aware of the gap in pain assessment with people like my mom. And then it also made me more aware that the onus then is on me as a caregiver to be doing it, and I feel woefully inadequate, that fact that I encountered the research has made me realize that it's me doing the diagnostic [work] and I have no medical skill at all.*

Greater insight into their own behavior was also reported by the participants. A clinician noted the following:

> *It also made me more aware for myself in my own practice...so that's changed my practice in that way. To be more cognizant that behaviors the patient is displaying could be manifested due to pain. So, I need to ask the caregivers and ask the family, "Has he or she changed in behaviors in any way recently?" "Have you noticed, you know, a consistent type of behavior? Is it a specific time of day, is it related to something?" So that I could look more into pain and assessing it in a roundabout way, rather than asking them straight, "Do you think that your husband or wife is in pain?"*

Other participants indicated that the initiative largely impacted their perspective on this issue (eg, "I would say it's definitely changed the viewpoint"). Finally, participants indicated that they shared the knowledge they obtained with others:

> *I share things that you guys put out there, if you look back at my timeline, you'll see periodically I make reference to you guys.*

Similarly, one participant noted the following:

> *I forward all this information off to my colleagues that work in this [area] that are even more focused in the nursing aspect that would have a more direct impact on client care needs.*

Value of Social Media as a Tool for Scientific Dissemination

Participants underscored the importance of leveraging social media to share research information in the age of the internet. Participants expressed that sharing evidence-based information fosters trust and credibility among users seeking information on social media platforms. For example, one participant noted the following:

> *I think it has a lot of positive benefits. Where to start? After this past year right, social media and technology were probably utilized more than they ever have been. So, I actually think it's a really great way to disseminate that information. And then further to that too, because I've been following all your accounts for a while, just there again, yeah, the quality of the content is also really good. So, with that being said, it creates that credibility and that trust. And then that also really feeds into where social media sometimes isn't the most trusted source. So, I do think that it's been a really great way to get that information out there.*

Participants also acknowledged the salience of social media platforms that needs to be further leveraged for scientific dissemination (eg, "social media certainly in light of COVID, like it is the way that information gets disseminated right now so I think it's very appropriate and it is a strength that you're on various platforms sharing resources"). Other participants expressed the importance of health initiatives in combating misinformation over the web:

> *I think a lot of times there's a lot of misinformation for people and families and health care practitioners and [they] want to have some valid research-based information for best practices and when you do things like this and have it more accessible then it's easier for people to gain the right information and make the best decisions for their family members or their clients that they can.*

Other participants commented on the reach that social media platforms hold in raising awareness of issues in a short amount of time and connecting knowledge users across the world. One participant indicated the following:

> *It's brilliant, social media has always been very, very good at distributing information. Creating awareness. Highlighting anything in social media catches the eye of the person. Because people are looking for answers.*

In particular, one participant commented on the utility of Facebook targeting specific demographic groups:

> *I think, using social media is great, you know, the thing about Facebook, is that it is now an older person's social media and people often think that that young people are caregivers of people with dementia. But it's not always so–it's old people who are caring for people with dementia. Facebook is good because most of us use Facebook.*

Suggestions for Improvement

Finally, participants made suggestions about scaling and improving the initiative. One participant said the following:

> *I think it would be effective for you to reach out to the Alzheimer's Society...I would love to see you partner with them in an active way on their media.*

One participant suggested focusing on reaching individuals who may not be directly reached by the initiative. For example, one participant noted individuals who may not be using or cannot access social media platforms:

> *I think smaller communities don't have the access or don't know about it. I mean now we do have the Internet and that sort of thing which is fabulous but lots of time we don't even know it's out there.*

As another example, one participant stated the following:

> *It's the reachability...say like you know, even for me, it was from [someone else] that I found out about this, I have never seen it while using any of the social media account before. And like that largely depends on my browsing habits too right? But it's the reachability that you guys have to concentrate on.*

Other participants suggested incorporating information to traditionally delivered pain education:

> *And so, if there was a way, we could get this added into a pain curriculum, I think that would be excellent, because I never had it in my course, and I've learned from this.*

In clinical practice, one participant expressed the following:

> *Well, I think, for so many people with dementia, their care is being provided by people with minimal education or I should say varying levels. If [people could get] a little certificate put into their little portfolios that would show, they have completed a course in pain assessment for people with dementia and that would somehow be an incentive for them as workers.*

Social Media Comments

Overview

A total of 895 comments were included in the analysis. Most of the comments were retrieved from Facebook (eg, 822/895, 91.8%), followed by Twitter (eg, 68/895, 7.6%), and a small subset was comments by users on Instagram (eg, 5/895, 0.6%). A randomly selected 20% (179/895) subset was coded by a second coder to assess for agreement. The overall intercoder agreement was excellent (ie, k=0.80). Six themes emerged from the analysis: (1) positive comments in response to the initiative, (2) sharing their personal experiences in response to the content, (3) criticisms about and suggestions to improve pain management practices, (4) responses related to the COVID-19 pandemic, (5) negative comments in response to the content, and (6) advertisements.

Positive Comments in Response to the Initiative

Many users provided positive comments in response to the content. Facebook users expressed empathy in response to the content shared in the form of comments (eg, "I am praying for you" and "Amen") and with the use of "emojis" (eg, praying emoji and red hearts). Other respondents commented on the importance of the initiative. For instance, a user on Facebook provided a comment noting the following:

> *The work you are doing is so important to all.*

As another example, other users commended the initiative (eg, "such an important campaign #seepainmoreclearly"). Blog posts written by care partners in which they relayed their experiences as caregivers stimulated various positive discussions about the initiative. For example, a user commented "thanks for bravely sharing your experience with having a spouse with dementia, what a difficult journey, I enjoy [your books] so much!" in response to Louise Penny's blog post shared on social media. As another example, a user expressed the following:

> *Thank you for this information which is truly important. Your story is important to open our minds to an area of Alzheimer's that many did not think of.*

Sharing Their Personal Experiences in Response to the Content

Other users responded to the initiative by sharing their personal experiences with the posted content. For example, one user stated the following:

> *My family went through this when my dad was only in his early 50s...no one had heard of*

> *Alzheimer's...this disease is so sad and robs the family of so much. I'm glad there's more support for families now, and wish we'd had more support when we needed it.*

Another user expressed their experience of caring for their mother:

> *I wonder this all the time. My mom is nearly 101 and has dementia. She rarely expressed having pain. But how can she not when she is quite hunched over and has arthritis.*

Other individuals provided additional commentary on the shared information. A user emphasized the importance of pain assessment:

> *People with dementia, people unable to clearly explain [their] pain, we need to look for clues daily that would help us determine if something out of the norm is going on.*

Criticisms About and Suggestions to Improve Pain Management Practices

Critical comments about current practices or advocating for improved practices were also present. For instance, a user expressed the following in response to a post:

> *There is a problem with doctors overlooking any kind of pain.*

Another user pointed out the issue of resource limitations in LTC facilities (eg, "staffing is a huge issue which needs a timely resolution"). Moreover, a user indicated that "seniors deserve much more than the less of minimum care they get." Other users provided suggestions to improve practices:

> *There are so many kinds of dementia, each with their own stages. We need more access to good education and support for home care to help families cope.*

Another user stated the following:

> *Pain assessment only on admission and then every 3 months? Pain must be assessed whenever there is the slightest indication of pain. A formal assessment every 3 months should reflect how effective the measures were.*

Responses Related to the COVID-19 Pandemic

As the campaign occurred during the COVID-19 pandemic and disseminated vaccination information related to residents in LTC, a subset of the comments was related to the pandemic. Some users noted the negative ramifications of isolation in LTC (eg, "I am sick of the lockdowns in care homes. Not being able to take them out for a day for visits...is absolutely insane. They are suffering terribly over this, and it has to stop.") Other comments denounced the significance of vaccines (eg, "the fake pandemic was created for the COVID vaccines").

Negative Comments in Response to the Content

A subset of the comments expressed negative responses to the information shared. A few of these comments perpetuated stereotypes about older adults (eg, "people with dementia still feel pain?") or dementia (eg, "reading this is enough to get dementia"). A user expressed disagreement with one of the information shared:

> *We assess residents for pain every time we see them. We are not stupid; we can tell when someone is in pain.*
>
> *Do any of you work in LTC facility? Staff in dementia units are trained to look for any behavioral issues that may arise from pain.*

Advertisements

Finally, a small subset of comments was from users advertising a product or information (eg, "Dementia and Alzheimer's affects so many. Please don't forget to check out my podcast, if you haven't already" and "Can we help your loved one/care home/hospital/nursing home in UK with our free mp3s preloaded with the music of their own choice?? Contact me asap please click on the link.").

Responses to the Evaluation Questionnaires

The demographic characteristics of the knowledge users who responded to the questionnaires are presented in Multimedia Appendix 4. The majority of the survey respondents were caregivers of people living with dementia. Moreover, most respondents indicated that they had found the #SeePainMoreClearly campaign on Facebook and were living in Canada. Not all participants who responded to the survey completed all the questionnaires; therefore, the number of respondents is indicated in Tables 2 and 3. Table 2 outlines the respondents' impression of the campaign. Across respondent groups, respondents endorsed a favorable impression of the campaign, a great likelihood of sharing information with others, and the use of social media for KM. Of note, the question regarding the new information provided by the content was rated lowest in each respondent group. Table 3 outlines the descriptive statistics based on the responses to the 6 general questions assessed by the IAM4all questionnaire. As noted in Table 3, responses indicated that most individuals (eg, 138/178, 77.5%) indicated the likelihood of using the information for themselves or someone else. Moreover, 77.1% (131/170) of the individuals expressed benefitting from the information shared during the initiative.

Table 2. Respondents' impression of the campaign.

	Caregivers	Public	Health professional	Person living with dementia	Researcher	Policy maker
Overall impression of the campaign[a]						
Value, mean (SD)	4.67 (1.63)	4.33 (1.49)	5.16 (1.72)	4.18 (1.72)	__[b]	—
Value, n[c]	78	24	25	11	—	—
Level of new information provided[d]						
Value, mean (SD)	3.91 (1.83)	4.21 (1.74)	4.04 (2.09)	3.50 (2.07)	—	—

Value, mean (SD)	5.48 (1.74)	5.00 (1.67)	5.44 (1.53)	5.00 (1.83)	—	—
Value, n[c]	87	25	25	10	—	—

[a] Ratings are based on a 7-point scale, ranging from 1 (not at all) to 7 (very much): "Overall, how much did you like the image/clip/video?"

[b] Cell sizes <5 were not reported to protect the confidentiality of the participants.

[c] n=not all participants who responded to the survey completed all the questionnaires in the study; this number represents the number of participants who answered this question.

[d] "Did the video/image/clip provide you with new information?"

[e] "Are you likely to seek additional information about pain in dementia (and its assessment) as a result of watching this video/viewing this content?"

[f] "It takes an average of 17 years until professionals start to use important research results into their practice Do you think social media (e.g., Twitter) is a good way to spread important health information to caregivers of people with dementia/to people with dementia?"

Table 3. Survey responses to the IAM4all[a] questionnaire (N=190).

Question	Respondents, n (%)
"Why did you look for this information?"[b]	
To answer a question about the health of someone else (total number of respondents=190)	116 (61.1)
To satisfy my curiosity about a health matter (total number of respondents=172)	108 (62.8)
To find choices different from those given by a health professional (total number of respondents=172)	61 (35.5)
To follow-up on the information given by a health professional (total number of respondents=168)	52 (31)
To prepare myself before talking to a health professional (total number of respondents=168)	50 (29.8)
To help me decide if I should see a health professional (total number of respondents=169)	40 (23.7)
To answer a question about my health (total number of respondents=177)	30 (17)
"Did you find the information you were looking for?" (total number of respondents=181)	
Yes	73 (40.3)
Yes, but I did not understand it	15 (8.3)
No, I did not find it	72 (39.8)
No, but I found something else	21 (11.6)
"What did you think about this information?"[b]	
Now I want to learn more about this health matter (total number of respondents=161)	112 (69.6)
Now I know something new (total number of respondents=163)	79 (48.5)
I am reminded of something I already knew (total number of respondents=157)	76 (48.4)
This information says I did, or I am doing the right thing (total number of respondents=158)	66 (41.8)
Now I am reassured (total number of respondents=158)	66 (41.8)
I am not satisfied with this information (total number of respondents=153)	33 (21.6)
I think there is a problem with this information (total number of respondents=151)	14 (9.3)
I think this information could be harmful (total number of respondents=148)	2 (1.4)
"Did you or will you use the information for yourself" (total number of respondents=178)	
Yes	55 (30.9)
No, not for myself, but I used it for someone else	83 (46.6)
No, I did not use this information for myself or for someone else	40 (22.5)
"Did you (do you expect to) benefit from this information?" (total number of respondents=170)	
Yes	131 (77.1)
No	39 (22.9)
Did something negative come out from using this information? (total number of respondents=148)	
Yes	4 (2.7)
No	144 (97.3)

[a] IAM4all: Information Assessment Method for all.

[b] Refers to participants who answered "Yes" with possible choices of yes, no, or possibly.

Comparison of Web-Based Discussions About Pain in Dementia

The extent of discussions about pain in dementia was assessed by examining the total number of posts on Twitter and Facebook. After excluding posts pertaining to pain as a metaphor, unrelated to the problem of pain in dementia, shared by our own research group, and not in the English language, the number of tweets that were retained doubled from the precampaign period compared with during the campaign period (see Multimedia Appendix 5). A similar increase was also observed on Facebook. The number of discussions about pain in dementia decreased in the postcampaign period compared with during the campaign period (see Multimedia Appendix 5). The number of excluded posts in each period is summarized in Multimedia Appendix 6.

Discussion

Principal Findings

Social media allows the immediate dissemination of information to a large number of knowledge users. Although our relatively short pilot KM campaign (phase I) was successful, its longer-term continuation by researchers alone was not feasible owing to competing demands. As such, we partnered with a digital media company to launch phase II of the #SeePainMoreClearly campaign with expanded social media platform coverage. The goal of the initiative was to increase awareness of the challenges in the assessment and management of pain among people with dementia. We codeveloped key messages with partners (eg, health professionals, caregivers, and researchers) that served as the basis of our messaging.

Our findings demonstrated the effectiveness of social media KM methods in reaching very broad audiences over a 12-month period. Evidence of positive impact on knowledge users' knowledge was demonstrated. The participants described positive perceptions in response to the information shared throughout the initiative. Survey respondents (eg, caregivers, health professionals, researchers, the public, and people with dementia) endorsed a favorable impression of the campaign. Overall, our initiative highlighted the advantages of using a science-media partnership (eg, collaboration with digital media experts, resources to develop tailored content and resources, and consistent dissemination of information). However, broad social campaigns require extensive resources and time commitments. We outline the recommendations to address these areas.

The current (phase II) initiative involving a science-media partnership was different in several regards from our pilot campaign that focused only on Twitter and a YouTube video. In comparison with the pilot campaign [9], visits to our web-based repository substantially increased in phase II, even when considering the difference in the lengths of the 2 campaigns. Phase II used extended evaluation metrics through the inclusion of interviews, in addition to social media analytics, questionnaires, and the analysis of social media responses over a 12-month period. Hashtag analytics on Twitter across the 2 phases were comparable, despite differences in the length of evaluation (eg, 5 months vs 12 months). We observed lower outside organization engagement during phase II of our initiative, which could have contributed to lower phase II engagement when accounting for the length of evaluation. Moreover, our social media presence was greater in phase II compared with our pilot campaign.

Overall, our findings demonstrated the effectiveness of social media KM methods in reaching very broad audiences quickly. In this study, we demonstrated success in directing knowledge users to a resource website with practical information for health professionals, caregivers, and people living with dementia. For instance, over 60,000 users from 82 countries viewed the web-based repository website over the 12-month period. In particular, the blog posts shared during the project attracted many readers. The blog web pages were viewed 59,919 times, providing evidence for their reach. This is comparable with other KM efforts showing the use of blogs as an engaging way of connecting to targeted users [32].

The reach and engagement of users on social media platforms also provided evidence for the success of the initiative in raising awareness about the problem of pain in dementia. Information shared on Facebook was successful at reaching a wide range of audience, with 1,313,485 people reached by the content shared on the Facebook page. However, it should be noted that some analytics (eg, reach and engagement) could not be obtained from social media sites (eg, LinkedIn) because these analytics were not provided by the platform. This limits our ability to deduce the full extent of engagement on these platforms. Nonetheless, the number of impressions on Facebook was the highest (eg, 4,100,000) compared with Twitter, Instagram, and LinkedIn. This is consistent with previous research showing extensive reach and engagement on Facebook compared with other platforms [6,33]. In contrast, Neil-Sztramko et al [34] conducted an awareness campaign targeted toward working caregivers and found that although Facebook posts generated the most reach, the quality of the engagement was low. The topic area, targeted audience, and length of evaluation could explain the differences between our findings and those of previous research. We observed the lowest reach and engagement on Instagram and LinkedIn. This is not surprising given that our primary audience comprised caregivers of people with dementia who tend to be older [35,36]. Older adults have shown a preference for Facebook in comparison with other social platforms [37]. Taken together, our findings suggest that Facebook may be the most suitable platform for disseminating information related to pain in dementia.

Our findings extend our pilot evaluation by including in-depth interviews with knowledge users who interacted with the campaign in addition to the analysis of social media analytics and evaluation questionnaires. Many interview participants indicated positive perceptions in response to the information shared throughout the initiative. Moreover, the participants expressed that the significance of the initiative was in bringing awareness to an underdiscussed problem. The interview participants acknowledged the utility of social media as a tool for scientific dissemination. Many participants noted the importance of leveraging social media to share research information. Other participants expressed the importance of health initiatives in combating misinformation over the web. Quantitative responses to the surveys also supported this view. Survey respondents endorsed the use of social media as a way of spreading important health information to caregivers of people with dementia and to people with dementia. We found evidence of the information and resources impacting users' knowledge and behavior. For example, interview participants noted increased awareness and advocacy in their personal life and awareness of assessing for pain in their clinical practice. More importantly, participants frequently expressed intent to share the knowledge they obtained with others. This is consistent with the survey responses, indicating that a majority of respondents intended to use the information for themselves or others. Moreover, the respondents expressed benefitting from the information shared during the initiative.

The initiative stimulated web-based discussions about pain in dementia. Consistent with themes that emerged from social media responses on Twitter during the pilot campaign [9], many web users expressed positive comments in response to the initiative. In particular, expressions of support were prevalent in both the pilot and phase II of our campaign. Many web users who responded to the content disseminated during the campaign shared their personal experiences or added commentary to the posted content. In addition to sentiments of advocacy for better care, which was observed in our pilot campaign, social media comments in response to phase II of our campaign also highlighted criticism and suggestions to improve practices related to pain management in dementia. Users highlighted the need for access to continuing education and support for staff and families to increase the frequency of pain assessment in LTC. This demonstrated meaningful engagement by users in response to posts. Increased discussions also highlighted negative responses about the information shared (eg, perpetuating stereotypes about older adults and dementia), which was not observed in the pilot campaign. Differences in themes that emerged between the pilot and phase II could be due to the broader reach of phase II (eg, inclusion of Facebook), as the pilot campaign only examined responses using the #SeePainMoreClearly hashtag on Twitter. We also found increased discussion about pain in dementia during the initiative on Twitter and Facebook in comparison with before and after the initiative. However, this discussion was not sustained months following the end of the campaign. This highlights the importance of continuous and meaningful engagement to maintain gains made by an initiative. Given our methodology, we collected a substantially lower number of posts on Facebook in comparison with Twitter. This discrepancy is likely owing to the manual search that was conducted to obtain Facebook posts in comparison with the data that were easily pulled by Keyhole for Twitter posts. Depending on a user's privacy settings, posts shared on personal or private accounts are excluded when conducting a general search on Facebook.

Limitations and Directions for Future Research

A particular strength of this study is that the content shared during the initiative was developed collaboratively with family caregiver partners, researchers, media experts, and health care professionals. Various measures were also used to assess not only the web-based reach of the initiative but also the perceptions of knowledge users. Nonetheless, we acknowledge that the use of social media for KM research represents a new area that does not lend itself to strict scientific control in the evaluation of its effectiveness. We adapted a more nuanced approach in developing partnerships and using multimodal approaches to show the impact in different ways. Although we aimed to assess the impact on users' knowledge and behavior, we did not directly evaluate behavior change. Future research should examine the associated behavior outcomes (eg, increased pain assessment) in addition to the spread of information (eg, analytics). It is also difficult to measure the impact of the initiative at an organizational or policy level. This could be an important avenue for future research. Individuals in our interview and surveys expressed their intention to use the information; however, the adoption and use of information was not obtained. Perhaps, a follow-up assessment of how or whether knowledge users applied learned information could be investigated. Moreover, the effectiveness of social and web modalities in creating meaningful changes in knowledge and behavior is subject to further examination. Notably, the landscape of social media is constantly changing, and researchers will need to adapt to these changes if they want to leverage this modality. For example, social media can be used to spread health misinformation [38]. Using social media for KM health efforts can also be used to combat false and unscientific web-based information. As such, ensuring the quality of scientific evidence disseminated on the web should be considered in the development of social media–based dissemination efforts. Although these findings may not be generalizable to other KM initiatives, our investigation adds to the growing body of knowledge leveraging social media as a KM tool.

Recommendations

Our study highlighted the successes and challenges of social media KM initiatives. When comparing the pilot with the scaled initiative (phase II), there appears to be no considerable difference with regard to views, impressions, or reach when accounting for the length of time of each initiative (5 months vs 12 months). Although this scaled initiative demonstrated success in garnering a large reach across social media platforms, broad initiatives such as phase II of our campaign require extensive resources and time commitment, which may not be feasible for researchers in the long term. The following recommendations are proposed to assist researchers and partners who may be interested in developing and maintaining a web-based KM initiative:

1. Researchers could collaborate with established communication and marketing departments at their institution or other digital media partners to aid in digital and social media outreach of research information and internal and external advertising. Granting agencies may be able to allocate funds for such purposes.
2. Facebook and Twitter appear to be the most relevant platforms for KM for the topic of pain and dementia. However, researchers from other disciplines may find other platforms more helpful in reaching their target audience. For example, if a researcher's area of research is adolescent mental health, Instagram or TikTok and the use of stories may increase engagement among knowledge users. Although we found success in using multiple social media platforms, it may be more sustainable to pool resources on 1 or 2 of the most used platforms based on the target audience.
3. Investments in targeted and paid advertisements can be an effective mechanism to increase the exposure and engagement of campaign posts at a low cost per engagement [39,40].
4. Our initiative highlighted the importance of codeveloping the initiative with partners of our intended target groups. Many of our partners developed blog posts about their lived experience, which generated the most engagement. As such, personalized blog posts and opportunities for knowledge users to share their experiences (ie, turning comments on)

can be an easy and cost-effective way to stimulate discussions.

5. The success of our pilot initiative was largely influenced by partnering with professional organizations that helped disseminate information and resources to their audiences. Engagement from external organizations was lower during phase II of our initiative, potentially contributing to the overall decrease in engagement. We observed that external organizations were more inclined to retweet our content when it originated from our individual researcher accounts rather than from a generic SeePainMoreClearly social media account. Researchers should collaborate with organizations within their specific area of interest who can support in meaningfully engaging with their targeted audiences. Connecting with trusted messengers (eg, influencers, people with lived experience, and large followings) could help to penetrate targeted groups.

Conclusions

We partnered with a digital media partner to launch phase II of the #SeePainMoreClearly campaign with expanded social media platform coverage. The goal of the initiative was to increase awareness of and provide resources related to the challenges in the assessment and management of pain among people with dementia. Although this scaled initiative demonstrated success in garnering large reach across social media platforms, broad initiatives such as phase II of our campaign (reported in this manuscript) require extensive resources and time commitments, which may not be feasible for researchers in the long term. Researchers should leverage collaborations with their institutions to aid in the digital media outreach of research information. Furthermore, granting agencies should consider allocating more funds for such KM purposes. Our initiative highlighted the importance of codeveloping KM efforts with the partners of our intended target groups and working with professional organizations to disseminate information to our target audience. Collaborations with people with lived experiences and professional organizations will be key to the success of any future KM effort. Our study adds to the growing body of knowledge that leverages social media as a KM tool.

Acknowledgments

This study was supported by funding from the Saskatchewan Centre for Patient-Oriented Research (#345325) and the Saskatchewan Health Research Foundation (#23629).

Authors' Contributions

TH wrote the grant application that supported this research; played a key role in project conceptualization, knowledge mobilization (KM) messaging, analytic direction, and manuscript writing; and oversaw all aspects of this study. LIRC prepared the first draft of this manuscript and played a key role in project conceptualization, data collection, data analysis, and KM messaging. MB, a partner with lived experience as a caregiver, played a key role in KM messaging; provided input in the manuscript; and contributed to team discussions. VT contributed to data analysis. CTC was a consultant on research design and development, provided detailed feedback on the manuscript, and participated in team discussions about project progress and development. SW, a digital media partner, oversaw the collection of web analytics and digital dissemination. All authors participated in team discussions that directed this work, provided input on multiple aspects of the project (eg, social media dissemination strategy) and messaging content, and reviewed and approved the manuscript.

Abstract

Background: In the United States, caregivers of people living with Alzheimer disease and Alzheimer disease–related dementias (AD/ADRD) provide >16 billion hours of unpaid care annually. These caregivers experience high levels of stress and burden related to the challenges associated with providing care. Social media is an emerging space for individuals to seek various forms of support.

Objective: We aimed to explore the primary topics of conversation on the social media site Reddit related to AD/ADRD. We then aimed to explore these topics in depth, specifically examining elements of social support and behavioral symptomology discussed by users.

Methods: We first generated an unsupervised topic model from 6563 posts made to 2 dementia-specific subreddit forums (r/Alzheimers and r/dementia). Then, we conducted a manual qualitative content analysis of a random subset of these data to further explore salient themes in the corpus.

Results: The topic model with the highest overall coherence score (0.38) included 10 topics, including caregiver burden, anxiety, support-seeking, and AD/ADRD behavioral symptomology. Qualitative analyses provided added context, wherein users sought emotional and informational support for many aspects of the care experience, including assistance in making key care-related decisions. Users expressed challenging and complex emotions on Reddit, which may be taboo to express in person.

Conclusions: Reddit users seek many different forms of support, including emotional and specific informational support, from others on the internet. Users expressed a variety of concerns, challenges, and behavioral symptoms to manage as part of the care experience. The unique (ie, anonymous and moderated) nature of the forum allowed for a safe space to express emotions free from documented caregiver stigma. Additional support structures are needed to assist caregivers of people living with AD/ADRD.

Introduction

Background

There are an estimated 11 million people in the United States currently living with Alzheimer disease and Alzheimer disease–related dementias (AD/ADRD)—a number that is expected to more than double by 2050 [1]. Most people living with AD/ADRD receive informal (ie, unpaid) care support from family members or other personal connections due to the high costs of professional care, the limited capacity of assisted living and memory care facilities, and a strong desire to age in place [2-5]. Recent estimates suggest informal AD/ADRD caregivers in the United States provide >16 billion hours of care labor annually. This has led to calls from national health organizations to prioritize the expansion of support systems for informal caregivers of people living with AD/ADRD. Caregiving for people living with AD/ADRD is a complex and challenging role that is associated with a broad set of suboptimal economic, physical, and psychological outcomes. For example, caregiver burden is associated with negative mental health outcomes, including high levels of stress and depressive symptomology. However, social support may offer a means for reducing caregiver burden and improving health outcomes for both caregiver and care recipient. This study aimed to understand the ways AD/ADRD caregivers seek and experience social support on the web, specifically through the social media platform Reddit (Reddit, Inc).

Caregiving for Individuals Living With AD/ADRD

Recent studies have estimated that approximately 15 million Americans currently provide care for individuals living with AD/ADRD [6]. Most are classified as informal caregivers, meaning they are not paid for labor and time associated with care responsibilities and are typically family members or friends of the person with AD/ADRD. The average life expectancy for individuals diagnosed with dementia can vary widely, from 3 to 10 years, depending on the specific diagnosis, age at the time of diagnosis, and other health factors [7]. Not surprisingly, the caregiving experience can also vary widely. A recent study found that near the time of diagnosis, people with AD/ADRD received an average of 151 hours (approximately 6.5 days) of caregiving monthly, typically provided by 1 caregiver. However, over time, their needs progress, requiring nearly twice the hours of care and support of additional caregivers [8].

Caregiver burden describes the multifaceted strain faced by individuals in providing care, which may include financial, emotional, and physical stressors [9,10]. The challenges of AD/ADRD care are associated with significant health impacts for caregivers [11,12]. Providing care is often associated with higher levels of reported stress [13]. Furthermore, caregivers report high levels of psychiatric symptoms, most commonly depressive symptoms—particularly as the care recipient's AD/ADRD symptomology progresses [14,15]. Caregivers also report high levels of financial strain related to high costs of care and lost earning potential due to time commitments of care responsibilities [9,16].

Regardless of the dementia subtype, a broad range of neuropsychiatric symptoms, including both behavioral and cognitive changes, can present [17]. Behavioral symptoms of AD/ADRD, for example, can include confusion, aggression, and increased hospital or emergency department visits. Dementia is also associated with neuropsychiatric symptoms, including agitation, depression, hallucinations, anxiety, and apathy [18-20]. Furthermore, dementia is often associated with reduced function of other organs, resulting in symptoms such as voice or speaking challenges, skin injuries, urinary incontinence, constipation, urinary tract infections, dental and vision problems, and hearing loss, among others [18-20]. Some symptoms, such as anxiety and depression, are fairly common across patients with AD/ADRD and with disease progression [20]. Others, such as psychosis, aggression, and agitation, are often exacerbated as cognitive decline increases and are thus associated with steep increases in caregiver burden due to the impact these symptoms have on the completion of basic activities of daily living [18].

As AD/ADRD progresses, more severe symptoms reduce individuals' capacity to independently complete activities of daily living, thereby necessitating increased assistance and caregiver supervision [21]. Therefore, the time spent on caregiving activities and the number of individuals providing care generally increase across the disease progression [2,3]. Naturally, increased time spent on care, combined with increasingly severe symptoms to manage, is associated with increased feelings of burden. As such, caregivers often spend less time and energy on their own self-care, particularly as the care recipient's neuropsychiatric symptoms worsen [22]. The emotional, financial, and physical strain of caregiving may contribute to reduced overall health of caregivers [5]. AD/ADRD caregivers often report high levels of stress and depression themselves, may get poor sleep, and neglect their own well-being (eg, diet and physical activity) [11,14,15]. As such, recent epidemiological research has found spousal caregivers are at increased risk of dementia themselves and has found caregiving to be an independent risk factor for mortality [23,24]. Notably, strategies and interventions are needed to reduce burden and improve outcomes for both the caregiver and care recipient.

Social Media and Caregiver Social Support

Over the past 3 decades, people have increasingly sought health information and support on the web. In high-resource countries, more than half of the adults use the internet for health reasons, often searching for information related to symptomology, diagnoses, and treatment options for health conditions. Online health information seeking is particularly common when users themselves or a close family member have a chronic health condition. While there are numerous websites from which users may access health information, they are increasingly likely to do so specifically via social media platforms.

Defining and delineating what constitutes a "social media platform" has proved challenging; however, most definitions broadly include a limitation to digital technologies, content generation by users, and the capacity for users to interact or share directly with others [25-27]. Over time, the use of social media has exploded, with a vast majority of adults in the United States reporting regular engagement with at least 1 platform and an average daily use of >2 hours [28,29]. Important to the current research, social media is widely used as a tool for people to connect with mutual friends, interests, circumstances, and hobbies [30-32].

To date, research related to caregivers' use of social media has spanned many chronic conditions (eg, cancer, diabetes, and physical and mental disability); ages (ie, older adults and children); and platforms (eg, Twitter, X, Facebook, Instagram, and Reddit). Much of this exploratory work has examined use patterns and user needs [33,34], broadly suggesting caregivers most often use social media to exchange information related to care recipient health, psychosocial issues, and daily care activities [33-35]. Among the latter, caregivers may use social media to discuss activities of living, sleep, diet, finance, showering or bathing, transportation, medical care, and formal disease diagnoses [35]. Some research suggests online support is associated with a positive impact on the emotional well-being of medical caregivers, especially for those who used online support for a long term [36]. However, to date, limited literature exists examining the use of social media for support-seeking among AD/ADRD caregivers, specifically [35,36].

AD/ADRD caregivers may be particularly likely to seek support on the web due to myriad factors that limit social support in their offline lives and community settings. For example, AD/ADRD caregivers face documented stigmatization and progressive social isolation as care recipient symptomology worsens and it becomes more challenging to engage in public social settings [6,34,37]. As such, early social interventions for AD/ADRD caregivers have often focused on creating shared spaces with others in similar situations [5,38]. However, rural residents and others who are not located near needed resources (eg, respite or adult day care and support groups) may face challenges in finding others who have similar experiences or a shared understanding of care responsibilities [39]. Furthermore, AD/ADRD caregiving requires substantial time and financial commitments, which create logistical limitations on opportunities for social engagement outside of one's care responsibilities [23,34,40]. Finally, even in shared spaces with similar others, it may be challenging to express complex or difficult emotions that are common among caregivers [15,22]. Notably, AD/ADRD caregivers may be particularly likely to pursue support on the web via social media, rather than through in-person or community-based programs.

Therefore, this study aimed to explore how caregivers use the social media platform Reddit, with particular emphasis on social support and AD/ADRD information seeking. To this end, we first collected and applied computational natural language processing (NLP) tools to a large corpus of Reddit posts to identify salient themes across the site. We then conducted a manual qualitative content analysis of a random subset (ie, 657/6563, 10.05%) of the corpus to gain a more nuanced understanding of support and information-seeking behaviors of AD/ADRD caregivers through the site.

Methods

Ethical Considerations

For this project, we analyzed only existing data (ie, publicly available information), posted directly to Reddit. All study procedures were approved by the Indiana University Institutional Review Board (#23662).

Data Collection

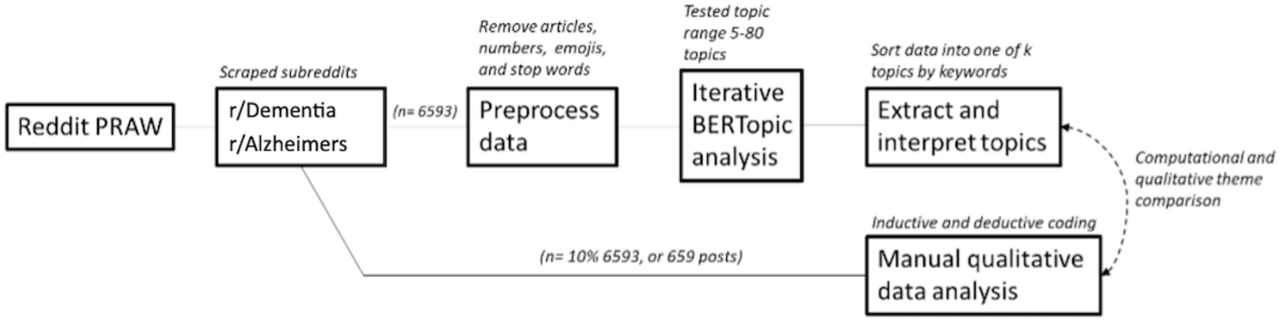
We collected data for this study from Reddit, a social news aggregation, content rating, and discussion social media platform. Unlike other social media platforms, including Instagram, TikTok, and X (formerly Twitter), Reddit represents a forum of communities where people can "opt in" to subreddits, which are moderated subspaces within the wider platform, dedicated to a certain topic. This allows users to seek community and interaction based on specific interests or needs [41]. Subreddit content varies extensively. However, in recent years, subreddits specific to health and well-being–related topics have become increasingly used by people in need of social support, connection, or solidarity [42,43]. Reddit data are also unique in that posts are unincumbered by length limitations. Therefore, data collected from Reddit tend to be more comprehensive and nuanced compared with data from other social media platforms.

Using the Python Reddit API Wrapper [44], a third-party Reddit data scraper, we identified 2 subreddits specific to our research purpose (r/Alzheimers and r/dementia). We then programmed the Python Reddit API Wrapper to collect new, popular, and trending posts, along with relevant metadata, in both subreddits between May and June 2022. These data were saved as a single CSV file for further computational and qualitative data analysis. Upon completion of data collection and excluding duplicates, blank entries, and those deemed irrelevant to discussions about AD/ADRD, we retained 6593 posts.

Analysis

Given our exploratory research purpose, we undertook a two-step process to analyze our data: (1) computational analyses and (2) manual qualitative coding and review. This 2-step approach afforded the ability to identify topics embedded across the entirety of our data using NLP methods and to understand the meaning of each topic at a deeper and more nuanced level through traditional qualitative analyses (Figure 1). We offer a brief explanation of each method applied to the data in subsequent sections.

Figure 1. Workflow depicting computational and qualitative data analyses pipeline. PRAW: Python Reddit API Wrapper.



Natural Language Processing

BERTopic

Topic models refer to any series of NLP tasks that consolidate large language data sets into representative topics or themes. While there are a variety of topic modeling tools, including the highly established latent Dirichlet allocation (LDA) approach, our study used a neural network pipeline leveraging Bidirectional Encoder Representations from Transformers (BERT) vectors using the BERTopic topic modeling tool [45,46]. Indeed, BERTopic is unique among established LDA approaches in that this pipeline specifically uses neural networks and BERT embeddings to approximate latent topics. Topics derived using the BERTopic tool tend to be clearer and more nuanced due to the encoding process, where raw text data are compared against a large language data set. At this stage, raw text data are converted into numerical form, which creates dense vector representations for each document in a given data set. These representations capture contextual nuances of each word across documents, which is not attainable using LDA or other probabilistic topic modeling approaches. Vectors are calculated for each document. As these vectors are difficult to model and interpret, we then perform a dimensionality reduction technique, principal components analysis. Following dimensionality reduction, we extract a series of topics that represent a synopsis of the entire corpus.

Coherence Score Check

BERTopic, and most other topic modeling tools, can generate any number of latent topics specified by a predetermined parameter *k*. However, this fixed topic number may not always reflect the optimal number of topics for a given corpus. Therefore, multiple models may be run and compared, retaining the best overall topic solution for the research. Coherence scores, which are a statistical value predicting the overall interpretability of topics, are a common metric for assessing model fit and choosing the optimal solution. Coherence scores are calculated using pointwise mutual information, which is a measure of the strength of association between 2 words in each document and a collection of documents. In brief, this calculation tells us the degree to which 2 words are more likely to appear together than what would be expected by chance. Therefore, higher coherence scores generally indicate a more interpretable topic solution, as words that co-occur in the corpus more often than they would by random chance are sorted together as topics.

Qualitative Content Analysis

To support findings derived from computational analyses and to better understand nuance related to social support and AD/ADRD information seeking within our data, we conducted a manual qualitative content analysis of a subset of posts previously analyzed. For this analysis, we adopted an approach that was both inductive and deductive in nature. Given our specific research interests related to the ways users sought support on the web, we deductively mapped data codes onto existing conceptual frameworks related to social support and known AD/ADRD behavioral symptomology. However, we inductively allowed for additional codes to emerge from the data.

Procedure

Natural Language Processing

Once we completed data collection, we began preprocessing our data, a common procedure in computational analyses that seeks to standardize and add cohesive structure to messy text data. Part of this standardization includes removing parts of speech that may detract from the clarity of the models, including first-person names, numbers, special characters, emojis, articles, and a series of stop words. Once our data were preprocessed, we proceeded to analyze the data with the BERTopic tool. To identify the optimal number of topics, we performed an iterative topic model analysis that tests a range of topics by iterations of 5 (eg, 5, 10, 15,......*k)*. For each iteration, we calculated coherence scores. We selected the optimal number of topics based on the highest coherence score among topics, ranging from 5 to 80. Once we identified the optimal topic number, we performed a sorting function, which triaged all tokenized sentences into one of *k* latent topics. This sorting feature allowed us to examine topic numbers, keywords associated with each topic, and the number of parsed sentences sorted in each topic. Once computational analyses were complete, we performed a manual review of a random 10.05% (657/6563) of posts within our larger sample. These posts were manually coded and independently compared to the BERTopic output to ascertain overlap.

Qualitative Content Analysis

Initial coding was undertaken by 3 individuals on the research team. First, coders trained together on sample data that were not included in later analyses. This initial coding was subsequently reviewed by 2 established researchers who were not initial coders. After review, the research team met 3 times to review the coding of the training data, which helped crystallize code definitions and identify early emergent themes. Any disagreements in the coding of these training data were discussed until a consensus was reached.

After training, a similar coding process was adopted for the larger data set. Initial coding was completed by the same 3 individuals who provided initial open codes in the training data. This initial coding was then reviewed independently by 2 established researchers from the team for consistency and accuracy. We began to draw connections between initial open codes via axial and selective coding processes to arrive at the final structure, as outlined in the Results section. The coding team met twice to discuss the overall coding structure, again resolving disagreements via discussion until a consensus was reached.

Results

Unsupervised Topic Modeling

Our first set of analyses used NLP to identify the broad themes discussed by users in subreddits related to AD/ADRD. The optimal solution, as determined by the coherence score, included 10 topics, with a coherence score of 0.38. Table 1 provides a summary of each topic, including each topic name, keywords associated with each topic, and its proportional representation within the larger corpus. Importantly, our analysis tokenized data at the sentence level. We chose to analyze at the sentence level, rather than the post level, to identify more granular topics within the corpus. Had we analyzed at the post level, the algorithm would have sought to identify the primary overarching theme across the entire post. Because Reddit posts have no limitations on length, users may include multiple topics in a single entry; such intrapost thematic variability would be poorly reflected with a postlevel analysis, likely resulting in very general and hard-to-interpret topics. Therefore, to avoid such a loss of nuance, we chose the more granular sentence-level approach.

Proportionally, the topic with the greatest representation in our corpus was topic 0, “Reddit inquiries, narratives, and advice,” comprising 17.45% (16,152/ 92,562) of sentences in the total corpus. Other prominent topics include topic 1, “venting/expressing feelings and emotions” (12,652/ 92,562, 13.67%); topic 2, “moving- and housing-related adjustments” (12,090/ 92,562, 13.06%); and topic 3, “ADRD diagnosis and other acute illnesses” (10,695/ 92,562, 11.55%). The remaining topics were marginally consistent in terms of distribution, with topic 9, “hospital, assisted living, and memory care,” having the lowest representation of 5.4% (4994/92,562).

Topics derived using any topic modeling tool are potentially overly generalized or difficult to parse if topics share similar keywords. As such, additional review of the topic solution by researchers with topical knowledge is needed to ascribe meaning to each latent topic. To do so, we applied a sorting function based on keywords to sort tokenized sentences into 1 of 10 possible topics. We then reviewed individual posts to understand and contextualize each topic. Table 2 provides excerpts of posts sorted into each topic to assist the reader in understanding the latent topics identified in the corpus. We observed some generalized themes, as well as more specific AD/ADRD caregiving and contextual topics.

The first 2 identified topics are more general in nature. For example, topic 0, “Reddit inquiries, narratives, and advice,” is quite general and reflects the common language of Redditors asking questions to the community. What follows in any given sentence varies (eg, diagnoses, caregiving advice, or difficulties associated with AD/ADRD symptoms), but there was a common theme of seeking, whether related to information or emotional support. Similarly, topic 1, the second most common in the corpus, encapsulated users’ many and varied expressions of emotion. These more generalized themes are often found in the first few sentences of a Reddit post, wherein the user expresses a wider sentiment before providing more specific and varied details.

Another grouping of topics related to the varied contexts of AD/ADRD caregiving and related decision-making. Topic 2, for example, focused on housing- and moving-related concerns, where users often sought information and advice related to the appropriate time to limit a loved one’s capacity to live alone or strategies for ensuring the safety of community-dwelling individuals living with AD/ADRD. Topics 7 and 9, respectively, centered on more professional care settings. Topic 9 focused on hospitals, assisted living, memory care, or other such facilities; many of these posts were regarding providing or seeking information about proper care, identifying a quality facility, financing options, or the appropriate timing for seeking professional care support. Finally, topic 7 included posts related to hospice (ie, end-of-life) care. Notably, users often sought guidance on the appropriate time to move their loved ones to this type of care and emotional support at this challenging stage.

The remaining topics related to different aspects of the caregiving experience, including the impact of diagnosis (and comorbidities) and care on the family, caregiver burden, and 2 general caregiving topics. In topic 3, for example, we observed many posts that related to physical symptoms related to both dementia and related health challenges (eg, injuries from falls). For many who may not have opportunities to connect with similar others, platforms such as Reddit may be the only source of support available (eg, “I really just don’t know where else to turn”). Others either sought or provided specific advice related to managing certain symptoms (eg, aggression and anxiety) and strategies for managing the burdens of care.

Notably, topics 6 and 4 were highly interrelated and discussed a broad set of caregiving-related topics. While the content in these 2 topics was highly related and posts were often similar, topic 4 focused more specifically on women, while topic 6 was less-based on gender overall. Because of the unsupervised nature of NLP, wherein latent topics are generated based on word co-occurrence but are not constrained to be perfectly orthogonal, it is possible to generate highly correlated topics, as in our data. To further contextualize this overlap (and other bivariate relationships between topics), we generated a correlation matrix using the BERTopic Python module (Figure 2). This figure offers a visual representation of relative topic overlap, with darker colors indicating higher levels of overlap. Not surprisingly, we can see high levels of overlap between topics 6 and 4. The presence of overlapping or highly correlated topics may imply the existence of more generalized themes or a hierarchical structure, which is beyond the scope of this analysis.

Table 1. BERTopic 10-topic solution, including topic name, top associated words, and overall corpus representation (N=92,562).

Topic ID	Topic name	Short name	Top associated words	Sentences, n (%)
0	Reddit inquiries, narratives, and advice	Inquiries	ago, today, night, say, asked, ask, day, asking, guess, idea	16,152 (17.45)
1	Venting or expressing feelings and emotions	Expressing emotion	situation, feel, say, talk, feeling, felt, saying, talking, thinking, think	12,652 (13.67)
2	Moving- and housing-related adjustments	Housing or moving	moved, house, moving, apartment, bedroom, phone, home, stay, job, contact	12,090 (13.06)
3	AD/ADRD[a] diagnosis and other acute illnesses	AD/ADRD diagnosis	treatment, patient, med, dr, doctor, hospital, diagnosis, medical, appointment, medicine	10,695 (11.55)
4	Women and caregiving	Women and caregiving	mom, mother, mum, parent, shes, upset, daughter, aunt, angry, grandma	9065 (9.79)
5	AD/ADRD caregiving burden	Caregiver burden	depression, depressed, cope, stress, stressed, caring, grief, feel, burden, family	7637 (8.25)
6	Family caregiving	Family caregiving	grandparent, grandchild, sibling, parent, caregiving, grandmother, grandpa, grandma, family, aunt	7624 (8.24)
7	Hospice care and decision-making	Hospice	caregiving, caregiver, hospice, wheelchair, hospital, aide, health care, rehab, nursing, home	6280 (6.78)
8	AD/ADRD impact	AD/ADRD impact	dementia, alzheimer, alzheimers, elderly, diagnosed, grandma, grandmother, diagnosis, grandpa, impairment	5373 (5.80)
9	Hospital, assisted living, and memory care	Professional care settings	Hospital, hospice, grandmother, nurse, nursing, grandma, illness, diagnosis, caregiver, medical	4994 (5.40)

[a] AD/ADRD: Alzheimer disease and Alzheimer disease–related dementias.

Table 2. Representative post excerpts per topic, derived from our sorting function.

Topic ID	Topic name	Representative quotation
0	Reddit inquiries, narratives, and advice	• “Just curious if anyone has more information.” • “I'll probably poke around this subreddit every once in a while.” • “Hey Lovelies - just bouncing in to share a little tip that has made a HUGE difference in our household.
1	Venting or expressing feelings and emotions	• “I made the mistake of lashing out when he asked why I didn't do his stretches Monday morning, saying ‘do you really think I have time in the mornings to do that?’...I feel like he only wants me around to do everything for him” • “Like, I have no one to talk to. No one will understand. I just want to run away and be left alone. I did not ask for this to be my life” • “Even before the pandemic I felt like my soul was being pulled from me. I just wish I could be around ‘normal’ people”
2	Moving- and housing-related adjustments	• “We recently bought some cameras and a door sensor and suddenly we know that he’ll go outside at 3 AM for whatever reason. Are there locks that can be connected to a C02 or smoke alarm?” • “He also shows no interest in leaving his home; he spends his days in his recliner reading or watching TV.” • “I want her to go to AL, which in our area averages about $5k a month [for care]. She has enough money in the bank to live in AL for 4-5 years. She doesn't want to go to AL because ‘It’s too expensive.’”
3	AD/ADRD[a] diagnosis and other acute illnesses	• “They told us they could force-feed her via intravenously or put a tube down her throat or stomach. The doctor’s other suggestion was to ‘make her comfortable.’” • “And then one morning...she fell and broke her hip because she didn't use her walker while heading to the bathroom.” • “Symptoms started last November. By January she was hospitalized. After the diagnosis of LBD, medical practitioners started treating her differently.”
4	Women and caregiving	• “I picked out a room yesterday and while the guilt is getting to me too, my sibling is having a harder time dealing with it. My heart is breaking over this cat and the bond my mom has with him.” • “We gave our youngest kids OUR house and animal because I had made a promise to my mother she wouldn't go into a home years before this s**t got real. My mother was still in total denial, and we were basically ignorant in a not stupid way.” • “My grandma is 75 years old and has been acting kinda not herself most of the time since February. But by this time I’ve noticed that she’s often confused, asks the same stuff a lot sometimes, has spontaneous bad mood, crying thinking of something bad.”
5	AD/ADRD caregiving burden	• “My thoughts run to upping my anxiety meds, cry in my mothers arms, post vague rants on Facebook, depress friends with the tearful story about my situation or pop a Xanax and sleep.” • “I always talk about the little adjustments you have to make as your loved one gets worse. I’ve cried for about 50 mins and done the stupid rocking myself back and forth in efforts to comfort myself.” • “I feel so powerless and I just want to make you healthy again. Every day I am so happy and put a smile on my face, trying to ignore the gnawing thoughts of your illness and how it is slowly destroying you from the inside.”
6	Family caregiving	• “My only experience with this sort of thing is with my spouses family situation. With their family, they do not let the grandma go to her old house any more. I was told by my wife not to bring my mom back to her old home, as it would cause trouble or upset her like how her grandma got upset.” • “My father-in-law was hiding from us just how bad it was (Not sure why as we where/are very active in their lives) and until FiL death she put on more of a front for us (didn’t always manage it, but managed enough to hide just how bad it was).” • “My dad started answering the phone as my mom became more confused and often asked for her mom (died 50 years ago). Constant desire to go home and find her mom. Not recognizing my dad has been her caregiver through it all.”
7	Hospice care and decision-making	• “She was released from the hospital into the care of one of her brothers, but as of today she has returned back home on her own. Basically, Family Care is not an option.” • “He’s at the stage where he can opt for hospice care, but he’s choosing to prolong life treatment (or at least try.) I told him if he wants to do whatever he wants then hospice care is an option but he will live a lot less longer.” • “After days of back-to-back seizures, she is in the hospital completely unresponsive and I got the news they don’t expect she will recover. I have an appointment tomorrow to go over our hospice care options. I thought we had more time. I wont ever hear her voice again. I used to get annoyed at all of the voicemails she would leave because I always called her back as soon as I could.”

Topic ID	Topic name	Representative quotation
8	AD/ADRD impact	• "The husband has dementia and his wife was taking care of him. I could feel the heart break behind her words as her husband had clearly deteriorated over the years to resemble less and less of the person she described." • "She passed last night, a decade since it first became clear that the disease that had taken her sister had come for her as well. For most deaths 'I'm sorry' suffices, but we all know that with dementia that's not exactly true." • "Over the past four years, my family has come to suspect that my mother has dementia, which doesn't make a whole lot of sense, given that she's 52. The further irony is that my grandmother has just now started displaying symptoms of dementia, at almost 90 years old."
9	Hospital, assisted living, or memory care	• "With my dad in the hospital, my mom has been a complete wreck! The doctor said she'd have to go into a home and she flipped out begging me to bring her to my house." • "My mother is in a memory care facility - she's been there since last July. My father cant face the fact that this is a behavior situation, not a 'see yet another doctor for a magic cream that will stop this.'" • "I have been slowly priming my sister regarding getting mom ready for a home, as she is now truly requiring intense supervision for just about everything and i think my sister is realizing this as her decline has been incredibly apparent over the last few months since dad is gone."

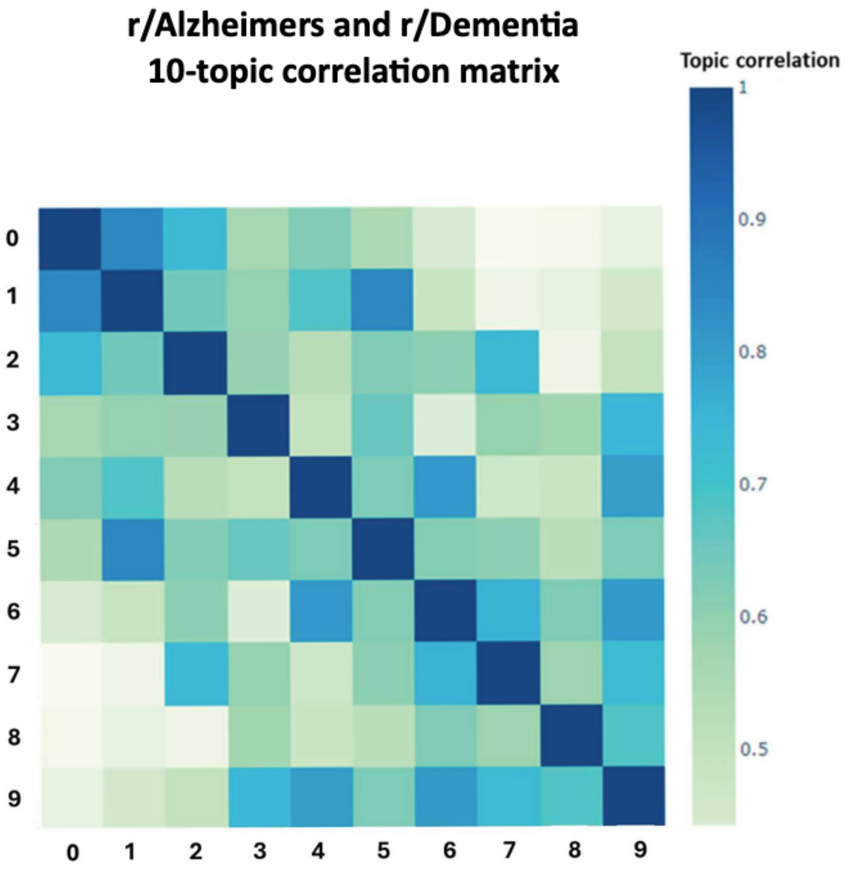
Figure 2. A 10-topic solution correlation matrix denoting topic similarity.



Qualitative Content Analysis

Overview

Through this analysis, we sought to situate prior NLP findings in the context of existing research on caregiving for people living with AD/ADRD. Specifically, we qualitatively analyzed a subset of our existing corpus, deductively mapping onto existing conceptual models of social support and AD/ADRD behavioral symptomology. We allowed for additional inductive themes to emerge.

Social Support

A total of 2 primary forms of social support were observed among Reddit users: informational and emotional. Of note, companionship behaviors and relatedness (other theoretical forms of social support) were not commonly observed in our data. Among the subcategories of informational forms of social support identified by Yao et al [47], 2 subcategories were observed frequently among our data: advice and teaching. Users sought advice from others related to a broad variety of topics, including help with decision-making (eg, seeking professional care support, admission to a care facility, and beginning hospice care); managing challenging symptomology (eg, aggression and wandering); coordinating care networks; and strategies to prevent burnout. For example, one user posted as follows:

> *I need help. With anger. With boundaries. Active things I already do: meditation, avoiding most substances, gardening, painting, journaling... tried therapy a few times they always offer meds which I dont [sic] want due to chronic illness I dont [sic] want to flare up... thank you.*

Beyond this more generalized advice seeking, users sometimes sought or provided specific forms of teaching informational support. Often, these threads surrounded discussions of new medications or clinical trials for people living with dementia. Others offered practical tips and supports. For example, one user described the placement of an "orientation board" in a conspicuous place to provide useful information for their care recipient, including the day or date, expected appointments, weather, and other basics that helped reduce confusion.

In addition, we observed users both seeking and providing emotional social support. We observed a broad array of emotional support, including words of affirmation, expressions of care or concern, encouragement, sympathy, and understanding. Frequently, users expressed a vague or nonspecific need for support—that they had come to the forum seeking others with similar experiences who understood the challenges associated with caregiving. However, many users noted the sense of community and the value of the group's shared experience in helping them individually. For example, a user thanked the group, saying the following:

> *I appreciate everyone so much. I know that what were [sic] experiencing with loved ones and or friends is painful, tiring, and other things. Your questions and experiences have given me a heads up on situations.*

In a different case, users specifically coalesced and supported a member who was going through a particularly challenging period, including providing donations and financial support. The user thanked the group, saying the following:

> *Feeling a little better today and am very overwhelmed by the support. You all really did make me feel less alone and I appreciate your support and offers to talk when you could have easily scrolled past. I also appreciate the awards but next time, take that money and please donate it to the Alz [sic] association. I do love the hug and silver award though, that is very very very kind.*

AD/ADRD Behavioral Symptomology

Overview

We coded AD/ADRD behavioral symptoms using the standard Neuropsychiatric Inventory [48]. We found users regularly discussed symptomology to approximate or assess disease progression, particularly in the context of major decision-making (eg, care levels and power of attorney). A total of 3 categories of neuropsychiatric behavioral symptoms were commonly observed in Reddit posts.

Agitation or Aggression

One primary behavioral concern that appeared consistently in the discussion was increasing levels of aggression or agitation. Users noted that as part of the disease progression, care recipients increasingly struggled with emotional regulation; this often led to outbursts and physical aggression. Users recalled incidents where care recipients had yelled at caregivers, thrown objects, and attempted physical violence—sometimes without explanation. For example, one user described attempts to keep a loved one from wandering by securing doors and fences on the property; during the resulting "tirade," the care recipient "grabbed my brother by the front of his shirt and began screaming in his face" and they also noted the following:

> *He has threatened to slash the tires on the car. The other day I caught him just before he swung a metal pipe at the windshield of my rental car.*

Among Reddit users, we found these discussions were often related to larger caregiving decisions. For some, the emergence of violence was an inflection point in seeking full-time or professional care. However, others sought help, as the aggressive behaviors of care recipients caused them to be removed from care facilities.

Delusions and Hallucinations

Another prominent theme in the data was increasing delusions among care recipients. These delusions often manifested as care recipients' mistrust of those around them due to unfounded beliefs that these individuals would harm them in some way (eg, physical violence and theft) or as a conspiracy against them. Episodes of delusion covered a broad range of experiences, from a more benign suspicion that others were lying to more elaborate, reoccurring fantasies. For example, one user posted regarding regular hallucinations their parent had about a fantasy world:

> *[A] fantasy world he created involving red-robed people who came into the room uninvited and stayed overnight.*

Regarding aggressive behaviors, many discussions around delusions and hallucinations were part of larger threads seeking support and understanding about dementia progression. Delusions were regularly discussed as a motivation for seeking external care support.

Nighttime Behaviors

The final commonly discussed behavioral symptom category related to nighttime issues. In the context of dementia, this category relates to a broad set of behaviors, including rising too early in the morning, awakening during the night, and excessive daytime napping—all generally related to sleep disturbance of some kind. Users regularly discussed the progression of sundowning—wherein individuals may experience restlessness, confusion, or irritability in the evening as daylight fades and progresses into the night. Users noted that sundowning symptoms continued into nighttime and often caused an inability to sleep or that patients would experience nightmares or terrors and stay awake throughout the night. In some cases, this inability to sleep resulted in the individual becoming fearful, seeking to escape, or taking additional medication. For example, one user noted the following about their mother:

> *[K]eeps getting up in the middle of the night, walking unassisted, digging around in her med suitcase taking God knows how many extra meds in the middle of the night.* [sic]

Commonly, these nighttime behaviors also had negative health repercussions for caregivers and family members who could not sleep themselves, either due to disturbances caused by the care recipient or by the need to provide supervision and care while the individual was awake.

Emergent Codes

Caregiver Anxiety or Guilt

The most frequently observed code across the entire data set related to caregiver guilt or anxiety, with users expressing distress related to their caring role and responsibilities, as well as their own emotions and personal challenges. For example, some users expressed fear of failing in their caregiving role, such as a user who expressed, “My biggest fear is that I’m not doing enough,” or another who said the following:

> *I’m struggling hard tonight. I want to want to fix this for my dad so badly but I can’t and I hate it. I hate that he has no idea what’s going on or why its happening and I hate that I can’t just make it all better for him.* [sic]

Another primary form of guilt and anxiety that emerged related to the users’ emotions and feelings. Some felt anger toward their care recipient. For example, some users noted they experienced emotional exhaustion related to caregiving and challenges coping with the loss of a loved one. One user, for example, lamented the loss of their mother’s cognitive function and was struggling with the decision to place her in an assisted living facility. The user experienced guilt around their feelings, noting the following:

> *[T]o me, my mother has been gone a long time. Am I an asshole for not wanting to see her...?* [sic]

Furthermore, multiple users expressed guilt associated with feelings of relief (both realized and expected) upon the passing of the person in their care, such as the user who stated the following:

> *I feel sad but also I feel free...I think sometimes “now I can start my life” and then I feel selfish and sad.*

Decisions-Making About Care Facilities

Another commonly observed theme in the data involved decision-making about care facilities and other forms of assisted living. Prospectively, users sought advice and validation related to deciding when in the disease progression it was appropriate to place their loved ones in an assisted living facility. In addition, users sought practical advice on finding and selecting the right place and evaluating quality of care. However, many posts discussed challenges related to patients already in an assisted living facility. For some, there were unexpected or short-notice care expectations, even after the individual was placed in an assisted living facility. One user noted as follows:

> *The facility staff are telling me we either need to coordinate a sitter to literally sit outside his door 24/7 and physically keep him from leaving, or to send him to a mental institution until they get his meds right. This change needs to happen within 24 hours.*

Other users were disappointed with the quality of care their loved ones were receiving. For example, one user said the following:

> *She was able to get out via an alarmed door, which apparently didn’t sound, get past reception, out the front door and walked up a super busy street to a grocery store 1/2 mile away! The street is almost a highway with. 3 lanes of traffic on each side. I don’t know all of the details yet but clearly this is not acceptable...I’m so angry that this could happen. My family is paying a ton of money to keep them safe and this happens.*

Therefore, the myriad challenges associated with care facilities were common themes in the discussion on dementia-related subreddits.

Legal and Financial Planning

Users also commonly discussed the challenges associated with legal and financial planning for their loved ones living with AD/ADRD. These posts largely centered on the high financial costs of professional care and assisted living facilities and the steps caregivers and families could take to afford this support and protect family assets. Many users noted that their loved ones did not have sufficient resources (eg, retirement savings, long-term care insurance, and state support) to cover the costs of needed full-time care. In some cases, users reported subsidizing their loved ones’ care with their own funds:

> *I used to be what I would consider reasonably well off, now I have nothing left and struggle daily to make ends meet.*

Others described an impossible tension, wherein they could neither afford to pay for needed care nor quit their own jobs to provide full-time care, such as the user who said the following:

> *My only word of advice is, unless you’re a millionaire and can afford home care, which we were most certainly not, there is no solution and no easy road to this disease.*

One common concern in the discussion of care was the protection or leveraged use of assets, specifically houses owned by the care recipient. For example, one user described a situation in which their parent could not live in his home because he needed rental income to pay for his care, effectively forcing him to move in with relatives. Others noted that owning a home precluded access to social support programs as it counted as a substantial asset that had to be depleted before receiving assistance. Several threads related to strategies for protecting such assets (eg, placing the home in a trust) or challenges in liquidating them (eg, relatives living in the house or unwillingness to sell). Furthermore, these conversations commonly discussed the need to get legal affairs in order, such as establishing power of attorney and writing a living will early in the disease progression.

Thematic Comparison

Across both forms of data analysis, we observed similar overall topical structures within Reddit posts related to AD/ADRD caregiving. The most salient NLP-identified topics were very general and focused on making inquiries or sharing emotions with the forum. In our qualitative analysis, the most common coding was quite similar, related to users' expressions of emotion. However, through qualitative coding, we identified added nuance to these emotions of guilt, anxiety, and the struggles of AD/ADRD caregiving. Furthermore, we noted users sometimes expressed feelings that may be socially unacceptable outside an anonymous online space. For example, some users expressed relief upon the death of their care recipient. While likely not an uncommon emotional response given the myriad challenges associated with care, this relief may be uncomfortable to express to others for fear of judgment.

Similarly, the corpus-wide NLP analysis identified information seeking as a primary use of Reddit forums for AD/ADRD caregivers. However, in our qualitative coding, we identified specific informational needs of caregivers (eg, legal and financial planning advice) that were not apparent in the wider analysis. Moreover, we found through the qualitative analysis that users often sought normative standards for decision-making at common key time points in the disease progression, such as the "right" time to move a care recipient to professional or end-of-life care. While we observed themes related to assisted living and hospice care in the NLP, the qualitative coding provided a deeper understanding, finding that users were most often seeking external standards from others, which they could then apply to their unique situations and reduce doubt in their own decision-making. Therefore, our broad NLP analyses gave a high-level, atheoretical overview of themes in a large corpus beyond what is generally feasible for manual, human-driven analysis. Our qualitative coding fleshed out these findings, incorporating existing conceptual frameworks to contextualize and provide a more detailed understanding of the social support and information-seeking behaviors of AD/ADRD caregivers on Reddit.

Discussion

Principal Findings

Users sought community and informational support in dealing with the challenges associated with caregiving for people living with AD/ADRD. Consistent with prior literature, users reported a variety of emotional challenges related to providing care [34-36]; caregiver guilt and anxiety was a highly salient theme across the forum. The sources and manifestations of these emotions were highly variable across the forum. For example, users noted feelings of inadequacy in their capacity to care for loved ones, guilt associated with a lack of patience for their care recipient, loneliness and social isolation, burnout, and anxiety related to the varied stressors associated with care. While caregiver burden is well-established in the literature [15], it was particularly salient in the online space, wherein this seemed to be a primary point of conversation between users. Given the documented social stigmatization of dementia caregivers [37], users may seek to express these feelings and find support online as they do not feel comfortable expressing their challenges in day-to-day life. Furthermore, and unique to the anonymous online space, users felt empowered to discuss potentially taboo topics, including relief upon the passing of their care recipient. It is important to note the subreddits analyzed in this study are moderated to avoid bullying and spam and to establish a respectful dialogue in the forum. Notably, users may feel particularly safe to express these otherwise stigmatized beliefs and challenges. Creating this trust and safe space to discuss the complex emotions associated with dementia care may be similarly useful in face-to-face caregiver support interventions.

Consistent with other studies, Reddit users discussed myriad behavioral symptoms of AD/ADRD and strategies for providing effective care related to each symptom [19,20]. Manual coding identified instances of 14 different behavioral symptoms of dementia. The most identified among these were agitation or aggression, delusions, and bathroom or toileting issues. These are, perhaps, not surprising, given that these are symptoms with higher associated costs or challenges of care. Therefore, these may be the symptoms most discussed when seeking support. Often, users reported multiple symptoms together in the same post, consistent with the nonlinear nature of disease progression. Many users sought to map symptomology onto a disease progression timeline to better understand their own situation. However, as was noted by multiple users, this is challenging as dementia can present and progress differently across individuals. As such, the presentation of behavioral symptomology was often highly variable across the sample.

Finally, discussions with the forum also often related to difficult decisions facing caregivers of people living with dementia [4,49]. Many posts focused, for example, on the legal and financial planning challenges of care; users provided resources to others to help create power of attorney documentation and to navigate health care systems. The complicated legal and financial challenges associated with dementia and end-of-life care have been documented elsewhere. In our sample, users sought to crowdsource resources to navigate these complex systems, potentially without the high costs associated with hiring specialist attorneys and personal financial planners. Furthermore, users sought feedback associated with care decisions, particularly the proper timing for moving their loved ones into a full-time care facility. User discussions often compared symptomology and family circumstances, seeking validation or support in making the choice to seek professional care help. Again, these discussions often centered on stigma, fears associated with care quality, and the financial costs of professional care. As users faced difficult but common decisions related to transitions in care—times associated with higher perceived caregiver burden—they sought online emotional and informational support.

Implications for Practice

Our study findings suggest the need for increased social support structures for AD/ADRD caregivers, a special population who may experience challenges associated with seeking information and other forms of support on the web. This is consistent with the wider literature surrounding caregiver burden, suggesting high rates of burnout and needs for additional support beyond localized networks [34,35]. However, our study findings introduce important additional considerations. Recent literature has begun to document mental health risks associated with extensive social media use, particularly linked to unfavorable social comparison (ie, to others with fewer perceived challenges) [50]. There are further risks associated with seeking health-related information on the internet, given the high rates of misinformation found on social media [51]. Therefore, despite the somewhat closed and moderated nature of dementia-related subreddit forums, the overall absolute value for AD/ADRD caregivers of seeking support and information therein is unknown. Online resources and spaces for social connection, such as Reddit, which also feature expert fact-checking and seek to reduce harmful social comparisons, may be needed to support caregivers. Furthermore, there are opportunities for the development of mobile apps specific to AD/ADRD caregiving; however, additional research on the relative benefit of new mobile apps versus commonly used social media platforms is needed [40].

In addition, users noted specific informational needs with which they struggled to find high-quality support, including legal or financial planning and strategies for coping with feelings of inadequacy or guilt. These gaps in readily available information offer opportunities for intervention. For example, programs designed to teach caregivers about complex legal and financial planning documents (eg, power of attorney, living wills, and advance directives) may reduce burden. Given the well-documented financial strain associated with providing care, a centralized, online information hub for legal and financial planning may increase the capacity to proactively manage the complex tasks associated with estate planning and long-term care financing. Furthermore, specialized support groups for caregivers may use acceptance and commitment therapy techniques, which emphasize self-compassion around perceived personal shortcomings [52]. Acceptance and commitment therapy techniques are increasingly used in family caregiving settings (including for dementia), with promising early acceptance or feasibility and results related to psychological flexibility, which is the capacity to stay in contact with the present, irrespective of negative thoughts or feelings [52-54]. Unfortunately, access to such interventions and therapies remains limited, leading caregivers to seek information and social support in free and open online spaces. Future intervention work may leverage such opportunities to create readily accessible supports to assist caregivers in managing both specific care tasks (eg, financial management) and emotional challenges associated with caring for a loved one living with AD/ADRD.

Limitations and Future Directions

As with all research, this study has certain limitations that should be considered. First, the sample was drawn from a single, moderated, online space, which may limit some of the most extreme responses from being published. Reddit users are, on average younger, highly educated, and more likely to be male than the general population. Furthermore, because data were published anonymously and are self-reported, we have no mechanism by which to directly assess truthfulness. However, this anonymity was a key feature to our findings and has been reported as a strength in other social media studies. Future research may explore AD/ADRD caregivers' use of different social media platforms, as social media use varies across demographic groups. Similarly, future research may examine differences between social media platforms, due to the differing nature of the content (ie, images, text, and video) found on each platform. In addition, while we analyzed a large sample using computational methods, the qualitative process for deeper analysis was limited to a smaller subsample. Therefore, our findings are not necessarily representative of all dementia caregivers and should be considered with these limitations in mind.

Conclusions

In this study, we used both computational and traditional qualitative analyses to explore the experiences of caregivers of people living with AD/ADRD who posted to the social media channel Reddit. Using an unsupervised topic modeling approach, we generated a 10-topic solution (coherence score=0.38) from a corpus of more than 6500 posts. These topics broadly centered on emotional and logistical challenges associated with care, as well as a cluster of topics associated with various symptomology. To gain a deeper understanding of these topics, we conducted a qualitative review of a subset of posts. Users noted high levels of burden, guilt, and anxiety associated with caregiving. Users sought emotional and informational support to manage the behavioral symptomology of their care recipients and to make key legal, financial, and other care-related decisions. Interestingly, the anonymous and moderated nature of the Reddit platform seemed to reduce the perceived risk of stigmatization, allowing users to express difficult and complex emotions related to the care experience, including resentment and relief upon the passing of a loved one. These findings suggest the need for additional caregiver support interventions to reduce burden and improve overall well-being for both the caregiver and care recipient.

Abstract

Background: Internet use has dramatically increased worldwide, with over two-thirds of the world's population using it, including the older adult population. Technical resources such as internet use have been shown to influence psychological processes such as stress positively. Following the Conservation of Resources theory by Hobfoll, stress experience largely depends on individuals' personal resources and the changes in these resources. While personal resource loss has been shown to lead to stress, we know little regarding the role that technical resources may play on the relationship between personal resources and stress.

Objective: This study aims to investigate the moderating effect of technical resources (internet use) on the relationship between personal resources and stress in younger and older adults.

Methods: A total of 275 younger adults (aged 18 to 30 years) and 224 older adults (aged ≥65 years) indicated their levels of stress; change in personal resources (ie, cognitive, social, and self-efficacy resource loss and gain); and internet use. Variance analyses, multiple regression, and moderation analyses were performed to investigate the correlates of stress.

Results: Results showed that older adults, despite experiencing higher levels of resource loss (questionnaire scores: 1.82 vs 1.54; $P<.001$) and less resource gain (questionnaire scores: 1.82 vs 2.31; $P<.001$), were less stressed than younger adults (questionnaire scores: 1.99 vs 2.47; $P<.001$). We observed that the relationship among resource loss, resource gain, and stress in older adults was moderated by their level of internet use ($\beta=.09$; $P=.05$). Specifically, older adults who used the internet more frequently were less stressed when they experienced high levels of both loss and gain compared to their counterparts who used internet the less in the same conditions. Furthermore, older adults with low resource gain and high resource loss expressed less stress when they used the internet more often compared to those with low internet use.

Conclusions: These findings highlight the importance of internet use in mitigating stress among older adults experiencing resource loss and gain, emphasizing the potential of digital interventions to promote mental health in this population.

Introduction

Background

Internet use has increased drastically in the last decade, with two-thirds of the world's population now being familiar with it [1]. For example, in Switzerland, 90% of people aged >15 years use the internet daily, and even 70.3% of people aged >65 years use it regularly [2]. However, few studies have explored the role of internet use on psychological processes such as stress in the context of personal resource loss and its age-related specificities.

Older adults are often confronted with a variety of challenges that can result in social, health, and cognitive losses. Specifically, older adults may experience reduced social support networks, decreased physical functioning, and a decline in cognitive abilities such as memory and executive functioning [3,4]. These losses can have a negative impact on overall well-being, including increased levels of stress, depression, and anxiety [5,6]. Moreover, individuals tend to place greater value on avoiding losses than on acquiring gains and, as a result, are often more motivated to take action to avoid potential losses than to pursue potential gains. Technical resources can serve as an additional resource that helps older adults maintain or improve their level of mental health in various ways [7,8], such as through web-based social interaction, web-based counseling, health services, or cognitive stimulation. In other words, technical resources can help older adults reach their maintenance and loss managements goals.

In this study, we investigated the effect of technical resources, specifically internet use, and the extent to which they can buffer the relationship between personal resources and stress in both younger and older adults.

Age-Related Differences in Personal Resources and Their Impact on Stress Levels

Personal resources are typically considered attributes that individuals value and that enhance their ability to function effectively in terms of controlling and impacting their environment [9,10]. Moreover, individuals' personal resources, including their health, social support, and financial means, along with their mental strengths such as self-efficacy, change over the course of life due to a combination of factors, including biological aging, life experiences, and environmental factors. According to the life span theory, personal resources tend to decrease as individuals age, putting older individuals at risk of decline in overall well-being [11]. For instance, age-related changes such as declining social networks, poor mobility, retirement, and development of chronic illness can contribute to social isolation and feelings of loneliness in older adults [12-14], which have been associated with increased stress and poor well-being [15-17].

Various theories suggest that older adults may develop compensatory strategies to manage the decline in personal resources and maintain well-being [5,18-22]. According to the Conservation of Resources (COR) theory by Hobfoll [20], individuals seek to gain new resources to maintain or enhance their well-being, particularly in the face of stress and adversity [6]. More specifically, when individuals experience a loss of resources, such as a decline in health or social support, they may be more vulnerable to stress and negative well-being outcomes. However, if they can gain new resources, this can help offset the negative impact of the loss and buffer against the effects of stress. Thus, while resource losses can have a significant negative impact on individuals' well-being, resource gains can help replenish those losses and promote resilience.

For older adults, resource gains may involve engaging in activities such as taking classes, volunteering, participating in social activities, or learning new skills. Specifically, technical resources provide a support to access new activities [23]. However, the extent to which internet use influences the relationship between personal resources and stress in aging is not yet fully understood. This study aimed to better understand how the internet can be used as a resource to support the well-being of older adults, particularly in the context of stress and aging.

Internet Use Role as a Resource Gain in the Context of Older Adults' Stress

Internet use can facilitate the gain of resources, providing older adults with additional means to cope with stress and improve their mental health outcomes [24-29]. For instance, the internet can serve as a platform for social support, information seeking, and engaging in meaningful activities, all of which can contribute to better mental health outcomes in later life [23]. More specifically, higher levels of internet use predict higher levels of social support, reduced loneliness, and better life satisfaction and psychological well-being among older adults [26].

For example, by using the internet for social interactions, older adults can increase their social networks, receive emotional support, and build relationships with others [28-30] to reduce social isolation and stress. For example, Li et al [31] examined the relationship among social isolation, cognitive functioning, depression, and internet use among older adults. The results showed that social isolation was significantly associated with poorer cognitive functioning and higher levels of depression among older adults. Moreover, internet use moderated the relationship between social isolation and cognitive functioning, suggesting that internet use may have a protective effect on cognitive functioning among socially isolated older adults. Finally, the results showed that internet use was associated with lower levels of depression among older adults regardless of their level of social isolation. This suggests that internet use could serve as a protective factor for cognitive functioning and that it represents an important factor for improving mental health outcomes among older adults.

Moreover, through information research using the internet, older adults can gain knowledge and skills to manage stressors that arise in later life. Being confronted with or anticipating age-related loss of physiological functioning, older adults are interested in acquiring health knowledge [32-34]. Higher web-based health literacy is associated with more positive health behaviors and better health knowledge and attitudes in older adults [35]. In addition, engaging in other meaningful activities such as web-based learning, gaming, shopping, and hobbies can also have positive effects on the psychological outcomes of older adults [36-41]. For example, Gallistl and Nimrod [36] examined the relationship between internet use for leisure activities and well-being among older adults. The results showed that older adults who used the internet for leisure activities reported higher levels of subjective well-being, social connectedness, and life satisfaction than those who did not use the internet for these activities. Moreover, several studies have reported that web-based gaming improves older adults' physical and cognitive functioning [42,43], social interaction, and enjoyment and decreases social isolation [44-46]. These studies commonly suggest that, by participating in web-based activities, older adults can gain new skills, challenge themselves, increase their social networks, and find enjoyment in their free time.

Little research has been conducted on the relationship among personal resources, internet use, and stress at different ages. However, determining the potential benefits of internet use in managing stress in later life may highlight the importance of promoting access to and use of technology among older adults.

This Study

The main objective of this study was to better understand the underlying mechanisms contributing to age-related differences in stress as a function of changes in personal resources and internet use. More specifically, we investigated (1) age-related differences in stress and its associated predictors; (2) whether the level of resource gains buffered the relationship between resource losses and stress in younger and older adults, replicating the findings by Hobfoll [20]; and (3) whether the profile of internet use in younger and older adults moderated the relationship between resource gains and losses and stress levels.

First, we tested the hypothesis that stress levels differed by age group. We expected that older adults would report lower levels of stress compared to younger adults. This hypothesis was based on previous research that has consistently demonstrated that older adults are exposed to fewer stressors than younger adults [46,47], leading to better well-being outcomes such as less stress [48-50].

The second set of hypotheses concerned the replication of the COR theory [20], describing that resource losses would have a considerably stronger impact than resource gains on individuals' stress perception [6]. Moreover, COR theory explains that resource gains buffer the effect of resource losses on stress [20]. Accordingly, we expected that (1) more resource losses would be associated with a higher level of stress; (2) resources losses would have a stronger impact on stress than resource gains; and (3) the relationship between resource losses and stress would be moderated by the level of resource gains, with higher levels of gains helping buffer the negative impact of losses on stress levels.

Finally, we hypothesized that the moderating effect of resource gains on the relationship between resource losses and stress would vary based on levels of internet use, presenting distinct profiles for the younger and older adults. First, given previous findings showing that internet use may have a positive impact on older adults' well-being and stress levels [51-53], we expected that internet use would moderate the relationship between resource gains and losses and stress—individuals who reported higher levels of internet use would experience a greater protective effect of resource gains (ie, stronger effect of gains) than those who reported lower levels of internet use. This hypothesis was based on previous studies demonstrating that higher use of the internet was associated with higher levels of stress, depression, loneliness, and anxiety in young adults [54,55].

Methods

Procedures and Participants

We conducted a cross-sectional study in the French-speaking part of Switzerland. The participants were native or fluent French speakers. We recruited 510 individuals, of whom 280 (54.9%) were aged <30 years (mean age 25.00, SD 2.09 y) and 230 (45.1%) were aged >65 years (mean age 73.55, SD 7.16 y; see Table 1 for detailed participant characteristics). Younger participants were mainly undergraduates from the University of Lausanne, whereas the rest of the participants were recruited using the snowball sampling technique [56]. Recruited individuals volunteered to participate in the study and were not remunerated. For being included, participants had to be able to speak and understand French and had to be aged between 18 and 30 years or >65 years. Participants filled out a web-based open questionnaire containing questions on stress and potential predictors or moderators such as personal resources and internet use (ie, questions presented in a specific order).

The sample size used in this experiment was based on an a priori power analysis conducted in G*Power (version 3.1) [57]. We assumed an effect size of Cohen f=0.06, which was derived from previous relevant studies on the buffer effect of resource gains on the association between resource losses and stress [58,59], and an α of .05. Specifically, a total sample size of 404 participants (n=202 per group) provided 90% power to detect effects. To exceed this criterion and achieve >80% power, we recruited 510 participants (ie, n=280, 54.9% younger adults and n=230, 45.1% older adults).

Table 1. Participant characteristics (N=510).

Variable	Younger adults (n=280)	Older adults (n=230)	Chi-square test for group comparison	
			Chi-square (*df*)	*P* value
Age (y), mean (SD; range)	25.00 (2.09; 18-29)	73.55 (7.16; 65-98)	—[a]	—
Gender, n (%)				
Women	190 (67.9)	130 (56.5)	6.9 (1, 510)	.01
Men	90 (32.1)	96 (41.7)	5.0 (1, 510)	.03
Educational level[b], n (%)				
Obligatory school not finished	1 (0.4)	16 (7)	17.1 (1, 510)	<.001
Obligatory school	4 (1.4)	51 (22.2)	56.5 (1, 510)	<.001
Professional formation	18 (6.4)	79 (34.3)	63.9 (1, 510)	<.001
General education	4 (1.4)	5 (2.2)	0.4 (1, 510)	.56
Professional maturity	15 (5.4)	10 (4.3)	0.3 (1, 510)	.60
Gymnasium maturity	49 (17.5)	9 (3.9)	24.0 (1, 510)	<.001
Specialized university	15 (5.4)	20 (8.7)	2.2 (1, 510)	.14
University	173 (61.8)	37 (16.1)	108.9 (1, 510)	<.001
Doctoral degree	0 (0)	3 (1.3)	3.7 (1, 510)	.06
Financial adequacy, n (%)				
More money than needed	54 (19.3)	59 (25.7)	3.2 (1, 510)	.08
Enough money	177 (63.2)	158 (68.7)	1.3 (1, 510)	.25
Less money than needed	48 (17.1)	13 (5.7)	15.6 (1, 510)	<.001

[a] Chi-square analyses were not conducted on participants' mean ages.

[b] The term *obligatory school not finished* corresponds to <11 years of education; *obligatory school* corresponds to 11 years of education; *professional formation, general education, professional maturity, and gymnasium maturity* correspond to 4 additional years of education; *university and specialized university* correspond to 3 to 5 additional years of education; and *doctoral degree* corresponds to 3 to 5 additional years of education.

Ethical Considerations

This study was approved by the Social and Political Sciences Ethics Committee of the University of Lausanne (C-SSP-092022-00002). Written informed consent was obtained from participants before the questionnaire was made available, and they were informed that they could decide to quit the study at any point. This ensured that participants were well informed of the study's objectives and the potential impact of their contribution. Furthermore, participants were made aware of the duration of their involvement, which entailed completing a web-based questionnaire lasting approximately 30 minutes (ie, the questionnaire comprised 27 pages with 15 items per page and the possibility to go back).

Before deployment, the questionnaire was tested to ensure its feasibility, enhancing its clarity and ease of completion. For nonapplicable items or when participants chose not to respond, options such as "not applicable" or "prefer not to say" were provided, respecting participant autonomy while preserving data integrity. In addition, to ensure valid responses, at least one answer selection per question was mandated, minimizing incomplete or inconsistent submissions and maintaining data reliability.

The informed consent process outlined the data management protocols, including the types of data collected, the methodologies used for data treatment using SPSS (IBM Corp), and the storage solutions provided by Switch Drive (Switch). A commitment was made to the participants that their data would be anonymized and held confidentially, with plans for eventual sharing in an open-access data repository (eg, SWISSUbase for 5 years) after the removal of any personally identifiable information. This study was developed using SurveyMonkey (for the Checklist for Reporting Results of Internet E-Surveys, see Multimedia Appendix 1), a web-based survey platform known for its ease of use and robust data analysis tools. It allows for the creation, distribution, and analysis of surveys, making it an ideal choice for collecting detailed feedback and insights. In addition, SurveyMonkey's strong emphasis on data security and privacy ensures the integrity and confidentiality of the data collected in the study. Multiple submissions were controlled by monitoring IP addresses and the anonymous codes assigned to each participant in addition to checking for consistency in the responses. Moreover, analyses were performed on questionnaires that were fully completed. No monetary compensation was provided to participants upon the completion of the questionnaire.

Measures

Predictors

Sociodemographic Variables

Demographic variables included age (in years), gender (0=*men*; 1=*women*), educational level (1=*obligatory school not finished*, 2=*obligatory school*, 3=*professional formation*, 4=*general education*, 5=*professional maturity*, 6=*gymnasium maturity*, 7=*specialized university*, 8=*university*, and 9=*doctoral degree*), and financial adequacy (1=*more money than needed*, 2=*enough money*, and 3=*less money than needed*).

Personal Resources

Personal resources were assessed using the 13-item Personal Resource Questionnaire–Short Form [60]. The short version of the questionnaire includes items concerning cognition, self-efficacy, and social relations. For this study, we used 2 parts of the questionnaire: losses ("To what extent did the listed resources decrease in the last year?") and gains ("To what extent did the listed resources increase in the last year?"; a total of 13 items × 2 = 26 items; for details, see Table 2). Each item was evaluated on a 5-point Likert scale ranging from 1=*none* to 5=*great amount*. Mean composite scores were calculated for losses and gains. Specifically, we created 2 types of indicators (ie, domain-general resources=resource gains and losses) and 3 types of resources in each condition (ie, domain-specific resources=self-efficacy, cognition, and social resources). Lower scores indicate lower levels of each personal resource condition.

Table 2. Details of the Personal Resource Questionnaire used in this study.

Resource	Number of items	Items	Cronbach α	
			Gains	Losses
Cognition	5	"Sound cognitive functioning" "Intelligence" "Good memory ability" "Ability to concentrate" "Ability to think and understand quickly"	0.96	0.93
Self-efficacy	4	"Sense of control over my life" "Ability to control my future" "Ability to achieve my goals" "Ability to put my plans into action"	0.95	0.92
Social relations	4	"Companionship of other people" "Close relationship to at least one friend" "Positive relationship partner" "Close relationship to one or more family members"	0.79	0.64

Internet Use

Internet use was assessed using the 8-item Mobile Device Proficiency Questionnaire [61] measuring participants' ability to perform on the internet using a mobile device (example item: "Using a mobile device I can read the news on the Internet?"). Each item was scored on a 5-point Likert scale ranging from 1=*never tried* to 5=*very easily*. A mean composite score was calculated, with lower scores indicating low levels of internet use. The Cronbach α for this study was 0.96.

Outcome Variable: Stress

Participants' stress level was assessed using the 5-item Perceived Stress Scale by Cohen et al [62] (eg, "In the last month, how often have you felt anxious and stressed?"). Each item was scored on a 4-point Likert scale ranging from 0=*never* to 4=*very often*. We calculated a mean composite score in which lower values indicated a less frequent experience of stress in the last month. The Cronbach α was 0.80.

Analytical Strategy

Differences between younger and older adults were first tested on stress and its predictors or moderators (eg, personal resources) using between-group ANOVAs. We then conducted correlation analyses to gain a better understanding of relationships among age, gender, educational level, financial adequacy, personal resources, internet use, and stress and prepare a more complex moderation analysis.

Second, to replicate the findings by Hobfoll and Lilly [6] and Hobfoll [21] regarding the stronger effect of resource losses than resource gains on stress, we conducted simple regression using participants' characteristics and personal resource variables as predictors. Moreover, to explore the moderating effect of resource gains on the relationship between resource losses and stress levels, we conducted moderation analyses using PROCESS (version 3.5) by Hayes [63], model 1. These analyses allowed for the examination of how the relationship between resource losses and stress levels varied depending on the level of resource gains reported by participants (ie, effect of the 2-way interaction gains × losses on stress).

Finally, to determine whether internet use influenced the moderation effect of resource gains on the association between resource losses and stress, a moderation analysis was performed using model 3 on PROCESS (ie, version 3.5 for SPSS by Hayes [63]). This method allowed for the testing of the effect of the triple interaction, internet use × gains × losses, on stress. In all moderation analyses, we controlled for age, gender, educational level, and financial adequacy.

In each regression and moderation analysis, we divided the analysis into 2 sets: the first set included the domain-general resources as general gains and losses, and the second set included the gains and losses of domain-specific resources such as social, cognition, and self-efficacy.

Unstandardized coefficients and 95% CIs were reported. The level of statistical significance was set at $P<.05$. All analyses were performed using SPSS (version 26; IBM Corp).

Results

Mean-Level Comparisons

Mean-level tests were conducted to determine the age-related differences in stress and personal resources (Table 3).

The results showed that older adults were less stressed than younger adults (1.99 vs 2.47; $P<.001$; ie, questionnaire scores). Older adults had more losses compared to younger adults (1.82 vs 1.54; $P<.001$; ie, questionnaire scores), whereas they presented less resource gains (1.82 vs 2.31; $P<.001$; ie, questionnaire scores). More specifically, the analyses conducted on domain-specific resources (ie, social, self-efficacy, and cognition) revealed that the resource losses in the social, self-efficacy, and cognitive domains tended to increase with age, whereas the social, self-efficacy, and cognitive resource gains tended to decrease with age. Finally, older adults reported less internet use than younger adults (3.35 vs 4.91; $P<.001$; ie, questionnaire scores).

Table 3. Younger and older adults' mean stress and personal resource variables (ie, questionnaire scores).

	Younger adults (n=275), mean (SD)	Older adults (n=224), mean (SD)	Test for mean-level differences (N=499)	
			F test (*df*)	*P* value
Stress	2.47 (0.70)	1.99 (0.69)	58.45 (1, 497)	<.001
Resources				
Losses	1.54 (0.63)	1.82 (0.76)	14.97 (1, 497)	<.001
Social	1.54 (0.63)	1.60 (0.72)	1.07 (1, 497)	.30
Self-efficacy	1.74 (0.92)	1.90 (0.93)	3.62 (1, 497)	<.06
Cognition	1.47 (0.73)	1.92 (0.88)	39.27 (1, 497)	<.001
Gains	2.31 (0.97)	1.82 (0.95)	32.72 (1, 497)	<.001
Social	2.57 (1.04)	2.00 (1.02)	37.37 (1, 497)	<.001
Self-efficacy	2.41 (1.14)	1.82 (1.06)	34.79 (1, 497)	<.001
Cognition	2.03 (1.08)	1.67 (0.99)	15.57 (1, 497)	<.001
Internet use	4.91 (0.23)	3.35 (1.38)	342.74 (1, 497)	<.001

Correlation Analysis

We performed correlational analyses to highlight relationships among sociodemographics, independent variables (domain-general and domain-specific resources and internet use), and stress (Table 4; for a complete table of correlations, see Multimedia Appendix 2).

In the total sample group, age, gender, and financial adequacy were correlated with stress; being female, having less money than needed, and being younger were associated with higher stress. Moreover, resource losses were related to higher stress. Specifically, higher stress was associated with more social, cognition, and self-efficacy losses. Participants who used the internet more often reported higher levels of stress.

In the separate age group analyses, we found that higher levels of stress were associated with higher levels of resources losses and, more specifically, social, cognitive, and self-efficacy losses in both younger and older adults. Moreover, correlations in the younger adult group revealed that being female and having less money than needed were associated with higher stress. Furthermore, higher levels of domain-general resource gains in younger adults were associated with stress, and domain-specific resource gains such as cognitive and self-efficacy were related to being less stressed. Concerning the older adult group, analyses revealed that having a higher level of education was associated with lower stress. Finally, while the use of the internet was not associated with stress scores among the younger participants, it was negatively associated with stress among the older participants, indicating that more internet use was linked to lower stress levels.

Table 4. Significant Pearson correlations (r) between participant characteristics and personal resources and stress levels for the total sample (younger and older adults; N=510).

	Younger adults (n=280)		Older adults (n=230)		Total sample	
	r	*P* value	*r*	*P* value	*r*	*P* value

Internet use	–0.05	.39	–0.17	.01	0.12	.005

Moderation Analyses

Overview

Regarding the profiles of internet use between younger and older adults, we found notable differences. Specifically, younger adults exhibited uniformly high use rates (median 5.00, range 3.38-5.00), whereas older adults demonstrated a considerable range in their internet use behavior, from very low to very high (median 3.56, range 1.00-5.00). To evaluate the moderating effect of age on the link between resource loss, resource gain, and internet use on stress, we initially tested a model including the age group variable in a quadruple interaction term (loss × gain × internet use × age groups; not presented). However, no significant interaction was found (β=–.02; P=.95), possibly due to the complexity of the interaction term and the unequal variances in internet use across age groups. Indeed, the assumption of homogeneity of variances for internet use was not respected (Levene test: $F_{1,502}$=536.63; P<.001), showing a difference in variances across groups. On the basis of these findings but also on previous research in the field suggesting that internet use may influence the level of stress, we decided to present the following analysis separately for younger and older individuals (although the results should be interpreted with caution). This methodological approach was crucial for understanding how internet use influenced the relationship between resource loss and gain and stress, allowing for an exploration of use trajectories characteristic of younger and older adults without the confounding influence of the homogeneous high internet use found in the younger cohort.

Domain-General Resources

First, simple regression (model 1; Multimedia Appendix 3) revealed that resource indicators accounted for 32% and 20% of the individual differences in stress levels in younger and older adults, respectively. Similarly, for younger and older adults, the strongest predictor was resource losses (younger adults: β=.45 and P<.001; older adults: β=.37 and P<.001) followed by resource gains (younger adults: β=–.20 and P<.001; older adults: β=–.13 and P=.01), suggesting that individuals who experienced higher resource losses and lower gains tended to feel more stressed as compared to those with lower levels of losses and higher levels of gains.

Second, we found a significant 2-way interaction (model 2; Multimedia Appendix 3 and Figure 1) between resource gains and resource losses on levels of stress as the dependent variable in both younger and older adults, confirming our second hypothesis (β=.26 and β=.16 for younger and older adults, respectively). Specifically, individuals with high levels of resource gains who also reported high levels of losses felt less stressed compared to individuals with lower levels of resource gains and higher levels of resource losses.

Finally, internet use influenced the moderation effect of resource gains on the relationship between resource losses and stress, as seen in a significant 3-way interaction among internet use, gains, and losses in older adults (model 3; Multimedia Appendix 3; β=.09). More specifically, compared to the second model, the third model presented an increase in the index of adjustment (ie, a change in explained variance) of 0.05 (ΔR^2=0.05; P=.002). The 3-way interaction was not significant in younger adults (β=.22).

To further the understanding of the 3-way interaction in older adults, we examined the conditional effects of resource losses at 1 SD above (+1 SD) and 1 SD below (–1 SD) the mean scores of resource gains (first moderator) and internet use (second moderator; Table 5 and Figure 2). As the 3-way interaction (losses × gains × internet use) was not significant in younger adults, we reported only the conditional effects of older adults. The results showed significant moderation effects of resource gains and internet use on the relationship between domain-general losses and stress. Specifically, significant moderation effects were observed only in cases in which individuals reported high levels of gains and high levels of internet use (β=.37), as well as in cases in which individuals reported low levels of gains and high levels of internet use (β=.55) and low levels of both gains and internet use (β=.66). These results suggest that the use of the internet reinforces the buffering effect of gains on the relationship between resource losses and stress.

According to the third hypothesis, we conducted an additional analysis to examine the differences between individuals with high internet use and those with low internet use in relation to their gains and losses (Table 6). As the 3-way interaction (losses × gains × internet use) was not significant in younger adults, we reported only the conditional effects of older adults. The results showed that internet use effects (ie, differences between participants with a higher internet use and participants with a lower internet use) were marginally significant only in cases in which individuals reported high levels of gains and low levels of losses (β=–.21).

	β coefficient (SE; 95% CI)	*P* value
Internet use at –1 SD of gains and –1 SD of losses	–0.01 (0.06; –0.12 to 0.10)	.89
Internet use at –1 SD of gains and +1 SD of losses	–0.07 (0.08; –0.23 to 0.09)	.40
Internet use at +1 SD of gains and –1 SD of losses	–0.21 (0.12; –0.44 to 0.02)	.08
Internet use at +1 SD of gains and +1 SD of losses	–0.03 (0.06; –0.14 to 0.09)	.67

Domain-Specific Resources

Similarly to the domain-general resources, we conducted 3 regression models for the domain-specific resources in both younger and older adults (self-efficacy, cognition, and social resources; Multimedia Appendix 4). The first model showed that resource losses were the strongest predictor of stress levels across different age groups regardless of the specific type of resource considered. The coefficient of losses for self-efficacy was found to be the highest in both younger and older adults, with more losses being related to higher levels of stress in both groups. Moreover, higher gains in self-efficacy, cognition, and social resources significantly predicted lower stress levels in younger adults. However, in older adults, the only significant predictor was self-efficacy gains, with more gains being associated with less stress. These findings suggest that different types of resource gains may play varying roles in shaping stress experiences across different age groups.

Moreover, the impact of resource losses on stress in younger and older adults was significantly influenced by their levels of gains, which varied depending on the type of resource. Those with high levels of self-efficacy and cognition gains tended to experience less stress when they also presented high levels of self-efficacy and cognition losses (younger adults: unstandardized coefficient $\beta_{\text{Cognition}}$=.21, 95% CI 008-0.34 and $\beta_{\text{Self-efficacy}}$=.20, 95% CI 0.08-0.32; older adults: $\beta_{\text{Cognition}}$=.23, 95% CI 0.11-0.34 and $\beta_{\text{Self-efficacy}}$=.23, 95% CI 0.13-0.34) compared to individuals with lower levels of resource gains who tended to experience higher levels of stress under similar circumstances (ie, younger adults: $\beta_{\text{Cognition}}$=.40, 95% CI 0.21-0.60 and $\beta_{\text{Self-efficacy}}$=.40, 95% CI 0.30-0.50; older adults: $\beta_{\text{Cognition}}$=.37, 95% CI 0.23-0.50 and $\beta_{\text{Self-efficacy}}$=.43, 95% CI 0.30-0.55). While there were no significant results regarding social resources for younger adults, older adults with high levels of social gains experienced less stress when they also presented high levels of social losses (β_{Social}=.18, 95% CI 0.04-0.32) compared to older adults with lower levels of resource gains who experienced higher levels of stress under similar circumstances (β_{Social}=.45, 95% CI 0.23-0.67).

This study also revealed a significant influence of internet use on the relationship between resource losses and stress levels in both younger and older adults, as indicated by the 2-way interaction effect (internet use × losses). Specifically, the interaction effect was found to be significant for different types of resources in younger and older adults. Among younger adults, a significant interaction effect was observed for self-efficacy and social resources ($\beta_{\text{Self–efficacy}}$=.30, 95% CI –0.02 to 0.31; β_{Social}=.67, 95% CI 0.09-1.25). Specifically, younger individuals who reported high losses in social and self-efficacy resources and had higher internet use experienced more stress compared to their counterparts with lower internet use. At the same time, younger adults with low levels of social and self-efficacy losses and higher internet use exhibited lower stress levels than those with lower internet use.

In the case of older adults, a significant interaction effect was observed specifically for cognition resources ($\beta_{\text{Cognition}}$=.08, 95% CI 0.00-0.16). Older individuals who experienced fewer losses in cognition and had higher levels of internet use reported lower levels of stress than individuals with lower internet use. In addition, a significant 2-way interaction effect between internet use and gain was marginally significant ($\beta_{\text{Cognition}}$=–.09, 95% CI –0.21 to .02). Older adults who had high gains in cognition resources and high levels of internet use exhibited lower levels of stress than older adults with lower internet use.

Finally, in older adults, internet use influenced the moderating effect of self-efficacy gains on the relationship between self-efficacy losses and stress and the moderating effect of social gains on the relationship between social losses and stress. This was evidenced by the significant 3-way interactions between internet use, self-efficacy gains, and self-efficacy losses ($\beta_{\text{Self-efficacy}}$=.07, 95% CI 0.01-0.14) but also between internet use, social gains, and social losses (β_{Social}=.11, 95% CI 0.03-0.19). Specifically, compared to the second model, the third model presented an increase in the index of adjustment (ie, a change in explained variance) of 0.02 (ΔR^2=0.02; *P*=.03) for the self-efficacy model and .03 (ΔR^2=0.03; *P*=.006) for the social model.

It is important to note that in younger adults, regardless of the type of resources, triple interactions between internet use, self-efficacy, cognition or social gains, and self-efficacy, cognition or social losses were not significant, in line with the findings on the triple interaction of the domain-general resources (Multimedia Appendix 4). As the 3-way interaction (losses × gains × internet use) was not significant in younger adults, we reported only the conditional effects of older adults. In older adults, conditional effects analyses (Table 7 and Figure 3) revealed significant moderation effects of self-efficacy gains and internet use on the relationship between self-efficacy losses and stress. Specifically, the moderation effects were observed only when individuals reported high levels of self-efficacy gains and high levels of internet use (β=.29), as well as when individuals reported low levels of self-efficacy gains and high levels of internet use (β=.38) and low levels of both self-efficacy gains and internet use (β=.45). Moreover, significant moderation effects of social gains and internet use on the relationship between social losses and stress were observed only when individuals reported high levels of social gains and high levels of internet use (β=.19) and low levels of both social gains and internet use (β=.64). Regarding domain-general resources, these results suggest that the use of the internet increases the buffering effect of self-efficacy and social gains on the relationship between self-efficacy and social losses and stress.

Regarding the domain-general resources, we conducted an additional analysis to examine the differences between older adults with high internet use and those with low internet use in relation to their gains and losses (Table 8). As the 3-way interaction (losses × gains × internet use) was not significant in younger adults, we reported only the conditional effects of older adults. The results showed that the internet use effects (ie, differences between participants with greater internet use and participants with lower internet use) were observed in older individuals who reported high levels of self-efficacy gains and low levels of self-efficacy losses (β=–.21). Moreover, significant internet use effects were observed in cases in which older adults experienced low levels of social gains and high levels of social losses (β=–.18), as well as in older individuals with low levels of social gains and high levels of social losses (β=–.17).

Discussion

Principal Findings

This study investigated the influence of internet use on the relationship between personal resources and stress in both younger and older adults. The findings indicated that older adults were less stressed than younger adults. Moreover, resource gains moderated the relationship between resource losses and stress, and this effect was similar in both younger and older individuals. Finally, internet use seems to act as a buffer on the dynamics between social and self-efficacy resource losses and stress, amplifying the positive influence of resource gains in reducing the adverse effects of these losses. In older adults, internet use was beneficial as a means of dealing with losses in social and self-efficacy resources.

Age-Associated Differences in Stress Levels

In support of our first hypothesis, we found that older individuals reported less stress than younger adults. This finding is consistent with those of extant research that has also documented the stress-buffering effect of age among older adults. This phenomenon has been attributed to several personal factors, including cognitive and emotional processing differences between age groups [64,65], greater use of emotion regulation strategies [66,67], and greater life experience and wisdom that allow for more effective coping with stressors [68,69]. Moreover, older adults may be more skilled at regulating their emotions, which may reduce the impact of stressful events on their psychological well-being.

Specifically, stress-inducing situations are related to an increase in negative emotions, and several studies have shown that older adults tend to experience more positive and less negative emotions [70-74]. Therefore, it can be inferred that older adults may possess a greater capacity to regulate and inhibit negative emotions, leading to a reduced impact of stressful events on their psychological well-being. Older adults may further be more resilient than younger adults due to their accumulated life experience and developed coping mechanisms, including proactive problem-solving strategies, effective emotion regulation, and strong sense of personal control and self-efficacy [75-78]. For example, several studies have reported a coping shift during aging to match the constraints experienced and preserve well-being [79-82]. Older adults, who often face a range of losses associated with aging such as declining health, social network changes (eg, death of partner), and retirement, tend to exhibit a greater preference for accommodation, including emotion- and cognition-focused coping. In contrast, younger adults, who typically have fewer losses, displayed a higher preference for assimilation, including problem-focused coping, and actively sought solutions to alleviate stress, reflecting their developmental stage characterized by a stronger drive for achievement, personal growth, and the ability to confront different types of challenges. The observed shift from assimilation to accommodation [19] across the life span suggests a developmental trajectory in coping strategies, with older adults adapting their coping approaches to address the unique challenges and losses they experience. Overall, older adults may be more resilient to stress than younger adults, and their adaptive coping strategies, social support, and emotion regulation strategies may contribute to their ability to maintain psychological well-being in the face of adversity.

Resource Gains Moderated the Relationship Between Resource Losses and Stress Levels

We found that resource gains moderated the relationship between resource losses and stress levels, confirming our second hypothesis. In line with the COR theory [20], we found that resource gains buffered the negative impact of resource losses on stress levels. More specifically, COR theory emphasizes the significance of resource gains, which have the potential to assist individuals in restoring their resources and avoiding further depletion. The gain paradox posits that individuals who have experienced losses are more likely to recognize and appreciate resource gains. This phenomenon can be attributed to the increased awareness among individuals of the value and importance of resources as a result of experiencing losses, which in turn serves as a motivation for them to actively seek and increase those resources. Consequently, resource gains are crucial in moderating the negative relationship between resource losses and stress levels as individuals with greater resource gains possess better coping abilities and are more likely to recover from losses [21].

Replicating the COR theory by Hobfoll [20], we also found that resource gains buffered the impact of resource losses in both age groups on stress. That the same buffering effect was found in both age groups could be attributed to some universality of the losses-gains dynamic across life phases. The COR theory posits that individuals across the life span share a fundamental drive to accumulate and protect resources as a means of maintaining well-being and minimizing stress [20]. Therefore, the importance of resource gains in mitigating the negative impact of resource losses on stress levels may hold regardless of age.

Effect of the Relationship Between Internet Use and Domain-Specific Resources on Stress in Younger and Older Adults

In addition, this study revealed distinct patterns of interaction between effect of internet use as an external technical resource and domain-specific personal resources on stress levels among younger and older adults. Our findings suggest that the relationship between social or self-efficacy losses and stress levels in younger individuals is significantly influenced by their use of the internet. Specifically, younger individuals who reported fewer social or self-efficacy losses experienced lower levels of stress when they used the internet, indicating a buffering effect. On the other hand, those who reported higher social or self-efficacy losses exhibited increased levels of stress when they used the internet, suggesting an exacerbating effect. These results highlight the complex interplay among social or self-efficacy losses, internet use, and stress levels in younger individuals. It appears that the internet may serve as a supportive resource for individuals with fewer social losses, providing them with a means for social connection and support [83]. Furthermore, the internet may serve as a resource for providing access to information, support, and opportunities for skill development, which can bolster self-efficacy beliefs and resilience and promote adaptive coping strategies [84-88]. However, for those experiencing higher social or self-efficacy losses, the internet may exacerbate stress. Indeed, the losses in social resources, such as social contacts, are associated with higher feelings of loneliness [89], which contribute to the development of excessive internet use, commonly referred to as internet addiction [90,91]. This pattern of excessive internet use, driven by the absence of social support and challenges in communication and in emotion identification and regulation, is linked to higher levels of stress [92,93]. This suggests that individuals experiencing significant social losses may increase their use of the internet as a compensatory mechanism to mitigate the impact of these losses, resulting in increased stress levels. Moreover, previous research has documented a generational-situated use of the internet, with younger adults using it for leisure activities whereas older individuals' preferred use of the internet is to facilitate the realization of daily activities such as medical consultations [94,95].

In addition, this study highlights an interesting pattern regarding the relationship among internet use, cognitive losses, and stress levels in older adults. Specifically, older adults with lower levels of cognitive losses who engaged in internet use experienced lower levels of stress compared to those who did not use the internet, suggesting that internet use may serve as a protective means against stress for older adults with fewer cognitive losses. One possible explanation can be that internet use provides opportunities to be engaged in web-based activities for cognitive stimulation, accessing information, or social interaction [8,96], which may help mitigate the negative effects of cognitive losses on stress levels. Considering that higher frequency of digital device use has been associated with fewer subjective cognitive concerns [97-99] and that cognitive losses have been associated with higher levels of stress in older adults [23,100,101], we found that older adults with less cognitive losses who used the internet more were less stressed compared to older adults who did not use the internet, suggesting a buffer effect of internet use on the relationship between cognitive losses and stress.

However, older adults with high levels of cognitive losses experienced similar levels of stress regardless of their internet use. This suggests that the influence of high cognitive losses on stress may remove any potential benefits derived from internet use. It is possible that older adults with high cognitive losses may have difficulties using the internet effectively due to their subjective cognitive losses, which could be explained by the digital distraction hypothesis [102-104]. According to this hypothesis, increased engagement with technology may have detrimental consequences for cognitive processes, manifesting as executive dysfunction characterized by heightened distractibility, superficial cognitive processing, and difficulties in task organization and completion. In addition, technology reliance may contribute to increased forgetfulness by undermining the natural memory systems used for tasks such as navigation or recalling personal information such as phone numbers [102,104]. The detrimental effects of excessive digital engagement on cognitive functioning may override any potential benefits of internet use for stress reduction in older adults with higher cognitive losses.

Internet Use Moderated the Relationship Between Resource Losses and Gains and Stress Levels in Older Adults

The final hypothesis of our study, which examined the influence of internet use on the relationship between resources and stress, was confirmed for older adults. More specifically, older adults with fewer losses in self-efficacy and social resources and greater gains in these domains experienced lower levels of stress when they engaged in more internet use. This suggests that the internet can be considered as an "amplifier" of the positive effects of resource gains, particularly in terms of self-efficacy and social resources.

Previous studies have reported that internet use by older adults has been associated with decreased loneliness and depression; better social connectedness, self-esteem, and cognitive functioning [105,106]; and improved self-efficacy, self-control, self-determination, and skill development [107-111]. For example, the study by Karavidas et al [110] examined the association between internet use, self-efficacy resources, and life satisfaction among older adults. The results revealed a positive correlation between internet use and life satisfaction. This relationship was mediated by self-efficacy resources, indicating that increased internet use among older individuals was associated with the development of higher self-efficacy skills, which in turn contributed to an improved overall quality of life. The findings suggest that frequent internet use may serve as a platform for older adults to develop and enhance their self-efficacy, leading to greater life satisfaction. Similarly, Chaumon et al [107] found that older adults with functional loss living in long-term care institutions showed a positive impact of internet use on self-sufficiency, self-efficiency, and psychological empowerment [112].

Moreover, the internet facilitates stronger social connections and easier access to social networks, such as through engaging in web-based conversations with new contacts or actively participating in web-based social events [76,105,107,113]. For example, White et al [105] presented a randomized controlled trial to investigate the psychosocial impact of providing internet training and access to older adults. The study involved a sample of older individuals who were randomly assigned to either an intervention group, which received internet training, or a control group that did not receive any intervention. The results showed significant improvements in several psychosocial factors among the intervention group compared to the control group. Specifically, older adults who received internet training reported increased social support, higher levels of social engagement, reduced feelings of loneliness, and enhanced subjective well-being. These findings suggest that providing older adults with internet training and access can have positive effects on their psychosocial well-being.

In line with previous findings, we found that internet use can support the buffer effects from gains in self-efficacy and social resources when individuals have low levels of losses in each type of resource. Moreover, internet use can also substitute the effects of gains in older adults with low gains and high losses. More specifically, our findings demonstrated that individuals who reported high losses and low gains in social resources experienced lower levels of stress when they engaged in more internet use. This can be attributed to the compensatory role of the internet in filling the gaps caused by the limited gains in social resources. Several studies have provided evidence supporting the notion that the internet can compensate for losses in social resources among individuals [114-118]. Older adults who experience a decline in face-to-face social interactions due to factors such as retirement or physical limitations can benefit from web-based social networking platforms. For example, Khoo and Yang [116] conducted a study that examined the impact of social media use on the perception of social support among middle-aged and older adults. The researchers found that using social media platforms for interactions with broader social networks such as friends was as beneficial as using them to connect with family members in terms of enhancing social support.

Limitations

This study entails certain limitations that warrant consideration. These pertain both to the representativeness of the recruited sample and to the measures used therein [119]. On the one hand, the results should be interpreted cautiously due to potential sampling error. Indeed, stemming from a nonprobabilistic sampling approach, the characteristics of the participants who voluntarily engaged in the study may also influence the variables of interest [119,120]. For instance, participants' income could influence their willingness to participate in surveys [121], their resource losses and gains, and their internet use [122]. Consequently, the sampling strategy used (ie, snowball volunteer sampling) likely did not capture older individuals marked by resource losses and sociodemographic characteristics (eg, isolation and low socioeconomic status) that are particularly stressful.

On the other hand, the nature of the measures used may introduce limitations. The results should be interpreted with caution when examining age-related differences in the role of internet use. Reflecting on the issue of causality, it is important to consider how the cross-sectional nature of our study limits our ability to ascertain changes in internet use and its effects over time, especially across different age groups [52]. While we identified associations among changes in personal resources, stress levels, and internet use, these findings are not sufficient to establish a causal link or to delineate the temporal evolution of internet use's impact on stress and personal resources. This caution extends to interpreting the dynamics of internet use across the life span, where cross-sequential research is essential for distinguishing between the effects of aging and those attributable to cohort-specific experiences or generational differences [94].

Moreover, the decision not to include age group as a factor in an interaction analysis was based on significant differences in internet use between younger and older adults. Preliminary findings indicated uniform high use among younger participants, which could confound nuanced age-related interactions with internet use and stress outcomes. Therefore, analyses were conducted separately for each age group to accurately capture distinct use patterns, especially among the older adults who demonstrated a broader range of internet behaviors. This approach helped avoid the confounding effects of uniform use in younger adults. However, it limited the exploration of broader age-related dynamics, potentially affecting a comprehensive understanding of how age influences the relationship between internet use and stress.

In addition, it is essential to recognize that this study's focus primarily lay on the frequency of internet use, measured equivalently for both younger and older adults. However, this approach disregards the plausible generational disparities in internet use patterns, as noted in previous research [94,123], which might inadvertently introduce errors in measurement [119]. Notably, the lack of statistical significance concerning the impact of internet use on stress in younger adults, a group extensively engaged with the internet, might potentially be attributed to the distinct "youthful" internet use styles, as proposed by Boullier [94]. Indeed, the presence of measurement errors, such as those arising from questionnaire elaboration, can introduce challenges such as ceiling and floor effects [119,124], impeding the identification of statistically significant differences between groups [125]. Moreover, future studies should develop measures to better capture interindividual differences in internet use in younger individuals to further investigate the multifaceted relationship between internet use and different age groups.

Moreover, the consideration of a singular internet use style in measurement limits the possibility of identifying the styles that may be most beneficial for each age group during resource losses. Indeed, the beneficial role of internet use derives from the meanings attributed to its use and the opportunities it offers to address needs [126-128]. Consequently, it would be of great interest for future studies to focus on identifying favorable internet use styles for stress reduction in a context of personal resource loss across different age groups.

Conclusions

This study examined the effect of internet use on the relationship between personal resources and stress. The findings revealed a nuanced understanding of how digital engagement can serve as a buffer against stress, particularly among older adults who experienced resource losses and gains. Specifically, older adults who frequently used the internet reported less stress when exposed to high levels of both resource losses and gains compared to their counterparts with lower levels of internet engagement. This underscores the importance of internet use in mitigating stress among older adults, highlighting the potential of digital tools in promoting well-being in older populations.

This study's novel contribution lies in its empirical support for the beneficial role of internet use among older adults within the framework of the COR theory by Hobfoll [20]. By demonstrating that internet use can moderate the effects of resource losses and gains on stress, this research provides valuable insights for developing targeted interventions aimed at leveraging technology to support well-being. Understanding these dynamics will help researchers, practitioners, and policy makers recognize the role of the internet as a facilitator of resource gains and a compensatory mechanism for social deficits in older adults. Encouraging and supporting older adults in using the internet can promote access to valuable resources and enhance their self-efficacy and social connections, ultimately contributing to improved stress management and, more generally, well-being.

Abstract

Background: The occurrence of the COVID-19 pandemic demanded fast changes in the delivery of health care. As a result, significant growth in the use of telemedicine services occurred. Research, especially from nationally representative German samples, is needed to better understand determinants of telemedicine use.

Objective: The purpose of this study was to identify determinants of telemedicine service use among middle-aged and older adults during the COVID-19 pandemic in Germany.

Methods: Cross-sectional, nationally representative data were taken from the German sample of the Survey of Health, Ageing and Retirement in Europe (SHARE). The German Corona Survey 2 (n=2039), which was conducted between June and August 2021, was used for this study. Reporting experience with remote medical consultations during the COVID-19 pandemic served as the outcome measure. Associations with socioeconomic, psychological, social, health-related, and COVID-19–related determinants were examined using multiple Firth logistic regressions.

Results: Psychological factors including feeling nervous, anxious, or on edge (odds ratio [OR] 1.61, 95% CI 1.04-2.50; *P*=.03), feeling sad or depressed (OR 1.62, 95% CI 1.05-2.51; *P*=.03) and feelings of loneliness (OR 1.66, 95% CI 1.07-2.58; *P*=.02) were positively associated with telemedicine use. Moreover, forgoing medical treatment because of being afraid of being infected by SARS-CoV-2 (OR 1.81, 95% CI 1.10-2.97; *P*=.02) and describing limitations because of a health problem as severe were positively associated with the outcome (OR 2.11, 95% CI 1.12-4.00; *P*=.02). Socioeconomic and social factors were not significantly associated with telemedicine use in our sample.

Conclusions: Middle-aged and older individuals in Germany seem to use telemedicine services according to psychological needs and health limitations. Especially when psychological symptoms are experienced, telemedicine seems to be a promising service option in this age group. Future research is needed to confirm these initial findings in postpandemic circumstances.

KEYWORDS

telemedicine; telehealth; digital health; service use; COVID-19

Introduction

Telemedicine has been a big part of the digital transformation of the health care sector. Multiple definitions of telemedicine have been introduced in the past [1]. The World Health Organization (WHO) Global Observatory for eHealth [2] identified the four key characteristics of telemedicine: (1) its purpose is to provide clinical support, (2) it is intended to overcome geographical barriers, connecting users who are not in the same physical location, (3) it involves the use of various types of information and communication technology, and (4) its goal is to improve health outcomes. Therefore, telemedicine includes synchronous (eg, videoconferencing, telephone) as well as asynchronous (eg, mobile apps) health services, which are delivered via electronic devices.

Telemedicine is a presumably promising method to provide health care in the future, as it can improve access to care, save costs, and close treatment gaps [3,4]. For example, it could be a potentially valuable tool when dealing with future shortages of physicians as well as the increased demand for health care services caused by population aging; underserved rural areas can also easily be reached through telemedicine [3,5]. In past research, telemedicine was found to be an effective and cost-effective service delivery model that can be equal to in-patient visits in a variety of specialties [3,6-9]. Additionally, practitioners (eg, physicians and psychotherapists), as well as patients with conditions covered by various specialties, were found to be greatly satisfied with this form of service [8-10]. Despite the clear advantages of telemedicine, it has not yet been widely implemented. Implementations have often been decelerated by limitations regarding reimbursement, as well as clinical, legal, cost, and social issues [11,12]. Telemedicine rates of use were gradually increasing over the previous years but remained at a low level [13].

The occurrence of the COVID-19 pandemic demanded fast changes in the delivery of health care. COVID-19 caused a major public health burden globally and it was essential to reduce in-person contacts to decrease further spreading of the virus [14]. Therefore, many nonessential appointments with physicians were canceled or postponed [15]. In a German population-based sample, this was the case for about one-third of respondents after containment measures were implemented in March 2020 [16]. Moreover, overall use of health care decreased in the first months of the pandemic, a phenomenon that was also observed in Germany [17].

Telemedicine appeared to be a key solution to major pandemic challenges. To facilitate the transformation to telemedicine, changes in infrastructure, reimbursement, and legal conditions were made worldwide. In Germany, legal efforts for the digital transformation of the health care system had already been made in November 2019 with the Digital Healthcare Act (Digitale-Versorgung-Gesetz) [18]. Consequently, it was easier for physicians to prescribe, deliver, and bill for telemedicine, and also for patients to use the services. In response to the pandemic, additional teleconsultation services were developed and regulations concerning video consultations were adapted [19,20]. Thus, telemedicine rates of use increased tremendously [21]. For example, the trend report of the Central Research Institute of Ambulatory Care in Germany reported that the number of video consultations increased from 743 conducted in December 2019 to 302,180 conducted in December 2020 [21]. Especially when there was limited access to in-person medical appointments during the pandemic in Germany, telemedicine services seemed to be a frequently used alternative, and satisfaction with the services was found to be moderately high [22,23]. Even though telephone services were used most frequently in Germany during the pandemic, a sharp increase was observed in the use of video consultations [24,25].

Besides technological, financial, organizational, and legal aspects, patient acceptance seems to be a crucial factor for the successful implementation of telemedicine services [26]. Patient characteristics that have been found to be associated with telemedicine use in past systematic reviews include, for example, age, gender, education, marital status, health status, and prior experience with computers and health technology [27,28]. A preliminary selective review of large-scale studies that were conducted during the pandemic in the United States found that telemedicine rates of use were higher among patients from urban areas, areas with greater broadband availability, and areas with higher prepandemic levels of telehealth use [29]. Moreover, being White; speaking English as first language; having health insurance, higher income, and greater disease burden; and being middle-aged were associated with greater use [29]. Nevertheless, more studies examining the use of telemedicine services and associated patient characteristics during pandemic times are needed.

Studies with samples from Germany, where telemedicine played a major role and was frequently used during the pandemic, are especially scarce. Few studies have looked at different German samples during the pandemic. While some of these studies examined large, nationally representative or quota-based samples [22,23,30], other studies only included convenience or smaller selective samples [31-33]. These studies identified potential socioeconomic (male sex, younger age, higher or lower education, living with a partner in the same household, having children younger than 18 years), psychosocial (increased loneliness, increased life satisfaction, severe psychological distress, frequent social isolation, lack of company), health-related (poor self-rated health), experience-related (higher electronic literacy, past use of telemedicine) and COVID-19–related (higher perceived severity of COVID-19 infection, having had COVID-19 infection, subjective COVID-19–related challenges, COVID-19–related cognitive preoccupation, anxiety, and worries) determinants that were positively associated with actual telemedicine use during the pandemic [22,23,30-33]. However, more studies including large nationally representative samples from Germany are needed to secure these initial findings. Moreover, the different categories of determinants, which were only partly included in single studies (eg, psychosocial or COVID-19–related determinants), should be explored further.

Middle-aged and older individuals represent the largest age group in the German population [34]. Considering population aging, the proportion of middle-aged and older adults will grow even further in the near future in Germany. Due to their increased need for health care (due to, eg, chronic conditions, frailty, and cognitive or functional decline) and potentially limited mobility, these age groups represent a major target group for future telemedicine services. Nevertheless, they seem to use telemedicine less often than other age groups [28]. Although past systematic reviews found that telemedicine is an effective and feasible service delivery model in older adults, it was also stated that further research was required to determine how services could be adapted to the individual needs of older patients [35-37]. Better understanding the telemedicine use behavior of middle-aged and older individuals could significantly contribute to increased use, as well as widespread acceptance and satisfaction with future telemedicine services. Therefore, this study aimed to explore determinants of patient use of telemedicine services in a nationally representative sample of middle-aged and older individuals during the COVID-19 pandemic in Germany.

Methods

Sample

Cross-sectional data for this study were taken from the Corona Survey 2 [38] of the Survey of Health, Ageing and Retirement in Europe (SHARE) study [39]. SHARE is a multidisciplinary and cross-national panel study that explores health, social, economic, and environmental policies in individuals aged 50 years or older and their partners (regardless of age) from 26

European countries, Switzerland, and Israel. Starting in 2004, SHARE has so far conducted 8 waves. In each wave, new respondents are added to the sample to compensate for attrition. In response to the global COVID-19 pandemic, a special Corona Survey, to examine the health-related and socioeconomic impact of COVID-19, was introduced in June 2020. In the course of this survey, the usual computer-assisted personal interviews were replaced by telephone-administered interviews.

Participation rates for waves 1 to 8 and the Corona Survey 1 have been provided by SHARE [40,41]. According to Bergmann et al [40], these rates increased over time and reflect high overall panel stability. The final rates for the Corona Survey 2 are not available yet; however, an average retention rate of 86% (excluding recovery of respondents) was confirmed by SHARE user support. Due to the fact that SHARE assessed telemedicine service use for the first time in the Corona Survey 2, only data from this survey, which was conducted from June until August 2021, were included in our analyses. Moreover, only the German subsample (n=2039) was considered, which was done to promote comparability among participants due to existing heterogeneity regarding characteristics of health care systems, telemedicine regulations, and telemedicine use across the different countries [20,42,43]. For example, whereas countries such as Denmark, Italy, and Germany are described as advanced in telemedicine use trends, countries like Poland, Portugal, or Slovakia are still developing in the telemedicine field since the pandemic [42].

Ethical Considerations

Verbal informed consent was collected from all individuals that participated in the telephone-administered interviews for the Corona Survey 2. The SHARE project has been repeatedly reviewed and approved by the ethics committee of the University of Mannheim (waves 1-3) and the Ethics Council of the Max Planck Society (waves 4-9; most recently in June 2021 with the ethics approval number 2021_24).

Dependent Variable

In the SHARE Corona Survey 2, telemedicine service use by middle-aged and older adults during the pandemic was assessed with a metric variable: “Since the outbreak of Corona, how many remote medical consultations over the phone, computer, or any other electronic means, did you have, if any, with or without video?” Therefore, this study did not focus on one specific form of telemedicine or patient group and included consultations on online platforms (eg, video calls), as well as telephone appointments. The response format in the original questionnaire was numerical (ie, the number of experienced telemedicine consultations). For the sake of this analysis, this item was dichotomized (1=one or more remote medical consultations since the outbreak of the COVID-19 pandemic; 0=no use) because of small case numbers.

Independent Variables

Independent variables were chosen in line with former research and based on theoretical considerations. Previous systematic reviews identified mostly socioeconomic (eg, sex, age, education, relationship status, area lived in) and health (eg, disease burden, psychological symptoms) determinants of telemedicine use [27-29]. Moreover, we considered the pandemic context, including the pandemic and social consequences, when choosing independent variables. Therefore, socioeconomic, psychological, social, health-related, and COVID-19–related factors were taken into account to explore their potential relationships with telemedicine service use. Socioeconomic factors that were included were sex, age, area lived in (big city, suburbs or outskirts of a big city, large town, small town, rural area or village), living with a partner in the same household (yes or no), employment status (retired, employed or self-employed, unemployed, or other) and the household’s ability to make ends meet regarding their total monthly income (with great difficulty or some difficulty, fairly easily, easily). Included psychological factors were feeling nervous, anxious, or on edge in the last month (yes or no), feeling sad or depressed in the last month (yes or no), and feeling lonely in the last month (yes or no). Furthermore, social factors included social and electronic contact frequency with people other than relatives (never, less than once a week, about once a week, several times a week, daily). Concerning health-related factors, having trouble sleeping recently (yes or no), the number of physical illnesses (including hip fracture; diabetes or high blood sugar; high blood pressure or hypertension; a heart attack, including myocardial infarction or coronary thrombosis; any other heart problem, including congestive heart failure; chronic lung diseases, such as chronic bronchitis or emphysema; and cancer or malignant tumor, including leukemia or lymphoma, but excluding minor skin cancers), limitations because of a health problem in usual activities (not limited; limited, but not severely; severely limited) and self-rated health (excellent, very good, good, fair, poor) were inspected. COVID-19–related factors that were included in the analyses were having received the COVID-19 vaccination (yes or no), oneself or anyone close having tested positive for COVID-19 (yes or no), forgoing medical treatment because of being afraid to become infected by SARS-CoV-2 (yes or no), and taking drugs or medicine as prevention against COVID-19 (yes or no).

Statistical Analysis

First, sample characteristics were computed. Second, Firth logistic regressions were conducted to identify determinants of telemedicine service use during the pandemic. The Firth method was used to reduce small-sample bias, considering the small case numbers for some of the variables [44]. Due to high correlations, the variables regarding psychological symptoms (including feeling nervous, anxious, or on edge; feeling sad or depressed; and feeling lonely in the last month) were entered separately into the model. For sensitivity analyses, conventional multiple logistic regressions were also performed. Moreover, we computed additional analyses with age as a categorical variable (40-64 years, 65-74 years, ≥75 years) to test for a nonlinear relationship with the outcome. Odds ratios (ORs) are presented with the 95% CI. *P* values were considered statistically significant at an α level of <.05. Since the number of missing values for the independent variables was very small (below 1%), we did not use imputation techniques. Small levels of missing values are usually less likely to significantly bias results [45,46]. Therefore, listwise deletion was applied. Stata (version 16.1; StataCorp) was used for all statistical analyses.

Results

Sample Characteristics

The total sample consisted of 2039 individuals. The sample characteristics for all included variables are presented in Table 1. Overall, 54.2% (1105/2039) of the sample were women. The mean age of the participants was 70.6 (SD 8.7) years. Considering telemedicine service use during the pandemic, 5.7% (115/2031) of the sample reported that they had had remote medical consultations at least once.

Table . Sample characteristics (N=2039).

Characteristics		Values
Telemedicine service use, n (%)		
	Never	1916 (94.3)
	At least once	115 (5.7)
Sex, n (%)		
	Male	934 (45.8)
	Female	1105 (54.2)

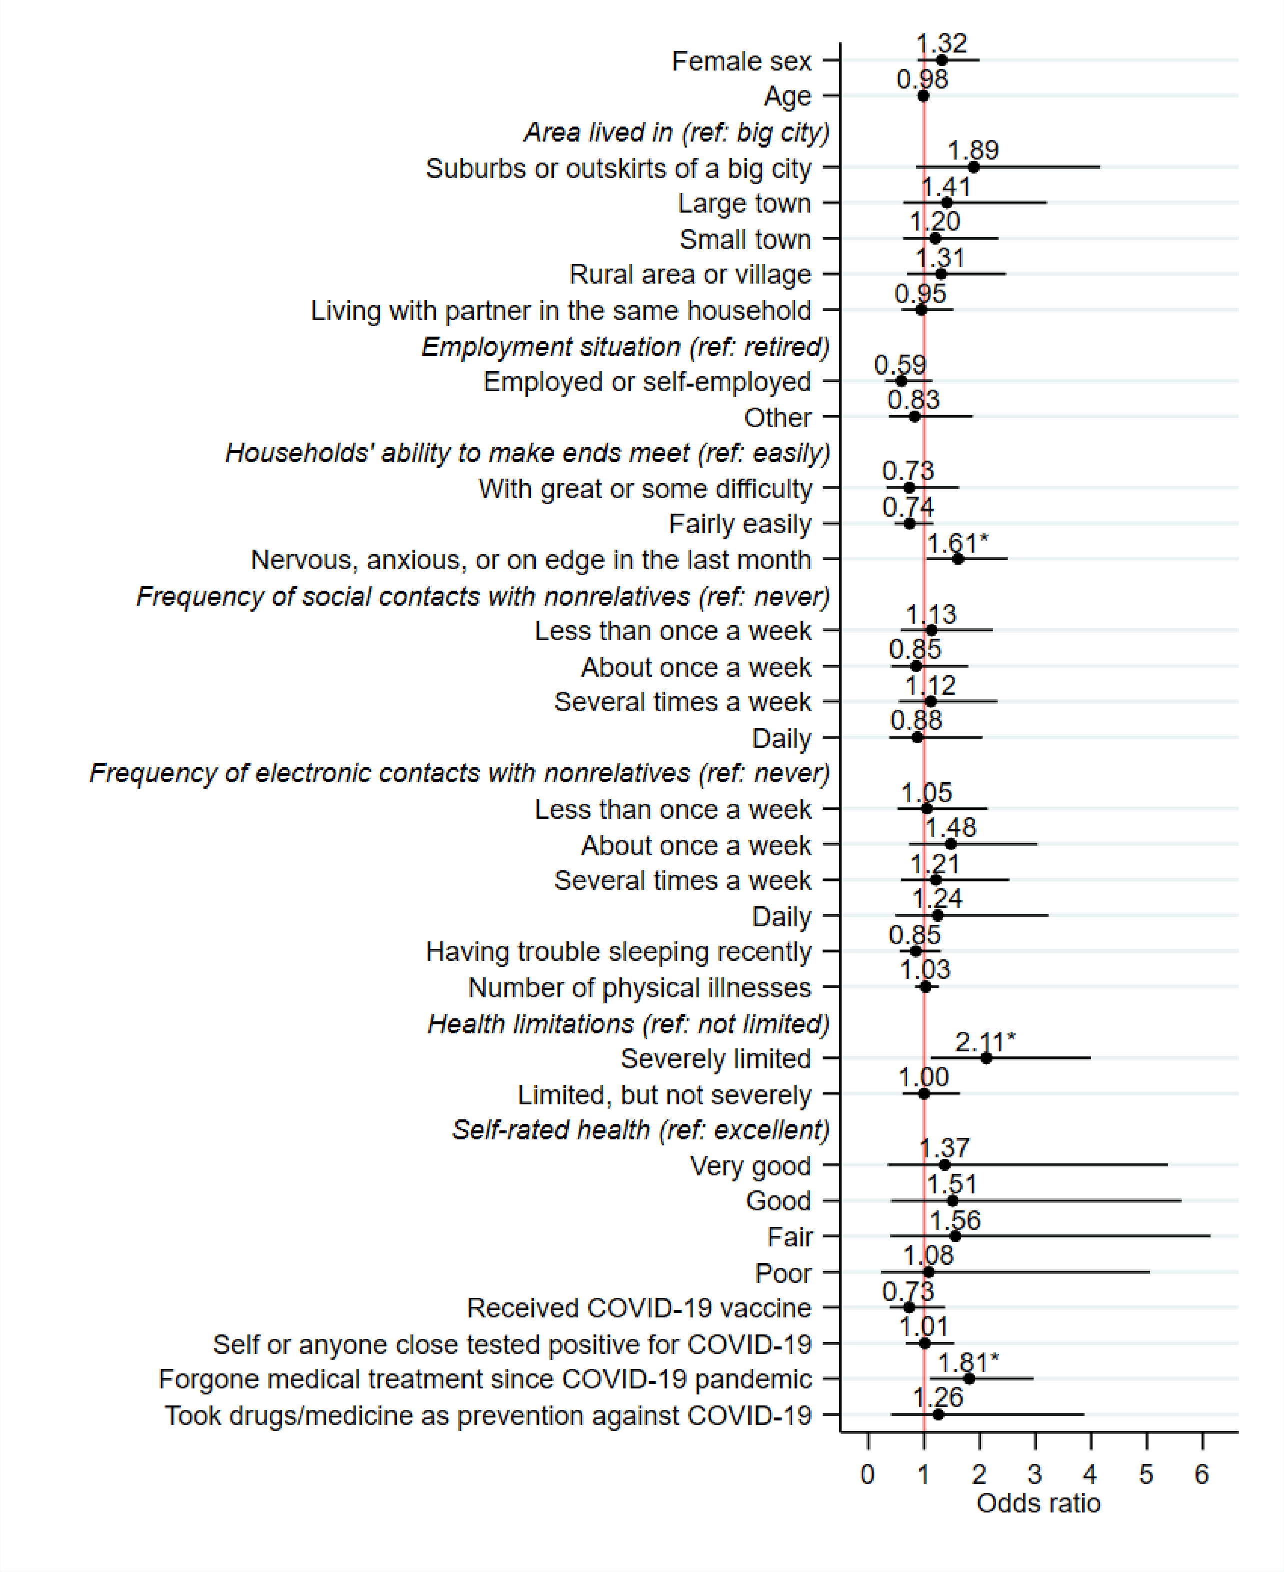
Regression Analysis

The analytic sample for the Firth logistic regressions included 1976 individuals. Results for the model, including anxiety symptoms, are presented in Figure 1 (see Multimedia Appendix 1 for detailed results for all models). Most of the included independent variables were not significantly associated with the outcome (*P*>.05). However, some associations were observed. Psychological factors, including feeling nervous, anxious, or on edge (OR 1.61, 95% CI 1.04-2.50; *P*=.03), feeling sad or depressed (OR 1.62, 95% CI 1.05-2.51; *P*=.03) and feeling lonely (OR 1.66, 95% CI 1.07-2.58; *P*=.02) in the last month were positively associated with the likelihood of telemedicine service use during the pandemic. Moreover, forgoing medical treatment because of being afraid to become infected by SARS-CoV-2 was positively associated with the outcome (OR 1.81, 95% CI 1.10-2.97; *P*=.02). Describing limitations because of health problems in the last 6 months as severe was also positively associated with the likelihood of telemedicine use during the pandemic (OR 2.11, 95% CI 1.12-4.00; *P*=.02).

Figure 1. Results from Firth logistic regression for determinants of telemedicine service use during the COVID-19 pandemic. The model includes anxiety symptoms. Numbers represent odds ratios, with the 95% CIs shown as bars. More detailed results are provided in Table S1 in Multimedia Appendix 1. ref: reference category. *P<.05.



In a sensitivity analysis in which Firth logistic regressions were replaced by conventional logistic regressions, similar associations were observed (see Tables S1-S3 in Multimedia Appendix 1 for detailed results). When age was included as a categorical variable in the models (see Table S4 in Multimedia Appendix 1 for detailed results), the youngest age group (40-64 years) was significantly more likely to use telemedicine services compared to the older age groups in our sample (65-74 and ≥75 years). Moreover, in these models, being employed or self-employed versus retired achieved statistical significance and was negatively associated with telemedicine use.

Discussion

Key Findings

This study aimed to identify determinants of telemedicine service use in a nationally representative sample of middle-aged and older adults during the COVID-19 pandemic in Germany. Based on data from the German sample of the SHARE Corona Survey 2, some associations of patient characteristics with telemedicine use were identified. This partly included health, psychological, and COVID-19–related factors. Socioeconomic and social determinants were not significantly associated with the outcome in this sample. So far, there has been limited research on determinants of telemedicine use in German samples. Our study findings thus extend our current knowledge regarding socioeconomic, social, health, psychological, and COVID-19–related determinants.

Relation to Previous Research

Whereas none of the included socioeconomic determinants were associated with telemedicine service use in our sample, some recent studies identified significant relationships. Findings regarding associations of sex and age with telemedicine use were mixed in recent studies conducted during the pandemic in Germany, with some studies observing higher rates of use in male and younger individuals [22,23,30-32]. When observing age groups in our sample, older age groups (65-74 and ≥75 years) were less likely to use telemedicine. While our study did not indicate a significant association, Hajek and König [30] observed that middle-aged and older individuals who reported living with a partner in the same household were more likely to have participated in online consultations with physicians or therapists during the pandemic. These mixed findings could potentially be explained by variations in outcomes (eg, web-based consultations vs mobile app use), samples (eg, all age groups vs only those middle-aged and older), and time frames (2020 vs 2021 vs 2022) of the different studies. This clearly highlights the need for further studies on sociodemographic determinants in German samples. Similar to our results, employment status, financial situation, and area lived in were not significantly associated with telemedicine use in other German samples during the pandemic [23,30]. However, this is in contrast to research from the United States regarding telemedicine use during the pandemic [29,47]. This contrast may be explained by a larger variation in state-specific telehealth policies before and during the pandemic [48], as well as access factors, such as possession of digital devices or availability of high speed internet [49] in the United States compared to the German samples. In contrast to Germany, health care insurance is not obligatory in the United States and additional costs arise for uninsured individuals [50], which could have contributed to telemedicine use disparities caused by socioeconomic factors in the United States [49,51-53]. Further attention should be given to the impact of socioeconomic factors on telemedicine use in future research, especially with respect to postpandemic changes and the increasing availability of in-person visits.

Our study is one of very few that has examined the association of social determinants (ie, electronic and social contact frequency) and telemedicine service use. These determinants were not significantly associated with telemedicine use in our sample. This could mean that middle-aged and older adults used telemedicine services during the pandemic based more on health factors than on reduced social contact. Nevertheless, Rauschenberg et al [33] observed that telemedicine use was higher among young individuals who reported higher perceived social isolation and lack of company during the pandemic in Germany. These contrasting findings may imply that younger individuals have used telemedicine more frequently to deal with reduced social contact during the pandemic.

Furthermore, we found that perceiving one’s limitations because of a health problem as severe was associated with telemedicine service use. This suggests that individuals with severe health limitations preferentially used telemedicine services during the pandemic. Likewise, Hajek and König [30] found a significant association of poor self-rated health and telemedicine use during the pandemic in Germany. Additionally, a positive association of disease burden and telemedicine use was observed by Harju and Neufeld [29] in large-scale US samples during the pandemic. Potential reasons for that could include the (urgent) need for treatment, limited mobility, or precautions due to high risk of severe illness from COVID-19. Patients might have used telemedicine because of health needs and lack of in-person services during the pandemic. In contrast, we found that the number of physical illnesses and self-rated health were not associated with telemedicine use during the pandemic in our sample. A potential reason for that could be that these determinants may not reflect the actual need for medicine or telemedicine services. For example, having ever received a diagnosis of physical illnesses such as hip fracture, high blood sugar, or high blood pressure does not indicate that there currently is a higher need for treatment. Other studies that observed German samples during the pandemic also found a nonsignificant association of the presence of chronic conditions and telemedicine use [22,23]. Moreover, necessary treatment for patients with severe diseases (eg, physical examination, cancer treatment) was potentially more likely to be in person and still available during the pandemic. Future telemedicine services might be less suitable for these patient groups. Further research is needed to gain a better understanding of the possible impact of physical illness on telemedicine service use, especially in German samples.

Since few recent studies have examined the association of psychological symptoms with telemedicine use, our findings contribute to existing knowledge concerning psychological determinants during the pandemic in Germany. We observed that symptoms of anxiety, depression, or loneliness increased the likelihood of telemedicine use in middle-aged and older adults. Similar to our results, Hajek and König [30] observed a significant positive association of loneliness and telemedicine use in middle-aged and older adults during the pandemic in Germany. Likewise, Rauschenberg et al [33] found that psychological distress was associated with the current use of mobile health apps in a representative sample of youth aged 16-25 years from the German general population. Other studies with samples from the United States also observed a positive relationship of psychological symptoms with telemedicine use during pandemic times [54,55]. Therefore, it may be the case that findings regarding higher health care use in individuals with mental illness [56-60] can be applied to the field of telemedicine and the pandemic context. These initial findings illustrate the future potential of telemedicine in the field of mental health for middle-aged and older patients, since those who experienced psychological symptoms appeared to preferentially opt for telemedicine services. Moreover, mental health problems, such as anxiety or depression, have been shown to be positively associated with fear of COVID-19 [61]. This fear could also favor increased telemedicine use due to concerns of being infected with SARS-CoV-2 during in-person health care visits—this association was also found in our sample.

Additionally, other COVID-19–related determinants that were included in our sample (ie, vaccine status, COVID-19 infection history in oneself or close others, and preventive medication), were not significantly associated with telemedicine use. This is in contrast with findings from German samples that looked at younger and adult individuals during the pandemic [23,32,33] and found significant associations of COVID-19–related factors with telemedicine use (ie, higher perceived severity of COVID-19 infection; having had COVID-19 infection; subjective COVID-19–related challenges; and COVID-19–related cognitive preoccupation, anxiety, and worries). However, when looking at a similar sample to our study, which consisted of middle-aged and older adults during the pandemic in Germany, Hajek and König [30] did not find significant associations of COVID-19–related factors with telemedicine service use. This could potentially mean that middle-aged and older individuals' decision to use telemedicine was less influenced by COVID-19–related factors than in the general adult or younger German population.

Strengths and Limitations

This study is one of only a few studies that explore determinants of use of remote medical consultations in German middle-aged and older adults. The nationally representative sample of the widely acknowledged SHARE panel study provides insight into the largest age group of the German population. The data were collected during the COVID-19 pandemic and therefore account for the unique circumstances that individuals were faced with during that time.

However, some limitations should be considered. Telemedicine service use was measured using only one item, which indicated experience with remote medical consultations over the phone, computer, or any other electronic means since the outbreak of the pandemic. Therefore, we did not differentiate between different patient groups, telemedicine modalities, or frequency of use. This should be explored further in future studies. Furthermore, the survey covered a limited selection of socioeconomic, health, and psychosocial aspects. Future studies should include more extensive instruments and variables to make more reliable and comprehensive conclusions. In addition, the majority of our sample did not use telemedicine and case numbers were small for some of the included determinants. This lack of statistical power might explain why some of the tested relationships did not reach statistical significance. Consequently, future studies with very large German samples are needed. Furthermore, this analysis was based on self-reported cross-sectional data, and it is therefore difficult to identify causal relationships. Finally, we only focused on the German context. Future research should also consider cross-cultural differences in use and determinants of telemedicine to better understand potential barriers and facilitators in different cultural contexts and improve worldwide implementations.

Conclusions

To achieve high rates of use and widespread acceptance of telemedicine, it is essential to understand determinants of telemedicine service use in middle-aged and older individuals. Our study findings stress the link between psychological symptoms and telemedicine use in Germany during the COVID-19 pandemic. Middle-aged and older adults seem to have used telemedicine services according to psychological needs and health limitations. One may conclude that, especially when they had psychological symptoms, middle-aged and older individuals accepted telemedicine as a service option. While socioeconomic and social factors were not associated with telemedicine service use, the associations of other health- and COVID-19-related determinants with use behavior remain unclear.

Future (longitudinal) studies are therefore required to confirm these initial findings and clarify whether they also apply to postpandemic circumstances, where widespread in-person visit availability returned. Some patients might have used telemedicine only because they had no other option. However, remote consultations might be especially suited for specific patient groups or forms of treatment and will remain part of postpandemic routine care. Furthermore, use of (remote) blended therapy might increase in the postpandemic context, as it combines the strengths of remote and in-person visits and can be adapted to individual patient preferences. Moreover, potential differences in determinants of telemedicine use between different service types (eg, asynchronous vs synchronous services) or patient groups (eg, mental health vs oncology patients) should be further investigated. Finally, it remains to be explored to what extent determinants of telemedicine use differ from determinants of general health care use, which could help to identify target groups and appropriate fields of application for future telemedicine services. This could be examined in the postpandemic context where both forms of services, in-person and telemedicine visits, are likely to be available to patients.

Abstract

Background: The COVID-19 pandemic has accelerated the shift toward the digital provision of many public services, including health and social care, public administration, and financial and leisure services. COVID-19 services including test appointments, results, vaccination appointments and more were primarily delivered through digital channels to the public. Many social, cultural, and economic activities (appointments, ticket bookings, tax and utility payments, shopping, etc) have transitioned to web-based platforms. To use web-based public services, individuals must be digitally included. This is influenced by 3 main factors: access (whether individuals have access to the internet), ability (having the requisite skills and confidence to participate over the web), and affordability (ability to pay for infrastructure [equipment] and data packages). Many older adults, especially those aged >75 years, are still digitally excluded.

Objective: This study aims to explore the views of adults aged >75 years on accessing public services digitally.

Methods: We conducted semistructured qualitative interviews with a variety of adults aged ≥75 years residing in Greater Manchester, United Kingdom. We also interviewed community support workers. Thematic analysis was used to identify the key themes from the data.

Results: Overall, 24 older adults (mean age 81, SD 4.54 y; 14/24, 58% female; 23/24, 96% White British; and 18/24, 75% digitally engaged to some extent) and 2 support workers participated. A total of five themes were identified as key in understanding issues around motivation, engagement, and participation: (1) “initial motivation to participate digitally”—for example, maintaining social connections and gaining skills to be able to connect with family and friends; (2) “narrow use and restricted activity on the web”—undertaking limited tasks on the web and in a modified manner, for example, limited use of web-based public services and selected use of specific services, such as checking but never transferring funds during web-based banking; (3) “impact of digital participation on well-being”—choosing to go to the shops or general practitioner’s surgery to get out of the house and get some exercise; (4) “the last generation?”—respondents feeling that there were generational barriers to adapting to new technology and change; and (5) “making digital accessible”—understanding the support needed to keep those engaged on the web.

Conclusions: As we transition toward greater digitalization of public services, it is crucial to incorporate the perspectives of older people. Failing to do so risks excluding them from accessing services they greatly rely on and need.

digital exclusion; digital inclusion; older people; technology; aged; web-based; internet

Introduction

Background

The shift toward digital technologies to provide access to essential and nonessential public services, such as health care, public administrative services, utilities, financial services, and leisure, has been accelerated by the COVID-19 pandemic [1-3]. In many countries, including the United Kingdom (the setting for the research reported in this paper), this shift has also been driven by national policy in attempts to maintain access to essential services during periods of social lockdown [4-6]. Many social, cultural, and economic activities, such as appointment or ticket booking, have transitioned to web-based platforms [7], whereas many COVID-19–related initiatives, such as booking and recording COVID-19 tests and vaccinations, were primarily offered through digital platforms to the public. In particular, during the COVID-19 lockdown periods, being on the web became critical for maintaining social ties and combating loneliness [8-10].

This may be convenient for many people, and there is evidence to show that digital inclusion, accelerated by the pandemic, has increased in recent years [11]. However, although in the United Kingdom, the "digital divide" (the gap between those who do and those who do not have access to new forms of information technology [12]) may have narrowed in recent years, the impact has not been felt equally and has widened for some groups [13,14]. The digital divide remains especially wide for older adults aged ≥75 years; this is further exacerbated by living alone, having a limiting long-term condition, and being financially susceptible [15,16]. An analysis of the English Longitudinal Study of Ageing data conducted early in the pandemic (June and July 2020) showed that 45% of adults aged 52 to 64 years and 41% of adults aged 65 to 74 years used the internet more since the COVID-19 outbreak, but only 24% of those aged >75 increased their use and 9% were using it less [17].

Digital exclusion, in its broadest definition [15], relates to three connected aspects: (1) access, that is, whether individuals have access to the internet at home or elsewhere; (2) ability, that is, having the skills and confidence to participate over the web; and (3) affordability, that is, the ability to pay for infrastructure (equipment) and adequate data packages [16]. In the United Kingdom, recent data from the national communications regulator (Ofcom) suggests that 6% of UK households do not have home internet access, but this figure rises to 26% of people aged ≥75 years [18]. It is also acknowledged that an additional 2 million households are experiencing financial difficulty, and this will likely increase given the cost-of-living crisis from 2021 to 2023 [19,20]. Digital exclusion is viewed as a "super" social determinant of health [21] as it impacts a variety of areas of life, including leading to poorer health outcomes [22,23] and challenges with employment, housing, education, and finance. It disproportionately affects many people, including people with low incomes, people living in social housing, people living with disabilities, people in rural areas, and people for whom English is not their first language, as well as other marginalized groups. Although all these factors are important indicators of who is likely to be digitally excluded, age remains the biggest indicator. According to data from the UK Office for National Statistics for 2020, a total of 99% of adults aged 16 to 44 years were recent internet users compared with only 54% of adults aged ≥75 years [24]. It is vital to understand the complexities of how digital exclusion exacerbates health and social inequalities so that adequate responsive action can be considered. For example, it is not simply the case that ensuring internet connectivity will mitigate digital exclusion. There is a need to understand structural challenges; financial barriers; digital literacy; and other aspects, such as the impacts of various health conditions and disabilities and concerns about privacy and data protection [25-28].

A recent scoping review explored the barriers to and facilitators of older people's digital engagement across the spectrum of nonuse through sustained use [29]. This review found that there are substantial overlaps between barriers and facilitators; for example, lack of knowledge of digital technologies is a barrier, prior knowledge is a facilitator, perceived lack of personal capability is a barrier, and a positive attitude toward oneself is a facilitator. The review also found a substantial gap regarding the determinants of technological nonuse. Although this review provides a thorough scope of the literature, it included studies involving participants with a mean age of ≥65 years and did not offer any further stratification by age. There is a need for a more nuanced focus on older groups of older people. Current insights into digital technology use often exclude a specific focus on people aged ≥75 years. The coverage of age groups in several major reports and surveys often stops at the age of 74 years or includes all people aged ≥65 years as 1 homogeneous age category [30].

Objectives

Given the increased risk of digital exclusion among older age groups and the fact that this may have been exacerbated by the COVID-19 pandemic, it is vital to gain a deeper understanding of the use, attitudes, and preferences of people aged ≥75 years.

In the United Kingdom, this gap has been recognized as a policy priority. In Greater Manchester, a city-region in North West England with a population of 2,867,800 in 2021, as many as 1.2 million residents are estimated to be limited digital users because of exclusion or personal preferences, with a substantial proportion of these being people in later life. To address this digital divide, the Greater Manchester Combined Authority (GMCA) established a Digital Inclusion Action Network and Taskforce in October 2020 [31], with the ambition to make Greater Manchester a 100% digitally enabled UK city-region. Older adults aged ≥75 years were included as a critical population group for targeted action related to digital inclusion. The aim of the paper is to report findings from a qualitative study exploring the views of adults aged ≥75 years on accessing web-based public services.

Methods

Study Design

The National Institute for Health and Care Research Applied Research Collaboration Greater Manchester was commissioned by the GMCA to gather insight into the barriers to and facilitators of older adults' (>75 y) digital participation within the region. To address this, we conducted semistructured qualitative interviews with adults aged ≥75 years residing in Greater Manchester.

Sampling, Recruitment, and Data Collection

Purposive and convenience sampling were used to identify and recruit participants. Adapting to web-based rather than face-to-face data collection during the COVID-19 pandemic lockdown meant that we had to use an approach that allowed us to use our existing networks and recruit via several third-party organizations affiliated with the GMCA Ageing Hub. We recruited a range of older adults; these included older adults who were fully engaged and participating in many web-based activities (often enrolled in a local support program), those who were just starting to receive support to get on the web, those who were previously engaged but were now lapsed users, and those who had no interest in getting on the web or using a computer or device at all. We also recruited community support workers to learn from the approaches they used to continue to engage with their communities, particularly during the COVID-19 pandemic period (from 2020 to 2022) [32].

Data were collected via semistructured interviews (conducted by AM) with a topic guide (Multimedia Appendix 1) developed from a rapid review of the literature [33] and from input from the project oversight team.

Data Analysis

Interviews were audio recorded, transcribed, and exported to NVivo Pro (version 12) software for data management [34]. Using a thematic analysis approach [35], initial themes were identified from the transcripts and indexed to develop the analytical categories. Via a process of constant comparison [36], these categories were reviewed and refined by 2 researchers (AM and DH), and any ambiguities in the coding framework were reconciled by a thorough discussion with the research team. All interviews were then fully coded using NVivo Pro for qualitative analysis (AM and DH).

Ethical Considerations

Ethics approval was granted by the University of Manchester Proportionate Research Ethics Committee (2021-12638-20811). All interviews were conducted virtually (by telephone or other remote means agreed upon with the participants) at a time convenient to the participants; the participants provided informed consent before data collection. The data were collected between October 2021 and February 2022. All data provided was anonymised by the research team with any personal identifying information removed. All participants received a £15 'Love2Shop' voucher as a thank you for their participation in the interview.

Results

Overview

The final sample comprised 26 interviews: 92% (24/26) with older adults aged >75 years and 8% (2/26) with community digital support officers. The older adult sample had a mean age of 81 (SD 4.54; range 75-91) years; 58% (14/24) of the participants were female, 96% (23/24) were White, and 4% (1/24) were of South Asian background. Participants were sampled from 4 (40%) of the 10 local authority areas in Greater Manchester, 75% (18/24) of the participants were users of the internet (to some degree), and interviews lasted on average 23 (SD 8.51; range 8-60) minutes.

A total of 5 themes were identified as being key in understanding the barriers to and facilitators of motivation, engagement, and participation in using web-based public services. The key themes and subthemes are presented in Textbox 1 and discussed in detail in the subsequent sections.

Textbox 1. Key themes and subthemes identified via thematic analysis.

- **Theme 1: initial motivation to participate digitally**
- **Theme 2: narrow use and restricted activity on the web**
    - Preference for choice of access
    - Narrow use driven by fear
    - Lack of interest in learning new digital skills and tasks
- **Theme 3: impact of digital participation on well-being**
- **Theme 4: the "last generation"?**
- **Theme 5: making digital accessible**
    - One-to-one support
    - Mitigating physical impairments

Theme 1: Initial Motivation to Participate Digitally

Among older adults who were using the internet, it was evident that their decision to do so was often driven by a particular, recent need that motivated them to go on the web. Unsurprisingly, given that COVID-19 pandemic lockdowns reduced face-to-face social contact [32], one of the major motivators related to maintaining social connections and gaining skills to be able to connect with family and friends in other parts of the world. A participant stated the following:

> *Well, I think that's vital really [being online]. It's kept me alive in that, you know, I feel as if I'm speaking to people. It's company there. I'm never isolated because I can always get in touch with somebody. So, to me, it has literally been a lifeline.* [Participant 19, female, aged 82 years]

There was also the need and convenience of being able to access certain services during the lockdown, in particular web-based ordering of prescriptions and shopping. A participant said the following:

> *That's the most brilliant thing I've ever used, Amazon. You don't even have to go outside the door.* [Participant 13, female, aged 75 years]

Theme 2: Narrow Use and Restricted Activity on the Web

Preference for Choice of Access

Although three-quarters (18/24, 75%) of the older adults interviewed were digitally engaged (to some extent), many of them were "narrow" users [11,15], in that they participated only in a handful of web-based activities or tasks. The participants reported very little interaction with web-based public administrative services (eg, local and national government services such as disabled parking applications, passport applications, driving licenses, and benefit applications). The participants were more positive about some aspects of web-based health services, particularly ordering prescriptions. When asked why they preferred to order prescriptions over the web, some commented that the system is "straightforward to use" and that they "find it very useful" to be able to order over the web, with some noting that if they did not do it over the web, it would involve them going to the surgery, "which is a bus ride away." However, when asked about the prospect of more public services moving to web-based access, most participants—both those who used the internet and those who did not—were in consensus that digital should not be the only option provided by organizations to access a service, for a variety of reasons. A participant stated the following:

> *The jabs that I had, it was telling me to go online, that's an example, and I phoned up my doctor's surgery and said, look, I can't go online, right, so they did the appointment for me. And also I had a bit of an argument with [large retail pharmacist named] and other stores like [pharmacy chain] because the flow thing, you know the flow thing, [Lateral Flow Test- rapid antigen test for COVID-19] you've got to go online although you didn't get any because they were sold out, they were out of them all the time...it's just ridiculous, nobody thinks about the older people.* [Participant 14, male, aged 83 years]

Another participant said the following:

> *Personally I don't think you can beat seeing the doctor face to face, they can pick up on your body language, colour of your skin. I think there's lots of things that you can pick up on face to face. So, I do think seeing the doctor face to face is essential for the majority, I really do. I think going online for some things is good, but I do think if you're not very sure about what you're doing, I think...I would imagine it could cause a lot of stress, if there's no alternative...* [Participant 24, female, aged 76 years]

Narrow Use Driven by Fear

Many participants adopted a granular approach to use, in which they had specific and limited web-based tasks they would undertake within particular domains of activity, such as banking or shopping. For example, many were happy to log on to banking apps or websites and view their balance—that is, to monitor their account—but stopped short of undertaking any transactions. Reasons for this limited use included a concern about having personal details "out there," pressing the wrong button and sending the money to the wrong place, and a fear of being scammed. A participant stated the following:

> *...No, I won't do finance at all, PayPal or anything, I really don't trust it because there are so many scams around, erm, I just think it's too easy, if you press the wrong button and its gone to Timbuktu, no I definitely won't have anything to do with online banking, and it's a shame because I know that I would shop online and it would save a trip to the Post Office or the bank or whatever, but I just wouldn't trust it...* [Participant 7, female, aged 79 years]

Another participant stated the following:

> *...I know I've got the banking online on the tablet if I want to use it for transactions, but I'm just quite happy seeing what I've got at the moment. I don't really feel confident enough to do transactions. I always worry, God if I do something wrong, I'm in trouble.* [Participant 24, female, aged 76 years]

In addition, another participant said the following:

> *I just feel as though I don't want to be divulging too much information about myself to the wide world, if you know what I mean.* [Participant 11, female, aged 87 years]

Community digital support officers highlighted fear and concerns around the safe sharing of personal information as a key barrier to engagement among older adults. In particular, media reports highlighting scams and frauds were deemed to exacerbate this barrier. The community officers were aware of the need to inform people of the potential risks, but "more positive campaigns about [the benefits of] using the internet [for older people] are needed" (digital support officer 2), as the negative stories reported on television were seen to deter older adults from benefiting from available web-based services. They reported that the word "scam" really "puts fear into older persons" and the media "cherry pick" the very worst scams to the point that people are convinced that these are happening on their very doorsteps:

> *...And this is no joke, I have had people say to me that they think there are people outside their house on a laptop in their car, you know they are parked on the*

> *street trying to use their Wi fi to scam them. That sort of thing.* [Digital support officer 1]

Lack of Interest in Learning New Digital Skills and Tasks

Where participants did use web-based services, once their initial needs had been met and they had gained the necessary skills to complete an activity, many lacked interest or were reluctant to undertake additional tasks or learn new activities. They were happy to maintain the skills and knowledge gained to undertake the tasks or activities that initially prompted them to get on the web. A participant stated the following:

> *I wouldn't use it for much really. I'm not ambitious about it. I have done what I wanted to do and anything else that I gained, it's a bonus.* [Participant 10, female, aged 91 years]

Another participant stated the following:

> *Are there any tasks that you haven't yet done online that you think you might want to try or you want to do in the future?* [Interviewer]
>
> *No, because I can use the computer and I can use the phone and the tablet for anything that I personally need to do.* [Participant 20, male, aged 76 years]

In addition, another participant said the following:

> *And are there things that you would want to do, that maybe you don't yet know how to do, or you'd need some support to be shown how to do it?* [Interviewer]
>
> *I don't think so. I think I do what I need to do...* [Participant 13, female, aged 75 years]

Theme 3: Impact of Digital Participation on Well-Being

For some participants, who were not digitally engaged and had no interest in getting on the web, social connections and social interaction were cited as a reason for not engaging. One participant stated the following:

> *No, I just think I've never been interested. I feel that if I did use something I'd be on my own doing it, and I don't like being on my own. Years ago I had one of these knitting machines and I had it for a while, and I hated it because it meant I was sat on my own knitting, and I don't want to do that. I like to go out and meet people while I can.* [Participant 3, female, aged 90 years]

Another participant stated the following:

> *This is the problem, lots of people don't talk anymore. They know...they don't know any other way of corresponding, getting in touch with people. I mean they go on the internet. They text, they don't talk...I mean you go out for a walk and you can more or less guarantee at least 50 per cent of people walk around with their phone.* [Participant 5, male, aged 83 years]

The participants also spoke about digital engagement in relation to aspects of physical and mental well-being. For example, for some, not using web-based services, such as to make a general practitioner (family physician in the United Kingdom) appointment, was seen as a positive because they had to get "out of the house" and, in doing so, had the benefit of getting "a little bit of exercise." For others, there was the acknowledgment of the advantages of being able to shop over the web during lockdowns, but now that restrictions had lifted, they had reverted to their preference to shop in person, which again was seen as an opportunity for exercise. Others talked about how it was sometimes "too easy" to depend on the internet to find out information that they could not immediately call to mind, and this was spoken about in terms of brain health and keeping the mind active. A participant stated the following:

> *So, in terms of doctors' appointments and things, you can still get to the surgery or you could ring. Is that something that you prefer to do?* [Interviewer]
>
> *Yes, I can ring on my landline and talk to a receptionist, or just toddle myself down to the surgery and go face to face with them, you know...Not that I would get an appointment any quicker with the doctor but, you know...And it gives me a little bit of exercise.* [Participant 18, female, aged 79 years]

Another participant stated:

> *I've gone back to going out because you get a little bit of exercise, you know. So yeah, I don't shop for groceries online anymore, no, I always go to the shop.* [Participant 20, male, aged 76 years]

Another participant stated the following:

> *...A couple of days ago, it sounds ridiculous this...I thought, what's the name of that pub at the top of Lancashire Road? I mean, what the hell I thought about that for, and I could not for the life of me, and I thought, no...remember it, because you do know it. And this morning, it's come to me, The Hinds Head it's called.* [Participant 13, female, aged 75 years]
>
> *Okay, so you resisted the urge to find out?* [Interviewer]
>
> *I did, yes, I did. I thought, no, that's too easy.* [Participant 13, female, aged 75 years]

Theme 4: The "Last Generation"?

Many participants, particularly those who were not on the web, spoke about barriers regarding generational issues and how they felt they might be the "last generation" to experience difficulty with digital participation:

> *But I do think that we're the last generation, almost the last generation that this will affect. Because from being babies now they have iPads now and what-have-you, don't they? It's just second nature to them. It puts you to shame when you watch them.* [Participant 12, female, aged 81 years]

This often went hand-in-hand with the perception that these difficulties were unique to their generation and that the younger generations experienced little difficulty in adapting to or embracing new technology. A participant stated the following:

> *Well, do you know what, to be honest with you, I could say I'm at the end of a generation. Because if you*

> *think of the youngsters today now and you think of...like my sons have no problem with this, that's another generation, and then the one below that is the youngsters, yeah, this will never happen again...it's unlucky, I'm at the end of a generation.* [Participant 14, male, aged 83 years]

Another participant stated the following:

> *The youngsters, from school onward, they know nothing but the internet. So everything is being geared toward them. And we older people, in my generation, have had to start learning various things which become harder and harder. It's second nature to younger people, to the 30s, 40s.* [Participant 5, male, aged 83 years]

Theme 5: Making Digital Accessible

For those older adults who were participating (to some extent) in web-based activities, it was important to discuss barriers and facilitators that might require consideration to keep older adults engaged and supported.

One-to-One Support

Participants emphasized the importance of having patient assistance while navigating tasks on the web. They also highlighted the value of receiving written instructions and having tasks demonstrated multiple times. The participants also valued the one-to-one support given to them but stressed that this needed to be ongoing support, noting that sometimes they would "get the hang of" one task (eg, shopping) only to find that the next time they logged on to the website, the landing page may have changed, which would "throw them off" and result in them feeling unsure whether they could continue in the manner they had been shown. A participant stated the following:

> *I'd love someone to sit and show me so I can write it down and if I get stuck I know how to do it myself.* [Participant 19, female, aged 82 years]

Other participants stated the following:

> *She writes things down for me, because I can't always remember what I've been told. If I've got it there in black and white then I can follow it. It does help.* [Participant 2, female, aged 76 years]
>
> *Yeah, sometimes it doesn't click immediately and you need them to go over it again. So you need somebody who's got a little bit of patience.* [Participant 21, male, aged 78 years]
>
> *...I could do this before and now I'm having too many problems. And it's the same with...so what it is, is what they call navigating the website becomes more difficult when they change the format, and that I find very, very annoying.* [Participant 8, male, aged 75 years]
>
> *You know, the system I have for my laptop, when they start changing things I get very annoyed and I think, oh, I've got to figure out how to get out of that or whatever it is, yes...I'm just getting really annoyed when I have to figure out how all of these things work again.* [Participant 1, female, aged 76 years]

Mitigating Physical Impairments

In addition, we asked respondents about physical impairments that might currently (or potentially in the future) make digital participation difficult. Arthritis, cataracts, Parkinson disease, diabetes, and tremors were all listed as having an effect on current internet use. Regarding future impact, although acknowledging uncertainty about how this could develop—"my eyes are not great. Yeah, I don't know how that's going to go." (participant 1, female, aged 76 y)—many of the respondents were quick to point out potential solutions to overcome these; for example, some had already been shown how to locate and use the microphone function in Google Assistant, how to use predictive text, and how to increase the font size of the text on the screen. Many respondents had already taken these issues into consideration when deciding on the type of device to use. A total of 61% (11/18) preferred to use tablets, and this was for several reasons, including their portability and ease of use. One participant stated the following:

> *I also like the fact that I can have it on my knee in the lounge or the chair that I'm in.* [Participant 19, female, aged 82 years]

Discussion

Principal Findings

The aim of this project was to explore the views of adults aged ≥75 years on accessing web-based public services in response to a policy initiative to further understand older people's digital behavior and engagement. The analysis of the semistructured interviews identified 5 themes that were key to understanding some of the barriers and facilitators experienced by the older adults participating in this project. The key facilitators included responses to meeting certain needs (particularly during national lockdowns) such as food shopping, ordering prescriptions, and staying connected with family and loved ones. The identified barriers included fear of scams and misuse of personal information, lack of ongoing support to maintain or learn new skills, preference for face-to-face interactions (especially for health appointments), and a wider generational belief (held by many) that difficulties getting on the web were "unique" to their generation and that older adults found it difficult to adapt or embrace new technology. Crucially, we also found that the potential unintended consequences of the benefits offered by digital technologies to access public services could be seen as a barrier to their use. In particular, this included their ease of access to information and their convenience, which were seen to reduce the need for people to engage cognitively elsewhere or to leave the house, thereby denying them exercise and social interaction opportunities.

Theoretically, there are several models that attempt to explain digital engagement and uptake. Two of the most well-known and widely used are the Technology Acceptance Model [37] and the Unified Theory of Acceptance and Use of Technology [38]. However, these models are primarily used to quantify the acceptance of technologies rather than to provide qualitative insights [29]. One straightforward categorization to facilitate an understanding of different "types" of older adults' digital behavior suggests they may fall into 1 of 4 groups—"engaged," "disheartened," "transitional," or "uninterested" [39]. "Engaged" refers to those older adults who believe they are capable of learning and perceive a value in using digital technology, that is, believe the internet is useful to them personally. "Disheartened" users also believe the internet to be useful and usually have more need for digital services but are worried about safety and associated risks and feel less confident in their ability and skills. "Transitional" older adults often have the highest need for use of digital services, but they are frequently lapsed users with narrow, if any, experience of digital engagement other than for social media purposes. "Uninterested" older adults do not perceive value in web-based activity and often have others access websites on their behalf. They usually have strong social connections and can be resistant to using the web. Although these categories are helpful in starting to think about digital behavior and potentially offer insights into how to support different "types" of older adults, the interviews presented here show that older adults' digital behavior may not always be neatly classified into 1 type of user versus another. A large proportion of the respondents could be classified as digitally "engaged" in the sense that they were keen to go on the web, felt capable of learning, and had many of the skills deemed "essential" [40] for digital participation.

However, it was not possible to map these older adults to 1 "type" as there was often an overlapping of categories (particularly "engaged" and "disheartened"), which required a more nuanced understanding of what digital participation means for older adults. During discussions around the motivations behind getting on the web for our older adults (particularly during the pandemic), the initial "engagement" was evident; however, this engagement for many appeared to ebb away, and subsequently, many of them fitted the descriptions for other categories, for example, "disheartened" users. Although many of our older adults admitted a perceived value in accessing the internet and participating digitally (ie, "engaged"), a lack of confidence, lack of support, or fear of sharing information would often result in them becoming "disheartened," disengaging from aspects of internet use, and not taking full advantage of the services available to them (eg, restricted use of web-based banking). Understanding that many older adults will not "fit" into 1 category highlights the need for a more individualized and nuanced approach to tailoring digital support services [41].

When considering the wider impacts of digital technology transformation, older adults' limited use of web-based activities such as banking and concerns over data protection were also amplified by a lack of confidence and skills. Added to this were the needs of older people to get out and to socialize, with health-related appointments, shopping, and banking forming part of how participants stayed active and well in their communities. Work undertaken with a range of individuals, including older adults, during the pandemic found that a move to internet-based general practitioner and health appointments was sometimes problematic for this group for a variety of reasons, including a lack of skills and confidence, no interest in engaging on the web, and a lack of trust [42-44]. In addition, web-based platforms provide a very limited 2D view of a person and their circumstances [45,46]. As such, it is critical that people are encouraged to leave their homes and are able to access and attend face-to-face appointments. We already know that far too many older people are sedentary and do not achieve the recommended levels of physical activity [47,48]. This worsened during the COVID-19 pandemic, negatively impacting health [49]. Therefore, adding to this burden by substituting physical activity with digital engagement should be avoided.

The pandemic and its successive lockdowns have moved much public and social activity to web-based platforms. Digital exclusion is often discussed in terms of "hard" (eg, never having used the internet or having no internet access) or "soft" (eg, improving digital engagement, skill level, or confidence) [7]. These changes driven by the pandemic are said to have improved "hard" exclusion for the general population. However, in terms of improving the "softer" areas of exclusion, the pandemic has done little to close the digital divide, particularly for older adults [50]. There is evidence to show rates of internet use increasing faster among younger cohorts and declining among older cohorts, demonstrating the digital divide naturally closing in time as generations who experience high levels of digital exclusion are replaced by younger generations who embrace and adapt to technological change [51,52]. This idea came through strongly in the interviews conducted, with many older adults expressing this view. However, it was not clear whether they attributed this to the impact of the rapid digitalization brought about by the pandemic or to the impact of a more general move toward digitalization over a longer period. However, the rapid development of technology combined with an individual's changes in physical health has been shown to worsen feelings of being unable to keep up or feeling too old to embrace new technology among older adults [53]. There is also the view that older adults can often internalize agism [54] and accede to the stereotype that they are not able to master technology and so do not attempt it. It seems plausible that the rapid increase in digitalization during the pandemic may have exacerbated these feelings of being left behind, but it is also important to note that inaccurate perceptions of young people as fluent technology users may be driven by a broad range of factors, including media representation, agism, and other social constructs related to digital inclusion and exclusion. Although the impact of the 2020 to 2023 COVID-19 pandemic brought many of these issues to the forefront in discussions around digital participation and the impact of the divide for older adults, these are not new issues related only to older adults' experiences during the pandemic [50].

This study highlights several digital technology features that have delivered positive outcomes for people aged ≥75 years. Among those we interviewed, there was a preference toward using tablets [55] as well as a willingness to order prescriptions and engage in web-based shopping. Shared learning across public institutions on aspects of digital technology transformation that have been delivered successfully for adults aged >75 years would be beneficial. For example, what can we learn from the experience of web-based ordering of prescriptions that could inform other public service digitalization infrastructure and processes? There is also the importance of ensuring digitalized services are fully accessible to all, including those living with long-term health conditions that may impact their ability to use digital devices (eg, arthritis) or access content easily (websites, text, etc). For older adults who wish to participate on the web, building confidence in undertaking tasks, such as banking, via support that is task focused and repeated is crucial [56,57].

Strengths and Weaknesses

Current data and insight into digital technology use may exclude people aged ≥75 years or may lack a specific focus on this age group. Often, available data on older adults' use stops around the age of 74 years or it provides information on all individuals aged ≥65 years. Given the increased risk of digital exclusion among older age groups and the fact that this may have been exacerbated by the COVID-19 pandemic, it is vital to gain a deeper understanding of the use, attitudes, and preferences of people aged >75 years. Although this research was relatively small in number, its strength is that it focuses on those aged >75 years (average respondent aged 81 years). A key message to take away from the work is one of choice: that those aged ≥75 are not digitally homogenous but rather require a range of options, both digital and nondigital, that will enable them to engage in ways that work best for them and do not further exacerbate digital inequalities [23,58-60]. A key finding adding to the literature [29] is that the benefits of technologies, such as ease of access to information and convenience, may actually have unintended consequences that put older adults off using them. This includes a desire among some participants to continue to access some public services in person for the indirect benefit of physical activity while doing so. This finding is particularly important in light of other healthy aging policies that promote physical activity to improve disability-free life expectancy [61].

Future research should investigate the experiences of older adults from ethnic minority groups. Although this study aimed to be as inclusive as possible, the recruitment of older adults from diverse ethnic minority groups proved challenging. It would also be beneficial to examine the influence of age-related sensory changes on digital inclusion. Investigating the preferences and experiences of older adults with hearing or visual impairments would provide valuable insights. Physical distancing and stay-at-home restrictions during pandemic lockdowns meant that our recruitment strategy had to be adapted to make use of our existing networks and ties with third-party organizations to be able to recruit older adults for the study. A reliance on web-based means of recruitment resulted in a more digitally engaged sample of older adults being recruited than originally intended, although the levels of engagement varied among the older adults. In an ideal setting, a study of this nature would have been conducted with older adults in a face-to-face setting rather than via telephone or video interviews [62-64]. However, data collection during the COVID-19 pandemic meant this approach was not possible, and this will have had an impact on the final sample of older adults, with a larger proportion of adults who were digitally engaged taking part.

Conclusions

The shift to digital delivery of public services, both throughout the pandemic and more generally as a driving force for future service provision, requires a focus on the needs and preferences of older people so that they are not excluded from service access. Mitigation against digital exclusion is a core component of 1 of the strategic priorities to reduce health inequalities across England [52]. It is vital that the needs and preferences of people of all ages are considered, particularly those aged >75 years, who are often underrepresented in research. Attempts to classify "types" of digital users may be a useful heuristic for thinking about digital engagement, but the boundaries between categories are permeable and complex. Those aged ≥75 years are not a digitally homogenous group but rather require a range of options, both digital and nondigital, that will enable them to access services without further exacerbating digital inequalities.

Acknowledgments

This project was funded by National Health Service (NHS) England through the Greater Manchester Health and Social Care Partnership and supported by the National Institute for Health and Care Research (NIHR) Applied Research Collaboration Greater Manchester (NIHR200174) and an NIHR Senior Investigator Award to CT (NIHR200299). The views expressed are those of the authors and not necessarily those of the NHS, the NIHR, or its partner organizations. The funders had no role in the design of the study; in the collection, analyses, or interpretation of data; in the writing of the manuscript; or in the decision to publish the results. The authors would like to thank all participants for their valuable insights and time in taking part in the interviews. The authors thank Alison Littlewood for her enthusiastic program administration and the Greater Manchester Aging Hub at the Greater Manchester Combined Authority for their support throughout this study.

Authors' Contributions

The conceptualization and design of the study was undertaken by AM, JM, and AH. Data collection was undertaken by AM. AM and DH coded and analyzed the data. AM drafted the original paper as first author and DH, JM, AH, CET, and CT worked on reviewing and editing subsequent drafts. All the authors have read and agreed to the published version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Cognitive stimulation therapy (CST) is an evidence-based, group psychosocial intervention for people with dementia, and it has a positive impact on cognition and quality of life. CST has been culturally adapted for use globally. It was developed as a face-to-face intervention but has recently been adapted for online delivery.

Objective: In this study, we aimed to explore the feasibility and acceptability of online or virtual CST (vCST) delivery in India and Brazil, emphasizing barriers and facilitators to implementation.

Methods: A single-group, multisite, mixed methods, feasibility study was conducted, with nested qualitative interviews. Primary feasibility outcomes were recruitment rate, attendance, attrition, acceptability, and outcome measure completion. Exploratory pre- and postintervention measures, including cognition and quality of life, were assessed. Qualitative interviews were conducted with people with dementia, family caregivers, and group and organizational leaders following intervention delivery, and the data were analyzed using the Consolidated Framework for Implementation Research.

Results: A total of 17 vCST group sessions with 59 participants were conducted for 7 weeks, with 53% (31/59) of participants attending all 14 sessions. Attrition rate was 7% (4/59), and outcome measure completion rate at follow-up was 68% (40/59). Interviews took place with 36 stakeholders. vCST was acceptable to participants and group leaders and enabled vital access to services during pandemic restrictions. While online services broadened geographic access, challenges emerged concerning inadequate computer literacy, poor technology access, and establishing interpersonal connections online. Exploratory, uncontrolled analyses indicated positive trends in quality of life but negative trends in cognition and activities of daily living, but these results were not statistically significant.

Conclusions: vCST demonstrated feasibility and acceptability, serving as a crucial resource during the pandemic but raised challenges related to technology access, computer literacy, and long-term implementation. The study highlights the potential of vCST while emphasizing ongoing development and solutions to address implementation challenges.

KEYWORDS

psychosocial; intervention; technology; COVID-19; LMIC; low and middle income countries

Introduction

Background

Dementia affects more than 57.4 million people worldwide [1]. People with dementia in low- and middle-income countries (LMICs) make up 60% of all global cases [2]; however, high-income countries account for around 74% of global expenditure on dementia [3]. There are an estimated 1.8 million people >60 years of age with dementia in Brazil [4] and 8.8 million in India, representing 5.8% and 7.4% of people >60 years of age, respectively [4-6]. While demographic and socioeconomic factors differ between Brazil and India, both countries experience low diagnosis rates, limited access to specialist treatment and care, high levels of stigma, and a lack of dementia awareness [7-9].

Worldwide, pharmacological treatments for dementia remain limited, so nonpharmacological interventions are needed to address cognitive and behavioral symptoms of dementia and improve quality of life for people with dementia and their families [10]. Many interventions are developed, but only a few are delivered at large scale and have been adopted in routine practice [11].

Cognitive stimulation therapy (CST) is a brief, manualized group program which has been found to improve cognition and quality of life in people with mild to moderate dementia [12]. It comprises themed activities that stimulate and engage participants in a social group environment led by a trained facilitator through tasks such as physical activity, word association, and discussion of current affairs [13]. Despite evidence for its effectiveness [12], cost-effectiveness [14], and its successful cultural adaptation internationally in more than 35 countries [15], CST is yet to be implemented in routine practice outside of the United Kingdom [16,17]. The 2022 World Alzheimer's Report recommended further research and implementation of CST globally [18].

This study was conducted as part of the CST-International research program, which explored the implementation of CST in 3 LMICs [19]: Brazil, an upper middle-income country; (2) India, a lower middle-income country; and (3) Tanzania, a low-income country [20]. In each country, research teams had previously translated and culturally adapted CST and carried out feasibility studies of face-to-face CST [16,17].

CST was developed as a face-to-face intervention. However, during the CST-International study, access to face-to-face health care services was rapidly restricted due to the COVID-19 pandemic [21]. CST started to be delivered virtually in international settings including the United Kingdom and New Zealand [22,23], but a standardized protocol was not available. An international collaboration resulted in a framework for global delivery, which was field-tested in Brazil and India, alongside the United Kingdom, Hong Kong, and Ireland [24].

Objectives

This study aimed to build upon the initial development and field-testing of the online or virtual CST (vCST) protocol in Brazil and India, with a focus on feasibility, acceptability, and implementation. Therefore, the aims of this study were to (1) explore the acceptability of vCST to people with dementia, family caregivers, CST facilitators, and service managers in Brazil and India; (2) test the feasibility of online recruitment, delivery, and assessment for CST in Brazil and India; and (3) explore factors affecting the implementation of vCST.

Methods

Design

This study was a single-group, multisite, mixed methods, feasibility study, with pre- and postintervention outcome measures followed by semistructured interviews with people with dementia, caregivers, and intervention group leaders.

Methodological Framework

This study is guided by the Consolidated Framework for Implementation Research (CFIR) [25]. The CFIR is a determinant framework, which incorporates domains that are hypothesized or found to influence implementation outcomes and has been applied in LMIC settings [26]. The five domains relate to (1) intervention characteristics (eg, evidence strength and quality as viewed by stakeholders and its core and adaptable components); (2) outer setting (eg, local attitudes to the condition of interest as well as external partnerships and financing); (3) inner setting (eg, available organizational resources and staffing); (4) characteristics of individuals involved in implementation, their need for the intervention and their capability, availability, and motivation to be involved (based on the capability, opportunity, and motivation behavior model) [27]; and (5) process of implementation (eg, assessing needs of intervention recipients, planning, and tailoring strategies). Use of the CFIR as a deductive qualitative framework enables comparisons of barriers and facilitators in other settings and for other interventions.

Participants

People with mild to moderate dementia, supported by their family caregivers, took part in vCST group sessions. For the qualitative component, people with dementia, caregivers, group leaders, and organizational decision makers were invited to participate in qualitative interviews following the completion of the vCST groups.

Setting

In Brazil, the study site was a psychology department at a university in Rio de Janeiro. In India, the study site was a mental health nongovernmental organization (NGO) in Chennai, offering outpatient, inpatient, and day center services for people with dementia. Both sites had previously been involved in cultural and virtual adaptation of CST [16,17,24] and therefore already had access to face-to-face CST manuals, vCST guidance, and CST trainers and facilitators.

Recruitment

In Brazil, recruitment took place through partnerships with memory clinics and NGOs, advertisements on social media and local media, and snowball sampling. In India, people with dementia were recruited from the patient caseload at the NGO, with additional promotion through caregiver support groups and mobile-messaging groups.

The inclusion criteria for people with dementia at both sites were as follows: they must (1) meet the ICD-10 criteria for dementia as assessed by a trained clinician [28], (2) be rated as having mild to moderate dementia on the Clinical Dementia Rating Scale [29], (3) have sufficient hearing and vision to follow conversation and comment on visual material, and (4) have the ability to participate in a online group for 1 hour.

Intervention Procedure

People with dementia were allocated to a vCST group. The vCST intervention was delivered according to the culturally adapted CST Brazil and India manuals [16,17], which had been further adapted according to the recently developed protocol for online delivery of CST [24]. Groups took place twice weekly over 7 weeks via Zoom videoconferencing software (Zoom Video Communications) between February 2021 and September 2022. Each group consisted of 3 to 5 participants. In Brazil, participants needed to use their own devices, whereas in India, devices were loaned from the NGO if needed. In Brazil, the language of instruction was Brazilian Portuguese, and in India, it was Tamil or English. Group facilitators were trained by site leaders and worked in pairs to deliver the intervention. In Brazil, the group leaders were 2 psychologists, a gerontologist, and 8 trainee psychologists. In India, the group leaders were 3 psychologists and a nursing assistant.

Feasibility Outcomes

The following prespecified main outcomes relating to intervention acceptability were adapted from the study by Proctor et al [30]:

- Recruitment rate: the recruitment target of 50 participants in Brazil and 15 in Chennai was intended to be achieved by September 2022. This target was calculated pragmatically based on available time and resources in each site and was deemed suitable to run enough vCST groups to explore feasibility, acceptability, and implementation issues.
- Attendance: overall attendance rate of >60%, based on the international team's judgment and experience of running CST groups and supporting people with dementia in each setting.
- Attrition: retention rate of at least 75% of participants to the follow-up, again based on the team's previous experience and judgment.
- Acceptability of intervention: this will be assessed through semistructured interviews (see the Semistructured Interviews section).
- Outcome measure completion: the inclusion of cognition, quality of life, activities of daily living, and caregiver burden measures are in line with those used in previous trials and studies of CST [12]. The main goal of the outcomes was to assess the feasibility and acceptability of collecting these data.

Outcome measures were translated, back-translated, and finalized by bilingual committee review. The following pre- and postintervention measures were completed by people with dementia:

- The Alzheimer's Disease Assessment Scale-Cognitive Subscale, an internationally used 21-item measure of cognitive function [31]
- The World Health Organization Quality of Life Brief Version, a 26-item quality-of-life measure addressing 4 domains: physical health, psychological health, social relationships, and environment, which was developed for use in LMICs [32]
- Alzheimer's Disease Cooperative Study-Activities of Daily Living Scale, a 23-item scale that addresses basic and instrumental activities of daily living and has been culturally adapted for use in Brazil [33,34]. This scale was used in Brazil only
- Scale for the Instrumental Activities of Daily Living in the Elderly, an 11-item scale developed in South India that addresses cognitive and physical disability [35]. This scale was used in India only

Family caregivers completed the following:

- The Zarit Burden Interview (ZBI), a widely used 22-item self-report measure of strain and stress [36].
- Dementia Caregiver Experience Scale, a 17-item measure to assess stress and strain (personal communication by Vaitheswaran, 2023), was included due to previous issues with the cross-cultural validity of the ZBI, which has been found to underestimate burden in LMIC settings [37].

Semistructured Interviews

To gather in-depth information about intervention acceptability, feasibility, and experiences of implementation, semistructured interviews were conducted with stakeholders. People with dementia and caregivers from the first 2 vCST groups in Brazil (12 dyads) and all vCST groups in India (15 dyads) were invited to take part in dyadic interviews. A convenience sample of group leaders from Brazil and India (n=7) and organizational decision makers (n=2, India only) was invited to take part in one-to-one interviews.

Interviews with people with dementia and caregivers were conducted in the language of vCST group instruction (English, Tamil, or Brazilian Portuguese) and were led by a researcher from the respective institution who had not facilitated the group to reduce response bias. Interviews with group leaders and organizational decision makers were conducted in English. To reduce response bias, these were led by UK-based researchers who were not members of the immediate project team. All interviews took place over videoconferencing software.

On the basis of constructs from the CFIR, the interview guide was developed by researchers and clinical psychologists, with questions relating to the participants' experience of taking part in the vCST group, experience of using a online platform, and barriers and facilitators to involvement.

Analysis

Quantitative

Primary analysis was descriptive and assessed recruitment, retention, and outcome measure completion. The pre- and postintervention outcome measures, that is, means and mean differences (calculated through paired 2-tailed *t* tests), were reported descriptively. Effect sizes were calculated using Cohen *d*. Statistical analysis was performed using SPSS (version 29; IBM Corp). All data were pseudoanonymized with a unique participant identification number.

Qualitative

Transcripts in Brazilian Portuguese or Tamil were translated before analysis. First, the researchers read the transcripts for data familiarization. We used a framework analysis approach to code the transcripts using inductive thematic analysis [38] and mapped inductive themes onto the CFIR. This enabled us to capture themes that were not covered by the CFIR. Transcripts were coded independently by 2 researchers using NVivo software (Lumivero), who met regularly to ensure that they were approaching the data in a similar way and then agreed on a final coding framework. Any discrepancies were examined and resolved through discussion. An exception is the interview transcripts of caregivers in India, as it was coded by an individual reviewer using Atlas software (Observational Health Data Sciences and Informatics) and discussed with a second researcher.

Ethical Considerations

Ethics approval was granted by the relevant body in each country. In Brazil, an ethics amendment was granted by the Federal University of Rio de Janeiro Institute of Psychiatry research ethics committee (ref: 57019616.5.1001.5263). In India, approval was granted by the institutional ethics committee at Schizophrenia Research Foundation; SCARF: Chennai (SRF-CR/17/0CT-2020). Informed consent was received from people with dementia and their caregivers upon recruitment. Participants did not receive compensation.

Interviews were recorded with consent and transcribed. All transcripts were pseudoanonymized with a unique participant ID number, and any identifying information was removed during transcription.

Results

Feasibility Outcomes

Recruitment Rate

A total of 59 participants were recruited to vCST groups, which was 91% of the target figure of 65 participants. Participant demographics are outlined in Table 1. In Brazil, 12 group sessions took place with a total of 44 participants between April 2021 and November 2022. In India, 5 group sessions were conducted with 15 participants between February 2021 and February 2022. This represents an average of 3.6 participants per group across both sites.

[a] Not applicable.

[b] Missing data for Brazil: caregiver age, n=7.

[c] Missing data for Brazil: relationship to person with dementia, n=1.

[d] Missing data for Brazil: living with person with dementia, n=7.

Attendance

In Brazil, 52% (23/44) of participants attended all 14 sessions, and in India, 53% (8/15) of participants had full attendance.

Attrition

In Brazil, the attrition rate was 9% (4/44), denoting the percentage of participants who did not complete the vCST program due to various reasons: caregiver unavailability to support the participant (n=2, 50%), hospitalization due to COVID-19 (n=1, 25%), and to go on a vacation (n=1, 25%). There were no dropouts from vCST groups in India.

Outcome Measure Completion

Researchers completed preintervention outcome assessments with all people with dementia; however, some caregivers (3/59, 5%) were unavailable to provide preassessment measures. Retention of people with dementia to follow-up was 89% (39/44) in Brazil and 93% (14/15) in India. In India, 87% (13/15) of caregivers completed all follow-up assessments, but this figure was lower in Brazil (31/44, 70%). This was attributed to the caregivers being occupied with family and work commitments, particularly at a time of increased pressure during the pandemic. In addition, some people with dementia did not have 1 named caregiver and were supported by many family members or paid caregivers who did not always feel that they could provide accurate information. Overall, 68% (40/59) of participant dyads across both sites completed all postintervention outcome measures. No measures caused distress, and no measures had individual items missing.

Pre- and postintervention means and mean differences are outlined in Table 2. Analyses were exploratory and not powered to detect specific changes. The results suggest a small decrease in cognitive ability from baseline to follow-up. Small improvements across quality-of-life domains were observed in people with dementia. We observed moderate reductions in the activity of daily living ability across all domains in both sites. Conflicting outcomes were observed in caregiver burden outcomes, with a small reduction in burden scores on the ZBI but an increase in burden scores according to the Dementia Caregiver Experience Scale measure.

Multimedia Appendix 1 presents results by country. The direction and magnitude of change were similar across both sites; however, notable differences emerged: cognition where the decrease was smaller in India, quality-of-life score (social relationships) where the increase was smaller in India, and quality-of-life score (psychological and environment domains) where a reduction was observed in India compared with an improvement in Brazil.

Table 2. Pre- and postintervention outcome measures[a,b].

Outcome (range)	Preintervention measures		Postintervention measures		Mean improvement (pretest-posttest)			
	Values, n (%)	Values, mean (SD)	Values, n (%)	Values, mean (SD)	Values, n (%)	Mean difference (95% CI)	*P* value	Effect size (95% CI)

Qualitative Results

Overview

A total of 36 qualitative interviews were conducted. In Brazil, 12 people with dementia and their caregivers took part. In India, interviews were conducted with 15 people with dementia and caregivers. This comprises all participants from the first 2 vCST groups in Brazil, and all participants from the 5 groups in India. In addition, 4 group leaders from Brazil took part in interviews, and from India, 3 group leaders and 2 organizational decision makers from the NGO in India. All participants who were invited to the interviews agreed to take part.

Guided by the CFIR, we explored 2 main areas in the analysis: (1) acceptability of vCST and (2) barriers and facilitators to implementation.

Acceptability of vCST

All interview participants were asked directly about their experiences of taking part in vCST and were asked to reflect on how it compared to previous face-to-face activities. Overall, participant and caregiver evaluation of vCST was positive, with key benefits relating to providing occupation, enjoyment, and social interaction at the time of isolation:

> *I liked her activeness and purposefulness...that itself is important. Earlier she used to simply sit but now she has something to do, so that kind of purposefulness is really appreciable.* [Caregiver 4, India]
>
> *We talk and such in the house, but we are only a few here. Now my family is almost just me and him...[the] television doesn’t interact.* [Caregiver 8, Brazil]

> *At first I didn't want to attend the sessions (laughs), I fought, I wanted to hit everyone, but I liked it.* [Person with dementia 1, Brazil]

The remote delivery and national recruitment in Brazil also enabled the attendance of some participants from outside the urban centers of Rio de Janeiro and São Paulo, where most services are provided:

> *You're interacting there from Rio, [name of another participant] there from Itapetininga, the other lady also from another place...with this pandemic business...we don't need to have physical contact. I think it's great.* [Caregiver 8, Brazil]

However, many, in particular, the facilitators who had had the experience of delivering both vCST and face-to-face CST, felt that the social connection and stimulation would have been stronger if the intervention had taken place face to face:

> *There are many more activities that can be done in person, rather than virtually...like for example, throwing ball to each other, doing physical activities together. Even sensory stimulation like...hearing sounds or seeing things...And I feel just physically being present and seeing other people is definitely...much more helpful.* [Group leader 3, India]

> *I think it would have been better if it could have happened in person. But during the COVID situation...this was more helpful and comfortable as anybody can attend from any place. Maybe still, I feel it would have been more beneficial for the dementia group if it were a direct session.* [Caregiver 6, India]

The participants observed additional issues with intervention acceptability that were related to the participants' access to suitable technology and computer literacy, which was compounded by cognitive impairment:

> *The main issue was internet. I would say… so we had only three participants in a group… along with a facilitator and a co-facilitator… which means that, like five different internet connections. So, the problem was if even one participant had a disruption in their internet, it tends to affect the whole group.* [Group leader 1, India]

> *At first it was more difficult, because the computer she could use at this time, I was using for work...so she had to do it on her phone...The images were too small for her to see, so that got in the way.* [Caregiver 7, Brazil]

Group leaders also reflected that it was more difficult to gauge engagement and facilitate a group virtually, as opposed to face to face:

> *Just knowing the body language, if the person is feeling sleepy, or the person's not enjoying it and stuff like that. You're not able to notice it as much because it is a virtual set up.* [Group leader 1, India]

> *Sometimes...the participants would talk over other people. We will ask someone a question, and that person...would answer, but then another person would answer also, and the two answers were colliding there, and it was hard to manage that, because it was virtual sessions.* [Group leader 2, Brazil]

Facilitators and Barriers to Implementation

Facilitators and barriers are included in Tables 3 and 4, categorized by CFIR domain with illustrative quotes. Key facilitators included the following:

- Innovation: Facilitators included the evidence base of CST and its advantage over other psychosocial interventions as a manualized intervention, which was also flexible to the needs of the participants. Some group leaders reflected that they were aware of few other interventions for people with dementia taking place virtually at the time.
- Outer setting: An international collaborative effort enabled funding and sharing of protocols and training materials. Many caregivers reflected that they were appreciative that the person with dementia could attend vCST at a time of social isolation due to COVID-19 restrictions.
- Inner setting: Staff in both sites were motivated to offer a service for people with dementia, and many participants reflected on the need for more support for people with dementia. Another facilitator to implementation was the training and supervision of staff at the NGO and trainee psychologists at the university. The NGO in India were able to appoint permanent staff members to take on vCST responsibilities as part of their role and integrate vCST into the existing services and caseload.
- Individuals: Most people with dementia relied on caregivers' support and would often miss sessions if their caregiver was unavailable. All groups also required 2 group leaders: one to lead the activities and another to provide technological support and to contact caregivers if a participant was struggling to engage. In India, group leaders reflected that adoption of vCST improved if it was suggested to participants by a clinician.
- Processes: Key implementation strategies included providing mock vCST sessions with caregivers and people with dementia to orient them to the platform and posting out activity packs to those who did not have resources at home.

Table 3. Facilitators to implementation.

CFIR[a] domain and subdomains[b]	Quotes
Innovation	
Innovation evidence-base	“In terms of evidence based published literature information… the effectiveness of CST and the cost effectiveness in other centers...That helped in choosing the most appropriate intervention.” [Decision maker 1, India]
Innovation relative advantage	“There was this one organization...a day center facility were doing... one-on-one video calls to have some sort of a social interaction during the pandemic.” [Group leader 2, Brazil]
Adaptability (of vCST[c] protocol)	“I think we had flexibility, because as I said one was the education level of patients and then the language that had to be used.” [Decision maker 2, India]
Outer setting	
Local conditions (need for socializing during lockdowns)	“He was...looking forward to the session, especially social interaction because the pandemic had obviously you know sort of cut down a lot of such interactions.” [Caregiver 1, India]
Partnerships and connections (international research partnership)	“We based it ourselves in this protocol, which was already published with some guidelines for developing the CST virtually.” [Group leader 1, Brazil]
Financing (international research funding)	“We were able to purchase the items that we need to deliver CST at our center. And for regarding technology...we were able to provide some of the participants with a tablet computer and the data for them.” [Decision maker 1, India]
Inner setting	
Tension for change (need for psychosocial treatment)	“There is no actual evidence based structured manual intervention available in India prior to this, so this provided as an opportunity to make it available for our patients.” [Decision maker 1, India]
Culture—learning centeredness (supporting trainee psychologists, Brazil)	“I really like participating on the project from my experience, in gaining experience, on like clinical experience and also a little bit of research too.” [Group leader 3, Brazil]
Compatibility (with service and caseload, India)	“We have a regular clinic so we identify participants from the clinic.” [Decision maker 1, India]
Access to knowledge and information (training and supervision)	“We had training, of course, and we also had regular supervision from our supervisor.” [Group leader 1, India]
Work infrastructure—staff (at NGO[d], India)	“Making sure that the facilitators are in substantive posts and not in fleeting positions so they are available for a longer time.” [Decision maker 1, India]
Individuals	
Opinion leaders (recommendation from doctors)	“If the doctor sometimes says, ‘you should do this, this will be beneficial for you,’ it really helps in the Indian context of the doctor’s word for you.” [Group leader 2, India]
Other implementation support—availability or capability (caregivers)	“Some of [the caregivers] would stay next to the person living with dementia...especially when the person was a little bit shy, [or] had more difficulty with technology...They were...mediating this communication.” [Group leader 2, Brazil]
Other implementation support—availability or capability (cofacilitator)	“One of the psychologists is delivering the session, and we need someone to support us at the technical end, we need someone to support us.” [Group leader 2, India]
Intervention recipient—need (person with dementia—need to stay home and subsequent isolation)	“Some of these people would not have come for in-person CST, because they could not afford transportation, did not have proper transportation, were frail, or had some kind of physical comorbidity or pain.” [Group leader 2, India]

CFIR[a] domain and subdomains[b]	Quotes
Implementation process	
Tailoring strategies (mock vCST sessions and activity packs)	• “We do have one trial session, where I sit with them individually. And then we have one group trial session, to see if they’re comfortable in a group.” [Group leader 2, India] • “We posted the materials...for number games, we had paper sheets. And colouring papers and some origami papers...We took printouts and posted it to their house.” [Group leader 1, India]

[a] CFIR: Consolidated Framework for Implementation Research.

[b] Context-specific descriptions are given in parentheses.

[c] vCST: virtual cognitive stimulation therapy.

[d] NGO: nongovernmental organization.

Table 4. Barriers to implementation.

CFIR[a] domain and subdomains[b]	Quotes
Innovation	
Adaptability (virtual delivery of CST[c])	• "I was running face-to-face sessions before they started [vCST]. Face-to-face CST was great...my group ran with eight members, six to eight, consistently. So, I had a huge group coming every Friday. It was amazing, they could form more connections, and turn taking is a little bit easier...It's a little harder like you with the Zoom." [Group leader 2, India
Innovation design (need for marketing)	• "It doesn't have much publicity. If it wasn't for chance, if this person hadn't put us in, I wouldn't have made it. So, I think in terms of dissemination it could be broader." [Caregiver 4, Brazil]
Outer setting	
Critical incidents (COVID-19 pandemic)	• "It was COVID and people are falling sick...even the facilitators are sick, at some point." [Group leader 1, India]
Local attitudes (dementia awareness)	• "In Brazil, I think it's a cultural thing to think that dementia symptoms it's part of a natural aging...So, when older people, and people living with dementia...come to a doctor to be evaluated they sometimes don't have mild symptoms anymore." [Group leader 2, Brazil]
Local attitudes (traditional focus on medical model)	• "People weren't aware of psychosocial interventions for dementia prior to this. They had very different model for working with people with dementia." [Decision maker 1, India]
Local conditions (access to technology)	• "Most of the people that we had in the groups were from the south eastern region. And that's kind of a more developed region financially...I think today most people in Brazil have access to internet. Maybe not their computer, but maybe cell phones and something like that." [Group leader 3, Brazil]
Inner setting	
Structural characteristics—work infrastructure (staff availability)	• "When we think of scaling it up, we might have to do it first of all in institutions where there is enough manpower of mental health professionals to deliver the CST...dementia care in India is still mental health care and we're still very under-resourced as far as manpower is concerned." [Decision maker 2, India]
Individuals	
High-level leaders—capability (lack of dementia awareness)	• "Some of the policymakers, who we interviewed at the beginning [in previous stakeholder engagement] weren't even aware of the issues relating to dementia." [Decision maker 1, India]
Intervention deliverers—capability (basics in clinical skills needed)	• "I think we if we didn't have the training, it would be very hard to just come to the groups...I didn't have any contact [with people with dementia] before." [Group leader 3, Brazil]
Intervention recipients—capability (sensory impairment and computer literacy)	• "So, one challenge was delivering it virtually. My mother was not able to hear very well. Now she has a hearing aid, she has the headphones but still that was a part of a problem of communication." [Caregiver 5, India] • "I don't know how to use the computer (laughs)." [Person with dementia 10, Brazil]
Implementation process	
Assessing needs—innovation recipients (severity of dementia)	• "If you have some difference in severity of dementia, because the activities demand something, and maybe it can be boring for who is not so severe." [Group leader 4, Brazil]
Assessing needs—innovation recipients (baseline assessments)	• "The first is, I think, the baseline evaluations were very long, and that was kind of hard on the, not on the people with dementia, but on their family members, the caregivers." [Group leader 3, Brazil]
Reflecting and evaluating—implementation (lack of long-term follow-up)	• "One question that most people with dementia their caregivers made was, if it was possible to have more than 14 sessions. So maybe adapting the maintenance CST for the virtual program. I think it would be a suggestion for the future." [Group leader 1, Brazil]

[a] CFIR: Consolidated Framework for Implementation Research.

[b] Context-specific descriptions are given in parentheses.

[c] CST: cognitive stimulation therapy.

Key barriers related to the 5 CFIR domains are as follows:

- Innovation. Most group leaders highlighted challenges with the online delivery of CST in terms of facilitating a group effectively, meeting individual needs, and supporting participants with the videoconferencing platform. Many leaders reflected on the comparative ease of facilitating a group in person. These issues are outlined in detail in the Acceptability of vCST
section. Finally, group leaders and caregivers highlighted the need for marketing to raise awareness of vCST
- Outer setting. While COVID-19 necessitated and possibly facilitated the online delivery of CST, staff and participant illness during the pandemic was a barrier to group delivery and attendance. Staff at both sites reflected on a lack of dementia awareness, resulting in participants presenting later to clinical services, which is a barrier to recruiting participants with mild to moderate dementia. Similarly, group leaders and decision makers reflected on a lack of awareness of psychosocial interventions for dementia, with the medical model tending to prevail. Finally, in both sites, it was highlighted that poor or limited access to technology is a barrier to involvement.
- Inner setting. The limited availability of mental health personnel was highlighted as a barrier to the wider scale-up of vCST in India.
- Individuals. People with dementia and caregivers faced barriers to taking part in vCST, including a lack of computer literacy and sensory impairment that impacted engagement. Organizational decision makers in India reflected on the lack of dementia awareness within high-level policy makers.
- Processes. One group leader reflected on the length and burden of the baseline assessments on people with dementia and caregivers. Many people with dementia and caregivers expressed a wish for the vCST groups to continue beyond the 14 sessions. At the NGO in India, it was possible to follow up with patients on the caseload; however, group leaders in Brazil wished to be able to continue to support participants and caregivers.

Discussion

Principal Findings

We found that it was feasible and acceptable to deliver CST virtually in Brazil and India. We recruited 91% (59/65) of the target sample and were able to run 17 vCST groups. Attrition was low (4/49, 7%), and attendance was moderate, with 53% (31/59) of participants attending all 14 sessions. This is in contrast to a previous trial of face-to-face CST in Brazil, where attrition was similar (6%) but attendance was high (mean 12.8 sessions, median 14 sessions) [39]. In a previous pilot study of face-to-face CST in Chennai, India, attrition was higher with 3 out of 9 participants dropping out [16]. However, these comparisons should be interpreted with care due to small sample sizes and the impact of COVID-19 in both countries.

Outcome measure completion was slightly lower than the target of 75%, as only 68% (40/59) of participant dyads completed all follow-up outcome measures, suggesting a possible measurement burden. Small improvements across all quality-of-life domains were observed in people with dementia. All results should be interpreted with care, as the study was not controlled. Any changes cannot be ascribed to the vCST intervention specifically, and the impact of COVID-19 and consequent social isolation may have played a role in pre- and postintervention measurement changes.

There were some differences in the barriers and facilitators to implementation across the 2 sites. vCST was delivered in an NGO in Chennai, where participants could be recruited from the patient caseload. In Brazil, vCST was delivered through a university where recruitment took place from the community and memory clinics and NGOs who were partnered with the study. Although staff turnover was a barrier to implementation in the NGO in India, decision makers reflected that it would be possible to build CST or vCST into services due to its compatibility with current ways of working. This may have been more of a challenge in the university setting in Brazil, where there is no patient caseload or clinic infrastructure. However, there is scope to build partnerships with community organizations and clinics to recruit participants. Upskilling trainee psychologists to deliver vCST in Brazil also presents a low-cost and scalable solution to implementing vCST in a university setting. Similar solutions have been used for other psychosocial interventions for dementia in other countries [40,41].

A major barrier in both sites was poor or limited access to technology and computer literacy. This issue was also highlighted in studies of vCST conducted in the United Kingdom [23,24]. A survey of the digital divide in India found that just 38% of households are digitally literate [42]. Access is higher in Brazil, where 80% of households have internet access [43]. In both countries, digital access intersects with age, gender, education level, and ethnicity [42-44]. While virtual interventions provide service access to those living in geographically isolated locations, the digital divide is greater in rural areas; in Brazil, only 53% of the rural population have internet access, while 88% in urban areas have internet access [43], and the figures are lower overall in India where in rural areas, only 31% of the population use the internet, while in the urban areas, the percentage rises to 67% [42]. To overcome the barriers to technology access in India, the NGO loaned tablets to participants, which required sufficient funding and resources. We addressed the issues related to digital literacy by implementing the following measures: (1) group leaders provided mock vCST sessions to familiarize participants with the videoconferencing platform, (2) a coleader was available specifically for technology support, and (3) groups sizes were smaller so that all participants could be viewed on the screen at once (average 3.6 participants compared with 6-8 according to the original CST protocol [12]).

Most people with dementia were reliant on caregivers' technical support to use the videoconferencing technology, and in some cases, caregivers remained present throughout the group sessions. This raises a key issue for those without caregivers, who could be systematically excluded from taking part in virtual psychosocial interventions. If vCST were implemented as a dyadic intervention, this could improve caregivers' awareness of dementia and person-centered approaches, which is important given the limited number of dementia awareness programs in LMIC settings [45]. However, it could also negatively impact the engagement of the person with dementia, as one of the proposed mechanisms of action of CST is the supportive learning environment, where people with dementia support each other without judgment or embarrassment [46]. If vCST is delivered dyadically, we recommend that participants are briefed at the start of the program to set expectations about the caregivers' level of involvement in the vCST sessions and that people with dementia are provided with opportunities to take part in activities and discussions alone. Further research could explore the impact of dyadic delivery on outcomes for people with dementia and their caregivers.

Limitations

In both sites, it is likely that the sample was not representative of the broader population of people living with dementia and their caregivers. Specifically, in Brazil, the sample comprised mostly White individuals (35/44, 80%), which does not reflect the majority Black and mixed Brazilian population. Most participants were from the urban region of southeast Brazil, although the remote method of recruitment did enable participation from areas outside of this region, which were underserved in terms of research and clinical services. In India, all participants were recruited from the same region and were already attending clinical services; this might have resulted in a sample skewed to those with the means to access services.

Online delivery may result in a self-selecting sample, who are more likely to be educated to a higher level and more affluent than the broader population. The mean number of years of schooling of our sample was 11.5 (SD 1.2) in Brazil and 13.0 (SD 2.6) in India. This compares to a national average of 2.5 in Brazil and 1.4 in India for the population aged ≥25 years in 1970 and 1971, respectively [47] although there is huge regional variation in education levels in both countries. To overcome issues related to digital exclusion in India, tablets were loaned to those who needed them. However, in Brazil, people without access to their own technology were excluded.

In terms of the qualitative component, most themes and quotes from a participant perspective were collected from caregivers rather than people with dementia. This is because cognitive impairment affected their recall of sessions. Despite this, caregivers and group leaders reflected on the perceived participant experience of vCST sessions. Interviews took place with all caregiver dyads from India, but only those from the first 2 vCST groups in Brazil due to staff availability. However, the reflections from group leaders and organizational decision makers relate to all vCST groups. Interviews with group leaders and decision makers were carried out in English by a UK-based researcher who was not a member of the immediate research team. This was to limit response bias and encourage honest and critical feedback; however, it limited the interview to people who speak English and may have compromised the representation of non-English speakers.

Finally, the vCST intervention was tested in 2 sites, a university in Brazil and an NGO in India, resulting in lessons for implementation that could be explored in other sites and countries; nevertheless, we acknowledge the limited generalizability of these findings.

Future Research

To date, vCST has only been trialed within a pandemic context. While this was acceptable to participants during a time of social isolation, many caregiver dyads and group leaders expressed a desire for CST to take place in person. Future research could explore the feasibility of vCST outside of the pandemic context, perhaps specifically targeting those who cannot access in-person services due to limited mobility, health issues, or geographic isolation.

In addition, although there is a strong evidence base for in-person CST, we do not know if the benefits to cognition and quality of life are conferred to the same level over online delivery. A recent feasibility study of vCST (in press Spector, 2023) has shown that a full-scale randomized controlled trial is warranted

Conclusions

The 14-session vCST program for people with dementia was successfully trialed in a university setting in Brazil and in an NGO in Chennai, India. vCST offered a feasible alternative to in-person groups during the period of pandemic restrictions with potential benefits to quality of life, but there were barriers related to technology access and computer literacy. Outside of the pandemic context, vCST could be provided to people with dementia who are geographically isolated or who have mobility- or health-related difficulties.

Acknowledgments

The authors would like to thank all the participants of the virtual cognitive stimulation therapy (vCST) groups and the vCST group leaders.

This work is supported by the following Global Alliance for Chronic Diseases (GACD) funding agencies: The United Kingdom Medical Research Council (MRC: MR/S004009/1) and the Indian Council of Medical Research (ICMR: Indo-foreign/67/M/2018-NCD-I). No funding bodies were involved in the design, collection, analysis, interpretation, or writing of the research or manuscript. The views expressed are those of the authors and not necessarily those of GACD, the MRC, or ICMR.

Conflicts of Interest

AS delivers occasional cognitive stimulation therapy (CST) training courses on a consultancy basis. DCM provides CST training in Brazil, and SV delivers CST training in India.

Abstract

Background: The demand for support among people with dementia is increasing, while caregiving capacity is declining. As the trend of aging at home continues, technologies can help maintain the autonomy of people with dementia, enabling them to live independently for as long as possible. Furthermore, digital applications can have numerous positive biopsychosocial effects on the health of people with dementia, enhancing their physical, cognitive, and social functioning.

Objective: This study aims to investigate the needs and experiences of people with dementia regarding a prototype tablet-based application designed to promote cognitive and physical activity.

Methods: We conducted a methodical triangulation by combining semistructured interviews with people with dementia and external overt participant observation while testing a tablet-based application. A qualitative content analysis, as outlined by Kuckartz, was used to analyze the data.

Results: Participants demonstrated varying levels of ability and prior experience with technology. While most were initially hesitant to use the tablet independently, they were more willing to try it after receiving encouragement. Some individuals required more assistance than others, indicating the need for individualized adjustments. Personal relevance to the content appeared to be crucial for cognitive tasks, as it helped to minimize overload for people with dementia. The participants appreciated social interaction with researchers and direct communication. Therefore, it is important to consider the role of personal support when developing and implementing technology.

Conclusions: The successful implementation and use of technology requires acceptance and an effective interaction between people with dementia, technology, and caregivers or caring relatives providing personal support. The acceptance of the application was found to be less influenced by the types and presentation of tasks and more by content relevance and social interaction. Ideally, one-on-one support will be provided during use, though this requires additional time and financial resources, which are often limited in caregiving settings.

(JMIR Aging 2024;7:e62689) doi:10.2196/62689

Introduction

Dementia is a leading cause of disability and care dependency among older adults worldwide [1]. Currently, around 50 million people are living with dementia; projections indicate that dementia prevalence will increase to 152 million by 2050 [2]. Consequently, the demand for support for people with dementia is increasing. This may become a key challenge due to the simultaneous decrease in caregiving capacity. In Germany, most people with dementia live in their own homes, where they receive care from family members acting as caring relatives (CRs) and from caregivers [3]. These support systems play a crucial role in dementia care, often by acquiring the skills to manage challenging behaviors associated with dementia [4].

Given the current trend toward aging at home, technology can help people with dementia preserve their autonomy, allowing them to live independently in familiar environments for as long as possible [5]. Integrating technology into dementia care can assist in preserving physical functions [6] and strengthening cognitive functions [7]. Personalized digital technologies have the potential to enhance the well-being of people with dementia by improving behavior, mood, sense of identity, and social interactions [8]. A holistic biopsychosocial approach is essential to address the complex needs of people with dementia, especially considering the frequent occurrence of multimorbidity in this population, which presents additional challenges for care and support [9].

The aim of this study is to investigate the needs and requirements of people with dementia regarding the use of interactive videos on a tablet computer, including cognitive and physical tasks to maintain their independence.

Methods

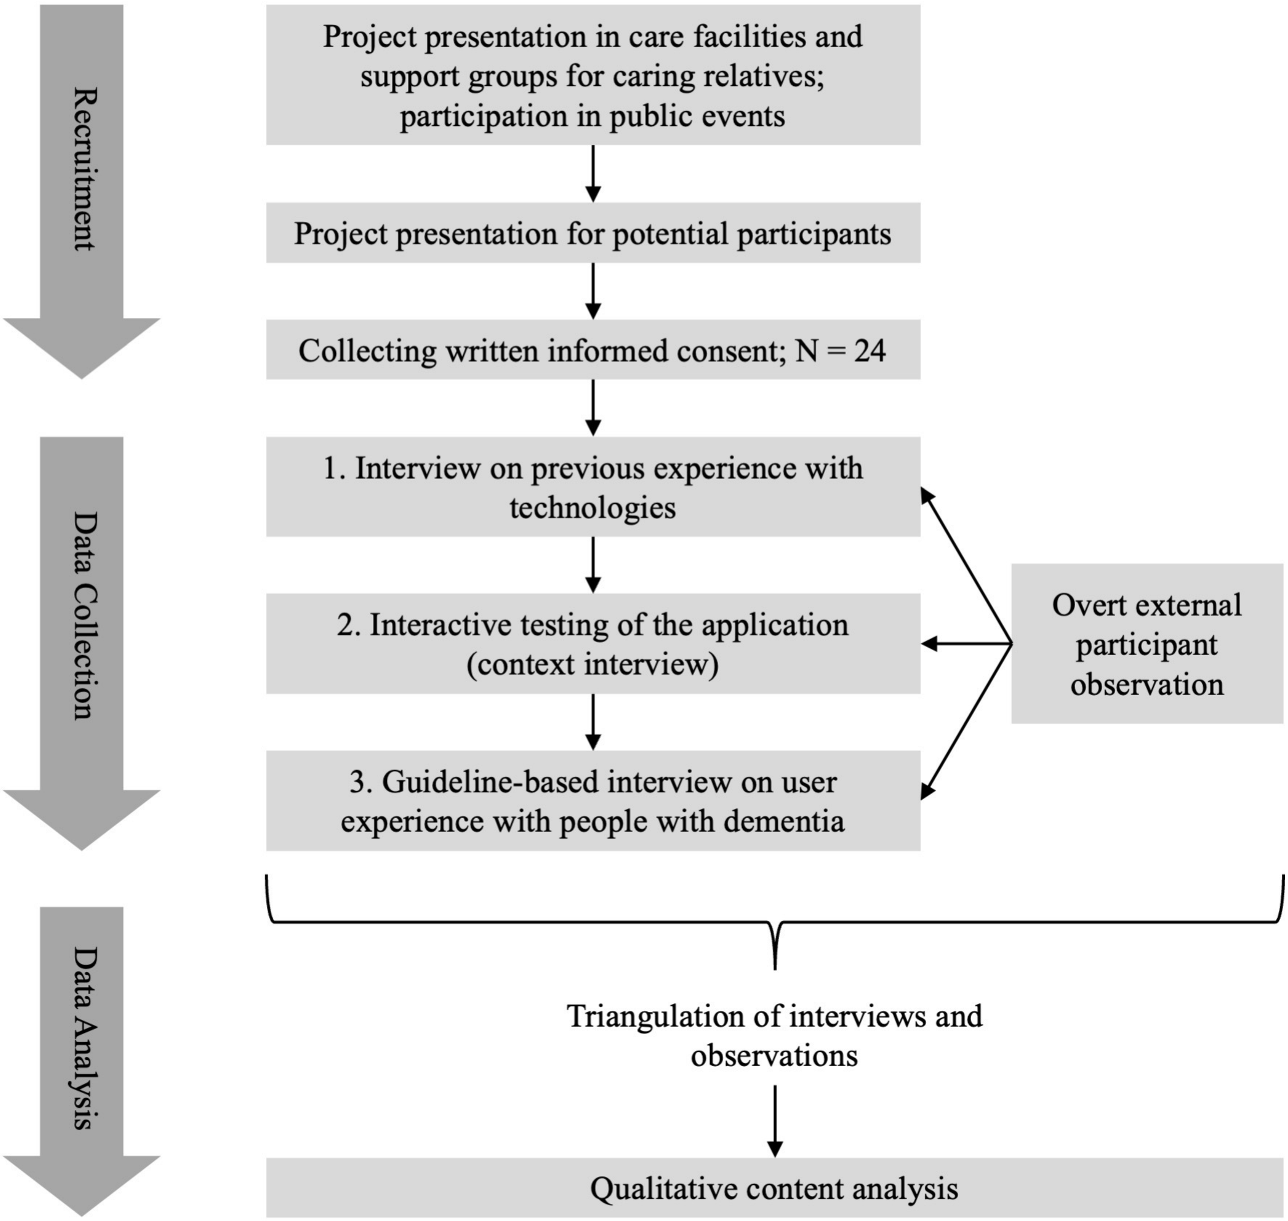
Ethical Considerations

The study was approved by the Ethics Committee of the German Society for Nursing Science (EK-22-038), and it complies with the Declaration of Helsinki. Prior to enrollment in the study, all participants provided written informed consent. All participants were anonymized. They did not receive any compensation.

Study Design

This study used a qualitative triangulation approach combining observations and interviews, with data from each method systematically aligned. The study was conducted in Germany and follows the SRQR (Standards for Reporting Qualitative Research) [10]. A summary of the study design and methodical approach is presented in Figure 1.

Figure 1. Methodical approach of presented study [11].



Sampling, Recruitment, and Field Access

The study included participants aged 50-90 years with mild cognitive impairment or early-stage dementia. They had to reside in Germany and were required to have sufficient verbal communication skills and adequate vision and hearing. Previous experience with mobile devices was intentionally not set as an inclusion criterion. Recruitment and access to participants were achieved by attending events; presentations in support groups; and visits to outpatient, semi-inpatient, and inpatient care facilities in Southwest Germany.

Data Collection

Data collection was done in day care centers or in participants' homes, using overt, external participant observations and guided context-driven interviews, which were recorded using a sound recorder. The process of data collection was divided into three phases:

1. A discussion of the participant's previous experience with digital technologies
2. Interactive testing of the application on a tablet computer (see Multimedia Appendix 1 for a section of the application's content)
3. A guideline-based interview to assess the user experience

We selected the interview questions considering the limited cognitive abilities of the participants. Therefore, they were formulated in a language that was easy to understand. Textbox 1 provides a summary of the key interview topics, along with representative examples of the types of questions posed.

Textbox 1. Key interview topics and representative questions

1. Prior experience and personal characteristics (age, ownership of a smartphone or tablet, use of a smartphone or tablet in daily life, reasons for utilisation or non-utilisation)

eg, Have you ever used a tablet computer before?

2. Overall evaluation of usage of the application (acceptance-rejection)

eg, How did you like using the tablet?

3. Usability and media presentation of the application (operability, design and layout, language)

eg, How clear was the sound?

4. Content of the application (evaluation of interaction content, evaluation of task types, personal content preferences)

eg, Which exercise did you like the most?

Each main question was followed by additional questions to gain a deeper insight into the context and motivations behind the participants' responses, ensuring a comprehensive understanding of their perspectives. We used a variety of open-ended and closed questions.

Two researchers conducted the data collection process. One researcher provided support during the use of the application by offering verbal assistance and aiding in the execution of the tasks to promote its use (Multimedia Appendix 2). The second researcher observed the process and made field notes based on predefined criteria, including attention span, facial expressions, and gestures, during the use of the application.

Data Analysis

After transcribing the meaning of the collected data, we carried out a qualitative content analysis according to Kuckartz [11]. The observation protocols were triangulated with the interviews. This allowed for unspoken aspects to be included in the analysis. Following the initial coding, related codes were grouped into categories, facilitating data organization and pattern recognition. Broader themes emerged through categorization, which was essential for understanding the data's underlying meaning. During data analysis, we supplemented deductive categories with inductive categories (Figure 1).

Results

Participants' General Perceptions of the Technology and Their Usage Patterns

The characteristics of the participants are presented in Table 1. The participants showed great heterogeneity in terms of skills and previous experience with technology, resulting in varying levels of proficiency in using a tablet computer. This is likely influenced by their prior experience, such as owning or not owning a mobile device. Overall, the participants demonstrated a high level of engagement while using the application, as indicated by focused attention on videos and comments related to the content. A majority of the participants expressed positive feedback regarding the application; however, many were unable to envision using the tablet computer independently.

Table . Profiles of people with dementia.

Study variables	Participants (N=24), n (%)
Sex	
Male	10 (42)
Female	14 (58)
Owning a smartphone or tablet	
Yes	10 (42)
No	14 (58)
Using a smartphone or tablet	
Often	5 (21)
Rarely	5 (21)
Never	14 (58)

Role of Technology Use

Most participants were proficient in recognizing visual elements, including both images and videos. However, observations regarding the varying effects of auditory stimuli on participants highlighted the challenge of designing an application that is balanced and accessible to different user groups.

Role of the Content Within the App

Cognitive Tasks

When evaluating preferences for task types, the participants demonstrated indifference toward task types, including arithmetic, pictorial, and auditory tasks. Instead, they were more engaged when the content was personally relevant to their experiences. Tasks within the application fell into three categories: those that can be solved based on personal experience, those that can only be solved in the context of the story, and those that require acquired knowledge or skills.

Personal Experiences

The individual experiences of people with dementia played a crucial role in recognizing locations depicted in the application scenes. In particular, visual and haptic experiences, such as walking through a meadow and associated memories of the perceived feeling, acted as triggers for verbal expressions from the participants. Familiar memories evoked by the content may have fostered interest and concentration.

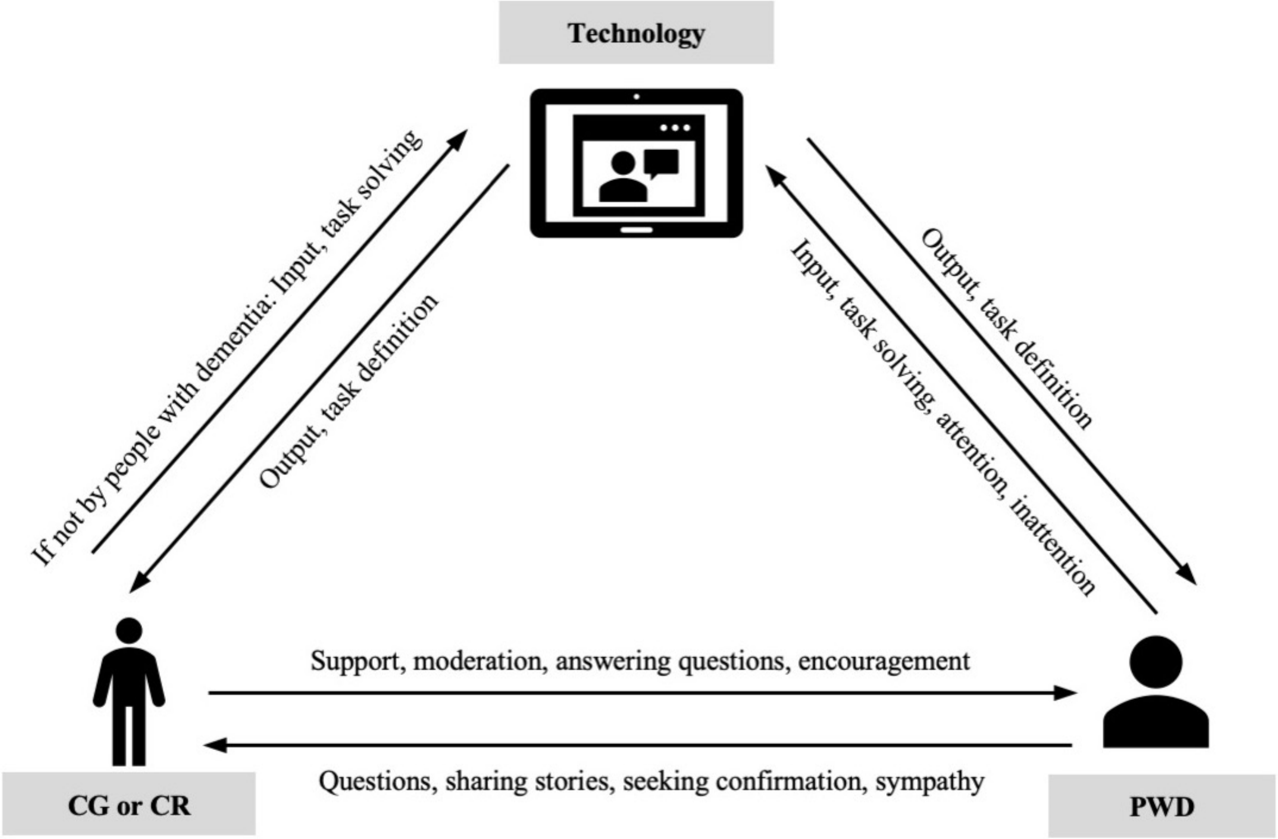
Role of Personal Support During Use

Initially, most participants were hesitant to use the tablet independently but were willing to try it after receiving positive reinforcement from the researcher.

It was noticeable that the participants often sought contact with the researchers for personal support and reassurance, frequently sharing personal stories, even while watching videos or receiving task instructions. This highlighted a strong desire for communication and social interaction while using the application.

When uncertain, the participants appreciated clear instructions from the researchers and were not hesitant to ask further questions (Figure 2). Data suggests that these positive feelings toward the researchers—whether, derived from sympathy, their presence or social interaction likely influenced their perceived acceptance and evaluation of the application positively. The participants’ politeness also contributed to their willingness to engage with the application and give positive feedback. In addition, participation in the study and the resulting change in the participants’ daily routine may have positively influenced the overall evaluation of the application.

Figure 2. Interaction between technology, PWD, and CGs or CRs [12]. CG: caregiver; CR: caring relative; PWD: people with dementia.



Discussion

Principal Results

The findings indicate that personal support is crucial for a successful overall interaction while using the application. If it is not possible for people with dementia to use the application independently, alternative scenarios for use must be considered. One such scenario is one-to-one support by CRs or caregivers, which fosters social interaction. This support can motivate users and encourage device use, highlighting the relational aspects of care that are important for people with dementia. However, providing direct support requires time, a resource that is often limited for caregivers [13]. Additionally, one-to-one support can be a financial burden, as CRs perceive the associated expenses as high and, consequently, may refrain from using the application [14].

We discovered that the type of task and the visual presentation of cognitive tasks (image-based, text-based, or auditory) were secondary in importance. Instead, the content of the tasks played a more crucial role. To develop tasks that activate cognition, it is necessary to design content that establishes an emotional connection for people with dementia with their prior experiences and interests. This approach is fundamental for the acceptance of the technology. Additionally, including relational aspects, such as sharing relevant anecdotes or engaging in social interaction, further enhances the effectiveness of the technology and its acceptance by people with dementia.

Limitations

The reliability of the study may be reduced due to participants potentially adopting a desirable response and behavior during interviews. To address this, we triangulated the data by including observations along with mutual verification among the researchers. The researchers’ reflexivity regarding their own roles in the study ensures a higher level of objectivity.

Comparison With Prior Work

In a previous study, expert interviews were conducted to analyze the requirements for an application for people with dementia. The application tested in the current study was designed based on those findings [15].

According to our study, acceptance is the base for a successful engagement with the application. A systematic review reported similar results, emphasizing the importance of acceptance [6]. For a successful engagement, social context is another crucial factor, as highlighted by our study findings. Smith et al [16] discovered that technology use is perceived more as a social event by people with dementia when they are in the presence of others or in groups. The tablet computer serves as a catalyst for conversation, facilitating the exchange of interesting anecdotes [16].

Woods et al [17] demonstrated that biographical reference plays an important role in solving cognitive tasks for people with dementia. Although they often struggle to recall recent events, they are able to retain childhood memories. Tasks that include biographical references can be easier for people with dementia, as they include leveraging their cognitive strengths and minimizing overload.

Conclusions

While designing an application for patients with dementia, it is important to consider the heterogeneity in this group and dependence on their daily fluctuating cognitive state. Therefore, providing opportunities for individualized adaptation of the technology is crucial for addressing diverse interests and abilities. Biographical content-related tasks can have a positive impact on cognitive activation. It is therefore reasonable to suggest that such interventions linked to biography could also be employed in individuals with other neurodegenerative diseases with the objective of preserving cognitive abilities and memories.

The participants in this study expressed a common interest in social interaction. Therefore, it is important to consider the significant role of personal support when developing and implementing technology, and ensuring easy access. Potential users, CRs, and caregivers should face as few barriers as possible when learning, purchasing, and using the application. This is particularly important, given the short period of use due to the changing cognitive state. If these conditions are met, this application has the potential to promote independent living among people with dementia.

Abstract

Background: Smartphone apps can be used to monitor chronic conditions and offer opportunities for self-assessment conveniently at home. However, few digital studies include older adults.

Objective: We aim to describe a new electronic cohort of older adults embedded in the Framingham Heart Study including baseline smartphone survey return rates and survey completion rates by smartphone type (iPhone [Apple Inc] and Android [Google LLC] users). We also aim to report survey results for selected baseline surveys and participant experience with this study's app.

Methods: Framingham Heart Study Offspring and Omni (multiethnic cohort) participants who owned a smartphone were invited to download this study's app that contained a range of survey types to report on different aspects of health including self-reported measures from the Patient-Reported Outcomes Measurement Information System (PROMIS). iPhone users also completed 4 tasks including 2 cognitive and 2 physical function testing tasks. Baseline survey return and completion rates were calculated for 12 surveys and compared between iPhone and Android users. We calculated standardized scores for the PROMIS surveys. The Mobile App Rating Scale (MARS) was deployed 30 days after enrollment to obtain participant feedback on app functionality and aesthetics.

Results: We enrolled 611 smartphone users (average age 73.6, SD 6.3 y; n=346, 56.6% women; n=88, 14.4% Omni participants; 478, 78.2% iPhone users) and 596 (97.5%) returned at least 1 baseline survey. iPhone users had higher app survey return rates than Android users for each survey (range 85.5% to 98.3% vs 73.8% to 95.2%, respectively), but survey completion rates did not differ in the 2 smartphone groups. The return rate for the 4 iPhone tasks ranged from 80.9% (380/470) for the gait task to 88.9% (418/470) for the Trail Making Test task. The Electronic Framingham Heart Study participants had better standardized *t* scores in 6 of 7 PROMIS surveys compared to the general population mean (*t* score=50) including higher cognitive function (n=55.6) and lower fatigue (n=45.5). Among 469 participants who returned the MARS survey, app functionality and aesthetics was rated high (total MARS score=8.6 on a 1 - 10 scale).

Conclusions: We effectively engaged community-dwelling older adults to use a smartphone app designed to collect health information relevant to older adults. High app survey return rates and very high app survey completion rates were observed along with high participant rating of this study's app.

Introduction

The use of information and communication technologies (ICTs) was essential to access health care and address everyday needs during the COVID-19 pandemic. ICTs were especially important for older adults during this time, as in-person health care encounters may have placed vulnerable older adults at risk for adverse health events. A nationwide representative survey of adults aged 65 years and older reported an increase of more than 50% in use of ICTs during the COVID-19 pandemic [1]. However, gaps remained, as ICT use was lower among groups that did not learn how to use a new technology reinforcing the known age disparity in technology use [2,3]. In addition to advanced age, lower education, lower income, and reported fair or poor general health were factors associated with not learning to use new technology [1]. A smartphone study of cognition among older adults also noted that older age was associated with less familiarity with and engagement with technology [4]. However, once older adults enrolled adherence was high and furthermore adherence was not associated with gender, race, education, or technology knowledge [4]. Hence, if barriers to engagement and appropriate technologic support can be improved for those older adults that need it, digital tools may improve the lives of older adults by permitting self-monitoring of health at home outside the clinical environment.

Smartphone apps are used to monitor chronic conditions and offer opportunities for cognitive and physical function self-assessment conveniently at home but the usability of the apps are often uncertain especially among older adults [5,6]. A small study of patients with heart failure from cardiac units at an academic medical center demonstrated the feasibility of collecting health information using short questionnaires delivered by mobile app [7]. The usability scores were high, including perceived ease of use [7]. Smartphone-based tools for cognitive assessment permit more frequent assessments at home ahead of health care provider visits and may also provide information about cognitive change in adults at risk for dementia [8]. Smartphone apps and digital sensors also have the ability to record real-world measures of physical activity, gait, and mobility known to be important to independent living [9]. However, older adults have been underrepresented in electronic cohort (eCohort) [10-12] with few digital health studies including larger numbers of older adults [13].

We recruited and enrolled an eCohort of older adults, mean age 73.6 (SD 6.3) years, across the COVID-19 pandemic, embedded in the well characterized Framingham Heart Study (FHS) Offspring and Omni cohorts. We designed a smartphone app to collect health information across a range of domains using different types of smartphone surveys, and smartphone cognitive and physical function testing tasks. We report our experience with baseline smartphone survey return and completion to understand how community-dwelling older adults interact with smartphone technologies. Further, we report the survey results for representative surveys and for a cognitive testing task. Finally, participant-reported usability was assessed with the Mobile App Rating Scale (MARS) survey to better understand the older user's experience with the app. Usability was investigated by device type (iPhone and Android smartphone type), participant age, and sex. We hypothesized that iPhone users and younger participants would perceive the smartphone app more favorably. We observed iPhone users to have greater survey return in our prior work in middle-aged participants and others have reported that Apple users are more familiar with technology and more likely to use apps [14,15].

Methods

Study Sample

The Electronic Framingham Heart Study (eFHS) enrolled participants from the FHS Offspring cohort (recruited in 1971 - 1975, n=5124) and the multiethnic Omni 1 cohort (recruited from 1994 - 1998, n=506). Both cohorts were recruited in Framingham Massachusetts and have been examined every 4 to 8 years since enrollment [16]. Beginning January 25, 2021, eligible participants enrolled in eFHS during their in-person research center examination (Offspring examination 10/Omni examination 5). English-speaking participants who owned a smartphone (iPhone running iOS 10 or higher or Android version 7 or higher) were invited to download the eFHS app designed for Offspring and Omni cohort participants. If participants did not own a smartphone or the smartphone was not compatible with this study's app, they were invited to participate using a computer if they had one at home. Participants examined in a nursing home were excluded. All participants provided informed consent as part of the overall parent Offspring examination 10/Omni examination 5 and electronic informed consent was part of the eFHS app. Participants signed the consent forms electronically and were able to access the signed consent forms within this study's app. Before June 2021, participants were offered the choice of receiving surveys every 4 weeks or every 2 weeks. Starting in June of 2021, participants additionally provided consent to be randomized to one of two groups for smartphone app survey deployment (randomized controlled trial, NCT04752657). One randomized group received all surveys every 4 weeks and the other group received the same number of surveys in 2 smaller batches every 2 weeks. For the purposes of this study baseline surveys were defined as surveys that went out at enrollment (wk 0) or at week 2 after enrollment.

This study's research technician assisted participants with app download from the App store or Android Google play store. A welcome screen appeared at the initial opening of this study's app (Figure S1 in Multimedia Appendix 1), along with a request for permission to receive study notifications, and steps with instructions for enrollment. Upon the completion of the enrollment and consent process, participants received their initial smartphone app surveys. For participants who did not come to the research center for the examination, this study's research technician provided enrollment support over the telephone or via Zoom. Participants also received step-by-step written instructions on how to download this study's app and enroll in eFHS, with a brief explanation of the purpose of each app survey and contact information should technical support be needed or questions arise. Study notifications were sent through this study's app to welcome participants to this study, to thank participants for completing surveys, to remind participants when surveys were due, and to inform participants when new surveys became available. Finally, this study's technician attempted to contact all participants1 week after enrollment to provide any needed technical support and answer any questions related to this study's app.

eFHS continued to enroll participants after the completion of Offspring examination 10/Omni examination 5 in order to (1) capture participants who came into the research center examination before the start of enrollment for eFHS and (2) to invite participants who did not come into the research center for the examination but participated in the examination by televisit only (Figure 1). Offspring examination 10/Omni examination 5 (September 2019 to June 2022) occurred across the COVID-19 pandemic (March 2020 to May 2023) and the parent study permitted participants to attend the examination in-person, by televisit, or by off-site visit by sending FHS staff to the participant's home. The COVID-19 pandemic coincided with eFHS enrollment as shown in Figure 2. Active COVID cases in Massachusetts reached a peak in January in both 2021 and 2022, which coincided with the lowest enrollments in eFHS. During summer months in both years, active COVID cases dropped to the lowest and the enrollments increased [17]. In total eFHS enrolled 620 Offspring and Omni participants including 478 iPhone users, 133 Android users, and 9 computer users (Figure 1). Computer users were excluded from this study.

Figure 1. eFHS Offspring and Omni enrollment. eFHS: Electronic Framingham Heart Study.

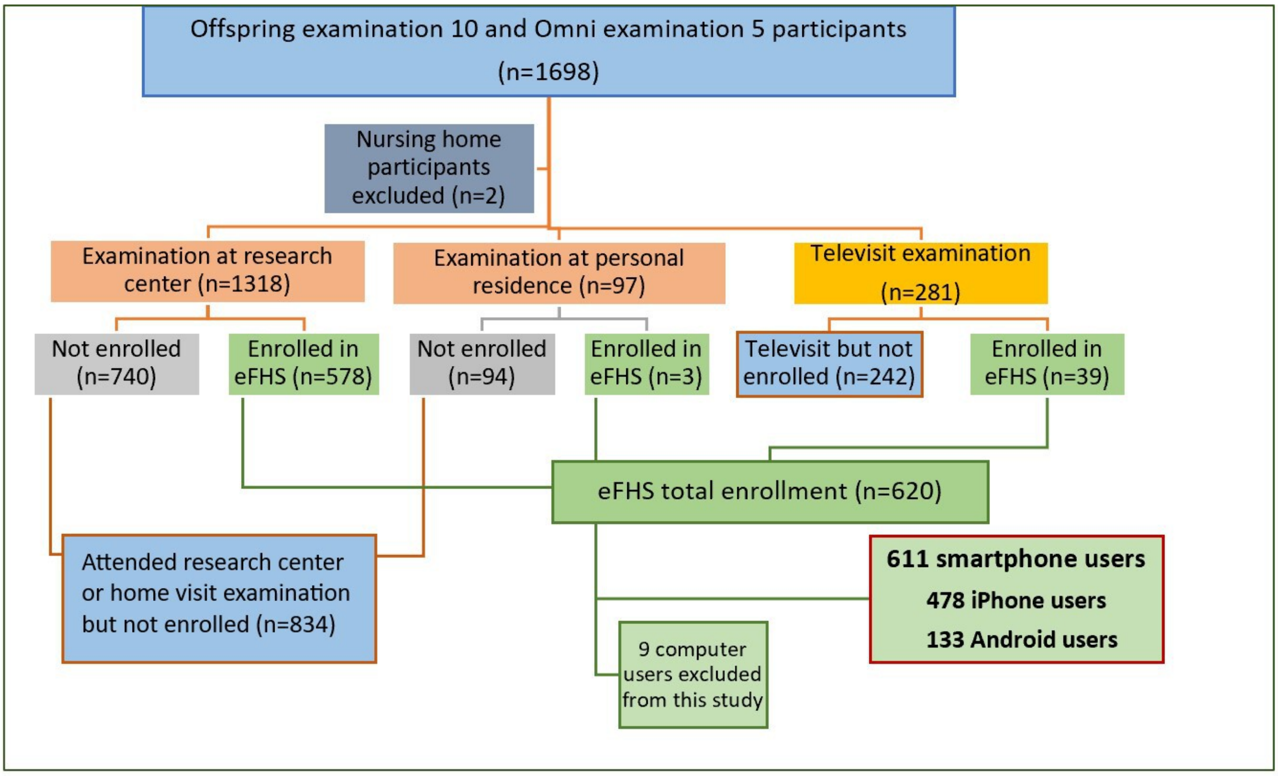

Figure 2. eFHS Offspring and Omni enrollment and timeline. eFHS: Electronic Framingham Heart Study; MA: Massachusetts.

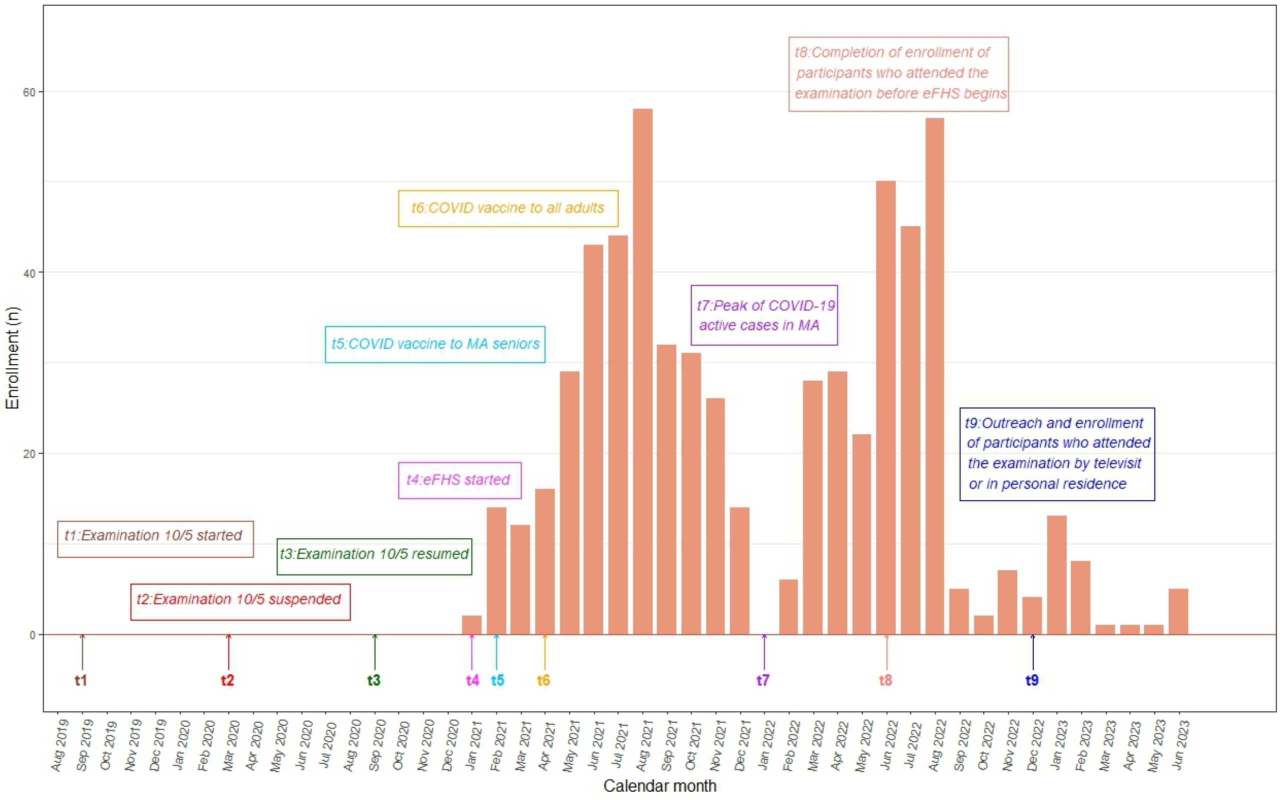

eFHS Offspring or Omni Smartphone App

We created smartphone surveys for the eFHS Offspring and Omni participants using CareEvolution's MyDataHelps Designer platform and the MyDataHelps mobile app container (CareEvolution). The MyDataHelps app hosts different types of surveys and tasks (Figure S1 in Multimedia Appendix 1), an account where participants can see their signed consent form, and a dashboard to provide participants with survey completion status and a "thank you" message of encouragement. The surveys and tasks were designed to be sent out on enrollment (wk 0) and at various intervals after enrollment for up to 1 year. At baseline, participants were asked to complete 12 health surveys through the app and iPhone owners were asked to complete an additional 4 tasks.

Survey assessments were chosen for relevance to the health of older adults and included assessments of cognition, mood, pain, physical function, physical activity, and events such as falls and hospitalizations. Self-reported surveys from the short form of the Patient-Reported Outcomes Measurement Information System (PROMIS) were selected and included [18]: anxiety, depression [18], fatigue [19,20], sleep [21], physical function [22], pain [23], cognitive abilities, and cognitive function [24]. Most of the PROMIS surveys were 4-item multiple choice questions with response choices that ranged from "never" to "always" for the mood surveys to "never" to "very often" or "not at all " to "very much" for the cognitive assessment surveys. A modified version of the Michigan Body Pain Map [25] was additionally used to collect information on chronic pain and included a pictorial image of the front and back of the human body (Figure S2 in Multimedia Appendix 1). Participants were asked to check the places on the body where they felt persistent or recurrent pain for 3 months or longer (chronic pain). If no chronic pain was experienced, a separate box of "no chronic pain" was provided. A second survey related to mood included 3 items used to define physical frailty including unintentional weight loss, and 2 items from the Center for Epidemiologic Studies-Depression Scale [26]. The final baseline surveys queried physical activity level with the Rapid Assessment of Physical Activity Survey [27], mobility outside the home including "other rooms," "outside your home," "neighborhood," "outside your neighborhood," and "outside your town" [28], and occurrences of falls and hospitalizations.

Four smartphone testing tasks operated on the iPhone and included 2 commonly used cognitive tests, a gait task, and a motor task. The Trail Making Test [29,30] is a timed assessment that requires the participant to tap a series of dots in order alternating between numbers and letters starting with the number "1" followed by tapping the letter "A" until the number "7" is reached. The completion time and errors are recorded. The Victoria Stroop Test (Stroop) [31] includes a series of 4 increasingly more difficult tasks with a practice session provided for each of the 4 tasks. People with color blindness were excluded as the tasks require the participant to be able to distinguish colors (yellow, green, red, and blue). In each of the 4 subtasks, participants are asked to select the matching color to the block color, the word color, the font color, and the word color if the word was underlined or the font color if the word was not underlined, respectively (Figure S2 in Multimedia Appendix 1). The gait task [32], instructs the participants, in a human voice, to walk a set distance and the walking time was recorded. The 2-finger tapping [33] asked participants to tap on the screen for 20 seconds on the designated spots as quickly as possible using 2 fingers. The tapping speed and accuracy were recorded.

Six baseline surveys (2 mood surveys, pain, body pain map, cognitive function, and cognitive abilities) and all 4 cognitive and physical function testing tasks were deployed at baseline week 0. Another 6 baseline surveys (physical function, sleep, fatigue, mobility outside the home, rapid assessment of physical activity, and falls and hospitalizations) were deployed at week 0 or week 2, depending on participants' choice or randomization group (4 wk vs 2 wk, respectively).

Participant Feedback on the Smartphone App

Participants completed the MARS survey [34] and the System Usability Scale (SUS) [35] on their smartphone to obtain feedback about their experience with the eFHS study app. The MARS included questions on app functionality and aesthetics including performance, ease of use, navigation, layout, graphics, and visual appeal. Items were rated by the participant using a 5-point Likert scale from 1=inadequate to 5=excellent. The SUS included 10 multiple choice questions including "I found the app unnecessarily complex" and "I thought the app was easy to use." We modified the response options for each question from the original 5-point Likert scale to 4 response options "strongly agree," "agree," "disagree," and "strongly disagree." The 4 options were assigned scores 1, 2, 4 and 5, respectively. The total SUS score was not computed because of the modification in response choices from a 5-point Likert scale to a 4-point Likert scale. The MARS and SUS were sent to participants 30 days after enrollment to allow participants an opportunity to use the app and complete the baseline surveys and tasks.

Offspring Examination 10 or Omni Examination 5 Data Collection

As part of the routine research examination participants self-reported data was collected on education, retirement status, marital status, and subjective health (in general would you say your health is excellent, very good, good, fair, or poor). Participants were asked to bring medications in a medication bag provided to the examination and medications were recorded. Trained technicians administered the 20-item Center for Epidemiologic Studies-Depression Scale with scores that range from 0 to 60 and the Mini-Mental State Examination cognitive screen (scores range 0 - 30).

Statistical Methods

Participant characteristics were calculated as means and SDs for continuous variables and counts and percentages for categorical variables. We compared characteristics of the eFHS study sample smartphone participants (n=611) to 2 groups of nonparticipants (Table S1 in Multimedia Appendix 1), those who attended the examination in-person (n=834) and those who attended the examination via televisit (n=242). Student *t* tests were performed for continuous variables and chi-square tests were performed for categorical variables. The smartphone survey return rates and completion rates were calculated. The return rate was defined as the percentage of participants who returned a specific baseline survey among the total number of participants who returned at least 1 baseline survey.

baselinereturnrate=nreturnedindividualbaselinesurveynreturnedatleastonebaselinesurveys

The completion rate was defined as the percentage of participants who completed a survey among participants who returned the survey. The completion of a survey was defined as answering 75% of the questions if the survey had 4 or more questions, answering at least 2 questions if the survey had 3 questions. For the falls and hospitalization survey, which has 2 main questions, completion was defined as answering both questions.

baselinecompletionrateforeachsurvey=ncompletedthesurveynreturnedthesurvey

The return rate and completion rate were compared between iPhone users and Android users and between the 2 deployment groups (app surveys sent every 4 wk vs app surveys sent every 2 wk in smaller batches), using chi-square tests.

We examined baseline surveys' results from the self-reported PROMIS surveys (anxiety, depression, fatigue, sleep, cognitive abilities, cognitive function, and physical function) and results from the cognitive function testing task using the Stroop cognitive test given the interest in the research community on incorporating standardized assessments for older adults [36] and mobile cognitive testing. The individual PROMIS surveys were scored and the raw scores were converted to the PROMIS standardized *t* scores [37]. One sample *t* test (2-tailed) was performed to compare scores from our sample to the *t* score of the general population [37]. For the Stroop cognitive testing task, we calculated the completion time and errors of each of the 4 subtasks for each participant. The total completion time of the Stroop Test was calculated and compared between male and female participants, and between age groups younger than 75 years and at or older than 75 years of age.

The MARS and the SUS scores were calculated to assess the usability of the app [35,38]. The total MARS score, the functionality score, and the aesthetics score were calculated and compared between smartphone user groups (iPhone users vs Android users), men and women, and age-groups. Total MARS score is the summation of functionality score and aesthetics score. We also calculated the individual scores for each item of the MARS and SUS and conducted subgroup comparisons (phone type, age group, or sex) using chi-square tests. Due to small sample sizes for some response choices, responses were recategorized. For the MARS, responses 1, 2, and 3 were grouped together and responses 4 and 5 were grouped together. Similarly in the SUS, responses were collapsed into 2 groups: agree or strongly agree and disagree or strongly disagree. The chi-square tests were performed on the regrouped 2-level variables. We performed all analyses with RStudio in R (version 4.3.1; R Foundation) for Windows and considered 2-sided $P<.05$ as statistically significant.

Ethical Considerations

The Offspring examination 10 and Omni examination 5 and the eFHS protocols were reviewed and approved by the Institutional Review Board at Boston University Medical Center (protocol numbers H-32132, H-36586, and H-40737). iPhone users were allowed to choose to use a study Apple Watch. No compensation was given to participants. Data were anonymized for analysis.

Results

Characteristics of eFHS Smartphone Participants

Among FHS Offspring and Omni participants, 611 smartphone users enrolled in eFHS, with a mean age of 73.6 (SD 6.3) years, and included 346 (56.6%) women, 88 (14.4%) multiethnic participants, and 478 (78.2%) iPhone users. eFHS smartphone users on average were well educated (396/610, 64.9% college degree or greater) and reported very good to excellent health (428/610, 70%; Table 1). Among 526 FHS participants who did not enroll in eFHS and provided a reason for declining, 118 (22.4%) did not own a smartphone or computer, 323 (61.4%) did not have an interest in this study, 61 (11.6%) owned technology that was incompatible with the application, and 24 (4.6%) reported a health issue or other reasons. Compared to FHS participants who attended examinations at the research center but did not enroll, eFHS participants using a smartphone on average were younger (73.6, SD 6.3 vs 78.4, SD 8.1, *P*<.001), healthier (428/610, 70.2% vs 480/820, 58.5% self-reported very good or excellent in health, *P*<.001), better educated (396/610, 64.9% vs 328/823, 39.9% with a bachelor's degree and above, *P*<.001), more likely to be married (421/609, 69.1% vs 453/824, 55.0%, *P*<.001), and more likely to be an iPhone user (478/611, 78.2% vs 248/728, 34.1%, *P*<.001) as presented in Table S1 in Multimedia Appendix 1.

Table . Characteristics of the Electronic Framingham Heart Study (eFHS) smartphone users.

Variables		eFHS participants (N=611)
Age (years), mean (SD)		73.6 (6.3)
Sex (female), n (%)		346 (56.6)
Cohort, n (%)		
	Offspring	523 (85.6)
	Omni	88 (14.4)
Smartphone, n (%)		
	iPhone	478 (78.2)
	Android	133 (21.8)
Education, n (%)		
	High school graduates or lower	67 (11)
	Some college or technology certificate	147 (24.1)
	Bachelor's degree and above	396 (64.9)
Income (US $), n (%)		
	<$35,000	50 (10.2)
	$35,000-$74,999	136 (27.8)
	≥$75,000	304 (62)
Retirement status, n (%)		
	Retired and not working	322 (52.8)
	Retired but working (pay or volunteer)	103 (16.9)
	Not retired	185 (30.3)
Marital status (married), n (%)		421 (69.1)
Subjective health, n (%)		
	Poor or fair	25 (4.1)
	Good	157 (25.7)
	Very good or excellent	428 (70.2)
Depressive symptoms, mean (SD)		5.6 (6.5)
Number of medications, mean (SD)		5.1 (3.8)
Mini-Mental State Examination score, mean (SD)		28.7 (1.4)
Walk test, meters/second, mean (SD)		1.13 (0.22)

Survey Return Rates and Completion Rates

Among the 611 eFHS smartphone users, 596 (97.5%) returned at least 1 baseline survey including 470 of 478 (98.3%) iPhone users and 126 of 133 (94.7%) Android users. The iPhone users had a slightly higher return of at least 1 baseline survey compared to Android users (98.3% vs 94.7%, *P*=.02). For nearly all the individual baseline surveys, compared to the Android users, the iPhone users had a higher return rate (Tables 2 and 3). For both iPhone and Android users, the set of individual surveys sent at week 0 had higher return than the set of individual surveys sent at week 0 or week 2 (iPhone wk 0 survey return, 437/470, 93% to 462/470, 98.3% vs wk 0 or wk 2 return 402/470, 85.5% to 437/470, 93%; and Android wk 0 survey return, 109/126, 86.5% to 120/126, 95.2% vs wk 0 or wk 2 return 93/126, 73.8% to 99/126, 78.6%). Both smartphone user groups had very high completion rates for all baseline surveys, all above 90% indicating once the participant returned the surveys, they were very likely to complete them (Tables 2 and 3). Individual survey return differed by deployment group. Participants who received baseline surveys in smaller batches every 2 weeks had lower return rates for the set of individual surveys sent out at week 2 compared to participants who received the same set of surveys at week 0 (Table S2 in Multimedia Appendix 1, all *P*<.002). Baseline survey return did not differ by deployment group for the set of individual surveys sent at enrollment (wk 0). There was no difference in completion rates between the 2 deployment groups (Table S2 in Multimedia Appendix 1). The return rate for the 4 tasks ranged from 380 of 470 (80.9%) for the gait task to 418 of 470 (88.9%) for the Trail Making Test task (Table 3).

Table . Survey return rates and completion rates in iPhone and Android users who returned at least 1 baseline survey. Some participants received all baseline surveys at week 0 and some participants received some baseline surveys at week 0 and the remaining at week 2. Surveys under all week 0 were deployed at week 0. Surveys under week 0 or week 2 were deployed at week 0 or week 2. All the *P* values in comparing the completion rates are >.05.

Survey or task		Return, n (%) iPhone users (n=470)	Return, n (%) Android users (n=126)	*P* value	Completion, n (%) iPhone users (n=470)	Completion, n (%) Android users (n=126)
All week 0						
	Mood (depression and anxiety)	444 (94.5)	109 (86.5)	.002	439 (98.9)	108 (99.1)

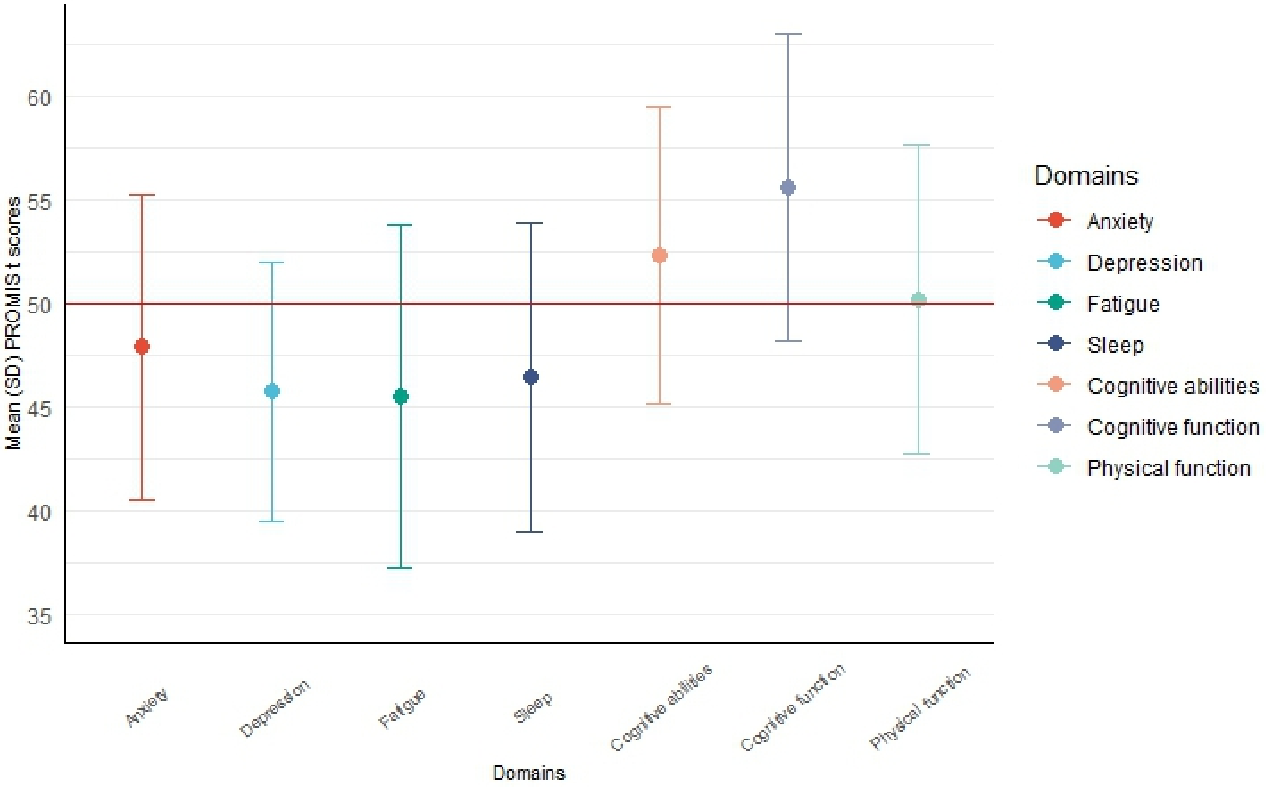
Stroop	404 (86)
Two-finger tap	417 (88.7)
Gait	380 (80.9)

Distribution of PROMIS Scores Across Domains and Stroop Task Completion Time

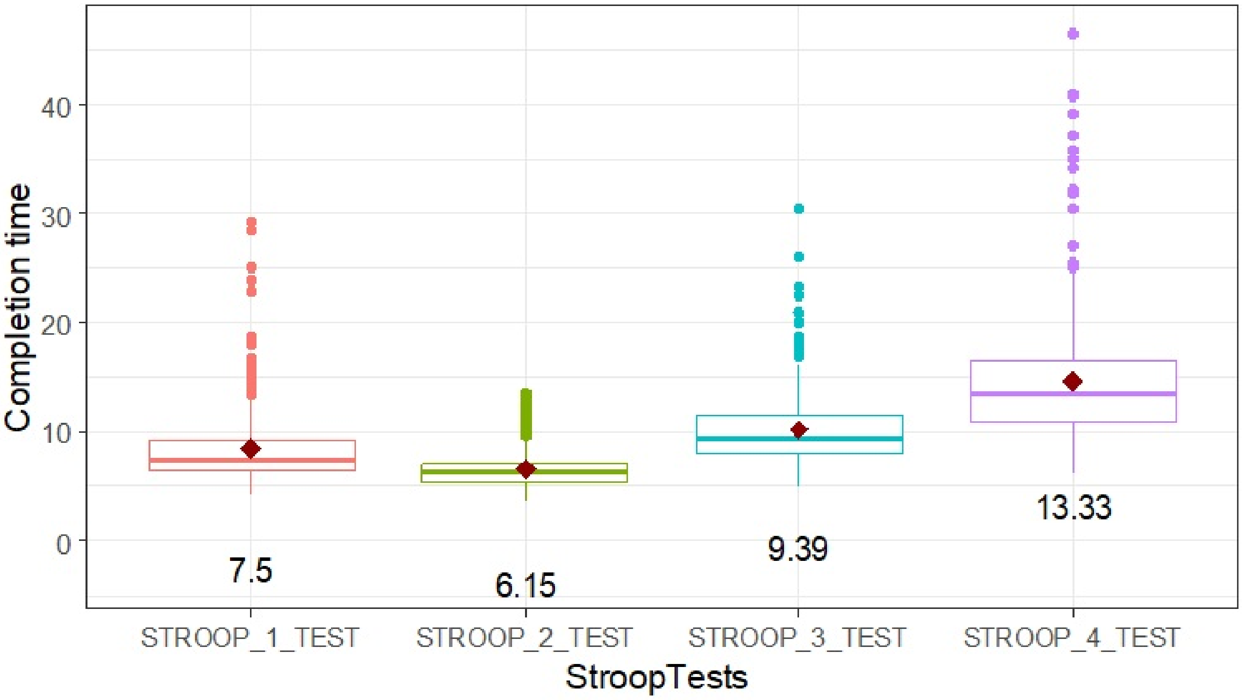
Means and SDs of each PROMIS domain survey are shown in Figure 3. Compared to the reference *t* score of 50 for the US general population, eFHS participants had lower scores in the anxiety (47.9), depression (45.7), fatigue (45.5) and sleep (46.4) domains, and higher scores in cognitive abilities (52.3) and cognitive function (55.6) domains indicating better functioning or lower symptoms (all *P*<.001).

Figure 3. Mean and SD of baseline PROMIS survey scores by domain. The red line represents the general population mean (*t* score=50) determined by PROMIS. Higher scores for cognitive abilities and cognitive function indicate better functioning whereas lower scores for anxiety, depression, fatigue, and sleep indicate better symptoms. PROMIS: Patient-Reported Outcomes Measurement Information System.



For the Stroop cognitive testing task, the mean total completion time for the 4 subtasks was 39.6 (SD 10.1) seconds. Participants spent more time on the most difficult subtask 4 than the other 3 subtasks and spent more time on subtask 3 than subtask 1 and subtask 2 (Figure 4). The mean completion times for the 4 Stroop subtasks ranged from 6.2 seconds for subtask 2 to 13.3 seconds for the most complex subtask 4. Time to complete the test was similar in males and females whereas the older age group (age 75 y and older) had longer completion times than the younger age group (under 75 y, mean 42.8, SD 11.7 vs mean 37.1, SD 7.8 s, *P*<.001).

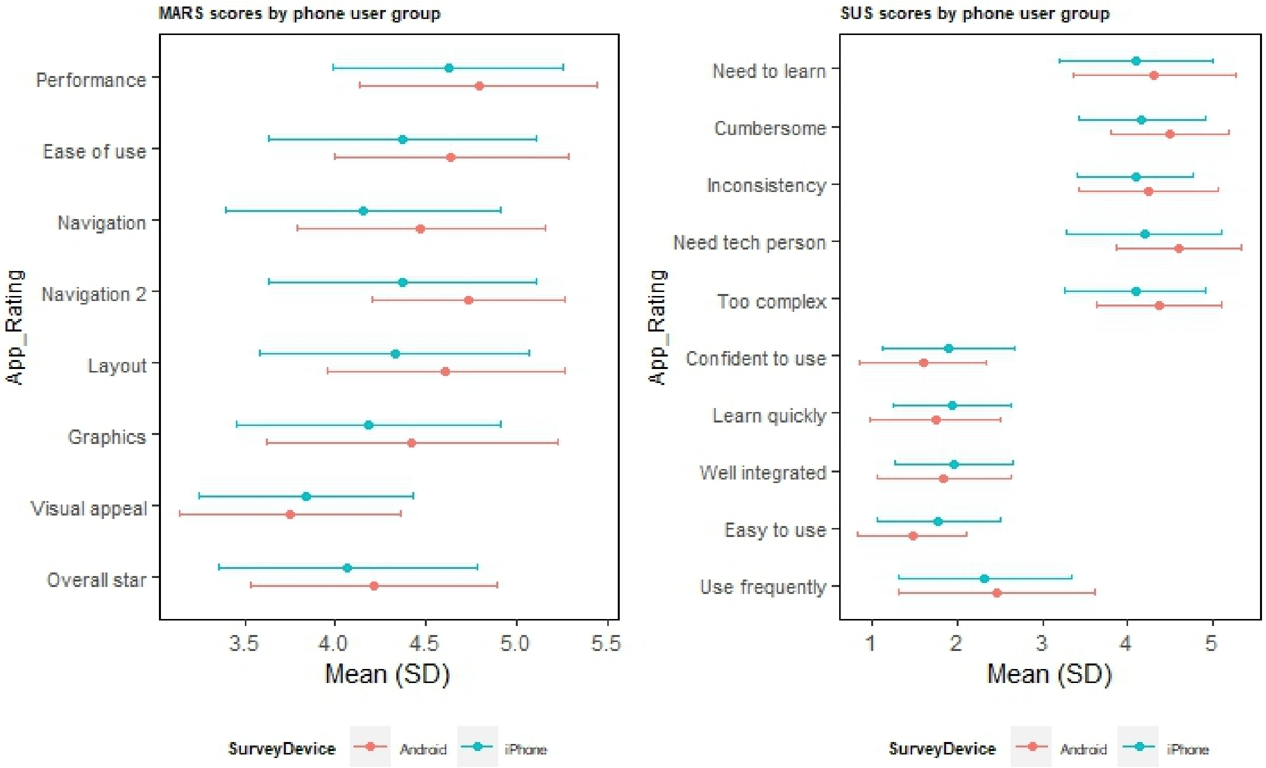
Figure 4. Stroop task distribution of test time scores in each of the 4 subtests. Completion time in seconds.



Satisfaction With the Smartphone App

There were 469 smartphone users who returned the MARS surveys including 80 Android users and 389 iPhone users. There were 475 smartphone users who returned the SUS survey including 81 Android users and 394 iPhone users. In general, eFHS participants were satisfied with the app with a mean total MARS score of 8.6 (SD 1.1), a functionality score 4.4 (SD 0.6), and aesthetics score (4.1, SD 0.6). Android users and women tended to have slightly higher functionality, aesthetics, and total MARS scores. Participants in the younger age group (<75 y) had a slightly higher functionality score (Figure S4 in Multimedia Appendix 1). Compared to iPhone users, Android users had higher scores for the individual MARS items including in performance, ease of use, navigation (navigating between screens), navigation 2 (navigating within screen and consistency across screens), layout, and graphics (Figure 5). However, only navigation (*P*=.005) was significantly different likely due to the small sample size of Android users. There was no difference for the individual MARS items between men and women or between the 2 age groups (<75 vs ≥75 y; Figure S3 in Multimedia Appendix 1).

Figure 5. MARS survey and SUS survey results by smartphone type. *P* value for navigation in MARS <.05, *P* values for all other surveys questions in MARS and SUS >.05. MARS: Mobile App Rating Scale; Navigation 2: navigating within screen and consistency across screens; SUS: System Usability Scale.



For the SUS survey, participants agreed or strongly agreed that the app was well designed or easy to use. The mean ratings were less than 2 in the 5 questions in favor of the app for which the response ratings 1 and 2 indicated "strongly agree" and "agree," respectively. They disagreed or strongly disagreed that the app was too complicated or burdensome. The mean ratings were greater than 4.1 in the 5 questions opposed to the app (too complex, cumbersome, need a technical person, inconsistent, and need to learn a lot of things), for which the response ratings of 4 and 5 indicated "disagree" and "strongly disagree" (Table S3 in Multimedia Appendix 1). In the SUS, the ratings did not differ in Android and iPhone users (Figure 5), in men and women and in the 2 age groups (Figure S3 in Multimedia Appendix 1). Participants also provided comments such as "too technical" or "tough to do without glasses" for "what were some obstacles you faced using this system?," and "very easy and convenient" or "to think more about my health & to increase my physical activity" for "what did you like the most about the system?"

Discussion

During the COVID-19 pandemic we successfully enrolled a new eCohort of community-dwelling older adults from the FHS to collect a variety of health information data using smartphone app-based surveys and tasks that the participants could complete at home at a time that was convenient for them. Survey return was high with 596 (97.5%) participants returning at least 1 survey. Importantly once surveys were returned, survey completion rates were greater than 90%. Participants who provided feedback using both the MARS and SUS surveys indicated satisfaction with the app, finding the app rather easy to use. Finally, we leveraged an in-person examination at the FHS research center to enroll most of the participants into our digital study. The in-person examination provided a touchpoint for this study's research assistant to provide one-on-one assistance with app download and the ability to answer other technologic queries the participant may have had. Our enrollment protocol was consistent with recent guidelines advocating face-to-face training to support older adults using smartphone apps [39] to improve confidence and lower potential for abandonment of technology.

Our study demonstrates the ability to collect a broad array of outcome measures and cognitive and physical function tasks important to older adults using smartphone app surveys including physical symptoms (eg, sleep and fatigue), mental health symptoms (eg, depression or anxiety), physical function, cognitive abilities, and cognitive tasks (Stroop and Trail Making). The ability to collect data remotely may facilitate inclusion of older adults in clinical trials by reducing the burden in time and cost for the participant associated with the need to travel to the clinical trial center [40]. Further, longitudinal smartphone based assessments may improve clinical care by permitting monitoring of older adults at risk for cognitive [41] or physical decline [9,42] and by empowering older adults to participate in management of chronic conditions. However persistent inequities in smartphone ownership and access to high-speed internet at home [43] will need to be addressed to ensure that technologic advances benefit all groups including older adults residing in rural locations and older adults with lower income and educational levels. Enrollment and engagement in our study differed by smartphone type with iPhone users having higher enrollment (478 of 829, 57.7% of iPhone users vs 133 of 342, 38.9% of Android users enrolled) and survey return. iPhone users had higher income compared to Android users (246 of 378, 65.1% vs 58 of 112, 51.8% reported an income of US $75,000 or more; Table S5 in Multimedia Appendix 1). The Android smartphone may be a proxy for sociodemographic factors associated with the digital divide while the iPhone may reflect a higher level of interest in digital devices and technology self-efficacy as observed in our younger eCohort [14]. Finally, others have shown technology use declines with changes in health status [44]. Consistent with this report, we observed that our eCohort of older adults had several favorable sociodemographic attributes and health metrics (lower number of self-reported medications or higher cognitive test scores). Future studies are needed to identify strategies to engage older adults with technologies they find meaningful as their health changes.

Our study had several strengths. Our eCohort was embedded in the FHS allowing us to understand the characteristics of participants who enrolled in the eCohort versus participants who did not. The high survey return rates observed may in part be due to participant loyalty to the parent FHS. Our study has some limitations that merit comment. The participants were primarily White, well-educated, and resided in New England and therefore may not be representative of older adults from more diverse backgrounds or geographic locations. However, 88 of 611 (14.4%) of our sample included older adults from more diverse racial or ethnic backgrounds (Omni cohort). Our eFHS sample had a higher proportion of iPhone users (478 of 611, 78.2%) than observed in older adults in the United States (49%) [45]. The eCohort was healthier than FHS participants who chose not to enroll and healthier than the general US population using standardized PROMIS scores (Figure 3) and may not reflect smartphone app survey use of older adults with poorer health metrics. Finally, we report survey return and completion for the baseline surveys only and more work is needed to determine longitudinal patterns of technology use.

Our study demonstrates the ability to engage older adults including those over age 75 years in the use of smartphone technology to monitor a range of health metrics. The high survey return and completion rates observed and high usability ratings suggest that smartphone app surveys may be an efficient tool to collect health data in this age group. Our study observations will be useful to researchers, clinicians, and public health professionals designing and implementing digital solutions so that older adults with highest risk for not engaging with technology can be targeted for meaningful supports. Future trials should assess the effect health-based smartphone surveys have on older adults' ability to self-monitor their own health and chronic conditions. Conducting these trials in the health care system with clinicians will be critical to the implementation of these efforts into usual clinical practice. More digital studies of older adults are needed to determine the perceived value to the older user and the health monitoring benefits from the health care provider perspective.

Abstract

Background: Older adults discharged from the emergency department (ED) face elevated risk of falls and functional decline. Smartphones might enable remote monitoring of mobility after ED discharge, yet their application in this context remains underexplored.

Objective: This study aimed to assess the feasibility of having older adults provide weekly accelerometer data from an instrumented Timed Up-and-Go (TUG) test over an 11-week period after ED discharge.

Methods: This single-center, prospective, observational, cohort study recruited patients aged 60 years and older from an academic ED. Participants downloaded the GaitMate app to their iPhones that recorded accelerometer data during 11 weekly at-home TUG tests. We measured adherence to TUG test completion, quality of transmitted accelerometer data, and participants' perceptions of the app's usability and safety.

Results: Of the 617 approached patients, 149 (24.1%) consented to participate, and of these 149 participants, 9 (6%) dropped out. Overall, participants completed 55.6% (912/1639) of TUG tests. Data quality was optimal in 31.1% (508/1639) of TUG tests. At 3-month follow-up, 83.2% (99/119) of respondents found the app easy to use, and 95% (114/120) felt safe performing the tasks at home. Barriers to adherence included the need for assistance, technical issues with the app, and forgetfulness.

Conclusions: The study demonstrates moderate adherence yet high usability and safety for the use of smartphone TUG tests to monitor mobility among older adults after ED discharge. Incomplete TUG test data were common, reflecting challenges in the collection of high-quality longitudinal mobility data in older adults. Identified barriers highlight the need for improvements in user engagement and technology design.

Introduction

Each year, millions of older adults are discharged from emergency departments (EDs) across the United States [1]. A growing body of evidence indicates that these individuals face high risks of adverse outcomes after ED discharge, including falls [2] and functional decline [3]. While guidelines aim to identify those at risk of poor outcomes [4], existing fall risk screening tools using data at the time of the ED encounter have limited ability to predict which patients will fall [2].

One way to improve the identification of older adults at risk for falls is to incorporate remote patient monitoring (RPM) of mobility into postdischarge care. Mobility, which includes gait and balance functions, requires the integration of sensory input, motor planning, and coordination. Gait alterations and balance issues are common in individuals aged 65 years and older [5,6] and both significantly increase the risk of falls [7]. RPM of gait and balance in home settings may identify mobility problems that are not readily apparent in controlled settings [8]. Additionally, RPM allows for examination of within-person changes over time, which can improve the discrimination of predictive models [9]. However, the success of any RPM depends heavily on the practicality and usability of the technology for older adults.

Numerous tools exist that allow for RPM of gait and balance, including external sensors (eg, cameras and force plates) and wearable sensors (eg, smartphones). Unlike external sensors, which require potentially expensive hardware and installation, wearable sensors are portable; cheaper; and in the case of smartphones, near ubiquitous [10]. Smartphones are equipped with inertial measurement units, typically composed of an accelerometer and a gyroscope. These sensors enable smartphones to accurately monitor gait mechanics [11], which can identify individuals at higher risk of falls [12]. Despite these capabilities, the potential of smartphone-based RPM of mobility after ED discharge remains largely unexplored. Describing and understanding the drivers of participants' engagement with RPM in research is necessary to determine the success of future real-world implementation of RPM in clinical services.

This study aimed to assess the feasibility of having older adults provide weekly accelerometer data from an instrumented Up-and-Go test [12] over an 11-week period after ED discharge. The Up-and-Go test (commonly referred to as the Timed Up-and-Go [TUG] test) involves an individual getting up from a chair, walking forward, turning, returning to the chair, and sitting. The TUG test was chosen because it is simple and quick and evaluates several key risk factors, including gait and balance, in a single assessment. Instrumented TUG tests using body-worn sensors can identify distinct gait patterns and balance issues [13], are validated against standard kinematic measures [14], and can distinguish between individuals who have experienced falls and those who have not [12]. To our knowledge, no prior study has reported on adherence to at-home TUG tests.

The primary focus of this study was on adherence, defined as the degree to which the user followed the program as designed [15], which involved completing weekly at-home instrumented TUG tests. Secondary aims focused on data quality, app usability, safety during at-home functional tasks, and barriers to adherence. Data quality is essential for generating meaningful gait and balance features, and various user-specific factors can negatively impact it [16,17]. Findings from this study provide foundational information for developing age-friendly RPM technologies, anticipating the increasing demand for improved postdischarge transitional care among older adults in the coming years.

Methods

Study Design

This study was a single-center, prospective, observational, cohort study of ED patients.

Ethical Considerations

This study was approved by the Stanford University institutional review board (IRB #64194), and written informed consent was obtained from all participants. The data collection app (GaitMate) was built using Stanford's Cardinal Kit and all data were stored in a secure Firebase account managed by Stanford Research IT. Participants were required to log in using a unique ID with each app task; this ID was the sole identifier linking them to the data. Compensation of up to US $90 was offered to study participants.

Study Setting and Participants

A convenience sample of patients was recruited by research associates (RAs) from a single academic ED with an annual volume of 100,000 visits. Patients were eligible for participation in the study if they were 60 years of age or older, were to be discharged home, and owned an iPhone. We excluded from the study patients currently living in a nursing home, patients with limited English proficiency, patients who could not walk unaided (ie, walking without an assistive aid), and patients without the capacity to provide informed consent. If a participant moved to a nursing home after the time of consent but during the follow-up period, they remained in the study. The study is reported in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for reporting observational studies [18].

Study Procedures

Overview

In the ED, RAs helped participants download the GaitMate app and led them through the self-report and functional baseline assessments. For 11 weeks after ED discharge, patients were asked to complete a weekly TUG test and to report any falls through the app. At 12 weeks after discharge or enrollment, we attempted to reach all participants by phone to collect data on perceived ease of app use and safety during at-home TUG tests.

Onboarding and Baseline Assessments

In the ED, each participant was guided by an RA to download the GaitMate from the Apple App Store and was assigned a unique ID they used to access the app thereafter. Next, participants were led by the RA through baseline survey questions. Subsequently, participants were presented with an in-app instructional video detailing the TUG test [19]. The RA then demonstrated the TUG procedures and helped participants complete the first task in the ED, which involved the participant standing up from a seated position, walking 2 meters, turning around, returning to the chair, and sitting down. To augment the assessment, we provided participants a waist belt equipped with a pouch to securely hold the smartphone during the TUG test. This setup enabled us to collect 3-axis accelerometer data from the phone, positioned near the body's center of mass, thereby allowing us to estimate spatial characteristics of steps. Participants who had difficulty placing the phone in the pouch and rotating to their back were instructed to keep it in the front. Multimedia Appendix 1 provides an example of the waist belt and phone placement. We chose a 2-meter walking distance for the TUG test instead of the original 3 meters given that there is limited space in the ED to perform the TUG test and concerns about the unobstructed space in patients' homes. After completing the task, participants removed the phone from the pouch and pressed the "DONE" button, prompting the transmission of the accelerometer data directly to institutional research servers for analysis. Multimedia Appendix 2 presents screenshots of the GaitMate app.

Home-Based Assessments

Each Sunday at 12 PM for 11 weeks following ED discharge, participants received a GaitMate notification prompting them to complete their weekly TUG test. After entering their ID, they were instructed to tap the "Weekly Check-in" button. Participants then viewed an instructional video on the task and were asked to complete a safety checklist. This included verification of having cleared a walking space, having set up a chair to one side, having put on regular footwear and the belt pouch, and having someone present to assist if needed. After completing the checklist, participants were asked to tap the "READY" button to start recording data. In addition, participants could log any fall by tapping the "Report a fall" button on the main screen, which would prompt the participant to record (1) the date of a fall, (2) time of fall, and (3) injury associated with fall. At-home TUG test completion was monitored by RAs. When a participant missed 3 weeks in a row, RAs attempted to reach that participant by email once and then phone to probe barriers to completing at-home tasks with open-ended questions. If a participant lost their ID, they were provided with the contact information of study investigators.

Follow-Up Phone Call

At 11 weeks following ED enrollment, a trained RA called all participants by phone, making up to 3 attempts before marking the participant as lost to follow-up. Follow-up phone calls assessed falls over the study period and whether any occurred during at-home TUG tests, perceived ease of app use, and safety while completing at-home TUG tests.

Measures

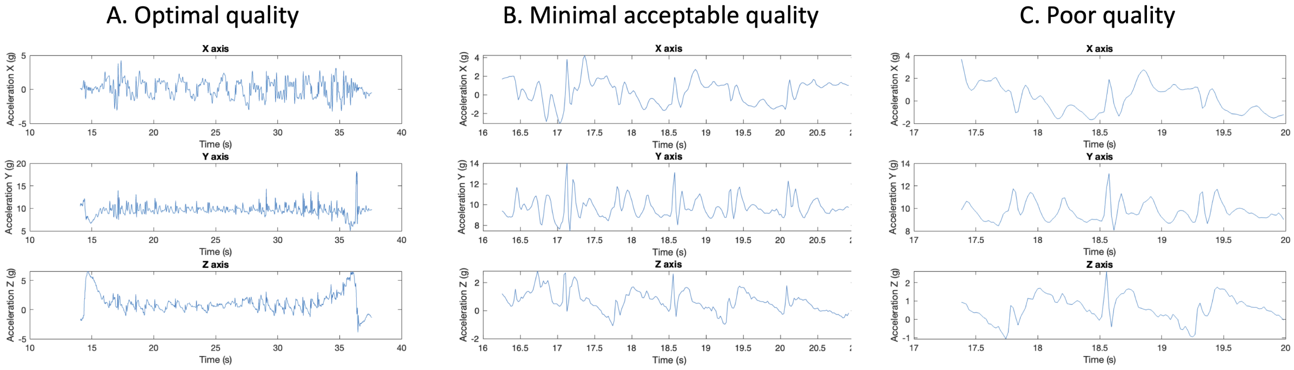
Baseline Assessments

To understand how ED patients who enrolled differ from those who did not, we collected limited information (ie, age, sex, chief complaint, and illness severity) on all prescreened patients. To understand the baseline characteristics of our participants, we additionally recorded race, ethnicity, ED chief complaints, and active medical problems.

Functional Task Completion

The primary outcome was the completion of the weekly TUG tests, defined as any transmitted accelerometer data for a given week. The secondary outcome was accelerometer data quality, assessed by 2 RAs independently, with the lead author serving as an arbiter when there was disagreement. All data-quality assessors have extensive training and experience segmenting and generating gait and balance features using accelerometer data. Each task submission was classified as one of four categories: (1) *Optimal data quality*, defined as unambiguous visual segmentation of the data into the sit-to-stand, walk-away, walk-back, and stand-to-sit portions of the gait task; (2) *Minimal acceptable data quality*, defined as whether at least 3 steps during the walk-away or walk-back segment could be visually identified; (3) *Poor data quality*, defined as cases that did not meet category 1 or 2 but where some data were transmitted; and (4) *Missing*, if no data were transmitted for active participants. Figure 1 illustrates accelerometer data in the first 3 categories.

Figure 1. Examples of accelerometer data quality. (A) Optimal quality: there are clear sit-to-stand, walk-away, walk-back, and stand-to-sit portions of the gait task as well as displacements indicative of steps. (B) Minimal acceptable quality: there is a truncated segment with a grouping of at least 3 steps. (C) Poor quality: there is a severely truncated segment without 3 consecutive displacements indicative of steps.



A. Optimal quality

B. Minimal acceptable quality

C. Poor quality

Follow-Up Assessments

To assess falls during the study period, we asked "In the past 3-months, how many times have you fallen?" followed by "Did any of these falls result in injury?" and "Did any of these falls result in the need to seek acute medical care?" Finally, we asked "Can you recall the situation that led to the fall?" To understand how participants perceived the GaitMate app, we asked "How much do you agree or disagree with the following statements: (1) Overall, the app was easy to use. (2) I felt safe completing the gait task at home." Response options ranged on a 5-point scale from strongly agree to strongly disagree. For simplicity, we collapsed the 5-point scale into 3 categories: agree, disagree, and neither agree nor disagree.

Data Analyses

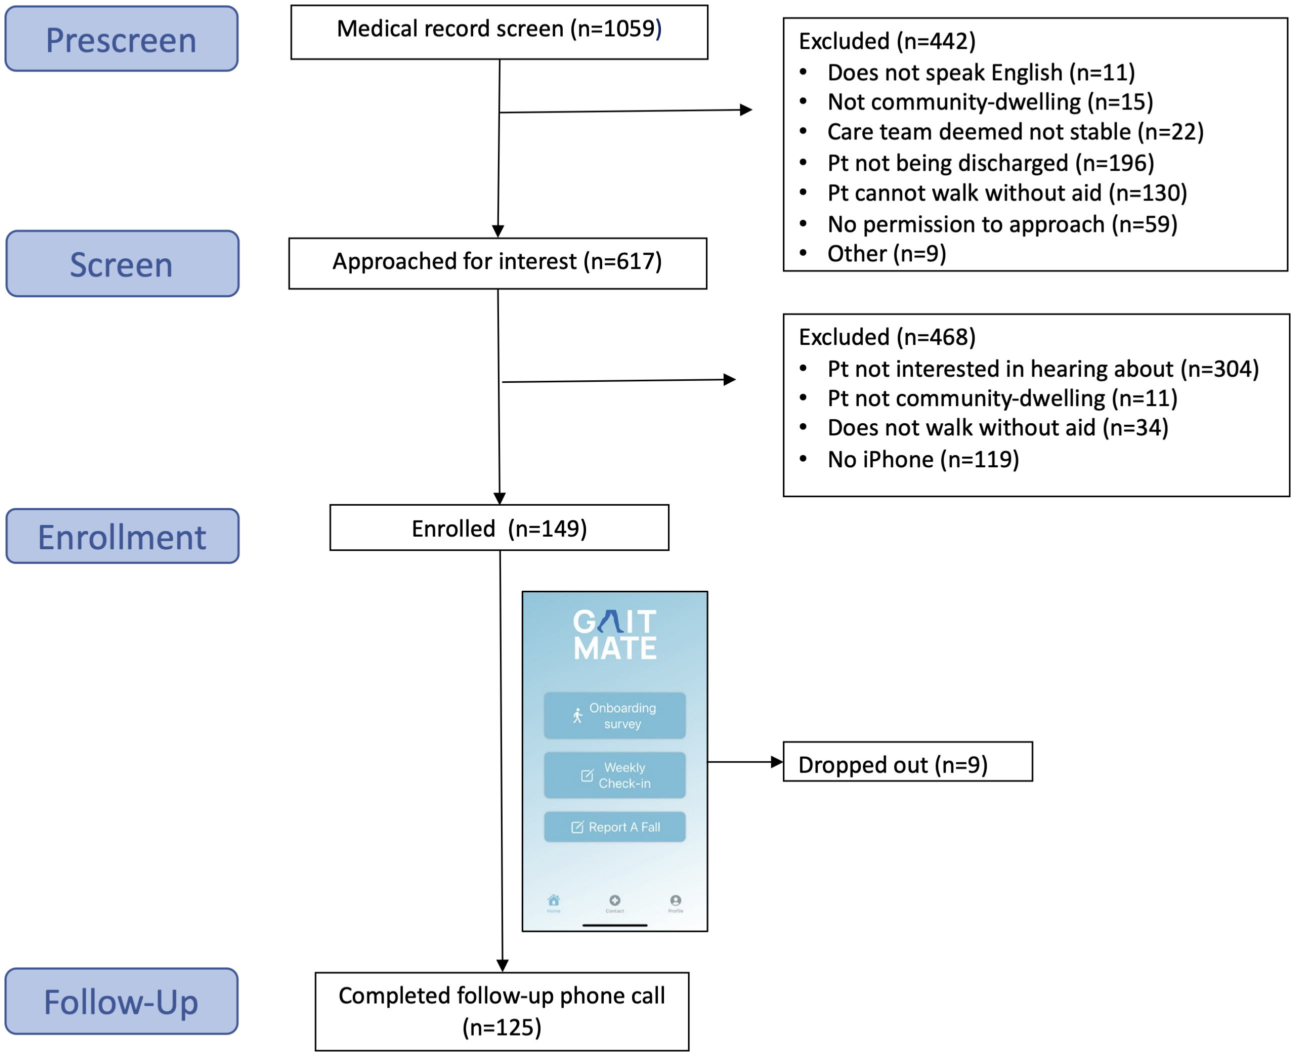
For our primary analysis, we first calculated the TUG test submission rates by week and by participant. We then categorized participants into low adherence (0%-49%), moderate adherence (50%-99%), or perfect adherence (100%) and used ordered logistic regression models to examine whether the adherence was associated with participant characteristics of age, sex, race, active medical problems, and chief complaint category. In secondary analyses, we calculated the distribution of data-quality categories for each week and by participant. To quantify older adult perceptions of GaitMate usability and safety, we calculated the percentage who agreed with the usability and safety statements. To understand barriers to adherence, we described qualitative feedback from participants when they reported difficulty with the app.

Results

Study Enrollment and Retention

Figure 2 outlines the flow of patients from enrollment through follow-up. From December 5, 2022, to August 9, 2023, we identified 1059 ED patients from the medical record who were aged 60 years or older. We excluded 442 ED patients after discussion with ED providers, with the majority excluded because they either were not being discharged to home (196/442, 44.3%) or could not ambulate unaided (130/442, 29.4%). We approached 617 patients for screening, among whom 468 (75.9%) were not interested in study participation, resulting in the recruitment of 149 participants. Common qualitative reasons for nonparticipation included feeling too sick, too busy, or lack of interest. There were no statistical differences in patient age, sex, or Emergency Severity Index between those who agreed to participate and those who did not. Of the 149 participants, 9 (6%) dropped out of the study: 4 (2.7%) participants prior to completing baseline assessments, 4 (2.7%) more participants in week 1, and 1 (0.7%) participant in week 7. Follow-up assessments at week 12 were completed by 125 (89.3%) of 140 retained participants.

Figure 2. Participant screening, enrollment, and follow-up. Pt: patient.



Participant Characteristics

Table 1 demonstrates the descriptive characteristics of the 149 enrolled participants. The mean age of the enrolled participants was 72.3 (SD 8.2) years, and the majority (n=91, 61.1%) were male. Almost half of participants (n=69, 46.3%) had fallen in the past year, indicating a fall-vulnerable cohort. The presenting ED complaints were highly varied, with only 10% (n=15) presenting for fall-related care. Participants had the comorbidity profile expected of older adults, with 63.8% (n=95) having high blood pressure, 40.9% (n=61) having heart disease, and 51.7% (n=77) reporting a past orthopedic surgery.

Table . Baseline characteristics.

Variable	Enrolled participants (n=149)
Demographics	
Age (year), mean (SD)	72.3 (8.2)
Female, n (%)	58 (38.9)
White, non-Hispanic, n (%)	98 (65.8)
Fall history, n (%)	
Any fall in the past year	69 (46.3)
ED[a] chief complaint category, n (%)	
Cardiac	27 (18.1)
Respiratory	5 (3.4)
Gastrointestinal	20 (13.4)
Neurological	31 (20.8)
Genitourinary	6 (4)
Fall	15 (10.1)
Musculoskeletal	22 (14.8)
Other	23 (15.4)
Medical history, n (%)	
Cardiac or heart disease	61 (40.9)

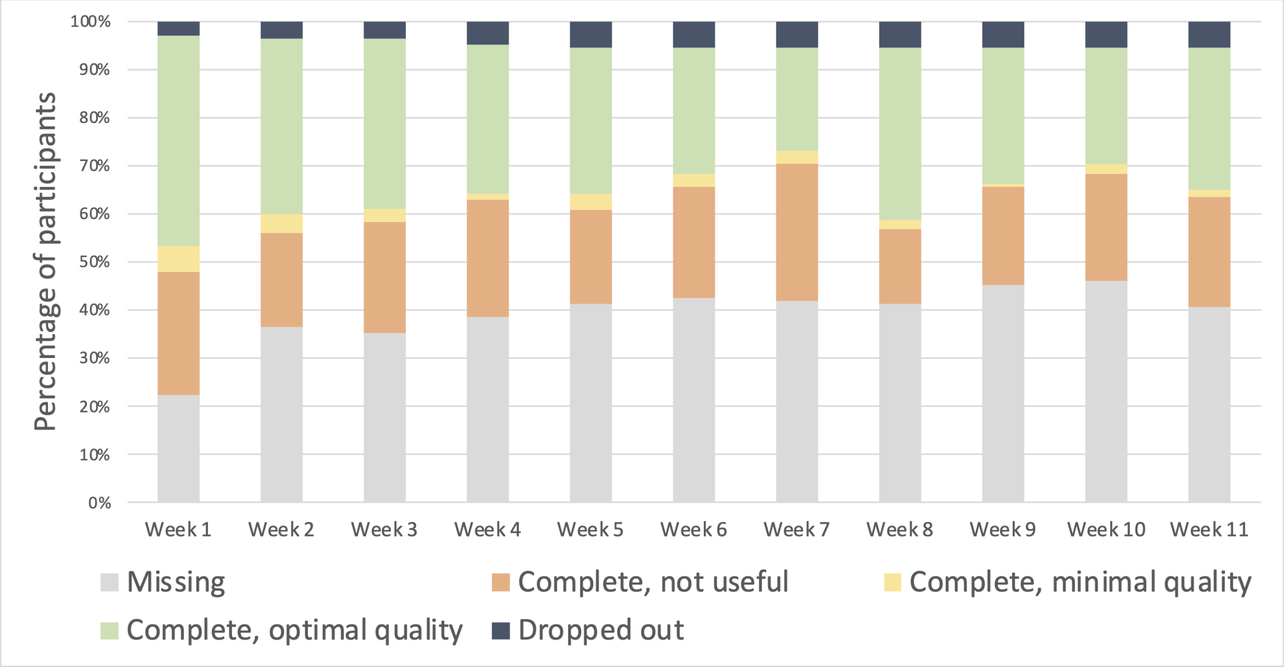
High blood pressure	95 (63.8)
Orthopedic surgeries	77 (51.7)

[a] ED: emergency department.

Task Completion Rates

Figure 3 summarizes task completion and data quality over the course of the study. Accelerometer data from 55.6% (912/1639) of weekly TUG tests was transmitted over 11 weeks after discharge. The completion rates declined from 59.7% (89/149) in week 1 to 53.7% (80/149) in week 11. Overall, 23.4% (35/149) of participants completed TUG tests in all 11 weeks, 18.8% (28/149) did not complete any TUG tests, and 57.7% (86/149) of participants completed TUG test in at least 6 weeks. Adherence was similar across sex, race and ethnicity, active medical problems, and chief complaint categories.

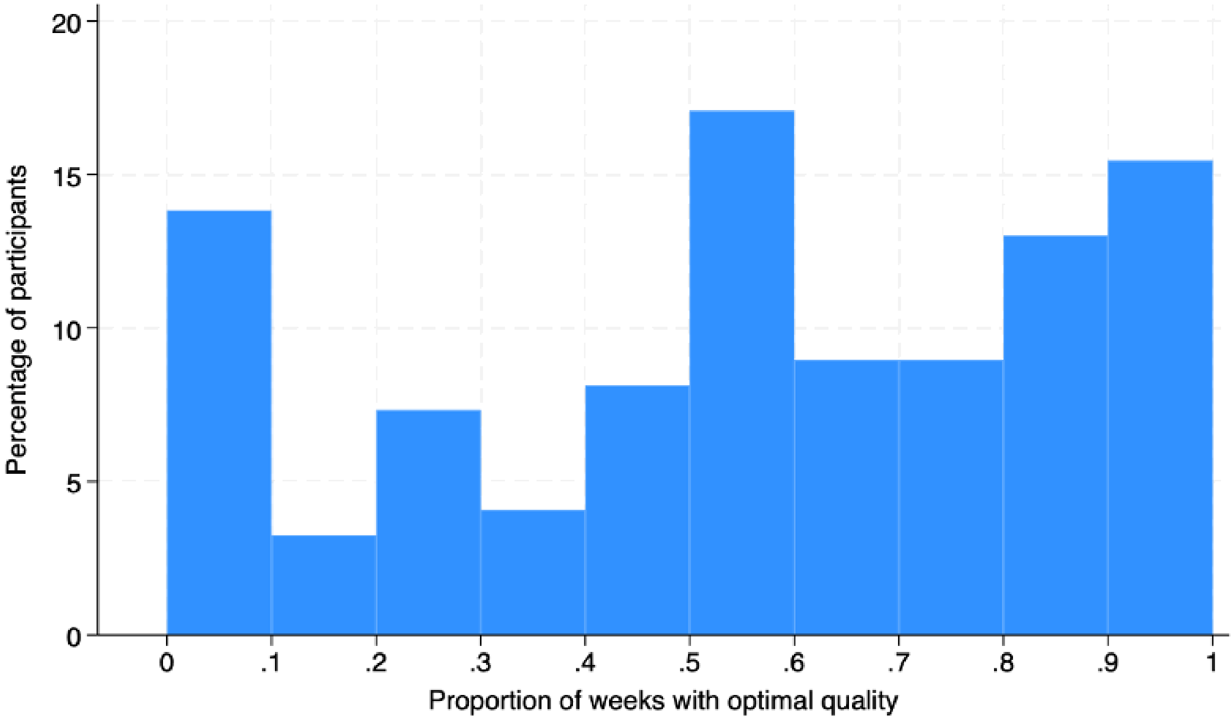
Figure 3. Gait data completeness and quality over the study period.



Data Quality

Overall, 31% (508/1639)of submitted data were rated as optimal quality, declining from 43.6% (65/149) in week 1 to 29.5% (44/149) in week 11. An additional 2.6% (42/1639) of submissions were rated as minimal acceptable quality, which remained relatively stable for the duration of the study. Almost exclusively, the submissions classified as poor quality seemed to be from truncated samples (see Figure 1 for an example). There was a high degree of variability across participants, as shown in Figure 4. For example, 14.1% (21/149) of participants did not have any weeks with optimal data quality, and 16.1% (24/149) of participants had optimal data quality in all 11 weeks.

Figure 4. Distribution of participants by proportion of weeks with optimal data.



Fall Rates

During the study period, 27 (21.6%) out of 125 participants reported falling at least once and 8 (6.4%) reported more than 1 fall. Among the 27 patients who fell, 13 (48%) reported the fall through the GaitMate app in addition to follow-up, whereas the remainder were reported through phone follow-up alone. A total of 13 (48%) out of 27 patient reported a fall injury and 2 (7%) reported needing acute medical care for the fall. None of the falls occurred during the at-home TUG tests.

Usability, Safety, and Qualitative Feedback

Among the 119 participants who completed phone follow-up, 99 (83.2%) agreed that the GaitMate app was easy to use, whereas 11 (9.2%) disagreed. A total of 114 (95.8%) agreed that they felt safe completing the at-home TUG tests, whereas only 1 (0.8%) disagreed. We identified several key barriers to completing at-home TUG tests. Several participants (n=3) related that they missed TUG test submissions because they did not have someone present with them and so could not fulfill the pretask safety checklist. A couple of participants (n=2) reported that they were busy with managing medical issues, and several (n=3) reported losing or forgetting their ID. Some participants (n=5) relayed that they either did not notice the app notification delivered each Sunday or found the “Weekly Check-in” button inactive when they had a TUG test due. Finally, some participants (n=5) stated that they accidentally tapped the “DONE” button when placing the phone in the waist belt pouch, thus prematurely ending the task for the week.

Discussion

This study explored the feasibility of collecting weekly accelerometer data during an instrumented TUG test from older adults after ED discharge using a custom iPhone app and the factors influencing adherence to this RPM technology. Our primary finding is that, among a diverse cohort of older ED patients with fall risk, the majority of weekly at-home TUG samples were submitted, with declines over 11 weeks after discharge. We also found that about a third of submitted accelerometer data were of optimal quality. Together, these findings suggest that collecting high-quality longitudinal mobility data in older adults is challenging.

To our knowledge, this is the first report of adherence to at-home functional mobility assessments in community-dwelling older adults. The adherence found in this study is better than most prior studies using app-based remote assessments. For example, a systematic review of 99 studies examining adherence to mobile health apps, most of short duration and few including older adults, found an average adherence of 56% [15]. Comparing our findings to other RPM studies is difficult given the lack of reliable reporting on longitudinal engagement in prior work [20].

Our findings provide insights into technical and human factors that may have influenced protocol adherence. For the participants who completed no weekly tasks, there seemed to be issues around technological literacy that could not be overcome in study orientation or follow-up support phone calls. For the participants with variable adherence, factors included needing assistance to perform tasks, technical issues with the app, forgetfulness, and acute health issues during the monitoring period. The GaitMate app prioritized safety by requiring participants to have another person present during task completion which was problematic for the participants who lived alone.

Other human factors influencing adherence included lost or forgotten user IDs, missed app notifications, and distracting acute health events. To meet regulatory concerns, we required re-entry of a unique ID for each app use, but several participants reported this as an undesired barrier to completion. Our finding that notifications were often missed suggests that alternative modalities such as SMS text messaging might improve task completion rates [21]. Technical difficulties such as premature TUG test closure due to accidental screen taps could be addressed by removing that design feature or requiring verification before ending. Addressing these barriers is crucial for boosting the engagement and effectiveness of RPM interventions.

We also identified human factors affecting data quality, with the majority of poor samples likely due to inadvertent button presses prematurely terminating data logging. Future versions should consider an extra verification step before stopping data capture. Variability in quality may also indicate difficulties in properly positioning or securing the smartphone in the waist-worn pouch. These findings highlight the need to carefully balance user experience with optimal data collection in RPM. Alternative wearable technologies such as Fitbits or smartwatches could allow easier data gathering but have other limitations around compliance, charging requirements, and costs. Prior work shows that older adults have high Fitbit adherence [22], but current models lack the high-resolution accelerometry needed for detailed gait or balance analysis. Smartwatches are promising [23] but limited by the costs of these devices. Further, reliably extracting high-quality gait metrics from wrist-worn sensors is technically challenging given that arm swing is uncoupled from leg motion.

Limitations of our study include the reliance on a convenience sample from a single academic ED, which may limit the generalizability of our findings. Our sample was also younger and more male than typical ED patients who fall [24]. Additionally, the study’s design did not allow for a comparison of adherence to other types of tasks and app designs, limiting the interpretation to TUG tasks with our specific app interface. Future research should aim to address these limitations by incorporating a more diverse participant pool, extending the follow-up period, and designing real-time analytics on gait and balance after discharge to focus fall prevention efforts. Further exploration into personalized interventions and feedback mechanisms within RPM technologies and how to incorporate these into health care systems could also enhance patient engagement and adherence.

In conclusion, our study contributes to growing evidence on the potential utility of RPM in postdischarge care [25], offering insights into the practical challenges and user experiences for older adults in completing smartphone functional mobility tasks at home. Addressing the human and technological barrier we identified can enable smartphone apps and RPM to play an important role in postdischarge care to reduce fall risk in older patients.

Abstract

Background: Advance care planning (ACP) is a process that involves patients expressing their personal goals, values, and future medical care preferences. Digital applications may help facilitate this process, though their use in older adults has not been adequately studied.

Objective: This pilot study aimed to evaluate the reach, adoption, and usability of Koda Health, a web-based patient-facing ACP platform, among older adults.

Methods: Older adults (aged 50 years and older) who had an active Epic MyChart account at an academic health care system in North Carolina were recruited to participate. A total of 2850 electronic invitations were sent through MyChart accounts with an embedded hyperlink to the Koda platform. Participants who agreed to participate were asked to complete pre- and posttest surveys before and after navigating through the Koda Health platform. Primary outcomes were reach, adoption, and System Usability Scale (SUS) scores. Exploratory outcomes included ACP knowledge and readiness.

Results: A total of 161 participants enrolled in the study and created an account on the platform (age: mean 63, SD 9.3 years), with 80% (129/161) of these participants going on to complete all steps of the intervention, thereby generating an advance directive. Participants reported minimal difficulty in using the Koda platform, with an overall SUS score of 76.2. Additionally, knowledge of ACP (eg, mean increase from 3.2 to 4.2 on 5-point scale; *P*<.001) and readiness (eg, mean increase from 2.6 to 3.2 on readiness to discuss ACP with health care provider; *P*<.001) significantly increased from before to after the intervention.

Conclusions: This study demonstrated that the Koda Health platform is feasible, had above-average usability, and improved ACP documentation of preferences in older adults. Our findings indicate that web-based health tools like Koda may help older individuals learn about and feel more comfortable with ACP while potentially facilitating greater engagement in care planning.

Introduction

Advance care planning (ACP) is a process by which individuals choose their goals of care, quality of life priorities, and potential future medical intervention preferences and then communicate these values [1-3]. Actions taken during ACP include choosing a surrogate decision-maker (SDM), completing advance directives, and discussing a patient's wishes with loved ones and health care providers. With increasing average lifespans, ACP is a vital component of high-quality care to ensure that patients' care when facing serious illness is concordant with their values and goals. Currently, anywhere between 3% to 47% of patients may receive medical care that is not consistent with the patient or their loved ones' wishes [4-6]. Because of these inconsistencies, it's estimated that US $75.7 billion to US $101.2 billion is spent on overtreatment or low-value care each year in the United States [7]. These findings highlight the need to increase communication regarding medical care planning.

ACP is associated with decreased anxiety among patients' family and caregivers [8], improved patient quality of life [9], decreased unwanted medical care [10-12], and decreased health care costs [13-16]. Despite the promising evidence of benefits [17], rates of ACP remain low, with many patients and families avoiding these discussions until the patient's condition has deteriorated and is suboptimal for end-of-life decision-making. In addition, less than 11% of Medicare beneficiaries discuss ACP with their medical providers [18-21]. In the United States, approximately 37% or less of individuals report having some kind of advance directive, which could include a medical power of attorney or a living will [22,23]. ACP rates are often even lower within historically marginalized communities in America [24-28].

While the majority of patients express positive views or interest in ACP [22,29], they may not know how to begin the process. Initiation of ACP conversations seems to be a major barrier, as patients may be reluctant to broach the subject with their health care providers, while clinicians report having insufficient training or time to conduct ACP discussions [22,30,31] during busy clinic visits. Though patients believe that their medical providers should initiate conversations about ACP [32,33], 17% or fewer of patients report discussing ACP with their medical team [34]. Given the barriers for many patients in learning about and completing ACP, it is important to explore alternative approaches that may better support health care providers in facilitating this vital service [29]. Digital health tools could be a potential solution to improve equitable access to ACP for patients and to engage loved ones and health care providers in the process [35,36]. Scoping reviews have concluded that currently available web-based ACP programs are feasible and generally well-received by users [37,38], but the quality of the content greatly varies [39].

Current ACP online programs are primarily static web-based forms and do not include interactive educational content, plain language, or the capability to allow for official signing of ACP documentation [40]. Other ACP programs are geared toward specific patient populations and are therefore not generalizable to all individuals. Additionally, the sections on medical interventions in many online ACP resources fail to mention some common life support treatments that an individual may experience at end of life or with serious illness [41]. Several available smartphone apps also provide some education or actionable decision-making in regard to ACP, but currently available apps lack sufficient features or have poor functionality, limiting their practicality [42].

The Koda digital ACP platform seeks to fill the gaps found in current offerings by providing a highly interactive solution that is suitable for all technological knowledge levels and more inclusive of the most common life-support treatment options. The platform guides patients through a personalized, interactive guide, which includes video-based educational content and decision-making guides for patients and their loved ones. Users are able to select health care goals and indicate their wishes regarding potential future medical interventions, all of which auto-generate into easily accessible documentation that can be shared with loved ones and health care providers. Koda was created to help facilitate informed discussions of ACP and to provide a tool that patients could use freely and effectively without an added time burden for clinicians.

A previous retrospective report on Koda [43] was conducted with a sample of patients with serious illness. The findings of that quality improvement report showed that 53% of referred patients completed their ACP through the platform. However, due to the retrospective nature of this prior study, we were unable to assess self-report usability metrics or change in opinions or knowledge after platform use. The main objective of this study was to determine the reach, adoption, and usability of Koda to conduct digital ACP within a university health system.

Methods

Population and Recruitment

This pilot study included adult patients aged 50 years or older who had an active MyChart account, defined as one that was used within the past 90 days. Participants were excluded if they were younger than 50 years, were non–English speaking, had a diagnosis of Alzheimer disease or Alzheimer disease–related dementias, or had blindness based on electronic health record (EHR) *International Classification of Diseases, 10th Edition* codes.

An EHR algorithm was created to identify eligible participants (eg, filtering for the inclusion criteria) from the Atrium Health Wake Forest Baptist network (AHWFB). The EHR included data on age, gender, race, and diagnoses. The AHWFB is a large, quaternary health system affiliated with an accountable care organization program that incorporates more than 150 primary care and multispecialty practices with more than 330 physicians and advanced practice providers in 80 different locations in communities throughout central North Carolina.

Eligible participants were sent an electronic invitation to participate via Epic MyChart with an informational message about the study and an embedded hyperlink to the Koda platform. If a participant was interested, they were directed to a web-based consent form, and electronic informed consent was obtained. Participants were instructed to create a Koda Health account, complete a preassessment survey, complete using the Koda platform, and then complete a postassessment survey. Follow-up messages were sent 2 weeks later to any nonresponders. If a participant pressed "accept" but did not create a Koda account, they were approached 2 weeks later by the research team to facilitate the process.

Ethical Considerations

This study was approved by the Atrium-Wake Forest Institutional Review Board (IRB00076779). All human subjects data were deidentified. Study participants were sent a US $25 gift card for completing the steps of the study.

Intervention: Koda Digital Platform

The Koda application was previously developed prior to this pilot study. Briefly, this occurred as an iterative process with input from ACP content experts (eg, geriatric and palliative medicine physicians), as well as input from end users surrounding their preferences, which was obtained by survey results. The patient-facing Koda ACP platform consists of 4 sections, focusing on values; individual definitions of quality of life; SDM preferences; and medical care preferences, with specific regard to cardiopulmonary resuscitation (CPR), mechanical ventilation, artificial nutrition via a feeding tube, and dialysis. This was in alignment with consensus recommendations on core components of ACP. Motivational interviewing techniques [44] were used to highlight the importance of planning and to motivate patients to communicate their wishes. Each section includes educational audio-video content and expandable information for additional questions users may have. For this study, platform completion progress was tracked through the Koda Health administration portal. Once the participant completed using the Koda platform by indicating their decisions within each section, their answers were autopopulated into a state-specific advance directive, which participants were able to sign or notarize online. Using the platform takes approximately 20-30 minutes. See Figure 1 for example displays directly from the platform.

Questions in the guide to help the patient understand what is important to them.

Medical care education videos, with the opportunity for the patient to input their medical care preferences.

Autogenerated plan.

Outcome Measures

Primary and secondary outcome measures consisted of reach, adoption, and usability. Reach was defined as the proportion of eligible participants who clicked on the embedded hyperlink to the Koda application. Adoption was defined as the proportion of participants who completed using the Koda platform. Usability was measured using the validated System Usability Scale (SUS) [45,46], a 10-item questionnaire. Items are rated on a 5-point (ie, 0 to 4) scale and responses to all items are summed and multiplied by 2.5. Possible scores range from 0 to 100, with scores of 68 or higher indicating above-average usability [47]. The SUS was reliable for the current sample with α=.87, which is comparable to psychometric findings from multiple studies of the SUS (ranging from α=.83 to α=.97) [48].

Exploratory outcomes included ACP knowledge and readiness using an adapted, self-report ACP engagement survey [49] and were measured before and after using the Koda platform. To assess patients' self-rated knowledge of ACP, 4 Likert-type questions were asked, which included "Do you know what Advance Care Planning is?" "How well informed are you about who can be a medical decision maker?" "How well informed are you about what makes a good medical decision maker?" and "How well informed are you about the different amounts of flexibility a person can give their medical decision maker?" The answer options were on a scale from 1 to 5, with higher scores correlating to higher ACP knowledge. Reliability for the adapted ACP Engagement Survey was good (α=.82) and comparable to previous psychometric research for other brief versions of this tool (ranging from α=.84 to α=.97) [49].

To assess patients' readiness to engage with ACP, 4 Likert-type questions were asked, which included "What describes you best when it comes to your comfort level in thinking about your care if you become seriously ill?" "How ready are you to talk to your decision maker about the kind of medical care you would want if you were very sick or near the end of life?" and "How ready are you to talk to your healthcare provider about the kind of medical care you would want if you were very sick or near the end of life?" These answer options were on a scale from 1 to 5, with higher scores indicating greater readiness. The fourth question, "How worried are you when you think about your future illnesses?" was reverse scored so that higher scores would indicate less ACP readiness.

Statistical Analyses

Reach, adoption, and SUS scores were calculated and reported as percentages and percentiles, respectively. Success was defined a priori by having ≥40% of enrolled participants complete using the Koda platform and obtaining an above-average SUS score of 68 or higher [50-52]. For descriptive analyses, means and SDs were used to describe continuous variables and percentages and frequencies were used to describe categorical variables. Shapiro-Wilk, D'Agostino-Pearson, and Anderson-Darling tests were conducted to assess data normality, and study variables were found to have non-Gaussian distribution. Therefore, nonparametric methods were used for any inferential analyses. Changes from pre- to post-Koda use were analyzed with the 2-tailed Wilcoxon signed rank test with continuity correction. Analyses were performed using R (version 4.2; R Foundation for Statistical Computing). $P<.05$ was considered to be statistically significant.

Results

Demographics

Table 1 shows participant demographic and baseline characteristics. The mean age was 62.8 (SD 9.3) years, with ages ranging from 50-99 years. Of enrolled participants, 127 (78.9%) were female, and 46 (28.6%) were Black or African American. A total of 49 patients (30.4%) self-reported poor to fair health, 55 (35.2%) had a personal loss or misfortune in the past year, and 103 (66%) had been a caregiver of a loved one with a serious illness.

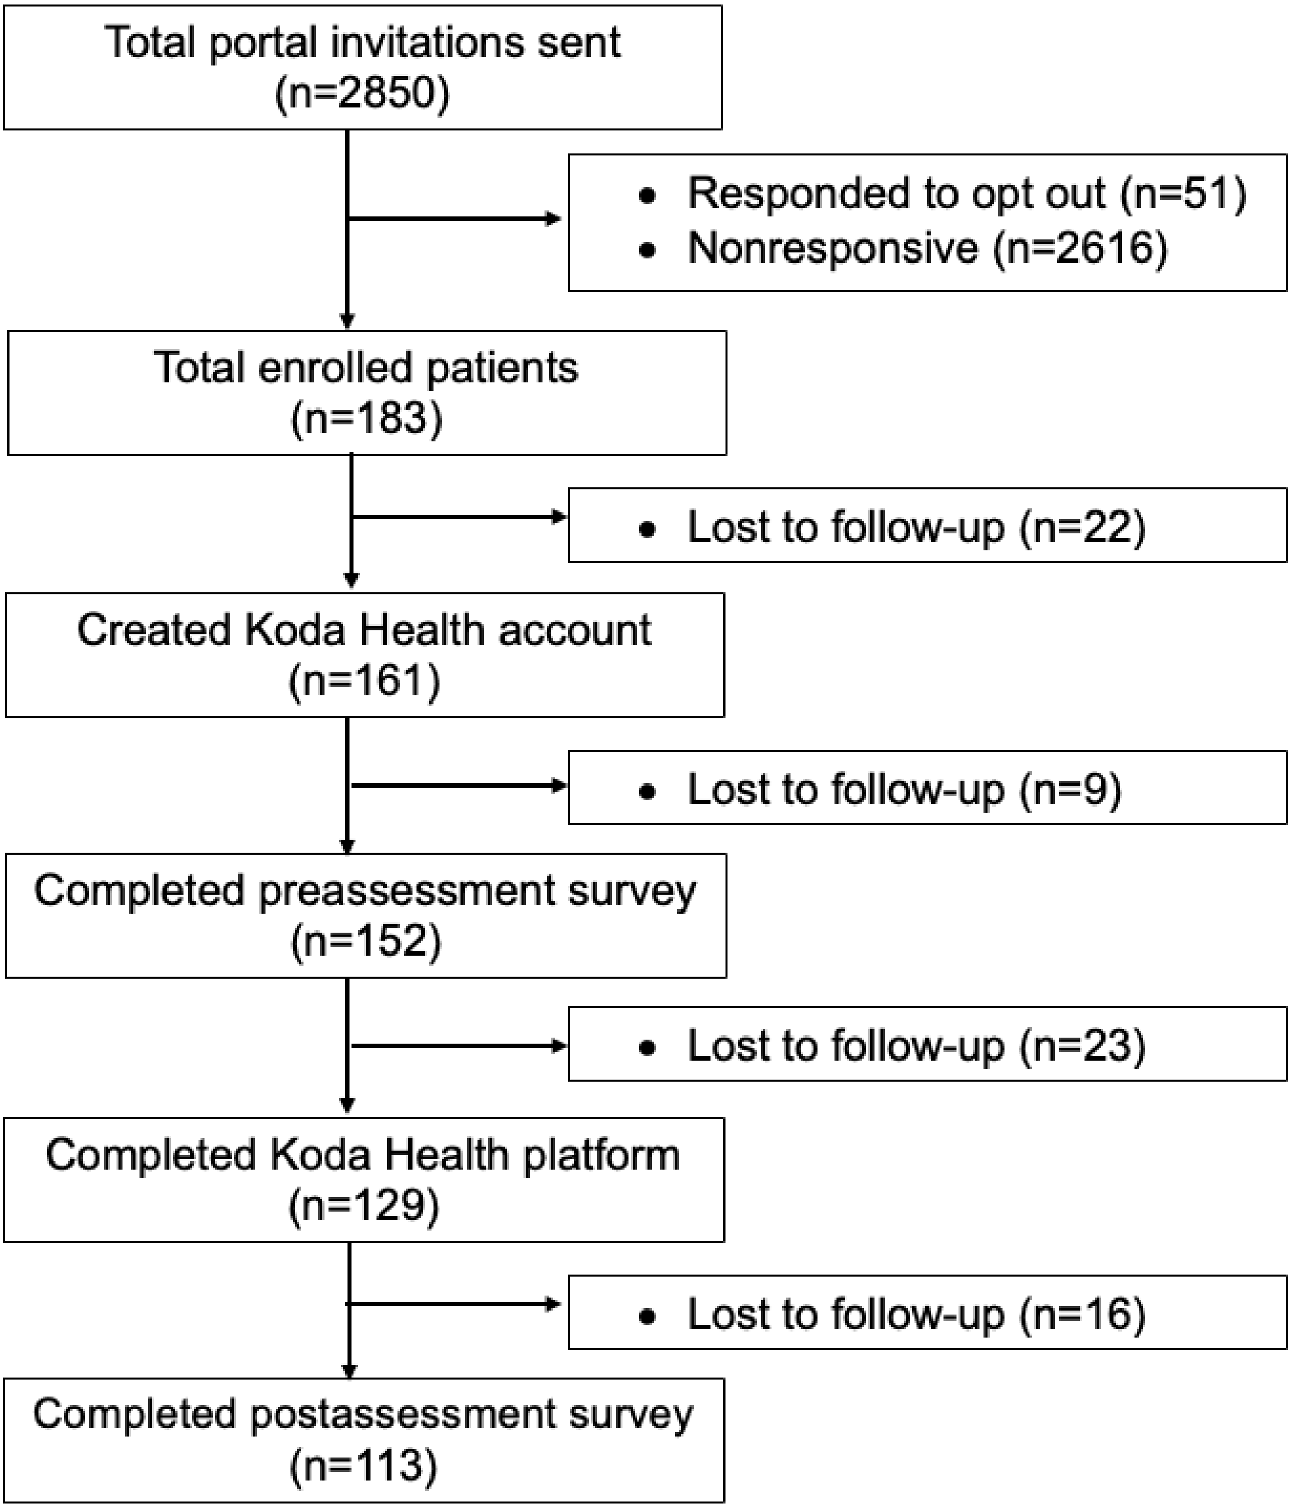
Table . Demographics of participants who created a Koda account.

Characteristics		Participants (n=161)
Age (years), mean (SD)		62.8 (9.3)
Sex , n (%)		
	Female	127 (78.9)
	Male	34 (21.1)
Ethnicity, n (%)		
	Hispanic or Latinx	1 (0.6)
	Not Hispanic or Latinx	159 (98.8)
	Not reported	1 (0.6)
Race, n (%)		
	American Indian/Alaska Native	1 (0.6)
	Black/African American	46 (28.6)
	White	113 (70.2)
Self-reportd health status, n (%)		
	Poor	10 (6.4)
	Fair	39 (25)
	Good	67 (42.9)
	Very good	36 (23.1)
	Excellent	4 (2.6)
Personal loss/misfortune in last year, n (%)		
	Yes, one	32 (20.5)
	Yes, more than one	23 (14.7)
	No	101 (64.7)
Taken care of someone seriously ill, n (%)		
	Yes	103 (66)
	No	53 (34)
Trust in the health care system, n (%)		
	Completely distrust	0 (0)
	Somewhat distrust	16 (9.9)
	Neither	23 (14.3)
	Somewhat trust	58 (36)
	Completely trust	14 (8.7)
	No response	50 (31.1)

Reach, Adoption, and Usability of the Digital Koda Platform

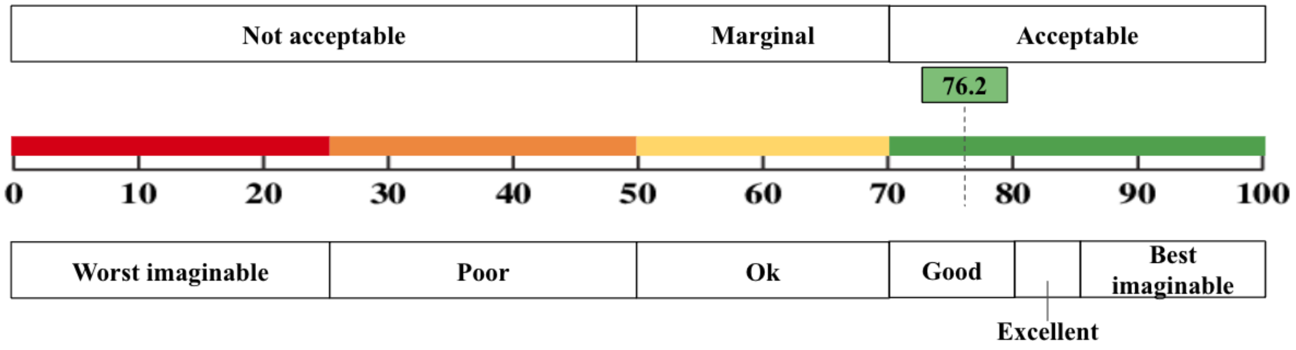
Of the 2850 patients who were sent the invitation to participate through their EHR patient portal, 183 participants read the message and clicked on the Koda link to enroll (6.4% response rate). Of those who responded to the invitation, 88% (n=161) created a Koda Health account to begin the study. Of the 161 participants who began their care plan on the platform, 129 (80.1%) completed the Koda platform intervention (Figure 2).

Figure 2. Flow diagram of participants through the study.



As measured by the SUS, the participant-reported usability of the digital Koda platform was 76.2, indicating good system usability (Figure 3). Out of possible scores from 0 to 100, the SUS scores ranged from 47.5 to 100.

Figure 3. Demonstration of the acceptability and score range interpretations for the Koda platform. The score was 76.2 on the System Usability Scale, indicating that the platform was acceptable and had a good score.



Knowledge of ACP

Wilcoxon signed-rank tests showed that there was a significant increase in knowledge of ACP after using the Koda platform compared to baseline. Ratings increased on all 4 knowledge items: knowing what ACP is (*Z*=119.5; *P*<.001), knowing who can be an SDM (*Z*=202; *P*<.001), what makes a good SDM (*Z*=235; *P*<.001), and the amount of flexibility an SDM can have (*Z*=289; *P*<.001). Table 2 shows means at each time point.

Table . Change in knowledge of advance care planning (ACP) before and after completing the digital platform (on a 5-point scale).

Knowledge items	Before Koda use, mean rating (SD)	After Koda use, mean rating (SD)	*P* value
Knowing what ACP is	3.23 (1.31)	4.19 (0.97)	<.001
Knowing who can be an SDM[a]	3.63 (1.14)	4.28 (0.93)	<.001
Knowing what makes a good SDM	3.60 (1.16)	4.28 (0.90)	<.001
Knowing what flexibility an SDM can have	3.26 (1.29)	4.19 (0.96)	<.001

[a] SDM: surrogate decision-maker.

Readiness to Make Decisions

Wilcoxon signed-rank tests showed that there was a statistically significant increase in readiness for ACP decisions after using the Koda platform compared to baseline. Ratings increased on 3 readiness items: comfort level thinking about serious illness care (*Z*=117; *P*<.001), readiness to discuss future medical care with an SDM (*Z*=316.5; *P*=.01), and readiness to discuss future medical care with a health care provider (*Z*=150; *P*<.001). The postassessment revealed a statistically significant decrease in ratings for how worried patients were about future illnesses (*Z*=536.5; *P*<.001). Table 3 shows means at each time point.

Table . Change in readiness for advance care planning (ACP) decisions and conversations before and after completing the digital platform (on a 5-point scale).

Readiness items	Before Koda use, mean rating (SD)	After Koda use, mean rating (SD)	*P* value
Comfort level thinking about serious illness care	2.89 (0.88)	3.06 (0.88)	<.001
Ready to discuss ACP with an SDM[a]	3.23 (1.46)	3.59 (1.32)	.007
Ready to discuss ACP with health care provider	2.78 (1.37)	3.26 (1.18)	<.001
Worried thinking about future illness[b]	3.32 (1.03)	3.07 (1.03)	<.001

[a] SDM: surrogate decision-maker.

[b] This item was reverse scored, so lower scores indicate higher ACP readiness.

Discussion

This pilot study assessed the feasibility and acceptability of using a web-based interactive ACP platform, Koda Health, to help older adults think about their overall health-related goals, document those goals in an advance directive, and assign an SDM. We found that the intervention was acceptable to older adults and feasible to implement. This was highlighted by the fact that 80% of enrolled participants completed the entire intervention and created an advance directive.

Our findings also suggest that the Koda platform was able to bridge the gap in ACP engagement between different racial groups. Previous reports have shown that individuals from often-marginalized racial communities are less likely to have engaged in ACP [26,28]. However, when comparing the 2 main self-identified race categories in our data, we found no substantial difference—80.95% of Black patients and 79.66% of White patients who enrolled in the study went on to complete using the Koda platform. This adds to the existing literature that indicates that digital ACP platforms have the potential to address health disparities by providing accessible, user-friendly tools to all users, regardless of their racial background [43,53].

In addition, the SUS score of 76.2 indicates that users generally found the Koda platform easy to use and had a positive overall experience. This score suggests that Koda’s interface and features were well designed, allowing users to navigate and interact with the system without substantial barriers. We also found that patient age was not correlated with system usability ratings (r=.03; P=.76), suggesting that the platform was similarly user-friendly across the sample age range (50-99 years). However, while the overall usability was rated as good, there may still be room for improvement. It will be important to analyze usability metrics in more detail to identify specific areas where the platform can be enhanced. This could involve conducting further user testing, collecting qualitative feedback, or conducting additional surveys to gather more insights.

Participants also reported learning new information about ACP and being more ready to have conversations about medical care after completing the plan. While the self-reported changes in knowledge and readiness were statistically significant, we cannot yet accurately determine the degree of clinical significance. Generally, clinically significant improvements are associated with any positive increase to an average 5-point rating. However, more research is needed to determine specific thresholds for outcomes on ACP-related metrics [17,49]. Nevertheless, these findings have positive implications for the ability of online health tools to promote ACP participation among patients and families, with the ultimate goal of bringing empowerment and peace of mind during serious illness or end-of-life care.

Despite these promising findings, several limitations must be acknowledged. First, the study intervention necessitates further validation through a randomized controlled trial. Second, the low enrollment rate compared to the total number of invitees suggest that more effective recruitment methods are needed than a single patient portal message, such as personalized ACP information from a nurse or other health care provider, posters placed in prominent areas, or additional contact methods. Additionally, as in any voluntary research, responses may have been affected by self-selection bias; those who agreed to participate in the study may be distinct from those who chose to ignore the invitation to participate. We saw evidence of this in the greater percentage of female-identifying participants in the study than in the general population. Future studies should consider appropriate sampling techniques like stratified randomization to ensure participation reflective of the larger population. Lastly, further studies should investigate the long-term impacts of the Koda platform on measures of patient and caregiver experience and goal-concordant care [54].

In conclusion, the Koda ACP platform represents a promising tool for promoting patient engagement in ACP, particularly among older adults and marginalized groups. By facilitating knowledge acquisition and readiness to engage in ACP, the Koda platform can help empower patients to make goal-informed medical decisions, especially regarding end-of-life care. Further research is needed to validate these findings and determine long-term impacts on patient and caregiver outcomes.

Abstract

Background: Digital neuropsychological tools for diagnosing neurodegenerative diseases in the older population are becoming more relevant and widely adopted because of their diagnostic capabilities. In this context, explicit memory is mainly examined. The assessment of implicit memory occurs to a lesser extent. A common measure for this assessment is the serial reaction time task (SRTT).

Objective: This study aims to develop and empirically test a digital tablet–based SRTT in older participants with cognitive impairment (CoI) and healthy control (HC) participants. On the basis of the parameters of response accuracy, reaction time, and learning curve, we measure implicit learning and compare the HC and CoI groups.

Methods: A total of 45 individuals (n=27, 60% HCs and n=18, 40% participants with CoI—diagnosed by an interdisciplinary team) completed a tablet-based SRTT. They were presented with 4 blocks of stimuli in sequence and a fifth block that consisted of stimuli appearing in random order. Statistical and machine learning modeling approaches were used to investigate how healthy individuals and individuals with CoI differed in their task performance and implicit learning.

Results: Linear mixed-effects models showed that individuals with CoI had significantly higher error rates (b=−3.64, SE 0.86; $z=-4.25$; $P<.001$); higher reaction times ($F_{1,41}=22.32$; $P<.001$); and lower implicit learning, measured via the response increase between sequence blocks and the random block ($\beta=-0.34$; SE 0.12; $t=-2.81$; $P=.007$). Furthermore, machine learning models based on these findings were able to reliably and accurately predict whether an individual was in the HC or CoI group, with an average prediction accuracy of 77.13% (95% CI 74.67%-81.33%).

Conclusions: Our results showed that the HC and CoI groups differed substantially in their performance in the SRTT. This highlights the promising potential of implicit learning paradigms in the detection of CoI. The short testing paradigm based on these results is easy to use in clinical practice.

Introduction

Memory, Neurodegeneration, and Aging

Overview

In an aging society, the number of individuals with neurodegenerative diseases is increasing. Alzheimer disease (AD) and Parkinson disease rank among the most prevalent neurodegenerative disorders. One of the most apparent cognitive symptoms of neurodegenerative diseases is a change in memory impairment, which can affect different cognitive and memory functions in different ways.

Memory functions differ in concepts and models [1-5]. When comparing different memory models, memory can be categorized into specific subsystems: intentional learning leads to explicit memory, and unintentional and incidental learning creates implicit memory [3-6]. Most studies on neuropsychological changes in neurodegenerative diseases focus on explicit memory, whereas studies examining the decline of implicit memory remain scarce [7-13]. Accordingly, many assessments for explicit memory are available, but only a few assessments are available for implicit memory, and most assessments are paper based. Paper-based examination of implicit memory is effortful and limited in its possibilities and test quality, although there are some digital tools available [8,14]. Still, solely examining explicit memory seems to be insufficient, as neurodegenerative disorders such as AD show changes in different cognitive domains, not just explicit memory but also implicit memory [14-19], among others. Thus, implicit memory paradigms are promising tools in addition to common explicit memory tasks in early diagnostics to assess memory dysfunctions more precisely and to determine the different causes of neuropsychological dysfunction. Reasons for reduced performance in implicit memory tasks can be independent of the reasons for deficits in regular tasks such as word lists used for explicit learning.

We introduce a digital tablet–based version of the serial reaction time task (SRTT) aimed at assessing implicit memory. We then use data gathered by this tool to develop machine learning (ML) models for predicting cognitive impairment without relying on diagnoses from comprehensive assessments such as the Montreal Cognitive Assessment or the Consortium to Establish a Registry for Alzheimer’s Disease. On the basis of computer-based studies, we developed an app for clinical application, aiming to provide results comparable with previous findings on the SRTT. This study examines a mobile touch–based SRTT on a tablet in healthy older participants and older participants with cognitive impairment (CoI).

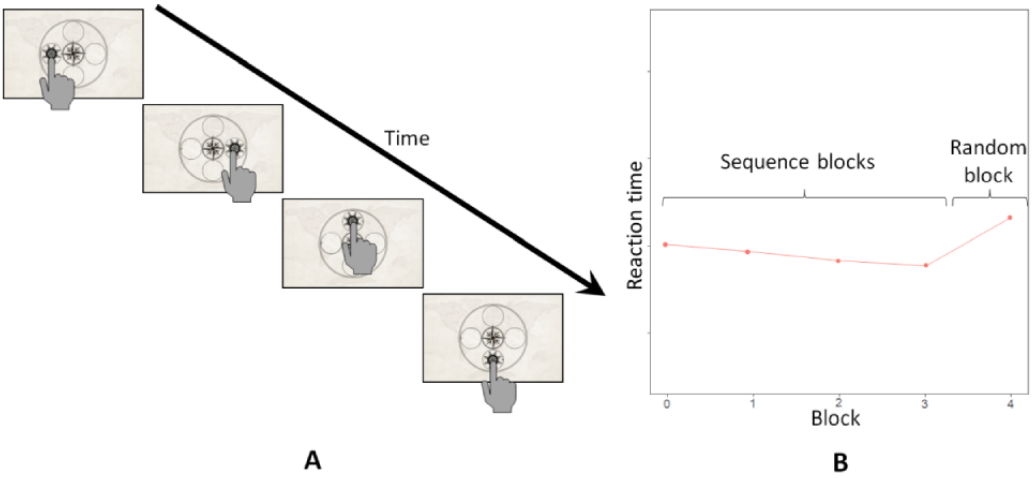
Implicit Learning

Researchers use various terms for implicit memory, referring to different concepts and processes inconsistently. Sometimes, these terms can refer to subtypes of a form of memory [8,14]. Although *implicit learning* is an umbrella term for the absence of awareness and intention, which means “a collection of abilities that are expressed through performance without requiring conscious memory content” [2], *statistical learning* “refers to the ability to detect and learn regularities in the environment” [13]. *Sequence learning* “describes the ability to incidentally acquire knowledge of sequences of events and actions” [20]. *Motor skill learning* “refers to the increasing spatial and temporal accuracy of movements with practice” [21]. *Procedural learning* is used as a synonym for sequence learning, referring to the learning of sensory-motor skills [10,13,22,23]. As we are focusing on a rather application-oriented approach, we further refer to the more general concept of implicit learning.

SRTT Paradigm

Different tasks have been used to assess implicit learning [8,14]. Among others, the SRTT was established as a widely used assessment. In the original version of the SRTT [24], participants react to stimuli presented in blocks with repeated sequences. After several blocks of repeated sequences (“sequence blocks”), a block with random sequences is presented (“random block”). Although reaction times usually improve throughout the blocks of repeated sequences, they decelerate in the blocks with a random sequence [16,24]. Implicit learning is assumed when there is a decrease in reaction time in blocks of repeated sequences and an increase in reaction time in the random block. Figure 1 shows an illustration based on the example of this study.

Figure 1. Illustration of the serial reaction task paradigm used in this study and the expected reaction times for healthy participants. (A) Touch-based variant used in the study. The participants' task was to respond with their finger to the target stimulus in the form of a ship's wheel on the tablet. (B) Expected reaction times for healthy participants. After the sequence is repeated in the first 4 blocks, leading to a decrease in participants' reaction time, a random sequence occurs in block 5, resulting in a significant increase in participants' reaction time.



SRTT Variants

There are many variations in the SRTT paradigm and ambiguous findings on the effects and results of different clinical syndromes. Variations in paradigms can significantly influence the patterns of results observed. Different versions of the SRTT may vary in factors such as the quantity and length of stimuli; number of trials and blocks; the arrangement, structure, and display of stimuli on screen; the method of response; and even the medium used. Stimuli are presented on a computer screen in most studies [14,25]. Participants are asked to indicate the position of the stimuli using buttons on a keyboard or button box. Very few studies used a touchscreen- or tablet-based presentation of the SRTT [9,26-31]. Thus, researchers have many degrees of freedom in adjusting the paradigms of the SRTT, especially when implementing a touch-based version for older participants. In this setup, the participants use their fingers to indicate the position of the stimuli directly on the touchscreen. The most appropriate specifications may vary based on the research question (RQ) and the sample under investigation.

As described by Hong et al [16], an alternating design, that is, a design with an alternating sequence and random blocks [32-34], has advantages in distinguishing between motor and cognitive learning, but progressions in sequence tasks cannot be analyzed. Moreover, alternating sequences lead to a longer overall assessment time. In contrast to laboratory studies, design decisions are limited in a clinical approach. An SRTT version suitable for clinical use with older participants should be as short as possible to meet their stamina and motivation, especially in the case of CoI. Although some researchers suggest the superiority of alternating SRTT variants because of their capacity to discriminate between sequence-specific and general skill learning [35], we decided to use the SRTT in a tablet-based version as a short SRTT version that only needs 5 blocks and thus is much shorter and more usable in clinical contexts.

Possible Distinguishing Features

The patient and control groups differ for various outcome measures. First, *reaction times* can differ between groups in general, meaning that healthy controls (HC) are faster than patient subgroups. Second, *learning curves* can vary between groups, meaning that HC participants should learn sequences faster. Third, the *response increase* between the groups may deviate. That is, the contrast in reaction times between sequence and random blocks becomes more pronounced after extensive learning of sequences, rather than just motor skill leaning or increased familiarity with the task. Finally, the *number of correct responses*, that is, the *response accuracy* (and vice versa *error rates*), is expected to differ between groups. That is, the CoI group should show more false responses than the HC group. In addition, when we combine these variables as features in a statistical model, we may discover findings not only about implicit memory but also about parameters such as limitations in task comprehension or altered reaction times, which serve as additional diagnostic information.

SRTT Findings

The SRTT and similar tasks to assess implicit learning have been used in numerous studies in different fields [25], reporting different variables, outcome measures, and results. Varying patterns of results can be explained by different design variations (eg, [32,33]) and experimental requirements and conditions [8,14]. In healthy adults, differences in response increase were found consistently between sequence and random blocks. There was a slight tendency of age-related deterioration in performance, learning, accuracy, and reaction times with higher age [20,36,37]. Worse performance can be observed in patients with strokes [38]. Numerous studies show a deterioration of performance in neurodegenerative disorders affecting the basal ganglia and the thalamus, such as Parkinson disease [25,39,40], and other neurodegenerative and neuropsychiatric diseases, such as Huntington disease [41-43] and Korsakoff syndrome [24].

Some SRTT studies were conducted with patients with AD as the clinical sample, whereas others were conducted with patients with mild cognitive impairment (MCI; for reviews, refer to the studies by de Wit et al [8] and van Halteren-van Tilborg et al [14]). Overall, there are mixed findings on the association between SRTT performance and cognitive impairment (such as AD, which can be a later stage of MCI). Comparing various studies poses a challenge because of differences in sample characteristics, such as the varying degrees of impairment severity (eg, MCI vs AD at different levels of severity), and the diverse inclusion criteria used for clinical samples (eg, specific diagnostic criteria vs various screening scores) [8]. In addition, inconsistent methodological approaches, including variations in the quantity and duration of stimuli, sequences, and blocks, further complicate comparisons between studies. Some studies revealed no significant differences in learning concerning response increase for participants with MCI compared with HC participants. That is, participants with MCI and HC participants showed similar response increases between sequence and random blocks [9,16,44,45], whereas other studies found differences [15,46]. Participants with AD, however, show less response increase than HC participants in some studies [47-49] and a comparable response increase in others [50-52].

Compared with learning curves, that is, the reduction in reaction time over sequence blocks, patients with MCI seem to have similar curves as HCs in most studies [9,15,16,44,45], whereas some studies found differences [46,48]. Patients with AD show more deficits than HCs, as indicated by a flatter learning curve in some studies [49,53], but this was not clearly evident in most studies [47,50-52].

When comparing accuracy or error rate, in some cases, no differences are found between participants with AD [41,51,52] and MCI [44,46]. In other cases, participants with AD [47,48,50] and MCI [16,45] differ from the reference groups.

In most cases, patients with MCI [16,46] and AD [47,50-53] had slower overall reaction time [54]. These differences can be explained by motoric demands, the experimental design of the tasks, and differences in sample selection. In addition, a large number of dementia diseases may be mixed pictures of different subtypes of dementia [55,56]. This phenomenon may further contribute to the divergent findings. In a review and meta-analysis, de Wit et al [8] discuss the difficulty of participants with AD in understanding and remembering the test instructions of SRTT paradigms. Most studies found differences in response accuracy and reaction times (with participants with CoI being slower than HC participants). These differences suggest that the understanding and execution of the task play a significant role in classifying differences between healthy individuals and individuals with CoI.

This Study

We developed a mobile SRTT version suitable for testing implicit memory in a clinical routine (in contrast to an extensive laboratory assessment). Working with older patients in everyday clinical routines, we recognized the need for a short, understandable, and highly accepted digital assessment that medical professionals can use in point-of-care or bedside tests without requiring additional technical equipment. We also expect a short and tablet-based variant to address the difficulties in task understanding and remembering task instructions among patients with CoI reported by de Wit et al [8]. Using a tablet in neuropsychological testing has benefits in terms of the availability of new data sources and its applicability outside the laboratory [57,58]. Furthermore, digitalized testing enables tasks and measures that are impossible in pen-and-paper testing [57]. Using a touchscreen is a considerable relief for older patients, and particularly patients with CoI, compared with using a keyboard [59-62]. Furthermore, motivational effects must be considered when designing tasks for older participants [57,63]. Not only the design of the task but also the task parameters are essential: the length of the sequence and the frequency of repetitions should capture implicit learning but should not be unnecessarily prolonged. Using ML approaches that combine various parameters, we may predict participants' cognitive status more accurately with less data than a traditional approach, which accommodates shorter assessments. Combining the SRTT with ML represents a more recent development in this research domain [9,10,16].

ML predictions based on these parameters can potentially lead to accurate predictions using fewer repetitions, which facilitate shorter assessments that are mandatory for acceptance in clinical outpatient and inpatient practice.

Research Questions

This study focuses on the following RQs, which are centered on the question of whether the findings for the computer-based version of the SRTT can be replicated and transferred to the tablet-based version of the SRTT used in this study.

We investigated the following RQs:

1. Do participants with CoI and HC participants differ significantly in response accuracy?
    - We expect participants with CoI to make more errors than HC participants.
2. Do HC participants and participants with CoI differ in their average reaction times during the learning phase?
    - We expect that participants with CoI are systematically slower than HC participants.
3. Do participants with CoI and HC participants differ in implicit learning? That is, is the response increase in the random block compared with the learning curve significantly lower for participants with CoI?
    - We expect that participants with CoI show less implicit learning than HC.
4. Do participants with CoI show a different learning curve during the learning phase than HC participants?
    - We expect HC participants to show a steeper learning curve than participants with CoI, which should show a flatter learning curve.
5. Can we reliably predict participants' groups using an ML prediction model?
    - We expect to classify participants with an accuracy comparable with that of Hong et al [16]. That is, we expect the 80.9% found by Hong et al [16] to be within our 95 % CI of prediction accuracy.

Methods

Participants

We recruited and tested 49 older participants at the Geriatric Center at the University Clinic for Psychiatry and Psychotherapy in Tübingen, Germany. A total of 2 participants discontinued the experiment. One participant had to be excluded owing to a low response accuracy of 40%, which indicates a failure to understand and complete the task appropriately. We later identified 1 participant with significantly prolonged reaction times as an outlier and had to exclude this participant. Within the scope of this project, we also collected data from 11 participants with depression, which we excluded from the analysis of this study because of the focus on neurodegeneration. The remaining 45 participants (26 female individuals), aged between 52 and 87 (mean 68.4, SD 9.82) years, consisted of 27 HC participants and 18 participants with CoI. A list of inclusion and exclusion criteria is presented in Textbox 1.

We based the allocation of groups on experienced physician examinations, confirmed by an interdisciplinary team (physicians, psychologists, specialized therapists, and nurses), as most participants were known to us as patients of our (day) hospital and their caregivers or relatives. We also recorded the participants’ educational level. Subsequently, we converted the educational levels into corresponding years representing the time typically taken to achieve them. The descriptive statistics of the demographics of the sample are provided in Table 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Adults aged ≥50 years
- Diagnosis of cognitive impairment (for patient group), confirmed by an interdisciplinary team
- Understanding and agreement of informed consent
- Participation on a voluntary basis

Exclusion criteria

- Unable to perform or a lack of understanding of the task requirements
- Visual impairment
- Refusal or inability to give informed consent
- Acute delirious or psychotic episode
- Acute medical or physical conditions

Table 1. Demographic data of the 2 groups (HC[a] and CoI[b]; N=45).

Characteristics	HC (n=27)	CoI (n=18)	Total (N=45)	*P* value
Age (y)				.002[c]
Mean (SD)	64.89 (9.66)	73.67 (7.62)	68.40 (9.82)	
Range	52-85	55-87	52-87	
Education (y)				.52[c]
Mean (SD)	11.74 (3.21)	11.06 (3.80)	11.47 (3.43)	
Range	8-17	8-19	8-19	
Sex, n (%)				.39[d]

Male	10 (37)	9 (50)	19 (42)	

[a] HC: healthy controls.

[b] CoI: participants with cognitive impairment.

[c] Linear model ANOVA.

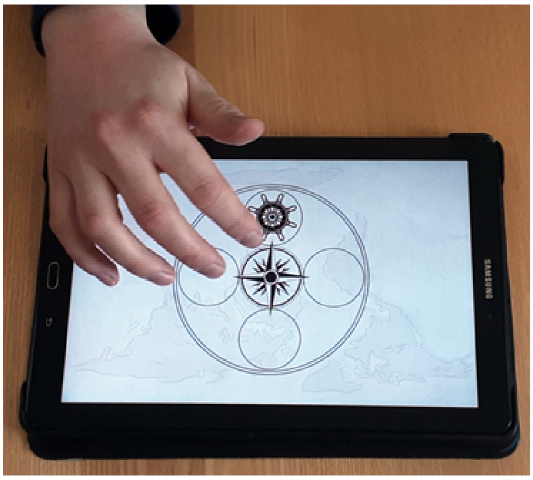
[d] Pearson chi-square test.

Materials

Overview

We used a tablet-based variant of the SRTT (described in the subsequent sections) designed for this study to meet the needs of older participants. The experiments were performed on a "Samsung Galaxy Tab A (2016) with S Pen" tablet (model SM-P580, Samsung Electronics) with a screen size of 10.1 inches, running on Android 7.0. Tablets were positioned on the table horizontally and planar in front of the participants (Figure 2). Thus, the participants were able to rest their elbows on the table. The participants' task was to repeatedly respond as quickly as possible to the target stimulus, whose position changed, with their fingers.

Figure 2. View of the setup and task in the app used for the study. Participants were allowed to rest their hands on the table.



SRTT Design

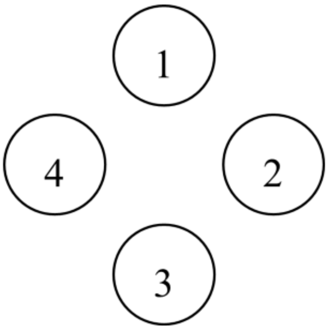
The experimental design of the SRTT used in this study is based on the study by Lum et al [64], as they used a shorter version with fewer trials than previous studies, which was necessary in working with older participants. Thus, following a 10-trial practice phase, the SRTT used in this study consisted of 5 blocks with 60 trials each. Blocks 1 to 4 are sequence blocks and contain the 10-item sequence, repeated 6 times per block. The repeated sequence 4-2-3-1-3-2-4-3-2-1 is based on the original design of Nissen and Bullemer [24] and was also used by Lum et al [64] and Lum and Kidd [65]. In the circular order we used, the top position (north) corresponds to 1, 2 corresponds to the right-hand position (east), 3 corresponds to the lowest position (south), and 4 corresponds to the left position (west; Figure 3).

When we developed the tablet-based variant, a circular order of stimuli [9,10,64,66-69] was chosen to ensure comparable spatial distances between stimuli on the screen (Figure 3). A horizontal arrangement of stimuli would lead to unequal distances between stimuli. A touchscreen-based version of the SRTT was used in only a few studies in general [26,29,31,70], specifically in samples consisting of older individuals [27]. To the best of our knowledge, apart from the study by Dominey et al [27], no study with older participants that exclusively used touchscreen versions of the SRTT on a larger sample was published. The motor skills required for responding on a tablet surface differ from those needed for pressing buttons on a response panel [29,31].

In *block 5*, based on the study by Lum et al [64], the stimulus appears in a pseudorandomized order. This order is based on 2 conditions: first, each stimulus appears as often as in the antecedent (learning) sequence blocks, and second, the probability of appearing at 1 of the 4 positions after its antecedent stimulus is the same as in the learning sequence. We precomputed 1 pseudorandomized sequence (Multimedia Appendix 1) and used the same pseudorandomized sequence for each participant. We did not inform participants about the given configuration. Using the difference between sequential and pseudorandomized trials yields a measure of skill acquisition from the SRTT that is specific and sensitive, as measuring implicit learning by only comparing improved reaction times in sequenced blocks is confounded by visuomotor association [71]. Multiple parameters captured through the app were used for statistical modeling to assess their predictive value, via the approach of Hong et al [16] using random forest classification.

After the stimulus appears at position 1, the probability that it will appear at either position 3 or position 4 is 50%, respectively. After appearing at position 2, it is equally likely that the stimulus appears next at positions 1, 2, or 4, corresponding to 33% for each position. After appearing at position 3, the probability for the stimulus to appear next is 33.33% for position 1 and 66.66% for position 2. After appearing at position 4, the probability for the stimulus to appear next at position 2 or position 3 is 50%, respectively. After a practice trial, the participants were advised to react to the stimulus, changing their position as quickly as possible throughout the blocks. The app recorded the reaction times and the correctness of the reactions.

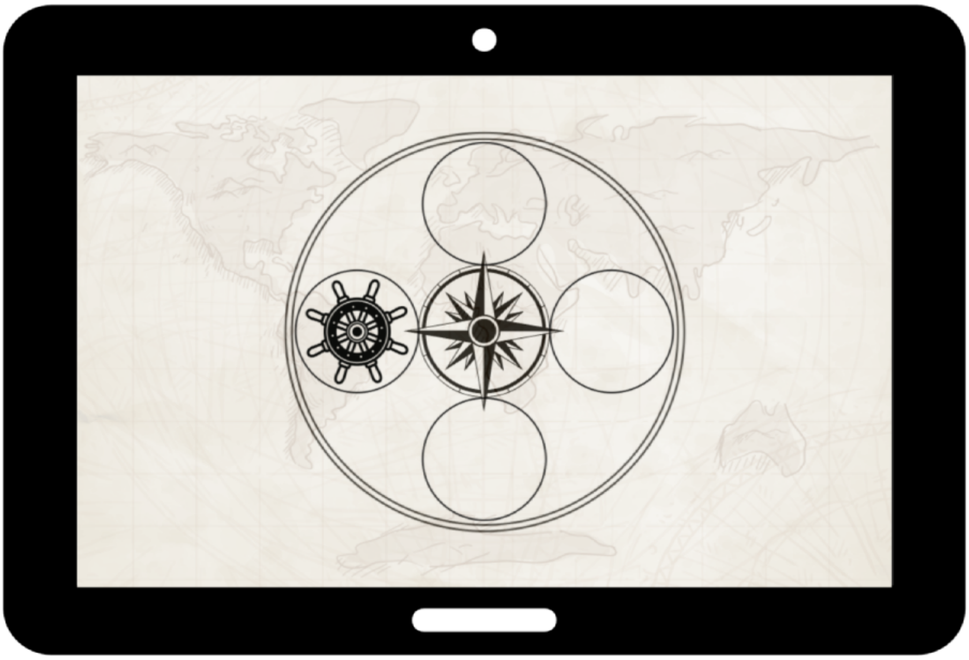
Figure 3. Circular order of the serial reaction time task.



Task Implementation

We developed the mobile touch–based SRTT in Unity 3D, version 2019.1.0f2 [72] as part of the TuCAN (Tübingen Cognitive Assessment for Neuropsychiatric Disorders) Project, which develops a tablet-based test battery app. In a first pilot study with university students, we showed that different user interface designs on the tablet are comparable and that no effects are attributable to the design. Moreover, we examined the usability and preferences of different designs with older participants in a second pilot study. The usability study is substantial for older participants to accommodate for possible low computer and tablet literacy and to ensure that an app is developed according to the needs of older participants [60,73,74]. In the preceding user tests and pilot studies described in this section, in which different designs were compared, we identified a circular compass design as the preferred design version for older participants (Figure 4). In this design, a compass dial is placed in the center of the screen and is surrounded by 4 circles. In the background, an ancient-looking map is depicted. A ship’s wheel, as the target stimulus, changes the positions between the 4 circles.

Figure 4. The compass design of the serial reaction time task developed to meet the needs of older participants.



Statistical Analysis

Overview

We performed analyses on the full sample of 45 participants. In addition, because of significant differences in age between the groups, all statistical analyses were rerun using an age-matched subsample of 36 participants (18 HCs and 18 participants with CoI). The pattern of the results remained identical, underlining the robustness of the findings to age differences. Therefore, we only report the results from the full sample in this study. The results of the matched samples are reported in the web supplement [75]. Similarly, the assumptions for all statistical models were checked. In case of assumption violation, we reran the analyses with robust models to ensure that the pattern of results remained identical. For the sake of readability, the results of the robust models are only reported in the web supplement [75].

Analyses Software

We conducted statistical analyses for RQs 1 to 4 using R software (R version 4.3.2, R Foundation for Statistical Computing) [76].

We used the *lme4* package (version 1.1-35) to fit (generalized) linear mixed-effect models [77]. The df and *P* values were calculated with the *lmerTest* package (version 3.1-3) [78] using Satterthwaite approximation for the denominator df. We calculated the CIs for logistic regressions with the *broom.mixed* package (version 0.2.9.4) [79] using Wald approximation. We used the *ggplot2* package (version 3.4.4) [80] to create plots, the *stargazer* (version 5.2.3) [81], the *arsenal* (version 3.6.3) [82], and *tab_model* from the *sjplot* (version 2.8.15) [83,84] packages to create tables.

The criterion of statistical significance was set at Cronbach α=.05. The raw data and *R* scripts detailing all analyses can be accessed in the web supplement [75].

Data Cleaning

For all analyses except for the accuracy analysis (RQ 1), we removed trials within blocks according to the following criteria in the following order: (1) the first trial of each block, as these trials succeed the fixation cross; (2) erroneous trials; (3) trials following erroneous trials; (4) trials with reaction times <200 ms; and (5) trials with reaction times deviating >2.5 SDs from the mean within a block, within participants. In total, we removed 5.36% (723/13,500) of trials.

General Modeling Approach (RQ 1+RQ 3+RQ 4)

Mixed-effect models will be hierarchically constructed from a full model (containing all fixed and random effects, including interactions) with a maximum random effects structure to the model with the best fit according to the Bayesian information criterion by removing the most complex fixed effects first (ie, interaction terms). If the complexity of the random effect structure is not supported by the data (ie, convergence issues), the random effects structure is reduced, similar to the fixed effects structure, by removing the most complex terms first.

Accuracy (RQ 1)

To contrast the difference in accuracy between the 2 groups, we ran generalized linear mixed-effects models using the logistic link function in all trials. Accuracy was computed as the proportion of correct trials to the total number of trials per participant per block. The models included group, block, their interaction, and age as fixed effects and random intercepts for the participant.

Average Reaction Time (RQ 2)

Analyses of covariance (ANCOVAs) were performed on the cleaned data (ie, correct trials only) to contrast the difference in the average reaction time across the learning phase, that is, excluding the random block. The average reaction time was computed per participant as the average of the median reaction time of each block. The fixed effects were group, with age, sex, and years of education as covariates.

On the basis of recommendations for good scientific practice for reporting ANCOVAs [85], an ANOVA comparing the average reaction times between groups was also performed, showcasing the impact of the covariates on the results.

Implicit Learning (RQ 3) and Learning Curve (RQ 4)

Linear mixed effect (LME) spline models with the last sequence block as the knot were performed on participants' median reaction times per block to contrast the influence of group, block, response increase, sex, age, education, and the interaction between block and group and response increase and group. The model included random slopes for block and response increase for the participants. The linear and quadratic effects of blocks were tested for their contribution to the model fit. To this end, orthogonal polynomials were computed to encode the linear and quadratic effects of time. The response increase between the expected reaction time in the random block, based on the estimated learning curve during the learning phase in the sequence blocks, and the measured reaction time in the random block was coded as follows: We used dummy coding for the response increase between the expected reaction time in the random block, based on the estimated learning curve during the learning phase in the sequence blocks and the measured reaction time in the random block. That is, the dummy variable for response increase is set to 0 for blocks 1 to 4, and to 1 for the last and fifth block ("Response increase = 1 if random block, else 0").

Prediction Model: Classification of Group (RQ 5)

In an exploratory step, we trained random forests to investigate how accurately the participants' group (CoI vs HC) could be predicted. The input features were participants' mean accuracy across blocks, participants' mean reaction time across the learning phase (refer to RQ 2), age, and participants' estimated learning curve and response increase. In addition, as features for learning curves (linear and quadratic effect of block) and implicit learning (response increase, coded as explained in the *Implicit Learning (RQ 3) and Learning Curve (RQ 4)* section, we extracted the predicted values of the LME model with the median of the *z*-transformed reaction time per participant per block as the response and learning curve and implicit learning as fixed effects. The model included random slopes for the learning curve and the response increase of the participants.

ML and Prediction Model (RQ 5)

ML approaches have shown promising results in predicting potential diagnoses and outcomes. These predictive models combine various parameters that were collected during the study. However, only 1 study by Hong et al [16] used an ML approach to predict participants' cognitive status. Using a random forest approach [86], they achieved a prediction accuracy of 80.9%. Thus, using ML approaches to predict participants' potential diagnoses rather than only examining group differences may improve the value of such tasks in cognitive assessments, enabling their broader use in populations of older individuals.

As explained previously, we used the random forest classifier to predict whether a participant belonged to the CoI group or the HC group. Repeated nested leave-one-out cross-validations were used to optimize hyperparameters and gain unbiased estimates of the model performance (eg, [86]). Specifically, each training data set from the initial leave-one-out cross-validation (outer cross-validation) was further split using a subsequent leave-one-out cross-validation (inner cross-validation). In the inner cross-validation, the number of trees per forest (range 10-100 in steps of 10), their maximum depth (range 1-7), and the minimum number of samples in each leaf (range 1-5) were optimized using grid search. Subsequently, to obtain an unbiased measure of accuracy, the best model from the inner cross-validation was used to predict the test set from the corresponding outer cross-validation. Finally, this procedure was repeated 15 times (ie, the same cross-validation procedure with varying random seeds) to account for random variations in the modeling procedure. These ML analyses (RQ 5) were conducted in Julia (version 1.9.3) [87] using the *Machine Learning in Julia* (MLJ, version 0.19.2) library [88].

Ethical Considerations

The study was approved by the ethics committee of the University Hospital of Tübingen (332/2016BO2). Participation was on a voluntary basis and after written informed consent and signature. Compliance with data protection and the implementation and evaluation were based on relevant regulations, guidelines, and protocols.

Results

Response Accuracy (RQ 1)

The descriptive statistics for the average response accuracy per group are shown in Figure 5. The most suitable generalized linear mixed-effects model using the logistic link function to predict participants' accuracy was obtained through hierarchical model comparisons, as outlined in the modeling approach in the *General Modeling Approach (RQ 1+RQ 3+RQ 4)* section. The final model contained block, group, and the interaction of block and group as fixed effects and a random intercept for participants. Hierarchical model analyses revealed that age did not contribute significantly to the model fit. The model revealed a significant main effect of group (*b*=−3.64, SE=0.86; *z*=−4.25; *P*<.001). We further found a significant interaction effect between block and group (*b*=0.53, SE=0.23; *z*=2.33; *P*=.02). The main effect of block was not significant (*b*=−0.18, SE=0.11; *z*=−1.54; *P*=.12). The models are listed in Table 2.

Average Reaction Times During the Learning Phase (RQ 2)

The ANCOVA comparing participants' average reaction time (computed as the average of the median reaction times per block) during the learning phase between groups while controlling for age and education revealed a significant difference in the mean reaction times between participants with CoI and HC participants ($F_{1,41}$=22.32; P<.001), with a large effect size of Cohen $d_{estimated}$=1.61 (η_p^2=0.35). Participants with CoI were, on average, 198.57 (SE 42.03) ms slower than the HCs (during the learning phase). Furthermore, an ANOVA comparing mean reaction times between groups without covariates was conducted to test the robustness of the findings. The results showed a significant difference in reaction time between the participants with CoI and the HC groups ($F_{1,43}$=37.02; P<.001), indicating a robust effect. Descriptive statistics for the average reaction times during the learning phase are presented in Figure 6, and the results of the statistical analyses are provided in Table 3.

Figure 6. Descriptive statistics of the average reaction times per group and block. Bars represent the SE of the mean. (A) untransformed reaction times and (B) *z*-transformed reaction times. CoI: participants with cognitive impairment; HC: healthy controls.

Implicit Learning and Learning Curve (RQ 3 and RQ 4)

The descriptive statistics of the average reaction times per group are displayed in Figure 6. As the final model predicting the raw reaction times obtained through the modeling approach outlined in the *Statistical Analysis* section in the *Methods* section resulted in nonnormally distributed residuals, we decided to use *z*-transformation of reaction times over the complete experiment per participant to reduce the effect of baseline differences in reaction times between individuals, which reduced skewness in the distribution of the residuals across participants. That is, we entered the median of the *z*-transformed reaction times per participant per block as the response into the LME. For models predicting the *z*-transformed reaction time, the visual inspection of the residual plot did not suggest a significant deviation from a normal distribution.

The final LME predicting *z*-transformed reaction times contained linear and quadratic terms of block, response increase, group, and the interaction between response increase and block, age, and education as fixed effects and random slopes for linear and quadratic terms of block as well as response increase of participants (formula: *median reaction time [z-transformed] ~ time [linear]+ time [quadratic]+response increase+group+age+education in years+response increase: group+time [linear]+ time [quadratic]+response increase|participant*). The hierarchical model analyses revealed that the interaction effect between the linear and quadratic effects of block and group did not significantly improve the model fit. The final model revealed a significant main effect of the linear effect of the block (β=−0.44, SE 0.09; *t*=−4.74; *P*<.001), a significant main effect of the quadratic effect of the block (β=0.46, SE 0.07; *t*=6.59; *P*<.001), a significant main effect of response increase (β=0.23, SE 0.11; *t*=2.21; *P*=.04), and a significant interaction effect of response increase and group (β=−0.34, SE 0.12; *t*=−2.81; *P*=.01). Regarding the interaction effect, participants with CoI had a significantly lower response increase between the random block and the last sequence block compared with HC participants. That is, there was a difference in response increase of *z*-transformed reaction times, obtained from the final model (β=−0.34, SE 0.12), and the difference in untransformed response increase between participants with CoI (mean 26.83, SD 46.09 ms) and HCs (mean 45.37, SD 35.59 ms) was 18.54 ms. The effects of group, age, and education were not significant. The final model, along with the models investigated using the hierarchical modeling approach, is provided in Table 4.

Table 4. Estimates for participants' *z*-transformed response increase of the linear mixed-effects models of the hierarchical modeling approach. The final model is listed in panel C.

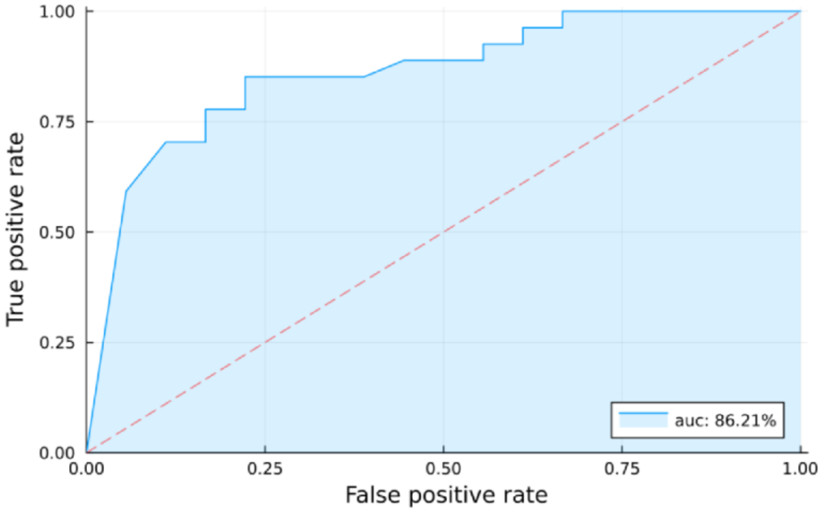
Prediction Model: Classification of Group (HC vs CoI; RQ 5)

Random forest classification predicting the group (CoI or HC) was computed using (1) standardized ordinal linear, (2) quadratic trends in reaction time for the sequence blocks, (3) standardized response increase, (4) age (years), (5) education (years), (6) response accuracy, and (7) average reaction time in milliseconds as features. To extract features 1 to 3, we refitted the LME from RQ 3 without the fixed effects of group, age, and education as well as the corresponding interaction terms. These models showed an average prediction accuracy of 77.13% (95% CI 74.67%-81.33%) across the repeated, nested leave-one-out cross-validation. The receiver operating characteristics curve is shown in Figure 7.

Figure 7. Receiver operating characteristic (ROC) curve for the prediction of cognitive impairment.



Discussion

Principal Findings

Overview

In this study, we presented and evaluated a digital tablet–based app featuring a variant of the SRTT to facilitate the diagnosis of implicit learning and memory and use it to predict the assignment of the diagnosis of CoI using an ML modeling approach. The app focuses on use in clinical routines and is based on computer-based studies and the findings of the SRTT. We evaluated our tablet-based SRTT with 27 HC participants and 18 older participants with mild to moderate CoI. We performed statistical analyses to evaluate the replicability and transfer of the results of previous (computer-based) SRTT studies with older participants with CoI to our tablet-based version of the SRTT. In addition, we deployed an ML modeling approach using a random forest classification to predict the participants' group assignments (HC vs CoI). On the basis of the RQs outlined in the *Introduction* section, the results indicate that we were able to transfer the findings of previous studies to a tablet-based implementation of the SRTT in this study. We found the same significant performance differences between HC and CoI groups, and our ML modeling approach achieves promising results in predicting participants' group assignments. In summary, our results indicate that the SRTT paradigm is transferable to (touch-based) tablet devices, and the results obtained with our app are comparable with previously published findings. The RQs and their findings are as follows:

1. Do participants with CoI and HC participants differ significantly in response accuracy? That is, do participants with CoI elicit more errors than HC participants?
    - Participants with CoI conducted, on average, significantly more errors per block than HC participants. We found no interaction between the block and the group.
2. Do participants with CoI and HC participants differ in average reaction times during the learning phase? That is, are participants with CoI systematically slower than HC participants?
    - Participants with CoI showed a significantly slower reaction time—on average, approximately 200 ms slower than HC participants (during the learning phase), with a large effect size of Cohen $d_{estimated}=1.61$ ($\eta_p^2=0.35$).
3. Do participants with CoI and HC participants differ in implicit learning? That is, is the response increase in the random block compared with the learning curve significantly lower?
    - Participants with CoI showed a significantly lower response increase than HC participants on *z*-transformed reaction times.
4. Do participants with CoI show a different learning curve during the learning phase than HC participants?

    - No significant differences were observed between participants with CoI and HC participants in terms of linear, quadratic, or cubic learning curves.
5. Can we reliably predict participants' groups using an ML prediction model?
    - A random forest classification achieved an average prediction accuracy of 77.13%.

In this study, we used a touchscreen-based version of the SRTT. Thus, our results may differ from those of previous studies using keyboard or button box input because of the change in medium. We found the same effects in our tablet-based version previously found in comparable SRTT setups [8,27]. Thus, changing the medium does not significantly change the pattern of implicit learning in older participants with little prior knowledge of technology. The analysis of the parameters of the SRTT with models predicting participants' groups allows us to make predictions about cognitive status and diagnoses with a relatively high accuracy. Even if only limited statements about isolated and pure implicit learning are possible [71,89], the app can be applied in daily clinical routines with older participants to collect diagnostic neuropsychological information.

Response Accuracy (RQ 1)

We found response accuracy to be lower in participants with CoI, in line with previous findings [8,14]. A low response accuracy may indicate difficulties in understanding and memorizing the task instruction, considering the hypothesis of difficulties with task comprehension [8,71,89]. In this study, we altogether excluded 4 participants from the analysis owing to difficulties with the task or attention and behavior difficulties or discontinuation of the examination. Among them, we excluded 2 participants who failed to complete the experiment, 1 participant because of low response accuracy, and 1 with exceptionally prolonged reaction times. This number is comparable with reported exclusions in other studies [8]. After exclusion, participants from the CoI group still had a percentage of correct trials of approximately 95%, compared with approximately 99% to 100% in the HC group. However, both numbers were still very high. Given the assumption of a strong influence of understanding the task instruction as a foremost parameter, as discussed in a recent review [8], we would suppose a lower response accuracy. Thus, the exclusion we made was in a manner that did not result in a systematic methodological error [8]. In summary, we were able to replicate previously published findings on a computer-based SRTT. At the same time, the results indicate that differences in response accuracy are not caused by task incomprehension or methodological errors, indicating the ecological reliability and applicability of our findings.

Reaction Time (RQ 2)

Similarly, we found differences in reaction times between the CoI and HC groups in the learning phase (Cohen $d_{\text{estimated}}$=1.61; η_p^2=0.35; participants with CoI were, on average, approximately 200 ms slower). This finding follows most previous studies on reaction times in general [90] and in the SRTT in particular [14,16,91]. This finding can be explained by general RT differences in participants with mild and moderate CoI and AD owing to vigilance, cognitive, and psychomotor impairments [92], for example, caused by degeneration of the locus coeruleus [90,93].

Response Increase (RQ 3)

As a third factor, we found a significant difference in the response increase between the groups, represented by the difference between the estimated reaction time of the fitted learning curve and the measured reaction time in the random block. As shown in Figure 6, we observed a response increase for both groups. However, the CoI group showed a significantly lower response increase than the HC group, which again is in line with previous findings [8,14]. A lower response increase indicates a less sustainable learning of the sequence. That is, this indicates more than just motor learning and growing familiarity with the task [71]. The response increase in the classical SRTT paradigm has been used as a valuable and verified measure for (differences in) implicit learning [8,24]. Although more basic research scholars recommend a more complex paradigm, for example, with alternating sequences to differentiate different forms of learning more precisely [71,89], we opted for the straightforward approach of contrasting sequenced blocks with a random block to gain a sensitive and specific measure of skill learning for practical use in everyday clinical practice through a short and easy-to-perform task.

Learning Curve (RQ 4)

According to RQ 4, all participants showed improved reaction times across the 4 sequence blocks, indicating learning gains in both groups. These findings align with those of previous studies with comparable paradigms and samples [8,14]. With a more differentiated group division, we may find differences in the slope of the curve, which may indicate a more distinguished learning gain in the HC group. Motor learning and familiarity with such tasks certainly interfere with this finding. To what extent motor learning and familiarity with the task affect the learning curve cannot be differentiated at this point.

Prediction Model: Classification of Group (RQ 5)

The prediction model obtained through a random forest classification showed an accuracy of 77.13% in predicting the participants' group (HC vs CoI) correctly. This performance is comparable with that of the study by Hong et al [16], who achieved an accuracy of 80.9% with a similar but lengthier version of the SRTT containing 4 learning and 4 random blocks of 48 trials each (384 trials total). In contrast, our version consisted of 5 blocks of 60 trials each, for a total of 300 trials. In addition, we achieved our results with a more robust ML approach using repeated nested cross-validation. Taken together, we achieved comparable accuracies using only the relatively short and straightforward SRTT paradigm combined with a robust random forest classification. This fact indicates the acceptable accuracy of the diagnosis classifications, despite only a coarse diagnosis classification. This insight is promising for future practical use.

Implicit Memory as a Part of Digital Neuropsychological Diagnostics

The development of neuropsychological deficits in explicit memory has been thoroughly researched and described and has become an integral part of dementia diagnostics. The role of implicit memory in the diagnosis and distinction of different subtypes of dementia has been scarcely investigated so far. In neuropsychological diagnostics and dementia research, implicit memory can be seen as an additional important domain in the entire pattern of deficits [94]. The use of digital assessment tools [57] can simplify examinations of implicit memory in clinical practice routines; even if overlaps in diseases exist, different participants show different deficit patterns in the process of neurodegeneration [95,96], partly also because of mixed subtypes of dementia [55,56]. This heterogeneity in neurodegeneration can also be seen as a relevant cause of inconsistent research outcomes [8,14] and, of course, needs further research on specific tasks such as the SRTT. On the basis of further research, differential diagnoses can be simplified using a tool similar to the one described in this study.

As different subtypes and mixed subtypes [55,56] have different progression types, paradigms such as the SRTT used for this study can help in the differential diagnosis of different dementia subtypes. When diagnosing the neuropsychological profiles of mixed dementia subtypes, a deeper and more differentiated examination at the level of explicit and implicit memory may be helpful. Using ML prediction can provide further benefit in differentiating diagnostic information based on future clinical studies that include more detailed and comprehensive diagnostics. Even this methodologically broad approach to group classification and the transdiagnostic and heterogeneous CoI group yielded significant results. Therefore, a more sophisticated approach to discriminate diagnosis groups will provide at least comparable results.

One goal of this study was to develop an assessment tool usable in clinical practice without exposing participants to unnecessary strains because of the length and complexity of the task. In developing a tablet-based tool relying on preceding user tests with older participants, we provided a short and transportable assessment instrument suitable even for older participants with CoI.

Relevance of This Study

In this study, we investigated a touch-based version of the SRTT in a sample of older participants. No control through hardware devices such as keyboards or response boxes was necessary; participants responded directly to the visual target stimuli with their fingers. The response increase and overall high response accuracy, even in participants with CoI, indicate that the paradigm we used is manageable and appropriate for older participants and that the original button-based paradigm is transferrable to tablets.

In our study, exploring an undifferentiated and roughly divided sample, significant differences between the groups were found. The application of statistical models enables the inclusion of features that exceed mere implicit memory, such as response increase. Therefore, the random forest trained achieved a prediction probability of the diagnosis groups of 77.13%. The accuracy of group prediction in our study is comparable with the accuracy reported by Hong et al [16].

Different definitions and concepts of learning are commonly used, based on different memory models, partly as different subtypes. We adhere to “implicit learning” as an umbrella term, as our task is too unspecific to distinguish more sophisticated terms and to differentiate which parts of the process can be explained through motor learning or sequence learning. Our essential objective was not to develop an experimental paradigm for the laboratory to distinguish forms of learning clearly but to provide a simple screening usable as part of a short battery of tests in clinical practice. Such tests could help to distinguish different diagnostic groups in real-life practice.

Limitations and Strengths

The study was initially part of a technical feasibility study for tablet use that did not address the conventional quality criteria of a clinical trial but had high ecological validity. Trained professional teams made the diagnoses after an extensive examination. Thus, classification into groups was based on the judgments of trained specialists and confirmed by interdisciplinary teams, as neuropsychological and depression scores were not available for all participants.

Divergent paradigms that can distinguish implicit and motor learning more sensitively are available. A more profound distinction between learning processes is not possible with the paradigm used in this study. We intended not to develop a tool for laboratory purposes but a user-centric tool that is usable in the clinic. Using statistical models, we are not limited to the exact distinction.

Taken together, the specific properties of the task partly explain the results found in our study. A pattern of stimuli alternating between random and sequence trials, for example, ensures the discrimination of explicit and implicit memory [32-34]. We chose a more focused approach without alternating patterns, as the use of statistical models for diagnostic information on implicit memory does not depend solely on accurately differentiated implicit memory processes in the experimental paradigm but on a variety of parameters. We also included parameters such as reaction times and learning gains in the statistical model. The objective of the task is not to map implicit learning as accurately as possible but to collect features that can be used in a statistical model to predict diagnostic information. The sequence length can be seen as a second factor. In this case, the well-proven and original sequence by Nissen and Bullemer [24] was used. Thus, we do not expect variations in the sequence or sequence length used in this study to result in the differences we found.

By contrast, a short tool that is easy to use in daily clinical practice is available to assess implicit memory on a tablet, for example, even at the bedside and not only in the laboratory. Because of the nature and implementation of the task, interruptions and early termination by participants who are stressed are less likely. In addition, participants do not receive negative feedback or feelings in the SRTT compared with explicit memory tasks, where they may experience failure in repeating words, drawing figures, or calculating numbers. By not only including pure reaction times but also response increase and response accuracy in a ML model, reliable predictions regarding diagnoses can be made with relatively little data and within a short time. Comparable results, as in previous studies, can be achieved with our app more quickly and simply.

Overall, a reliable assignment of the diagnoses and high ecological validity are possible with the app's relatively simple and short execution because of the use of ML algorithms. This assignment is preferable for a clinical setting, where brief assessments are essential. The data show that the short procedure is effective and yields results comparable with those obtained with more extended tests.

Future Studies

In the future, larger samples are needed to test the ability to discriminate similar conditions with heterogeneous cognitive symptom patterns such as dementia and delirium and different dementia subtypes. As implicit impairments are transdiagnostic, the SRTT and similar tasks have been examined with different samples [25]; however, only a few studies were performed with a touchscreen. Shortened versions of the task may facilitate the execution of the task to prevent cognitive overload in participants considered more impaired.

On the basis of more differentiated neuropsychological assessments, the parameters influencing test performance can be identified, especially when implementing additional information into statistical models. The SRTT can also be combined with another short task as another promising way to improve the accuracy of dementia diagnostics with the tablet. For example, this task could be a verbal task addressing different cognitive domains or a proven method such as the clock drawing test.

Acknowledgments

The study was performed as part of the TuCAN (Tübingen Cognitive Assessment for Neuropsychiatric Disorders) Project at the Geriatric Center Tübingen at the university clinic Tübingen, funded between 2018-2022 by the German Federal Ministry of Education and Research (BMBF, Start-interaktiv; grant 16SV8120). FW was supported by UKRI Economic and Social Research Council (grant number ES/W002914/1). The authors acknowledge the support from the Open Access Publication Fund of the University of Tübingen. The authors would like to thank all participants for their contribution.

Authors' Contributions

NM, HH, and CM conceptualized the study. NM programmed the app and conducted the research as part of her master's thesis under the supervision of CM, HH, FW, and KD. HH, CM, and FW performed the statistical evaluations. CM, HH, and FW wrote the first draft of the manuscript. FGM and GWE participated in the subsequent editing process. CM, HH, FW, FGM, and GWE read, reviewed, and edited the entire manuscript.

Conflicts of Interest

Abstract

Background: Assistive technologies can help people living with dementia maintain their everyday activities. Nevertheless, there is a gap between the potential and use of these materials. Involving future users may help close this gap, but the impact on people with dementia is unclear.

Objective: We aimed to determine if user-centered development of smartwatch-based interventions together with people with dementia is feasible. In addition, we evaluated the extent to which user feedback is plausible and therefore helpful for technological improvements.

Methods: We examined the interactions between smartwatches and people with dementia or people with mild cognitive impairment. All participants were prompted to complete 2 tasks (drinking water and a specific cognitive task). Prompts were triggered using a smartphone as a remote control and were repeated up to 3 times if participants failed to complete a task. Overall, 50% (20/40) of the participants received *regular* prompts, and 50% (20/40) received *intensive* audiovisual prompts to perform everyday tasks. Participants' reactions were observed remotely via cameras. User feedback was captured via questionnaires, which included topics like usability, design, usefulness, and concerns. The internal consistency of the subscales was calculated. Plausibility was also checked using qualitative approaches.

Results: Participants noted their preferences for particular functions and improvements. Patients struggled with rating using the Likert scale; therefore, we assisted them with completing the questionnaire. Usability (mean 78 out of 100, SD 15.22) and usefulness (mean 9 out of 12) were rated high. The smartwatch design was appealing to most participants (31/40, 76%). Only a few participants (6/40, 15%) were concerned about using the watch. Better usability was associated with better cognition. The observed success and self-rated task comprehension were in agreement for most participants (32/40, 80%). In different qualitative analyses, participants' responses were, in most cases, plausible. Only 8% (3/40) of the participants were completely unaware of their irregular task performance.

Conclusions: People with dementia can have positive experiences with smartwatches. Most people with dementia provided valuable information. Developing assistive technologies together with people with dementia can help to prioritize the future development of functional and nonfunctional features.

Introduction

Background

Dementia is associated with a loss of autonomy and restrictions in coping with everyday tasks [1], which often lead to caregiver burden [2]. There are still no curative treatments for dementia. Assistive technologies (ATs) can help people with dementia maintain their level of everyday activity [3]. To date, digital ATs have not been broadly applied in support and care for people with dementia.

Several systematic reviews regarding digital ATs for people with dementia [4-6] indicate increasing attention being given to wearable devices, for example, smartwatches, which represent the most intimate form of noninvasive ATs. Early digital ATs were aimed at increasing a person's security by detecting falls and alerting caregivers. Current ATs interact with the wearer and address more than a single domain, for example, reminding the wearer about an event or detecting when the wearer falls [7,8]. The measurement of activities and physiological parameters and the application of user interfaces allow for more flexible support of daily living activities [7,9-12]. Despite the promising potential of ATs, many people with dementia do not use such technologies [13-15]. The reason for this could be that the needs of the target group were not adequately considered, for example, in terms of functional scope or usability of ATs [16]. According to the International Organization for Standardization and the International Electrotechnical Commission 9241-11 standard, usability is defined as the "extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use" [17].

User-centered innovations address unmet needs and play an important role in breaking barriers and increasing access to ATs [14,18]. Previous studies have shown that the analysis of stakeholder needs, wishes, and values is crucial for sustainable innovations [15,19,20], and focusing on users' needs potentially prevents ATs from being nonusable or abandoned [13,21,22]. Considering the needs of future users from the beginning of development is mandatory from an ethical and a practical perspective [10,22].

However, placing people with dementia at the center of AT development can be challenging in the following ways: economically—patient involvement may increase the time and cost for organizations involved [23]; empirically—some scholars do not consider accounts of people with dementia to be reliable [24,25]; and ultimately, participation may distress or overwhelm people with dementia [25,26]. In addition, established tools for assessing user experience or usability may be insufficient and difficult to use for people with dementia because their ability to provide insight may be limited [27].

Objective

We analyzed the usability of a smartwatch application for addressing the needs of people with cognitive impairment based on a user-centered design approach together with people with mild cognitive impairment (MCI) or dementia. This study aimed to contribute to a better understanding of the values and limitations of user involvement in the development of a smartwatch to support people with dementia in their daily lives.

Methods

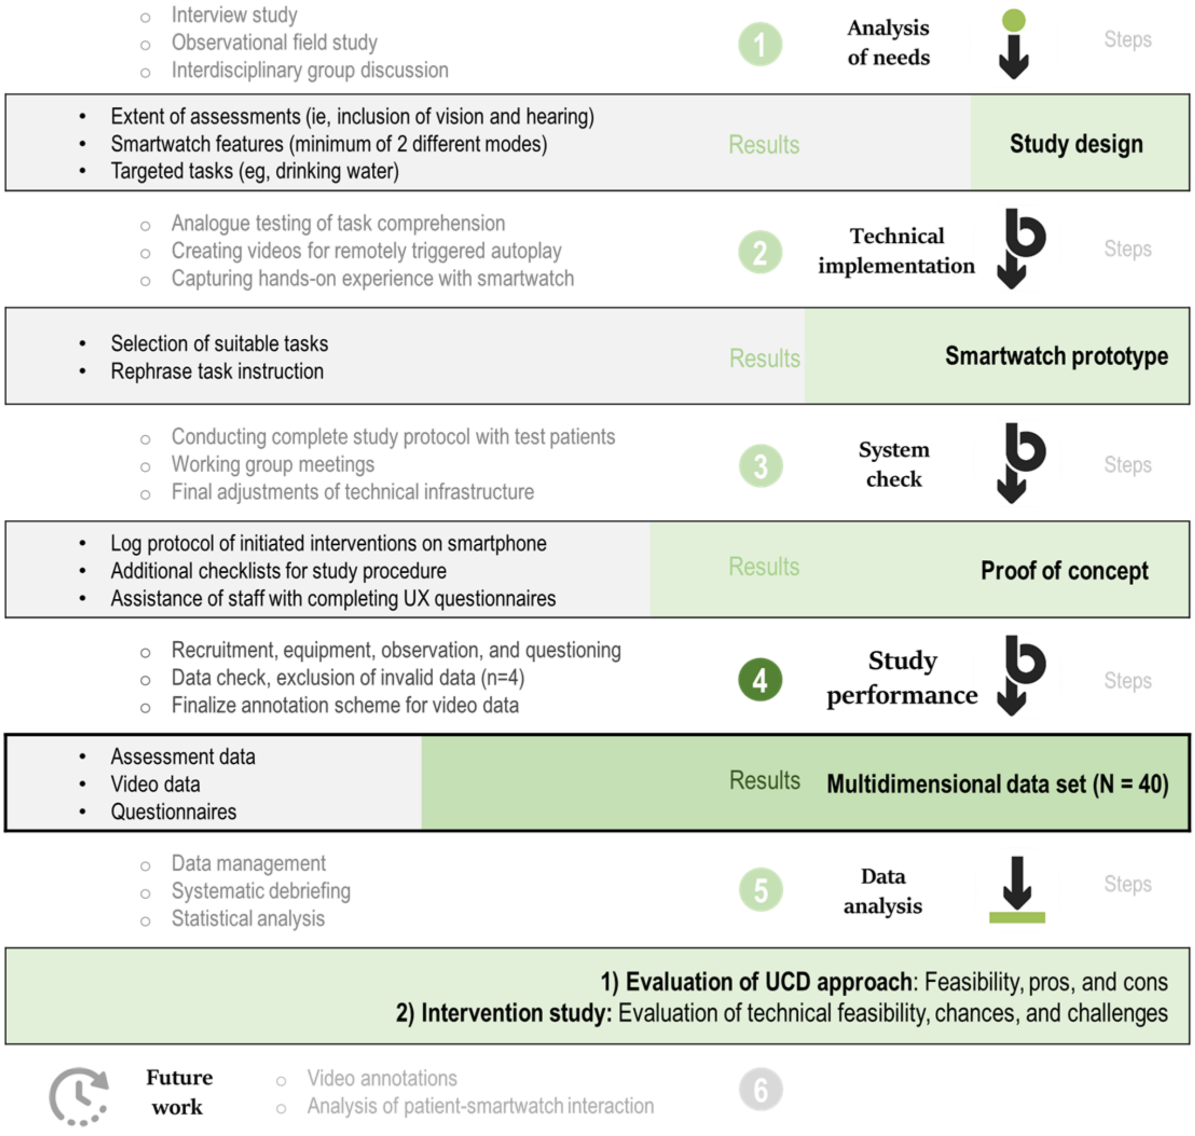
User-Centered Design Framework of the Sensor-Based Individualized Activity Management System for People With Dementia Study

The interdisciplinary *Sensor-Based Individualized Activity Management System for People With Dementia* (SAMi) study aimed to develop a mobile assistive device for people with memory impairments to support activities of daily living. The study was planned with a user-centered design approach from the beginning and included stepwise feedback from different stakeholders (Figure 1).

In step 1, we analyzed unmet needs. In a preparatory interview study, we conducted 30 semistructured interviews with stakeholders (people with dementia, health care professionals, and relatives of people with dementia) from a collaborating nursing home located in Pinnow and the geriatric ward of a hospital in Bad Doberan (both are small cities in Northeast Germany). We specifically asked about daily routines and situations in which people with dementia needed help or support. We also addressed the issue of technical assistance, design ideas, and circumstances that promote or hinder the acceptance and adoption of existing and potential future technologies. We applied qualitative content analysis according to Mayring [28] to analyze the material (refer to the study by Köhler et al [29]).

In a parallel, observational field study, we gave a passive smartwatch to 12 people with dementia residing in a nursing home and observed their behavior over a day. This smartwatch passively monitored activity via accelerometers and enabled indoor positioning via Bluetooth. It provided the users with no information except what time of day it was. During the monitoring period, participants' behavior was annotated in real time by trained observers using the Pocket observer tool (version 3.3; Noldus IT), which included a customized annotation scheme (Multimedia Appendix 1). On the basis of the analysis of needs (step 1 in Figure 1), we conducted an intervention study that aimed to increase certain daily activities by prompting the participants. We have published the results of the interviews elsewhere [29]. The core element of this paper is the results of the intervention study, which represents the final part of the SAMi study.

Figure 1. User-centered design framework. Iterative approach to study performance, with the integration of feedback from different stakeholders. Circles indicate different steps. UX: user experience.



Selection of Tasks for the Intervention Study

We decided to prompt participants to engage in 1 task each from the "activity" and "nursing" fields [29]. We implemented short instructions that completely appeared on the smartwatch's screen. Consequently, we tested different tasks and task comprehension in person with patients from the memory clinic in step 2 (Figure 1). Finally, we implemented a prompt to drink some water (task A; "nursing") and the "circling bells task" (task B; "activity") on the smartwatch, as both tasks appeared to be comprehensible and suitable. Instructions for task B explicitly included the instructions to circle bells on a sheet. Further details about step 2 can be found in Multimedia Appendix 2.

Intervention Study

Study Population

The study is registered in ClinicalTrials.gov with the brief title, "SAIN_UMR" (NCT05885620). After a short test phase for system checks (step 3), we started the intervention study (step 4). Participants were recruited from the memory clinic of the Rostock University Medical Center. The inclusion criteria were being aged >50 years, having a diagnosis of MCI or dementia, and having a Mini Mental Status Examination (MMSE) score ≥9 and ≤28 points. The exclusion criteria were presence of clinically relevant impairment of visual acuity or hearing or relevant speech or language impairment. Patients were diagnosed according to international scientific diagnostic criteria, neuropsychological testing (Consortium to Establish a Registry for Alzheimer's Disease [30]), and brain imaging; 78% (31/40) of the patients underwent cerebrospinal fluid analysis. Of the 40 patients, 12 (30%) were diagnosed with MCI [31,32], and 28 (70%) were diagnosed with dementia. Among these 28 patients, 24 (60%) were suspected to be in the Alzheimer spectrum: 18 (45%) with typical Alzheimer disease (AD) [33], 5 (13%) with mixed AD pathology [34,35], and 1 (3%) with atypical AD [33]. Of the 40 participants, 2 (5%) were diagnosed with primary progressive aphasia [36,37], 1 (3%) with a behavioral variant of frontotemporal degeneration [38], and 1 (3%) with Lewy body dementia [35].

Participants underwent clinical and neuropsychological examination—they received standardized examination of visual acuity. Near visual acuity was tested using a standardized optotype card with a decimal scale [39]. Distance acuity was assessed using a standardized eye chart at 4 to 5–m intervals (Oculus, number 4634). Both measurements were uncorrected and, when applicable, corrected with personal glasses. Hearing capabilities were assessed using a tablet-based certified app with a pure-tone threshold test (Mimi Health GmbH). Despite our efforts, we found that a standardized tablet hearing test could not be performed with our participants because they did not tap the button in time. Therefore, we decided to omit the regular test after 20 participants were assessed and did not include the results in our analysis.

As a global score for cognition, we used MMSE [40]. Visual constructive capabilities were assessed using a clock completion test [41] and the Rey complex figure direct copy (Rey Fig Copy) test [42]. Visual attention, processing speed, and task-switching abilities were measured using the Trail Making Test A (TMT-A) and Trail Making Test B (TMT-B) [43]. The results are presented in Table 1. We recruited 44 participants, 4 (9%) of whom had to be excluded. Of the 40 participants, 2 (5%) were diagnosed with subjective cognitive decline, and 1 (3%) had an MMSE score that did not match the inclusion criteria, and the trial procedure of 1 (3%) participant was incorrect because we missed repeating the intervention even though the participant did not complete the task. Finally, for the analysis, we obtained complete data sets from 40 participants. In summary, we included 50% (20/40) women and 50% (20/40) men with a mean age of 75 (SD 6.8; range 58-85) years.

Table 1. Demographics and characteristics of the participants[a]. The table includes success scores based on observations and usability scores based on 10 items of the questionnaire.

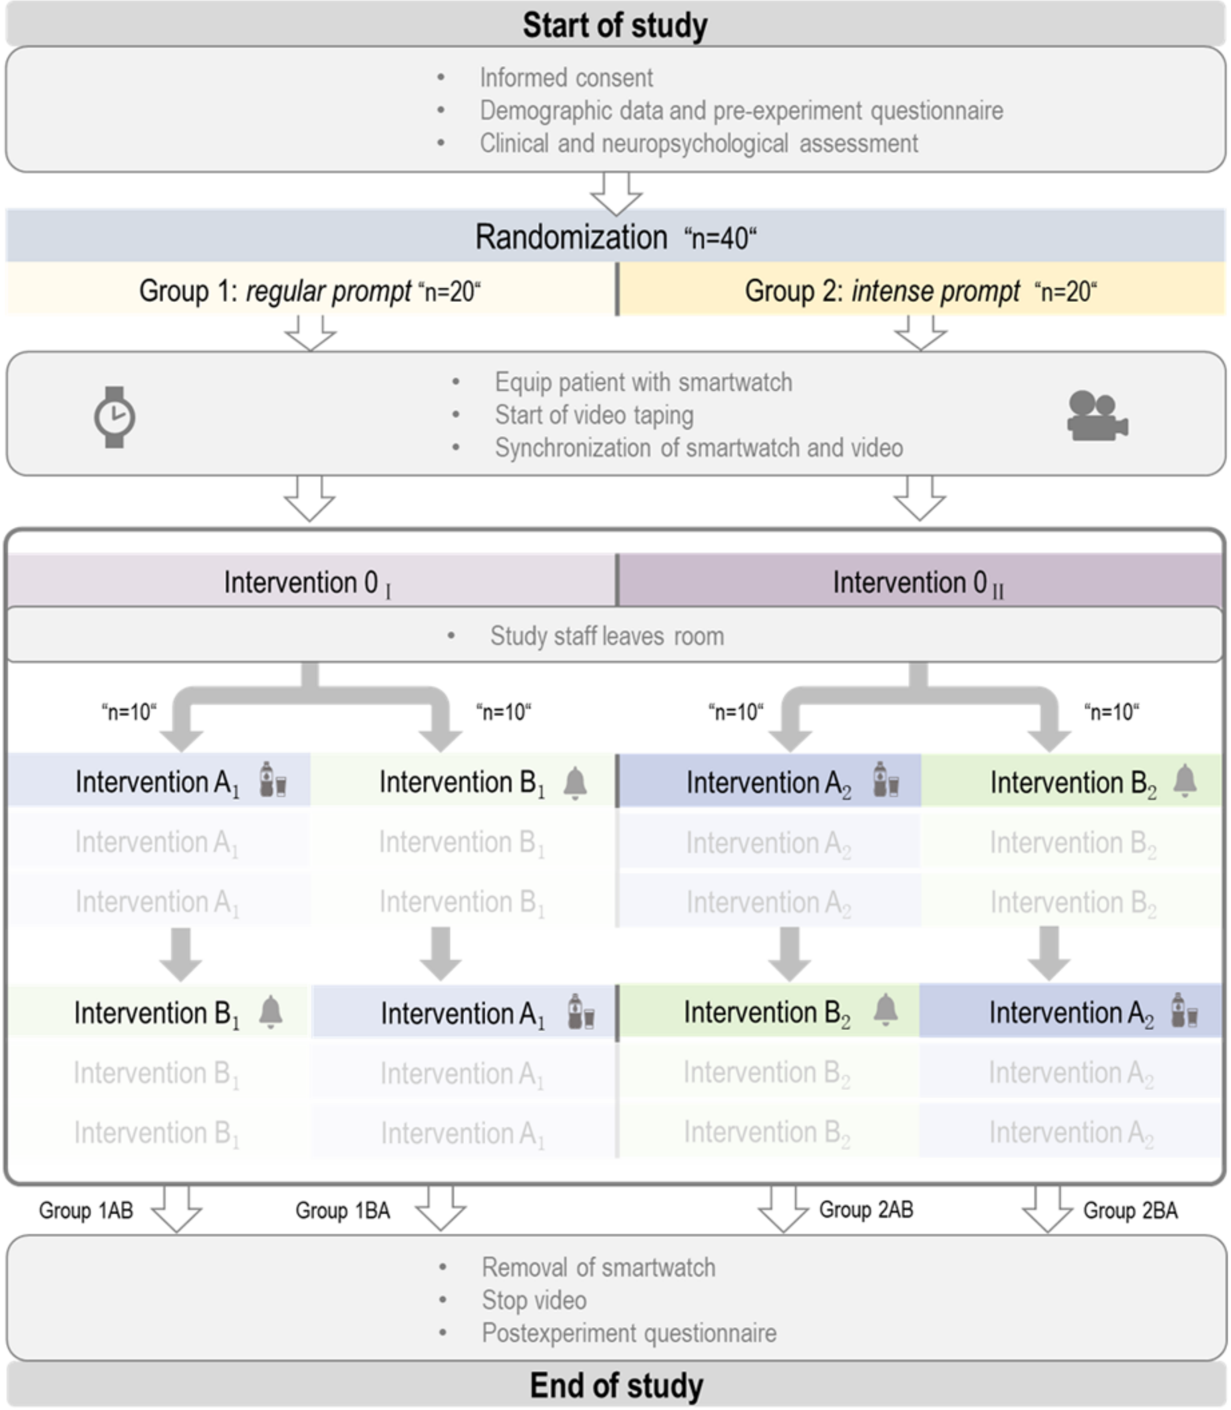
[j] Sum of task-A and task-B scores.

We conceptualized the observational intervention study based on the feedback obtained from the interview study and the experiences from the field study. Participants received interventions either in the "regular" or "intense" mode, under the observation of 2 cameras. Patients were assigned to one of the groups regardless of their neuropsychological test results. We applied an adaptive randomization procedure to balance the groups regarding participants' age and sex. Compared to those in the "regular group," the "intense group" received longer audio and vibration prompts and additional spoken output in response to the written instructions. Finally, a task-related picture appeared on both groups; this picture was animated in the "intense group." To determine whether the order of the tasks had an effect on their completion, this was tested in both groups additionally. The final result was a study with 2 intervention arms (modus: intense or regular), each consisting of 2 subgroups (order of tasks: AB or BA; Figure 2).

Figure 2. Diagram of the study design.



To avoid anxiety, all participants were introduced to the study with a trial prompt initiated by a researcher immediately next to the participant. The trial prompt instructed participants to close their eyes. Then, the participants were instructed to make themselves comfortable and feel free to move within the room. When participants were familiarized with the device and the study procedure, the researchers left the room. After a 5-minute break, the first prompt was triggered remotely. All participants were given both tasks (drinking and circling bells), and prompts were repeated a maximum of 2 times if participants failed to comply. The time delay until repetition was set as 1 minute after the previous prompt.

Participants completed 2 questionnaires. One of the questionnaires captured participants' previous experiences and affinity with technologies, and the other obtained feedback after wearing the smartwatch under camera observation. The summarized demographic information, test results, and outcomes are listed in Table 1, and additional details are provided in Multimedia Appendix 3.

Technological Specifications

A Huawei Watch 2 (4G) smartwatch was used. We designed the experiment in a Wizard-of-Oz-setting system using a smartphone as a remote control for the smartwatch (Figure 3). Consequently, we were able to repeat the interventions depending on the remotely observed participant's compliance (success or failure) or to continue with the next intervention without needing instantaneous detection of behavior via sensors. We set specifications for the smartwatch based on previous experience [44,45] and updated our prototype iteratively; refer to steps 2 and 3 Figure 1. The smartwatch was set to a maximum brightness and volume, with a display size of 1.2 inches. Loudspeakers were limited to 85 dB due to European Union restrictions. In hearing distance, we measured the volume of audio output during interventions to be 56 to 66 dB. The volume varies during signals and speech output from the male voice. We remotely triggered video playback. This approach allowed full control of the font size and audio of the prompts. The length of the videos did not vary between groups. The smartwatch displayed time with the clock hands when no intervention was displayed.

Session 'sain20' running.

Warte auf Antwort der Uhr...

Figure 3. Images and embedding of the applied prototype—smartphone with an app to manually trigger interventions on a watch, which is mounted on the patient's wrist, showing instructions (in this case, "Bitte trinken Sie etwas Wasser," which means "please drink some water").

Questionnaire

We administered 2 questionnaires to the participants, 1 before and 1 after the intervention. The preintervention questionnaire contained three parts: (1) affinity for technology, based on the Affinity for Technology Interaction scale [46]; (2) personal experiences with technologies; and (3) motivation to participate. It contains 13 items. The postintervention questionnaire was developed according to the Technology Acceptance Model [47], System Usability Scale (SUS) [48], and Technology Usage Inventory [49]. The survey included six subscales: (1) usability, (2) design, (3) perceived usefulness, (4) concerns, (5) realization, and (6) experience during the study. A translated version of the questionnaire with items assigned to the subscales and item coding is available in Multimedia Appendix 4. This questionnaire contains 40 items: 33 closed questions to be answered on a 5-point Likert scale (from strongly agree to strongly disagree), 4 multiple-choice questions, 3 open-ended questions, and 1 opportunity for closing remarks by participants and staff. When we observed participants having difficulty with using the Likert scale, for example, due to alternating positively and negatively worded items, we moderated if necessary. In the moderating questionnaires, we assisted all the respondents while they were completing the questionnaires. If a participant was unsure about what the response scale indicated and whether "agree" or "disagree" indicated their opinion about the particular item, we explained the item in more detail. We also asked participants to review their answers when they accidently skipped questions.

Internal Consistency, Usability Score, and Perceived Usefulness

Overall, 3 items of the usability subscale were adapted from the SUS [48], whereas 7 were customized. To obtain a more intuitive score for the usability measurement, we processed the results of our 10-item usability scale analogous to the SUS [48]. In other words, each item was rated 0, 1, 2, 3, or 4 according to the answer on the Likert scale in the following direction: 0 was used for the strongest disagreement and 4 was used for the strongest agreement. The sum of all the scores was subsequently multiplied by 2.5, leading to possible usability scores ranging from 0 to 100. Higher scores indicate better usability.

Answers to the "perceived usefulness" subscale were interpreted similarly. We applied the scale from 0 to 4 for each of the 3 items, resulting in a sum of 0 to 12 responses per participant. Then, the average value of all participants was converted into percentage.

For the subscales related to usability, design, usefulness, and concerns, we calculated the internal consistency as Cronbach α and McDonald ω based on principal factor analysis using Jeffrey's Amazing Statistics Program (JASP; version 0.16; JASP Team 2021; University of Amsterdam). Missing values were excluded pairwise. The reliability (α and ω) ranges between 0 and 1. Higher values indicate greater agreement among items and suggest that participants' responses throughout a set of questions were consistent. Cronbach α is a special case of McDonald ω: whereas Cronbach α is based on the assumptions of unidimensionality, equal factor loadings, and uncorrelated errors, whereas McDonald ω accounts for varying factor loadings and error variances, making ω more appropriate to use. Cronbach α also is reported to be consistent with most previous literature.

Measure of Success

We observed reactions to the manually triggered interventions via video cameras and rated behavior based on a protocol to decide whether to repeat the intervention. Task A was rated as successful and scored 1 point if the participant drank some water. Task B was rated as successful and scored 1 point if the participant circled something on the worksheet with the pencil. Actions resulting in incomplete task fulfillment were rated with 0.5 points, for example, when a participant went to the table with the worksheet but without using the pen. When no activity that could lead to task fulfillment was initiated, 0 points were assigned. Only the best performance for each task was rated. Repetitions were not scored. The scores for both tasks were summarized, resulting in success values ranging from 0 to 2 points.

Statistical Analysis

Descriptive statistics, correlations, and 2-tailed *t* tests were performed using JASP (version 0.16). To check for normality, we used the Shapiro-Wilk test. *P* value >.05 was considered to indicate normal distribution. *P* value >.05 in Leven test was considered to be consistent with the equality of variances. For variables that were not normally distributed, we calculated the Spearman rank-order correlation. Otherwise, we used Pearson correlation coefficient. For analysis of the questionnaire items, we used Kendall τ, as the answers on the Likert scale are ordinal data. We chose a significance level of .05, with a corresponding confidence level of 95%.

Ethical Considerations

Ethics approval was obtained from Rostock Ethics Committee (A 2020-0071). All participants provided written informed consent.

Results

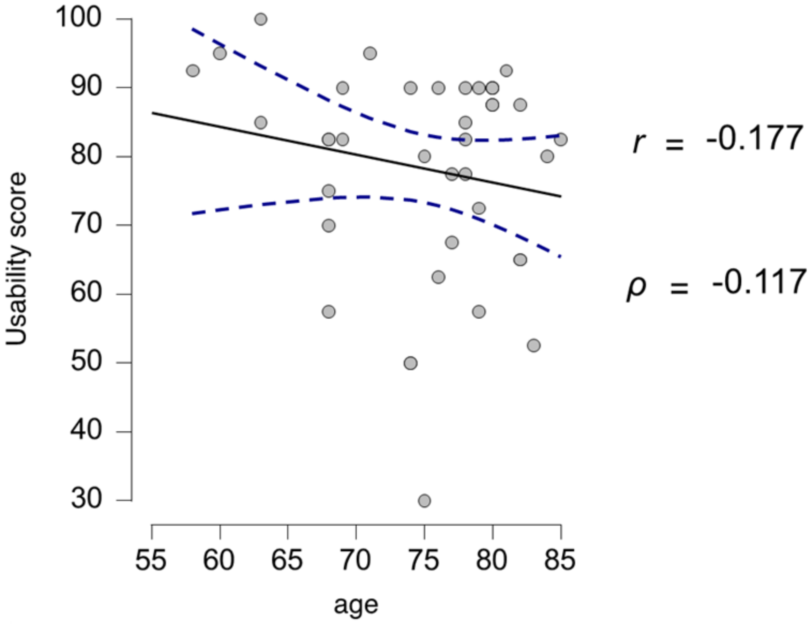
Demographics, clinical and neuropsychological test results, measures of success, and descriptive measures of the postintervention questionnaire are presented in Table 1 and Multimedia Appendix 5.

Contributions From Respondents

Results Derived From Single-Choice Items

Participants agreed very often with positively worded usability items (Multimedia Appendix 5). Most strongly agreed that they could sense vibration, hear sounds, and recognize visual cues well and had enough time to process the input. Of the 40 participants, 29 (73%) did not find the prompt disruptive. Of the 40 participants, 10 (25%) could not sense the vibration well. Interestingly, of the 40 participants, 23 (58%) agreed with the need to be supported by a technical person. Only one-third (14/40, 35%) were interested in more interactions with the smartwatch. When we processed the usability items analogously to the SUS [48], the mean usability score reached 78.3 (SD 15.4; range 30-100). The score translates as "good" usability score on the original SUS. The score did not significantly differ between men (mean 76.1) and women (mean 80.4; *P*=.39) according to the *t* test. Usability decreased with age, but the effect was not statistically significant (Figure 4).

Figure 4. Correlations and regressions between usability and age. The blue lines indicate CIs.



The design features were satisfactory to many participants. Most (30/40, 75%) found the appearance appealing, and 70% (28/40) found the watch to be properly sized. Further feedback about size was uniformly negative (12/40, 30%), with the watch being criticized for being very large. Of the 40 participants, 37 (93%) stated that the wristband was comfortable to wear. Some participants said that the wristband should be softer (user10), longer (user23), or made from a different material (user17). It was suggested that its clasp be replaced with a magnet clasp (user11). Regarding usefulness, most participants (27/40, 68%) were interested in using the smartwatch frequently and saw a personal benefit in doing so (31/40, 78%). Approximately one-third (13/40, 33%) did not have any idea how the watch could be beneficial. Regarding perceived usefulness of the tool, participants scored an average value of 8.7 (corresponds to 72%), a median value of 9.5 (corresponds to 79%, SD 3.4) Only few were concerned that other people might hear the smartwatches’ announcements (17/40, 43%) or find the watch to be very conspicuous (12/40, 30%). Of the 40 participants, 6 (15%) were concerned about stigmatization because of the watch. Overall, two-thirds of the participants (27/40, 68%) felt a sense of safety while wearing the watch. Of the 40 participants, 5 (13%) were concerned about data protection. Of the 40 participants, 4 (10%) worried about their personal health when using the smartwatch. None of them (0/40, 0%) provided further explanations about these worries. Of the 40 participants, 29 (73%) expressed the wish for a permanent contact person for service. Most (36/40, 90%) felt comfortable with using the watch. Only 8% (3/40) of the participants felt stressed during the trial.

Items to Assess Practical Implementation

Practical implementation was investigated using multiple-choice or open-ended questions. We found a preference for less intrusive notifications. A single vibration was favored over multiple vibrations (20>11 checked boxes; 20 persons ticked “single vibrations” and 11 persons ticked the box “multiple vibrations), while a single tone was preferred over ringtones (24>9). Of the 40 participants, 9 (23%) did not indicate their preferred vibration pattern, and 8 (20%) indicated no preferences for ringtones. Of the 40 participants, 24 (60%) thought that instructions should be delivered as spoken output, 20 (50%) preferred written output, and 18 (45%) preferred images. Of the 40 participants, 6 (15%) preferred animations. Of the 40 participants, 17 (43%) indicated only 1 preferred mode of instruction delivery (n=9, 53% chose speech, n=6, 35% chose text, and n=2, 12% chose animation), 18 (45%) preferred a combination of 2 modalities, and 5 (13%) preferred a combination of 3 modalities.

Elaborated feedback was given in the latter part of the questionnaire. Positive feedback was related to the “clear,” “legible,” or “well-arranged” display (user05, user07, user11, user19, and user37); the “easy to understand” audio output (user02, user08, and user41); or the “highly visible timing pointers” (user07). The issues to be optimized included the length of the text display (user04, user27, and user35) and the length of the audio and vibration (user26) files. User07 suggested that “the display should be brighter for a longer time.” The top 5 functions that were chosen for implementation were time display (38/40, 95%), emergency button (34/40, 85%), reminder function (24/40, 60%), telephone option (22/40, 55%), and alarm clock (20/40, 50%). The least useful functions were writing messages (8/40, 20%) or making notes (10/40, 25%).

The answers to the open questions confirmed the preferred functions, especially the need to be supported in navigation (and self-localization) or to be reminded about dates or appointments. In addition, vital parameters were measured. Participants expressed the wish to be directed “within an environment” (user11) and “en route” (user08) and “to find the correct path” (user10) but without further specification. Explicit ideas with points of action were provided for reminders: appointments, daily structure, anniversaries and birthdays, medication, drinking, or reminders of where the house keys are. In terms of vital parameters, people were interested in information about blood pressure, heart rate, sleep, steps, activity, and energy rate. A desired function that was not listed in the questionnaire was the interest in weather forecasting. The extent of overall assistance ranged from “never” (user05) to “for all activities” (user29).

After completing the formal part of the questionnaire, the study staff asked participants who did not respond successfully to the prompts to comment individually. The responses revealed problems with different aspects of the drinking task. User02 said they did not recognize that the watch gave them this instruction. User17 initially could not find the water bottle. User05 did not dare to drink the water provided, and user23 answered that they were not thirsty. We also asked participants for further explanation when they circled the bell on the smartwatch screen instead of the worksheet. Of the 40 participants, 2 (5%) did not think they were supposed to do something in the real world (user33 and user05). User17 indicated that they did not realize that the instructions included the specification, “circle the bells on the sheet.” User34 said they heard the instructions but could not explain why they did not follow it. In addition, user10 stated that they had no idea what to do with the worksheet.

Internal Consistency of Subscales

We hypothesized that (1) usability, (2) design factors, (3) perceived usefulness, and (4) concerns play major roles in the user experience. Therefore, we organized the questionnaires into 4 subscales. Internal consistency was determined for each scale (Table 2).

Table 2. Internal consistency of subscales.

Subscale	Items, n	McDonald ω (in descending order)	Cronbach α
Usefulness	3	0.81	.81
Concerns	7	0.79	.77
Design	6	0.75	.64
Usability	10	0.65	.64

“Good” internal consistency (ω>0.8) was achieved by the perceived usefulness scale, with concerns and design issues achieving “acceptable” consistency (ω>0.7) and usability features achieving “questionable” levels of internal consistency (ω<0.7). Overall, 3 items proved to be critical (Δ ω>0.1 if the item was excluded) for the internal consistency of their respective scales. Specifically, the items asked about the appropriate watch size, length of the instruction displayed, and desire for frequent use.

Plausibility of Statements

Approach

We evaluated the plausibility of the statements to examine the reliability of the feedback. In this paper, the term, “plausibility,” means “reasonable” or “consistent.” The responses to the items on our questionnaires were neither “right” or “wrong” nor expected by the researchers. Our approach to evaluating plausibility included 3 steps. First, we checked for discrepancies within the questionnaires; second, we compared the questionnaire responses and clinical assessments; and third, we compared the answers from the questionnaires with the observed task performance.

Discrepancies Within the Questionnaires

On an intraindividual level, we found very few inconsistencies due to contradictory answers to different items. In the first step, we checked whether positively or negatively worded items were answered consistently, that is, whether the respondent agreed with the positive items and disagreed with the negative items and vice versa. Of the 40 participants, 6 (15%) agreed (“agree” and “strongly agree”) disproportionately with all items (>mean + SD). Of those 6 participants, 5 (83%; user01, user07, user08, user11, and user28) mostly disagreed with the 8 negatively worded items, indicating a positive attitude toward the smartwatch rather than a bias toward positive answers. Only 1 respondent (1/40, 3%; user03) who agreed with the positively worded items also agreed with the negatively worded items. She exhibited an uncritical tendency to confirm statements presented to her (“acquiescence bias”), making it unclear whether her answers truly reflected her point of view or if she misunderstood the questions.

In the second step, we analyzed the participants’ answers regarding the content of their statements. The most implausible answers were found in the questionnaire of user05. She personally completed the questionnaire and indicated high usability (usability score=90) and satisfaction with the design of our smartwatch. Otherwise, she disagreed with the desire to wear the watch in daily life and disagreed with all the questions about usefulness, although she already used a smartwatch in her daily life. She used open-ended questions, for example, to suggest a smaller size but did not explain the reason for indicating high usability and satisfaction with the app design despite her concerns. She answered the question for desired domains of support with “not at all” after canceling her initial answer, “always.” Fewer inconsistencies were found in the questionnaires of user26. She preferred single vibrations and short ringtones instead of multiple or repeated vibrations and longer ringtones but recommended prolonged vibration and anticipated possible difficulties in hearing the sounds of the smartwatch for people with hearing impairment. In addition, user22 did not clearly indicate his preference regarding sounds. He selected both sound options even though they were mutually exclusive.

At a group level, it appeared implausible that less obtrusive notifications regarding audio (24>9) and vibration patterns (20>11) were favored, whereas speech output was a desired characteristic for most participants (24/40, 60%).

Correlations Between the Questionnaire and Assessment Data

When asked to mention situations in their daily lives that should be supported by a smartwatch, 11% (3/28) of the people with dementia stated no need for support (refer to the Items to Assess Practical Implementation section), although their caregivers reported a need for help that led to the diagnosis of dementia. This implies that these participants have lost insight into their functioning in daily life, limiting their reliability in naming domains for necessary support. Otherwise, they also anticipated a decline, as indicated by the added terms, “not yet,” “not to date,” and “not at present.” In addition, there was a discrepancy between the need for support for people with dementia and the severity of their impairment. One of the patients with MCI (1/12, 8%; user29) felt the need for support “for all activities.”

We also correlated the neuropsychological test results with the results from the subscales of the questionnaire. A better usability score (the higher the score is, the more usable the smartwatch appears to be) was significantly correlated with better cognition, as suggested by a positive association with the MMSE score (*P*=.04) and negative associations with the Shulman score on the clock completion test (*P*=.02) and time on the TMT-A (*P*=.01) and TMT-B (*P*=.04; Figure 5).

This confirmed our hypothesis that neuropsychological performance is associated with usability. The 3 other subscales did not correlate significantly with any neuropsychological test. Regarding sex, the 4 subscales did not significantly differ between the 2 groups.

We also checked for conformity of single items with the clinical test results. We correlated item 5 in scale 1 (recognizability of visual prompts on the smartwatch screen) with the visual acuity test results and found no relevant correlation ($\tau_{\text{Visual acuity N}}$ –0.24, *P*=.09; $\tau_{\text{Visual acuity D}}$ –0.16, *P*=.23) Only 5% (2/40) of the participants disagreed with good visibility. Both had a visual acuity below average. The 2 items focusing on latency, asking whether participants had sufficient time to notice that the watch notified them and whether instructions were shown for an adequate time, were correlated with the results of the TMT-A and TMT-B. In addition, no correlations were found (ρ<0.3; τ<0.2; *P*>.05, respectively).

Questionnaires and Observed Task Performance

At the group level, single vibrations and less intrusive audio were preferred (refer to the Items to Assess Practical Implementation section). Regarding completion rates, participants in the “intense” group were more often successful. Here, we can see a discrepancy between the desire for less intrusive signals and better outcomes in participants with more intense intrusiveness.

We correlated the success (for the score calculation, refer to the Measure of Success section) with the usability score (Figure 6). Here, we found a significant positive correlation between the 2 measures; however, the effect size was small to moderate (τ=0.27). The higher the usability was, the more successful the participant was.

We also checked for concordance between self-evaluations and observed behaviors at the individual level by investigating the overlap between success and specific items from the questionnaire. We divided each data set into 2 groups, resulting in 4 clusters (Figure 7). Regarding self-reflection, we distinguished between participants who agreed (clusters 1 and 3) and those who disagreed (clusters 2 and 4) based on item 7 of the usability scale, which assessed task comprehension. Regarding success, we distinguished between participants who completed no more than 1 task (clusters 2 and 3) and others (clusters 1 and 4).

We could see the concordance of self-reflection and observation in most participants (cluster 1: 26/40, 65% and cluster 2: 6/40, 15%). Of those people with appropriate self-reflection, most were successful (14/40, 35%) or almost completely successful (9/40, 23%). They correctly stated that they knew what they had to do. All the 12 people who were not completely successful had trouble with task B (circling bells). Of the 12 participants, 11 (92%) circled the bell on the smartwatch screen and 1 (8%) with the finger on the worksheet. In addition, participants from cluster 2, who were not able to complete >1 task, concordantly disagreed with good task comprehension. Interestingly, no one, including participants who did not attempt either task, strongly disagreed. Few (8/40, 20%) participants showed a discrepancy between self-reports and observations (clusters 3 and 4). We identified 3 possible reasons for the deviation in people in cluster 3. As shown previously, user05 was suspected to have had trouble in completing the questionnaire. We found inconsistencies within their questionnaire and suspected misinterpretation of questions or rating scales. Moreover, memory impairment might limit self-reflection. When completing the questionnaire, user02 indicated that she preferred to have had it handed out beforehand because she could not remember specific details (eg, vibration). User02 was diagnosed with AD dementia and had a score of 22 on the MMSE.

Finally, we found that incomplete or irregular fulfillment of tasks was not recognized by the concerned participants. Except for 1 participant (1/8, 13%; user02), all participants from clusters 3 and 4 completed task B and circled the bell image that appeared on the smartwatch screen. The individuals in cluster 3 felt that their understanding of the task was good, as they felt that they solved the task, even if they did not perform the task according to the researchers’ success protocol. This clear discrepancy between self-reflection and observation might indicate a loss of insight into their abilities and behavior. User33 explained that he did not consider using objects from the real world. User33 and user05 did not drink when prompted. Both belong to cluster 3. It is conceivable that some participants did not expect any actions involving their environment. Otherwise, all people in cluster 4 (5/5, 100%) managed the drinking task and circled the bell on the screen. It is unclear why they disagreed with task comprehension.

Figure 6. Association between success and usability. Success was rated based on observations, and usability was self-rated by participants via questionnaire.

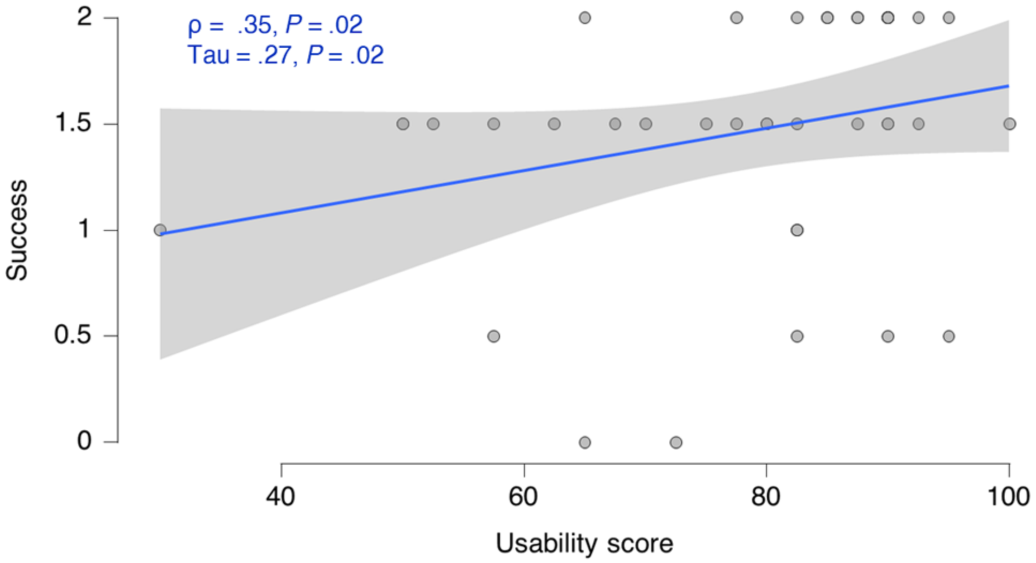

Figure 7. Matrix of self-evaluations and observed task performance. The number in gray circles corresponds to the number of participants. Cluster 1: successful participants with concordant self-reflection, cluster 2: unsuccessful participants with concordant self-reflection, cluster 3: unsuccessful participants with disconcordant self-reflection, and cluster 4: successful participants with disconcordant self-reflection.

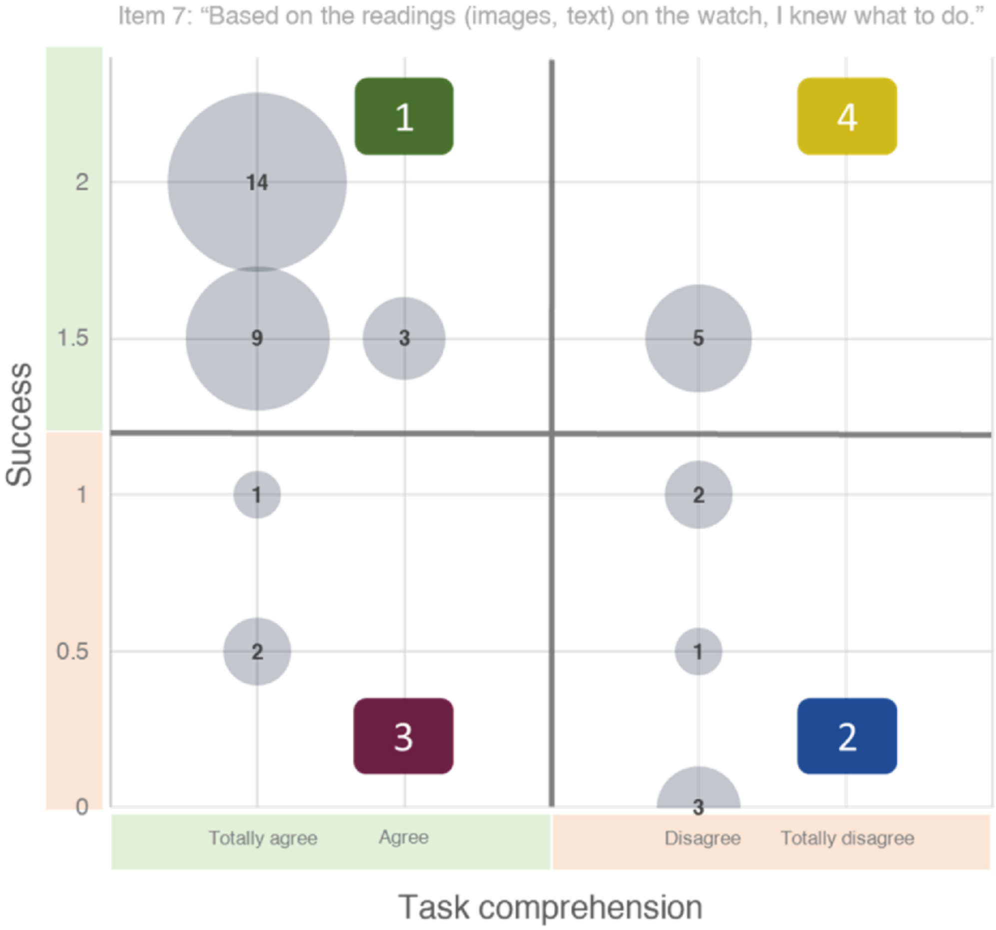

Summary

This paper describes an interdisciplinary study to identify the needs regarding and analyze the effects of multimodal interventions using auditory, haptic, and visual information provided by a smartwatch.

We hypothesized that perceived usability, design, usefulness, and concerns would influence the user experience with our smartwatch and, consequently, included those topics using our questionnaire. We saw interest and commitment from the participants. Some participants struggled with the Likert scale, which might be avoided by guiding them or modifying the questionnaire. Usability was evaluated using complementary approaches, including questionnaire-derived measures and observational ratings of success based on completion rates. Usability, quantified through a 10-item score, reached a mean of 78 (maximum possible score=100). This finding is consistent with the remote observations: 35% (14/40) of the participants were able to complete both tasks, and 50% (20/40) of the participants solved one of both tasks. Only 15% (6/40) of the participants were unable to complete either task. Nonetheless, more than half of the respondents (23/40, 58%) thought they would need the support of a tech-savvy person to use the watch in the long term, and many (29/40, 73%) expressed the wish for a permanent contact person for maintenance. Only one-third (14/40, 35%) wanted more interaction with the smartwatch. The design was appealing to most participants, even though feedback about the size of the watch was primarily negative, with participants expressing that they felt the watch was very large. Various elements of the hardware have received suggestions for improvement. Perceived usefulness was rated high. Overall, two-thirds of the participants (27/40, 68%) had a sense of safety with the watch, and one-third of the participants (13/40, 33%) did not believe that the smartwatch would be beneficial. Only few respondents were concerned about using the watch. We also assessed nonfunctional requirements. We observed a preference for less intrusive notifications on the one hand and a desire for voice output on the other. Sophisticated feedback was provided about the wristband and the display latencies. Several specific use cases for possible reminder functions were mentioned. The internal consistency of the subscales varied between “questionable” and “good.” Lower cognitive ability was associated with lower usability.

We evaluated the plausibility of the feedback by checking for discrepancies. Only very few intraindividual inconsistencies were found within the questionnaires. There were no signs of a general acquiescence bias. When comparing self-rated task comprehension and observations, we observed concordance in 80% (32/40) of the participants. Mild deviation of self-reflection and task completion was observed in 13% (5/40) of the participants, and strong deviation was observed in 8% (3/40) of the participants. Participants seemed to lack insight into incomplete or irregular task performance. At the group level, we observed conflicting findings related to intrusiveness. Preferences for less audio and vibration conflicted with the desire for voice output, and more intrusiveness led to more successful task completion.

Discussion

Indications of Bias

Participants provided very favorable feedback. It is possible that our participants were not overly critical because they had little experience with better-designed, equivalent technologies. Older adults have a limited understanding of the potential implications for their privacy [50]. High usability could also be a sign of recruitment bias. Our recruitment strategy was not biased toward people who are interested in technology, as we invited all participants from the memory clinic. Previous experience with mobile technologies was not necessary. However, interest in the research topic is a major driver of participation; therefore, one must assume that participants were interested in technologies at least slightly.

We cannot rule out acquiescence bias, a tendency to choose the first option or a tendency to choose positive response options (agreement). We controlled for this bias by considering answers to inverted items: most of those items were consistently answered. This makes agreement bias unlikely. High levels of agreement possibly reflect a courtesy bias: the tendency to understate dissatisfaction or challenges with a system, driven by politeness. It is possible that respondents who anticipated positive feedback would be more desirable to researchers than those who provided negative feedback. At a metalevel, this poses a problem in participatory research and should be further investigated. When treated as coresearchers, people may be confused with different roles [51] and transform their commitment to science and innovations into less critical feedback in return for their empowerment. The participants were also reported to be motivated by family members and researchers [25]. Uncertainties regarding participants’ roles in participatory research have already been noted [26]. Otherwise, the participants who actively provide feedback or even participate as coresearchers are motivated to make a difference and transfer scientific results into practice [52]. Regarding ATs for people with dementia, professional researchers and coresearchers share the same need for technology transfer. Neither would benefit from spending resources for the development of unsuitable technologies as a result of uncritical evaluation. Transparency and clarification of expectations, roles, and goals could help resolve this conflict.

Rating of Usability and Review of Internal Consistency

Our calculated usability score cannot be compared directly with other scores resulting from SUS ratings, as we deviated from the original SUS by 7 items [48]. However, regarding the mean and SD, our score is similar to other SUS scores [53,54]. As described previously, usability decreases with age [53] and poorer cognition. We presented data about the internal consistency of the subscales of our questionnaire, with McDonald ω being between 0.65 and 0.81. These findings are consistent with those of previous studies about the internal consistency of usability questionnaires administered to older adults or people with cognitive impairment [54,55]; however, we found only a small number of studies regarding this topic.

Feasibility and Significance of User-Centered Design

There is an ongoing discussion about the extent to which people with dementia can be involved in research and in the development of ATs [20,25]. The ambiguous nature of participation has been examined in several recent reviews. Brett et al [23] showed many positive aspects of patient and public involvement in general; however, they also stressed that the outcomes were found more randomly than methodically. Kowe et al [26] summarized many advantages and disadvantages of participatory dementia research for researchers. Fischer et al

[20] discovered positive and negative effects of involvement of older users in technology design but were unable to determine its impact on technology adoption and acceptance. However, Bethell et al [56] focused on engagement of patients with dementia but could not determine its impact on the research process or outcomes. All of them concluded that more evidence is needed to illustrate the impacts on the involved parties. Therefore, we aimed to determine the feasibility of user-centered development of smartwatch-based interventions for people with dementia.

We based our analysis on 3 aspects: study implementation, intervention outcome (success metrics), and qualitative measures (user experience and perceived usefulness). Regarding recruitment, we had no difficulty in identifying and enrolling suitable study participants. We found participants to be interested and dedicated to this field of research. We had only a small amount of missing data. This indicates that our study addressed a problem relevant to the target group. As we wanted to evaluate the feasibility of the user-centered design approach, we do not discuss about its technical feasibility in this paper. Regarding intervention outcome, we could see that 80% (32/40) of the participants were able to completely solve task A and 40% (16/40) of the participants completely solved task B; a further 50% (20/40) of the participants completed task B at least partially. As these values are study specific and there are no values in the literature for comparison, it is difficult to determine what was to be expected. Many researchers portray older adults as technologically illiterate [20]. Many people in the target group had significant visual, hearing, and tactile impairments [57,58]; therefore, it was not clear whether a smartwatch would even be able to reach the threshold required to gain the attention and task understanding of these people. In this regard, the task completion rate in our study seems to be high. This high rate could also be explained by our interventions being common tasks requiring little effort. In addition, our tasks did not require participants to directly interact with the smartwatch.

Finally, regarding user experience, we received very positive feedback. Most participants felt comfortable with using the watch and would be willing to participate again in the study. Overall, three-fourth of the participants (31/40, 78%) could imagine having a personal benefit from using the watch, which is indicative of a high level of perceived usefulness. On the basis of the evaluation of these 3 aspects, we definitively consider the feasibility as given, but note that user involvement is more resource intensive [20].

The involvement of various stakeholders represents an additional expense [24]. On the one hand, it takes more time to conduct and, above all, evaluate interviews. On the other hand, the creation of suitable questionnaires is methodologically challenging. The scope (number of questions), the number of response levels, or the alternation of positively and negatively worded questions [59] are essential aspects that need to be considered [60]. The iterative approach [20] means that substeps and project goals cannot be defined and planned from the outset. Instead, interim evaluations and adjustments are necessary, which require consistent project management and effective team communication. In our case, the many years of expertise in this area and the commitment of the study staff contributed to our success, as did the long-term, third-party funded financial support over 3 years.

Plausibility Analyses

The second objective was to evaluate the extent to which user feedback from people with dementia regarding ATs is plausible. Our approach to evaluate plausibility included three steps: (1) analysis of discrepancies within questionnaires, (2) comparison of questionnaire responses and clinical assessments, and (3) comparison of questionnaires and observations.

Individual-based analyses revealed only isolated inconsistencies, and group-based analyses revealed inconsistencies that may indicate mutually exclusive needs. Participants showed a wish for less obtrusive notifications and dislike toward a watch that was very conspicuous but also stated a wish for speech output. This shows that there will be no technology that can address all needs equally. There can be conflicting needs both interindividually and intraindividually. This inconsistency in the statements is not due to cognitive deficits but reflects ambivalent attitudes that exist in all people to a greater or lesser extent [29]. We emphasize that unreliability in certain individual cases should not be a reason to prevent the whole group of patients with dementia from participating via self-reports [51].

Our results showed a moderate correlation between perceived usability and cognition (Figure 5). These findings were previously described [53] and confirmed our hypothesis that neuropsychological performance is associated with usability.

In contrast to previous studies [61], we observed high rates of overlap between self-reflection and success metrics such as completion rates. The concordance was evident in both directions. Objectively successful participants mostly indicated a good understanding of the task, whereas less successful participants disagreed with this statement. Only 8% (3/40) of the participants showed a clear discrepancy in the sense that they did not recognize their failure. Overall, 18% (7/40) of the participants did not recognize incomplete or irregular task fulfillment.

The answers were generally plausible and, in part, even elaborated.

Added Value of Our Study

This study is one of the few investigations of the interaction of people with dementia with an interactive smartwatch. Particularly noteworthy is the detailed clinical characterization of the study participants and the exact description of the technical features of the smartwatch interventions. The publication of the results of the survey about the wishes and needs of people with proven memory impairment regarding a smartwatch alone is valuable, even if the sample size of 40 individuals is not particularly large. Several specific use cases were mentioned, and new ideas for wishful smartwatch features were suggested.

Although there are numerous recommendations regarding the design of user interfaces of new technologies, for example, user interface design, these have rarely been tested in a scientific setting in practice on older adults or people with memory impairment. This target group is extremely heterogeneous, and it must be assumed that general recommendations are of limited value [20]. Therefore, it was not clear whether a smartwatch would even be able to reach the threshold required to gain the attention and task understanding of these people.

Most studies of smartwatches for patients with dementia have no interactive claim but, instead, use passive monitoring [62]. We could only find 3 studies that used an interactive smartwatch for people with dementia to support activities of daily life [8,63,64]. König et al [8] designed a system in which a smartwatch was embedded into an infrastructure with tablets and a web platform to evaluate usability in a 3-month trial. The authors did not observe significant changes in the quantitative measurements. They did not assess single interactions. Thorpe et al [63] tested smartwatches capable of scheduling, navigation, communication, and orientation using an off-the-shelf wearable device in 5 participants. Personalization and familiarity appeared to be key drivers of smartwatch adoption. The task completion rates varied greatly among the participants, as in our study. McCarron et al [64] tested a face recognition application for smartwatches paired with smartphones to improve the quality of social interactions and quality of life among people with dementia. The authors had no trouble with study implementation and reported no problems with feasibility. Furthermore, they found no overall impact on the quality of life of the 48 participants when they used the smartwatch for 6 months.

Compared to other studies, our study has a sound sample size [12,15] and represents great added value, as it expands the small body of scientific literature in this specific area.

At a metalevel, this study is important because it highlights the practical implications of user-centered design in the development of novel technologies together with people with cognitive impairment, for example with giving precise recommendations for usability questionnaires for people with dementia, (Multimedia Appendix 6).

Limitations

Specific reasons for discomfort or concerns could not be captured using the questionnaire. In addition, contradictory information regarding the preferred intrusiveness of smartwatch notifications could not be resolved in this study. Some other questions remain open. What authority do we ascribe to technical devices? In this study, 1 participant (1/40, 3%) commented that they would not willingly drink the water that was provided even though the smartwatch prompted them to drink it. Another user stated that they were not thirsty. Such context-related information cannot be measured by sensors. If we want users to actively interact with a device, then questions about the immersive character arise. How should users know when they should interact with the smartwatch and when they should interact with their environment? The smartwatch specifications that we applied in our study seem to match the needs of users. Minor adjustments should focus on optimizing display latencies and wristbands. Future studies should implement more functions and test those functions in practice with more participants in real-world scenarios in the long term.

Conclusions

To determine whether user-centered design featuring people with cognitive impairment in the development of digital assistive devices is worthwhile, one needs to measure the utility of the developed technology. This can be accomplished by evaluating the usability, usefulness, and success metrics. All 3 approaches provide unique challenges because the available measuring tools may be inapplicable for the technology at hand or for the group of potential users. On the basis of the results of our study, we derived specific recommendations for questionnaires for people with dementia. Measures of internal consistency should not be overrated.

To improve technology adoption, the concept of "technical dyads" might be useful: each user is assigned to a person who is willing and capable of adjusting and maintaining devices for users who are technically inexperienced. This would be consistent with the needs of our participants, who expressed the wish for a permanent contact person for service. This wish also confirms the results that have already been found by others [10].

Our study is one of few studies that examined an interactive smartwatch for people with dementia. Although there are some methodological challenges for such studies, we and others have shown that both the inclusion of future users and the use of smartwatches by people with dementia are possible.

Acknowledgments

This study was funded by grants from the European Union (Europäischer Fonds für regionale Entwicklung [European Regional Development Fund]; TBI-V-1-100-VBW-035 and TBI-V-1-101-VBW-035). The funder played no role in study design, data collection, analysis and interpretation of data, or the writing of this paper. All authors declare no financial or non-financial competing interests. The authors have commissioned American Journal Experts, Durham, North Carolina, USA, to revise the language of the paper. The authors thank all participants for their participation and commitment.

Data Availability

The data sets used and analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

DG and ST conceptualized and designed the study with input from SK and GB. GB built the smartwatch prototype with feedback from DG and SK. DG, ER, and SK performed the study. DG analyzed the data. DG drafted the manuscript, which was edited and critically reviewed by ER, SK, GB, AGT, IK, and ST. ER contributed to literature review. AGT focused on language editing and coherence of content. SK and IK focused on shortening the manuscript and enhancing comprehensibility. All authors read and approved the final manuscript.

Conflicts of Interest

ST is a member of the advisory boards for Lilly, Eisai, and Biogen. He is also a member of the Independent Data Safety and Monitoring Board of the study ENVISION (Biogen). All the other authors have no conflicts to declare.

Abstract

Background: Frontotemporal lobar degeneration (FTLD) is a leading cause of dementia in individuals aged <65 years. Several challenges to conducting in-person evaluations in FTLD illustrate an urgent need to develop remote, accessible, and low-burden assessment techniques. Studies of unobtrusive monitoring of at-home computer use in older adults with mild cognitive impairment show that declining function is reflected in reduced computer use; however, associations with smartphone use are unknown.

Objective: This study aims to characterize daily trajectories in smartphone battery use, a proxy for smartphone use, and examine relationships with clinical indicators of severity in FTLD.

Methods: Participants were 231 adults (mean age 52.5, SD 14.9 years; n=94, 40.7% men; n=223, 96.5% non-Hispanic White) enrolled in the Advancing Research and Treatment of Frontotemporal Lobar Degeneration (ARTFL study) and Longitudinal Evaluation of Familial Frontotemporal Dementia Subjects (LEFFTDS study) Longitudinal Frontotemporal Lobar Degeneration (ALLFTD) Mobile App study, including 49 (21.2%) with mild neurobehavioral changes and no functional impairment (ie, prodromal FTLD), 43 (18.6%) with neurobehavioral changes and functional impairment (ie, symptomatic FTLD), and 139 (60.2%) clinically normal adults, of whom 55 (39.6%) harbored heterozygous pathogenic or likely pathogenic variants in an autosomal dominant FTLD gene. Participants completed the Clinical Dementia Rating plus National Alzheimer's Coordinating Center Frontotemporal Lobar Degeneration Behavior and Language Domains (CDR+NACC FTLD) scale, a neuropsychological battery; the Neuropsychiatric Inventory; and brain magnetic resonance imaging. The ALLFTD Mobile App was installed on participants' smartphones for remote, passive, and continuous monitoring of smartphone use. Battery percentage was collected every 15 minutes over an average of 28 (SD 4.2; range 14-30) days. To determine whether temporal patterns of battery percentage varied as a function of disease severity, linear mixed effects models examined linear, quadratic, and cubic effects of the time of day and their interactions with each measure of disease severity on battery percentage. Models covaried for age, sex, smartphone type, and estimated smartphone age.

Results: The CDR+NACC FTLD global score interacted with time on battery percentage such that participants with prodromal or symptomatic FTLD demonstrated less change in battery percentage throughout the day (a proxy for less smartphone use) than clinically normal participants (P<.001 in both cases). Additional models showed that worse performance in all cognitive domains assessed (ie, executive functioning, memory, language, and visuospatial skills), more neuropsychiatric symptoms, and smaller brain volumes also associated with less battery use throughout the day (P<.001 in all cases).

Conclusions: These findings support a proof of concept that passively collected data about smartphone use behaviors associate with clinical impairment in FTLD. This work underscores the need for future studies to develop and validate passive digital markers sensitive to longitudinal clinical decline across neurodegenerative diseases, with potential to enhance real-world monitoring of neurobehavioral change.

Introduction

Background

Frontotemporal lobar degeneration (FTLD) is a common cause of dementia in individuals aged <65 years [1,2]. FTLD encompasses a group of neuropathologically distinct diseases that result in an overlapping set of dementia syndromes with heterogeneous symptoms, including those defined by primary behavior, language, or sensorimotor changes [3,4]. The timely detection of neurodegenerative diseases such as FTLD is a core public health strategy to reduce the individual, caregiver, and socioeconomic burden of dementia [5-7]. As we enter the era of disease-modifying treatments for neurodegenerative diseases, early detection is critical to identify those eligible for clinical trial participation and early treatment to slow or stop disease progression [8-10].

However, current assessment practices for detecting neurobehavioral changes associated with neurodegenerative disease are limited. In-person neuropsychological and neurological evaluations are the gold standard for determining the presence of cognitive impairment and identifying clinical phenotypes suggestive of an underlying neurodegenerative process; unfortunately, their high costs and restricted availability via specialty dementia clinics and research centers limit access for those with fewer financial resources and lower health literacy as well as those who reside in more remote geographic locations. In addition, evaluating a person at a single appointment provides only a *snapshot* of neurobehavioral functioning, which does not account for the dynamic nature of human behavior that fluctuates diurnally and is influenced by other dynamic factors (eg, sleep, fatigue, mood, and medications), limiting sensitivity for detecting early subtle declines [11,12]. Traditional neuropsychological assessment also lacks ecological validity because interpretations of functioning are based on task performance in a tightly controlled testing environment, which seldom reflects a patient's typical daily experience.

Remote monitoring of health status and behavior through the use of digital health tools is a promising solution to overcome the numerous limitations of in-person assessment and has been identified as a priority by several leading health organizations, including the US Food and Drug Administration [13], the US Department of Health and Human Services [14], and the National Institutes of Health [15,16]. Passive digital monitoring in particular (ie, monitoring behavior passively and unobtrusively through remote sensors) represents a low-burden and highly scalable method for improved detection and monitoring of *real-world* neurobehavioral change in neurodegenerative disease. Naturalistic behavioral data collected via in-home remote sensors have shown sensitivity to clinical severity in Alzheimer disease [17-25]; for example, older adults with mild cognitive impairment exhibit significant declines in the number of days with computer use and daily time spent on the computer per day compared to those without cognitive impairment [18]. As an extension of this work, we aim to examine overall daily smartphone use and its association with clinical severity in FTLD. We focused on FTLD as a specific use case to study the construct of passively collected smartphone data in the context of a neurodegenerative disease that manifests with well-characterized neurobehavioral changes.

Objectives

Thus, the aims of this study were to (1) examine passively collected battery percentage trajectories as a proxy for smartphone use throughout the day and (2) test associations between daily battery percentage trajectories and measures of cognitive and functional impairment and neurodegeneration in FTLD. Time-stamped battery percentage data can be easily accessed through public application programming interfaces (APIs) for both iOS and Android devices and have previously been associated with smartphone use [26-28]. Although smartphone screen time or app use time may be a more face-valid measure of smartphone use, access to these data has historically been restricted on iOS devices. This has been a major barrier to accessibility in passive monitoring research because nearly 30% of smartphone users worldwide have iOS devices [29]. Thus, it is worthwhile to examine battery percentage as a more accessible proxy for overall smartphone use. Consistent with prior research on computer use in older adults with cognitive impairment, we hypothesized that individuals with greater FTLD overall disease severity (ie, more severe functional impairment, worse cognitive performance, greater neuropsychiatric symptoms, and more brain atrophy) would demonstrate lower levels of daily smartphone use.

Methods

Participants

Participants were enrolled in the ARTFL (Advancing Research and Treatment of Frontotemporal Lobar Degeneration) study and LEFFTDS (Longitudinal Evaluation of Familial Frontotemporal Dementia Subjects) Longitudinal Frontotemporal Lobar Degeneration (ALLFTD) Mobile App study through the multisite ALLFTD (NCT04363684) study and University of California San Francisco studies of FTLD (AG038791, AG062422, and AG019724), as described previously [30]. The participants were those who had a referring diagnosis of an FTLD clinical syndrome or those who were members of a family with a strong family history of an FTLD syndrome. Additional inclusion criteria were as follows: (1) aged ≥18 years, (2) access to a smartphone, and (3) English reported as the primary language. Participants were asked to use their own smartphones. Recruitment primarily targeted those with Clinical Dementia Rating Dementia Staging Instrument plus National Alzheimer's Coordinating Center Frontotemporal Lobar Degeneration Behavior and Language Domains (CDR+NACC FTLD) global scores of <2, but participants who were more severely impaired were not excluded. Data for this study were collected from August 2020 to April 2023. During this period, 257 participants were enrolled and logged into the ALLFTD Mobile App on their personal smartphones. Participants were only included in this secondary analysis of the ALLFTD Mobile App study if they had at least 14 continuous days of passive smartphone monitoring data, consistent with prior digital phenotyping studies attempting to capture typical daily behavior [31]. Thus, of the initial 257 participants, 231 (89.9%) were included in the final sample after 26 (10.1%) participants were excluded because they first logged in <14 days before the date on which these data were pulled in April 2023. Of these 231 participants, 92 (39.8%) were classified as having neurobehavioral symptoms at the prodromal stage (ie, no functional impairment) or fully symptomatic (ie, with functional impairment) level of severity that are consistent with an FTLD-related clinical phenotype per conference consensus with neurologists and neuropsychologists following published criteria [32-35]. Participants who were symptomatic had either sporadic FTLD or a confirmed pathogenic or likely pathogenic variant in an autosomal dominant FTLD gene (ie, a pathogenic expansion in the chromosome 9 open reading frame 72 [C9orf72] gene or a known pathogenic or likely pathogenic variant in the progranulin (GRN) or microtubule-associated protein tau [MAPT] genes; conducted as described previously [36]). The remaining participants (139/231, 60.2%) were asymptomatic clinically normal family members of the prodromal or symptomatic individuals who (1) carried a pathogenic or likely pathogenic FTLD gene variant (55/139, 39.6%), (2) tested negative for known pathogenic or likely pathogenic FTLD variants (50/139, 36%), or (3) did not yet have results available from genetic testing (34/139, 24.5%).

Ethical Considerations

The study was approved by a centralized single institutional review board at Johns Hopkins Medicine (IRB # 20-29891), and all participants provided written informed consent.

Measures

Passively Monitored Smartphone Battery Percentage

We used the first 30 days of participants' smartphone data for this study with the goal of understanding whether approximately 1 month of smartphone monitoring could reflect baseline neurobehavioral status without capturing longitudinal disease-related decline [18,37]. Participants downloaded the

ALLFTD Mobile App onto their personal smartphones. The app is designed to deliver both active mobile cognitive assessments and passively collect smartphone use data [30], including battery percentage. The ALLFTD Mobile App was programmed to collect battery percentage every 15 minutes. Due to some variability around this timing in the actual data collected (ie, some missing data points and some data collected over shorter intervals), data were aggregated to reflect the average battery percentage per hour of each study day per participant. This resulted in a comparable number of data points per day across participants. The ALLFTD Mobile App also recorded information about participants' smartphone model, which was used to estimate the age of the smartphone (ie, calculated on the basis of the smartphone model release date and the first date of participation in this study).

Functional, Cognitive, and Neuropsychiatric Assessment

All participants underwent comprehensive functional and cognitive assessment at a parent study visit at the beginning of their smartphone monitoring study period. Informant and participant interviews were conducted to characterize the level of cognitive and everyday functioning impairment using the CDR+NACC FTLD scale [38], which is a validated, modified version of the CDR [39] that has higher sensitivity to functional impairment in FTLD. CDR+NACC FTLD global scores [40] were used to categorize participants into disease severity groups: 0=unimpaired, 0.5=prodromal, and ≥1=symptomatic. Domain-specific cognitive functioning was assessed via a comprehensive battery of well-validated neuropsychological tests. The previously published Uniform Data Set (Version 3) Executive Function composite score was used as our measure of executive functioning, comprising Trail Making Test A and B, phonemic fluency (generating words beginning with F and L), number span backwards, and category fluency (animals and vegetables) [41,42]. Sample-based *z* scores were calculated for indices of memory, including immediate and delayed free recall on the California Verbal Learning Test-3 Brief Form [43], as well as Benson Complex Figure Delayed Recall [44,45]. A composite memory *z* score was created by taking the mean of the *z* scores across these memory tests. Language functioning was assessed via the Multilingual Naming Test [46]. Visuospatial functioning was assessed via the Benson Complex Figure Copy [45]. Informants also completed the Neuropsychiatric Inventory [47] to assess the presence and severity of neuropsychiatric symptoms in participants.

Neuroimaging

Of the 231 participants, a subset (n=189, 81.8%) completed neuroimaging. Participants were scanned on 3 Tesla magnetic resonance imaging (MRI) scanners. T1-weighted images were acquired as magnetization-prepared rapid gradient echo images using the following parameters: 240×256×256 matrix; approximately 170 slices; voxel size=1.05×1.05×1.25 mm^3; and flip angle, echo time, and repetition time varied by vendor. A standard imaging protocol was used across all centers, and all images were reviewed for quality by a core group at the Mayo Clinic, Rochester, Minnesota, United States. Details of image acquisition, processing, and harmonization have been published elsewhere [48]. Total gray matter volume was used as the primary neuroimaging variable of interest. Total intracranial volumes were regressed out (using a simple linear regression with gray matter volume as outcome and total intracranial volume as the only predictor) before inclusion in analyses to account for interindividual volumetric differences in head size on gray matter volume.

Statistical Analyses

Differences in demographic and clinical characteristics across the CDR+NACC FTLD–defined disease severity groups were tested with 1-way ANOVA and chi-square tests for continuous variables and categorical variables, respectively. Raw battery percentage data were plotted against the time of day to inform statistical analysis. Linear mixed effects (LME) regression models were then used to model the linear, quadratic, and cubic effects of time (ie, hour of the day; 0=midnight; 23=11 PM) on battery percentage. Person-specific random intercepts and random effects of time (linear, quadratic, and cubic) were modeled. To determine whether daily patterns of battery percentage trajectories (ie, a proxy for smartphone use) varied as a function of FTLD disease severity, LME models examined linear, quadratic, and cubic effects of time and their interaction with each measure of disease severity separately (ie, CDR+NACC FTLD group, cognitive domain *z* scores, neuropsychiatric symptoms, and whole brain gray matter volumes). All LME models covaried for age, sex, smartphone type (iOS vs Android), and estimated smartphone age (calculated on the basis of the smartphone model release date and the first date of participation in this study). A post hoc sensitivity analysis was conducted in a subset of participants (162/231, 70.1%) whose age range was matched across the CDR+NACC FTLD groups. To understand whether subtle differences in neurobehavioral functioning related to daily smartphone battery use trajectories in an *unimpaired* sample, we conducted additional sensitivity analyses, which repeated all models in the subset of participants who were clinically normal (139/231, 60.2%). Regression estimates are reported as standardized betas, which represent the predicted change in the outcome as a function of each predictor in units of SDs. All analyses were performed using R (version 4.2.0; R Foundation for Statistical Computing). The *lme4* package was used to conduct the LME regressions [49].

Results

Participant Characteristics

Table 1 shows demographic and clinical characteristics by disease severity group. Participants had a mean age of 52.5 (SD 14.9) years and a mean of 16 (SD 2.2) years of education. Of the 231 participants, 94 (40.7%) were men, and 223 (96.5%) identified as non-Hispanic White. Nearly three-fourths of the participants (171/231, 74%) had results of genetic testing available, of whom 45% (77/171) had heterozygous pathogenic or likely pathogenic variants in an FTLD gene. Clinically normal participants were statistically significantly younger ($P<.001$) and more likely to be women ($P<.001$) than those with prodromal or symptomatic FTLD, consistent with the larger parent study samples (ALLFTD Mobile App study [30]; ALLFTD [40,50]). There were no other clear imbalances in other demographic and clinical characteristics across the 3 groups. Overall, participants had a mean of 28.3 (SD 4.19; range 14-30) days of smartphone monitoring data. On average, participants’ smartphones were 2.8 (SD 1.53; range 0-7) years old.

[c] C9orf72: chromosome 9 open reading frame 72.

[d] GRN: progranulin.

[e] MAPT: microtubule-associated protein tau.

[f] Identified pathogenic or likely pathogenic variants in genes less commonly identified as genetic causes of frontotemporal lobar degeneration (FTLD; ie, other than C9orf72, GRN, or MAPT). The specific genetic variant is not provided to protect participant anonymity.

[g] Includes behavior-, cognitive-, and language-predominant mild cognitive impairment syndromes.

[h] bvFTD: behavioral variant frontotemporal dementia.

[i] svPPA: semantic variant primary progressive aphasia.

[j] nfvPPA: nonfluent variant primary progressive aphasia.

[k] lvPPA: logopenic variant primary progressive aphasia.

[l] PSP-RS: progressive supranuclear palsy–Richardson syndrome.

[m] CBS: corticobasal syndrome.

[n] Includes FTLD-amyotrophic lateral sclerosis or a change in neurobehavior that may not meet full diagnostic criteria for any particular FTLD syndrome.

Daily Smartphone Battery Percentage

Visualization of the raw battery percentage data by the time of day (Figure 1) shows a nonlinear trajectory such that, on average, battery percentage increased from midnight to approximately 6 AM, then decreased until about 7 PM, and then increased again through 11 PM. These temporal patterns presumably represent typical patterns of charging and charge use of the smartphone throughout the day. Multimedia Appendix 1 presents raw battery percentage data by disease severity group. The shape of these raw data motivated consideration of a cubic model. Thus, we first tested the fit of the LME regression modeling the linear, quadratic, and cubic effects of the time of day on battery percentage, covarying for age, sex, smartphone type, and estimated smartphone age. The cubic model's conditional pseudo-R^2 (ie, the proportion of variance explained by both fixed and random factors) was 0.37. The likelihood ratio tests indicated that the full cubic model had statistically significantly better fit than LME regressions modeling only the linear (χ^2_2=4283.6; P<.001) and quadratic (χ^2_1=4118.8; P<.001) effects of time.

LME regression indicated that the interactions between disease severity group and the linear, quadratic, and cubic effects of the time of day were associated with battery percentage (Table 2). Visualization of model results suggests that participants with prodromal FTLD and those with symptomatic FTLD had *flatter* battery curves throughout the day (ie, shallower decreases from maximum to minimum battery percentage as well as a higher minimum battery percentage; a proxy for less smartphone use) than clinically normal participants on average (Figure 2). Examination of pairwise disease severity group contrasts showed that participants with symptomatic FTLD also had significantly less battery use than participants with prodromal FTLD (P=.003 or P<.001 in all cases).

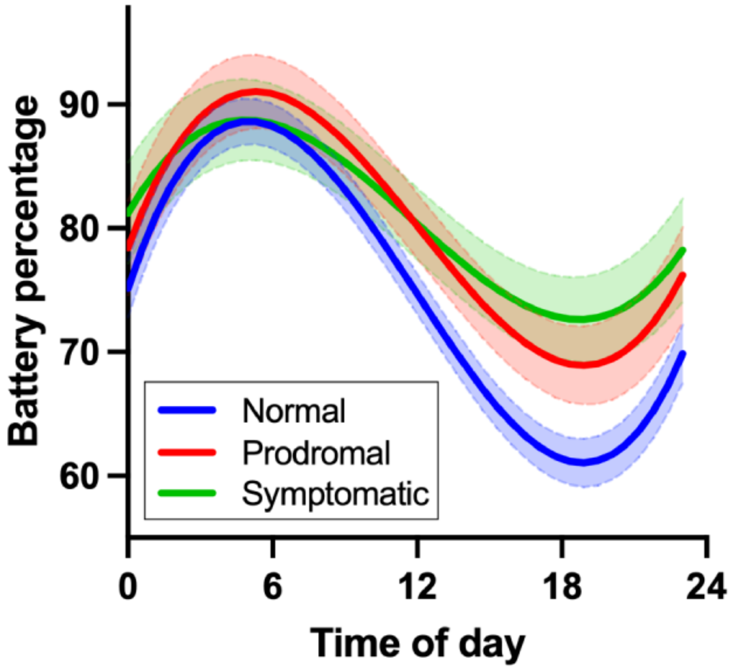
Figure 2. Participants with prodromal frontotemporal lobar degeneration (FTLD) and those with symptomatic FTLD had flatter battery curves throughout the day (ie, a proxy for less smartphone use) than clinically normal participants on average. Error bands represent pointwise 95% CIs.



Similar patterns emerged when examining all other indices of clinical severity. Each cognitive domain statistically significantly moderated the relationship between the time of day and battery percentage such that participants with worse cognitive functioning had flatter battery curves throughout the day, suggesting less smartphone use (Table 3 [executive functioning, memory, language, and visuospatial skills]; Figures 3A-3D). Neuropsychiatric symptom severity also moderated the relationship between the time of day and battery percentage such that participants with higher neuropsychiatric symptom ratings had flatter battery curves throughout the day, suggesting less smartphone use (Table 3 [neuropsychiatric symptoms]; Figure 3E). Examination of each Neuropsychiatric Inventory item (*yes* or *no*) in separate LME models suggested that participants with agitation, depression, apathy, disinhibition, irritability, motor disturbance, nighttime behaviors, and changes in appetite had less smartphone use (Table 4). Delusions, hallucinations, anxiety, and elation did not statistically significantly relate to battery use trajectories throughout the day (Table 4). Finally, total gray matter volume also moderated the relationship between the time of day and battery percentage such that participants with smaller gray matter volumes had flatter battery curves throughout the day, suggesting less smartphone use (Table 3 [gray matter volume]; Figure 3F). Of all indices of clinical severity presented in Table 3, executive functioning and total gray matter volume appeared to have the largest effect sizes on smartphone battery trajectories.

Given the age difference across disease severity groups, we repeated the first LME model examining battery percentage trajectories by CDR+NACC FTLD group after restricting the age range of the clinically normal group to be identical to that of the group with prodromal FTLD and the group with symptomatic FTLD (participants aged 44-81 years in all groups; clinically normal: 70/139, 50.4%). The interactions between disease severity group and the linear, quadratic, and cubic effects of the time of day on battery percentage are fairly consistent, showing that the participants who were symptomatic had lower battery use than clinically normal participants (interaction with linear time: β=−.23, 95% CI −.40 to −.06; *P*=.009; interaction with quadratic time: β=.65, 95% CI .23 to 1.07; *P*=.003; interaction with cubic time: β=−.39, 95% CI −.66 to −.12; *P*=.004). However, the difference between the prodromal and clinically normal participants no longer reached statistical significance (interaction with linear time: β=−.05, 95% CI −.13 to .22; *P*=.586; interaction with quadratic time: β=−.07, 95% CI −.50 to .36; *P*=.76; interaction with cubic time: β=.05, 95% CI −.22 to .33; *P*=.70).

[a] *P* values met the threshold for significance.

Sensitivity analyses conducted among the 139 clinically normal participants showed that the following neurobehavioral measures were associated with daily battery percentage trajectories: executive functioning (interaction with linear time: β=.21, 95% CI .12 to .30; *P*<.001; interaction with quadratic time: β=−.57, 95% CI −.76 to −.38; *P*<.001; interaction with cubic time: β=.34, 95% CI .21 to .46; *P*<.001); memory (interaction with linear time: β=.33, 95% CI .24 to .42; *P*<.001; interaction with quadratic time: β=−.83, 95% CI −1.02 to −.63; *P*<.001; interaction with cubic time: β=.47, 95% CI .35 to .60; *P*<.001), and total gray matter volume (interaction with linear time: β=.32, 95% CI .22 to .41; *P*<.001; interaction with quadratic time:

β=−.84, 95% CI −1.03 to −.64; *P*<.001; interaction with cubic time: β=.48, 95% CI .36 to .61; *P*<.001). Language, visuospatial functioning, and neuropsychiatric symptoms did not strongly associate with daily battery percentage trajectories in clinically normal participants. The directions of associations in these clinically normal participants were consistent with relationships described in the entire sample.

Discussion

Principal Findings

This study is the first to our knowledge to examine passively collected smartphone use data in a sample with neurodegenerative disease. The results highlight an accessible, low-burden, and scalable remote monitoring method that captured behaviors associated with cognitive, neuropsychiatric, and brain health outcomes in a sample of participants with FTLD. The findings support a proof of concept that this passive digital monitoring approach, in combination with other methods, warrants further evaluation as a potential tool to augment screening and monitoring neurobehavioral change in clinical populations. Consistent with our hypotheses, we found that daily trajectories of smartphone battery use (a proxy for overall smartphone use) were associated with gold standard measures of clinical severity in FTLD such that those with more severe levels of impairment had less smartphone use throughout the day. Relationships between battery percentage trajectories and executive functioning, memory, and gray matter volume also held in the subset of clinically normal participants, suggesting potential sensitivity to subclinical neurobehavioral differences.

Comparison to Prior Work

These findings are consistent with previous studies showing that older adults with cognitive impairment have greater declines in everyday technology use compared to cognitively unimpaired older adults [18,51,52]. Other studies have shown that older adults with cognitive impairment report more difficulties using technology, representing a potential barrier to technology use [53,54]. Notably, the observed associations between battery percentage trajectories and cognitive functioning were not specific to particular cognitive domains, suggesting that the metrics of overall smartphone use may reflect a global transdiagnostic marker of functioning rather than a phenotype-specific marker (eg, executive functioning–predominant or language-predominant dysfunction). Thus, our findings may also not be specific to FTLD, and future work is needed to replicate findings in other populations with neurologic conditions. The use of a smartphone, like the use of a computer [18], is a cognitively complex task requiring the resources of many functions (eg, attention, executive function, working memory, and fine motor skill). As such, smartphone use patterns may be a particularly sensitive marker of early and subtle neurobehavioral change; however, additional research examining longitudinal changes in smartphone use over time is needed to support this hypothesis.

While this is the first study to our knowledge to report on passively collected smartphone use data in the context of neurodegenerative disease, there is a growing body of literature examining other passive streams of smartphone data as potential markers of neurobehavioral function in older adults; for example, passively collected data from smartphone accelerometers, GPS location, and touchscreen typing have been associated with symptom and disease severity in Parkinson disease, multiple sclerosis, and amyotrophic lateral sclerosis [55-64]. Future work should incorporate multiple passive smartphone data types for more comprehensive digital phenotyping and potentially improved clinical relevance in monitoring neurodegenerative disease.

Regarding the more technological aspects of passive smartphone data collection, previous studies have also reported similar variability around the frequency and timing of data collected per person. These studies have identified a number of factors that influence the collection and transfer of smartphone data to secure cloud-based servers, including smartphone hardware, data permissions, app engagement, wireless service, capacity of local data storage, data transmission limits, and even sociodemographic factors [65-67]. This has also been reported in other devices as well, including wearables [68-70]. Thus, thorough data cleaning is necessary to ensure that enough data points are captured to accurately represent activity for a given time period, as has been described previously [71,72].

Visualizing the raw battery percentage data was important for understanding daily patterns and supported the utility of daily smartphone battery percentage trajectories as a proxy for smartphone use. Average patterns in battery percentage appeared to track with typical diurnal sleep-wake rhythms: percentages increased up to morning (when mobile phones are likely charging) and decreased throughout the day (when participants were presumably awake and using their smartphones) until nighttime when percentages began to increase again. Careful examination of these raw data patterns, alongside measures of clinical severity, may support the development of specific metrics using battery percentage data that can be easily tracked over longer periods of time (eg, total battery drainage per day). Future work in this field should also consider examining the frequency and timing of smartphone battery charging as a way to track routine daily use patterns that may be clinically relevant. Tracking these metrics over many months or years would allow for future studies to examine person-specific changes in battery use over time and test longitudinal associations with neurodegenerative disease progression.

Strengths and Limitations

The strengths of this study include a large, extensively characterized cohort with FTLD; the reporting of novel smartphone use data; and the use of passive digital monitoring techniques. However, we also acknowledge several limitations. First, there are certainly caveats to our approach using battery percentage as a proxy for smartphone use, including factors that are difficult to quantify and adjust for, such as the impact of hardware, software, and service connection on battery life [73]. In addition, the ALLFTD Mobile App does not record when a smartphone may have been plugged in for charging, potentially preventing periods of battery decline even when the smartphone may have been in use. Even so, the robust relationships observed with gold standard measures of functional impairment, cognition, neuropsychiatric symptoms, and brain volumes are encouraging. Second, it is likely that the mobile cognitive testing sessions administered by the ALLFTD Mobile App contributed to some smartphone battery use and that battery use may subsequently be affected by adherence to the mobile cognitive testing protocol. However, we have previously reported on adherence to mobile cognitive testing through this app [30], which showed that cognitive testing completion rates among asymptomatic participants, participants with prodromal FTLD, and participants with symptomatic FTLD were 71.4%, 78.4%, and 59%, respectively. These adherence rates do not match the stairstep effect of battery use reported in this study whereby cognitively normal participants exhibited the highest smartphone battery use, participants with prodromal FTLD demonstrated intermediate smartphone battery use, and participants with symptomatic FTLD showed the lowest smartphone battery use, suggesting that our results are not simply driven by adherence to the mobile cognitive testing protocol. Third, although we importantly controlled for the effects of age, sex, smartphone type, and estimated smartphone age in our statistical analyses, further replication is needed in samples whose disease severity groups are demographically matched. Fourth, it is possible that a 30-day monitoring period may not be enough time to most accurately capture routine smartphone use behavior. Future studies are needed to evaluate the psychometrics of passive smartphone use metrics across different periods of time to identify optimal lengths of follow-up. Fifth, our sample was also limited in demographic diversity because participants mostly identified as non-Hispanic White and were highly educated, reflective of the cohort in the ALLFTD study [10]. This is a crucial consideration when examining new tools that require access to technology because the implementation of such digital tools may inadvertently increase disparities among those with fewer resources to obtain technology that meets required software specifications. However, with the steadily increasing rates of smartphone ownership worldwide in addition to the implementation of government-funded programs to provide access to technology (eg, the Lifeline Program or “Obama Phone” [74]), there is growing consensus that smartphone monitoring could become universally accessible.

Conclusions

In sum, our novel results demonstrate the feasibility of continuous, unobtrusive smartphone use monitoring, while also showing that smartphone use relates to the severity of neurobehavioral impairment in a sample with FTLD. We highlight these results as proof of concept because we believe that they support future research examining whether specific smartphone use metrics are clinically relevant and may have utility for monitoring clinical disease progression in FTLD and other neurodegenerative diseases. With continued validation, such passive monitoring methodologies for real-time, real-world, and remote monitoring have the potential to improve the monitoring of clinically meaningful neurobehavioral changes in individuals at risk for dementia.

This work was also supported by the Association for Frontotemporal Degeneration, the Bluefield Project to Cure Frontotemporal Dementia (FTD), the Rainwater Charitable Foundation, AlzOut, the John Douglas French Alzheimer’s Foundation, and the Alzheimer’s Association (AARF-22-974065, principal investigator: EWP; AARF-23-1145318, principal investigator: RS). The authors thank the organizers of the the International Society to Advance Alzheimer's Research and Treatment (ISTAART) Design and Data Analytics Professional Interest Area Workshop, *Applying Novel Models for Longitudinal Outcomes*, who provided consultation on the statistical analyses in this study.

The members of ALLFTD Consortium are Liana Apostolova, MD, Indiana University; Sami Barmada, MD, PhD, University of Michigan; Ece Bayram, MD, PhD, UCSD; Hugo Botha, MD, Mayo Clinic, Rochester; Andrea Bozoki, MD, University of North Carolina; Yann Cobigo, PhD, UCSF; Gregg S Day MD, MSc, Mayo Clinic Jacksonville; Dennis Dickson, MD, Mayo Clinic, Jacksonville; Kelley Faber, MS, Indiana University (NCRAD); Anne Fagan, PhD, Washington University, St. Louis; Jamie Fong, MS, UCSF; Tatiana Foroud, PhD, Indiana University (NCRAD); Douglas R. Galasko, MD, UCSD; Ralitza Gavrilova, MD, Mayo Clinic, Rochester; Tania Gendron, PhD, Mayo Clinic Jacksonville; Daniel Geschwind, MD, PhD, UCLA; Jill Goldman, MS, MPhil, Columbia University; Jonathan Graff-Radford, MD, Mayo Clinic, Rochester; Ian M. Grant, MD, Northwestern University; Murray Grossman, MD, EdD, University of Pennsylvania; Chadwick M. Hales, MD, PhD, Emory; Hilary W. Heuer, PhD, UCSF; Ging-Yuek (Robin) Hsiung, MD, University of British Columbia; Eric Huang, PhD, UCSF; David Irwin, MD, University of Pennsylvania; Noah Johnson, BA, Mayo Clinic, Rochester; David T. Jones, MD, Mayo Clinic, Rochester; Kejal Kantarci, MD, Mayo Clinic, Rochester; David Knopman, MD, Mayo Clinic, Rochester; Tyler Kolander, BA, Mayo Clinic, Rochester; Justin Kwan, MD, National Institutes of Health; Argentina Lario Lago, PhD, UCSF; Shannon B. Lavigne, PhD, UT Health San Antonio; Suzee Lee, MD, UCSF; Gabriel C. Léger, MD, UCSD; Peter Ljubenkov, MD, UCSF; Diane Lucente, MS, MGH; Masood Manoochehri, BA, Columbia University; Lauren Massimo, PhD, University of Pennsylvania; Scott McGinnis, MD, MGH; Corey T. McMillan, PhD, University of Pennsylvania; Joie Molden, PhD, University of Colorado; Chiadi Onyike, MBBS, MHS Johns Hopkins University; Alexander Pantelyat, MD, Johns Hopkins University; Henry Paulson, MD, PhD, University of Michigan; Leonard Petrucelli, PhD, Mayo Clinic Jacksonville; Rosa Rademakers, PhD, University of Antwerp; Vijay Ramanan MD, PhD, Mayo Clinic, Rochester; Meghana Rao, BS, MPH Mayo Clinic, Rochester; Katya Rascovsky, PhD, University of Pennsylvania; Kristoffer W. Rhoads, PhD, University of Washington; Aaron Ritter, MD, Cleveland Clinic Las Vegas; Erik D. Roberson MD, PhD, University of Alabama at Birmingham; Emily Rogalski, PhD, Northwestern University; Rodolfo Savica, MD, PhD, Mayo Clinic, Rochester; William Seeley, MD, UCSF; Allison Snyder, MD, National Institutes of Health; Anne C. Sullivan, PhD, UT Health San Antonio ; Jeremy M. Syrjanen, MS, Mayo Clinic, Rochester; M. Carmela Tartaglia, MD, University of Toronto; Philip W. Tipton, MD, Mayo Clinic Jacksonville; Marijne Vandebergh, PhD, University of Antwerp; Arthur Toga, PhD, Keck School of Medicine of University of Southern California; Sandra Weintraub, PhD, Northwestern University; Dylan Wint, MD, Cleveland Clinic Las Vegas; Amy Wolf, BS, UCSF; Jennifer Yokoyoma, PhD, UCSF.

Conflicts of Interest

BA has received research funding from the National Institutes of Health (NIH), the Centers for Disease Control and Prevention, the CJD Foundation, Alector, and Ionis; consulting fees from Acadia, Ionis, Sangamo, Gate, and Merck; and royalties from Wolters Kluwer. GSD reports no conflicts of interest that are directly relevant to this work. His research is supported by the NIH (K23AG064029, U01AG057195, U01NS120901, and U19AG032438), the Alzheimer’s Association, and the Chan Zuckerberg Initiative. He serves as a consultant for Parabon Nanolabs Inc; as a topic editor (dementia) for DynaMed (EBSCO); and as the clinical director of the Anti-NMDA Receptor Encephalitis Foundation Inc, Canada (uncompensated). He is the co–project principal investigator for a clinical trial in anti–N-methyl-D-aspartate (NMDA) receptor encephalitis, which receives support from Horizon Pharmaceuticals. He has developed educational materials for PeerView, and Continuing Education Inc. He owns stock in ANI Pharmaceuticals. His institution has received support from Eli Lilly for development and participation in an educational event promoting early diagnosis of symptomatic Alzheimer disease and in-kind contributions of radiotracer precursors for tau–positron emission tomography (PET) neuroimaging in studies of memory and aging (via Avid Radiopharmaceuticals, a wholly owned subsidiary of Eli Lilly). NG has participated, or is currently participating, in clinical trials of antidementia drugs sponsored by Bristol Myers Squibb, Eli Lilly and Avid Radiopharmaceuticals, Janssen Immunotherapy, Novartis, Pfizer, and Wyeth, as well as the Study of Nasal Insulin to Fight Forgetfulness (SNIFF) and the Anti-Amyloid Treatment in Asymptomatic Alzheimer’s Disease (A4) trial. She receives research support from the Tau Consortium and the Association for Frontotemporal Dementia and is funded by the NIH. IL’s research is supported by the NIH (2R01AG038791-06A, U01NS100610, R25NS098999, U19 AG063911-1, and 1R21NS114764-01A1), the Michael J Fox Foundation, the Parkinson’s Foundation, the Lewy Body Dementia Association, CurePSP, Roche, Abbvie, Biogen, Centogene, EIP Pharma, Biohaven Pharmaceuticals, Novartis, United BioPharma, and UCB. She is a member of the scientific advisory board for Amydis but does not receive funds and from the Rossy Progressive Supranuclear Palsy Program at the University of Toronto. She receives her salary from the University of California San Diego and as chief editor of Frontiers in Neurology. JCR is the site principal investigator for clinical trials sponsored by Eli Lilly and Eisai. He receives consulting fees from Roon. LVV is the site principal investigator for clinical trials sponsored by Biogen and has consulted for Retrotope. All other authors declare no other conflicts of interest.

Multimedia Appendix 1

Visualization of raw battery percentage data binned by time of day (0=midnight; 23=11 PM) by disease severity group: (A) clinically normal, (B) prodromal frontotemporal lobar degeneration (FTLD), and (C) symptomatic FTLD.

Abstract

Background: Assistive technology is becoming increasingly accessible and affordable for supporting people with dementia and their care partners living at home, with strong potential for technology-based prompting to assist with initiation and tracking of complex, multistep activities of daily living. However, there is limited direct comparison of different prompt features to guide optimal technology design.

Objective: Across 3 experiments, we investigated the features of tablet-based prompts that best support people with dementia to complete activities of daily living at home, measuring prompt effectiveness and gaining feedback from people with dementia and their care partners about their experiences.

Methods: Across experiments, we developed a specialized iPad app to enable data collection with people with dementia at home over an extended experimental period. In experiment 1, we varied the prompts in a 3 (visual type: text instruction, iconic image, and photographic image) × 3 (audio type: no sound, symbolic sound, and verbal instruction) experimental design using repeated measures across multiple testing sessions involving single-step activities. In experiment 2, we tested the most effective prompt breakdown for complex multistep tasks comparing 3 conditions (1-prompt, 3-prompt, and 7-prompt conditions). In experiment 3, we compared initiation and maintenance alerts that involved either an auditory tone or an auditory tone combined with a verbal instruction. Throughout, we asked people with dementia and their care partners to reflect on the usefulness of prompting technology in their everyday lives and what could be developed to better meet their needs.

Results: First, our results showed that audible verbal instructions were more useful for task completion than either tone-based or visual prompts. Second, a more granular breakdown of tasks was generally more useful and increased independent use, but this varied across individuals. Third, while a voice or text maintenance alert enabled people with dementia to persist with a multistep task for longer when it was more frequent, task initiation still frequently required support from a care partner.

Conclusions: These findings can help inform developers of assistive technology about the design features that promote the usefulness of home prompting systems for people with dementia as well as the preferences and insights of people with dementia and their care partners regarding assistive technology design.

Introduction

Background

Dementia is a progressive neurological condition that results in a range of cognitive and motor impairments that can have an impact on an individual's well-being and capacity to live independently. These impacts include difficulties with orientation in time and space; noticing body signals such as hunger, thirst, or temperature; initiating activities; and keeping track of a sequence of tasks [1]. Assistive technology that provides prompts for activities of daily living (ADLs) is a form of environmental support that can help people living with dementia by reducing the impact of their cognitive impairment and enabling active living and independence [2]. In daily practical terms, a prompting device could be an effective way to support people with dementia to first notice that an ADL needs to be done; then initiate the ADL; and, finally, undertake each step of the ADL in the necessary sequence to see it through to completion. In this way, assistive technology has strong potential to support people with dementia compensate for their cognitive disability. However, the cognitive, sensory, and motor changes associated with aging and dementia may have an impact on design features of technology interfaces that are useful for this user group [3]. So far, little research has directly compared the outcomes of different types of prompts (eg, visual vs auditory) to test what is most useful for people with dementia. Across 3 experiments, we addressed this gap, with the aim of informing general assistive technology design for people with dementia.

ADLs are functional, multistep, complex tasks related to self-care, domestic duties, socialization, and leisure. Difficulties with completing ADLs can arise for a range of reasons, and these difficulties have a substantial impact on quality of life for people with dementia. People with dementia often experience reduced ability to initiate activities as well as executive functioning changes that make accurate tracking of multistep activities challenging [4,5]. These difficulties with ADLs increase dependence on others for support [6] and are a common reason for moving to residential care [7]. Supporting people with dementia to both initiate activities and accurately and independently complete the steps involved in daily tasks has the potential to improve well-being for both people with dementia and their family care partners [6,8]. Therefore, cognitive rehabilitation approaches emphasize the potential for the right support tools and strategies to enable successful ADL completion and support people with dementia in living independently for longer [9].

Assistive technology has increasingly received attention for its potential to reduce the impact of cognitive impairments on an individual's day-to-day functioning [10]. However, existing research on prompting technology for people with dementia has adopted a wide range of approaches, which makes drawing general conclusions and developing recommendations challenging. Technology solutions vary in several ways, including what kinds of tasks they aim to support, what kind of device they adopt, prompt features, and the amount of user involvement required. Typically, a single version of the prompting system is developed and then user tested, often involving small feasibility trials [11]. Studies that directly compare design features in terms of their outcomes for people with dementia are scarce [11]. More broadly, technological research and development at the cutting edge of innovation has to date been unable to generate solutions that are readily available on the market. One reason is that people with dementia and family care partners experience barriers and challenges in incorporating assistive technology into daily care practice, contributing to the low uptake of existing devices [12-14]. Therefore, experimental work and an evidence base with end users is required to inform general technology design for people with dementia to ensure that assistive technology solutions go beyond research studies and become part of everyday life [15,16].

Device Types and User Involvement

A recent review identified 30 published studies of prompting systems to support people with a cognitive impairment in completing ADLs [11]. The authors classified 6 broad types of devices, with varying hardware approaches and corresponding variance in the extent to which users were involved in mediating prompt delivery. Technology solutions ranged from fully autonomous sensor-based home systems designed to detect completed steps in a sequence and provide prompts when needed to social robots and prompts delivered in readily available consumer devices such as tablets and smartphones. Systems that are autonomous, without user input, typically use sensors and smart technology to monitor a person's activity and detect where they are up to in a sequence of steps [17] to determine when a prompt may need to be given. Examples of these systems tend to focus on supporting a specific ADL for which the system is designed and trained, such as the Cognitive Orthosis for Assisting Activities in the Home (COACH) system for handwashing [18]. Alternative approaches involve input from either people with dementia or care partners to determine when tasks are initiated and when prompts are delivered. Examples of these include app-based prompting software where the user themselves selects *next* to move through steps and receive the next prompt in a sequence [19], although these solutions may not align with people with dementia's need for support with activity initiation. Interestingly, in a recent version of the COACH handwashing system [20], researchers reported that voice-based interaction with the system was much more effective for users with dementia than the previous iterations that had used a camera to detect step completion, indicating that a human-in-the-loop system may be more effective than a fully automated one. Across these varying device types and technologies—from apps to sensors to social robots—the features of effective prompts have not yet been taxonomized. We aimed to test general principles about the optimal design features of effective prompts for people with dementia in ways that could be applied to these widely ranging device types, technologies, and intended tasks.

Optimizing Prompt Design: Modality, Timing, and Breakdown

Existing research provides a limited evidence base on how to optimize prompts for people with dementia in terms of features such as modality, timing, and task breakdown. Prompting technologies in the published literature have adopted a range of modalities for prompt delivery, including a visual (eg, image- or video-based instruction) or auditory (eg, verbal instruction [21]) element or a combination of both [22,23]. Prompt modality has been frequently determined by device design, although some researchers have provided the individual user with a choice [12,24]. In the subset of studies in which outcomes have been measured and reported, studies that have compared a *prompting* to a *no prompting* condition generally have demonstrated some advantage to using prompts [11]. For example, a recent experimental study tested a smartphone app that prompted water drinking and found significantly better performance in the prompted than in the unprompted condition [25]. Reviews have identified benefits of step-based prompting in other populations (eg, those with an intellectual disability [26]). The social robot Tessa has been used to provide people with dementia with support to complete a predetermined ADL goal [27]. The eWare system integrates the social robot Tessa with sensor monitoring technology (eg, door contact sensors) with the aim of using the sensor data to generate verbal reminders and motivating comments for people with dementia. A small pilot study of 9 dyads who were monitored over 6 months [28] found promising results of this system but with limited benefits for carer burden and the need for further research identified.

Despite promising evidence that technology-based prompting can support ADL completion for people with dementia, few studies have directly compared different prompt modalities, timings, and task breakdown options to determine which design features are the most useful and direct future technology development. In one exception, a study directly comparing prompt features found that text-based and verbal prompts were more effective than image-based prompts for a card-and-envelope task but not for putting on a CD to play music [19]. The authors concluded that the most effective prompt modality may depend on aspects of the task, including complexity and familiarity (see also the study by Braley et al [22]). In a qualitative study with the social robot Tessa, people with a cognitive disability and their carers preferred prompts with an auditory element compared to visual-only prompts [29]. Conversely, other research has suggested no advantage in adding verbal instructions to visual (pictorial or video) prompts, albeit with small sample sizes [30,31]. Overall, although there is some evidence that the presence of prompts is better than no prompts, there are limited data to guide choices about optimal prompt design, including prompt modality, task breakdown, and timing.

Task Types and Task Breakdown

Within the literature, a number of prompting systems have been developed that are specialized to support 1 key activity of ranging complexity, including washing hands [32,33], putting on prosthetic limbs [34], making pizza [35], morning routine [36], and cooking tasks [37]. Some prompting systems could theoretically be applied to any task but were tested with a small range of predetermined tasks for the purposes of evaluation [23,25,30,31]. Other devices have focused on a generic interface that can support any kind of user-chosen task. For instance, research that examined a personalized tablet-based prompter found that people with dementia and their care partners could select and load their own tasks and steps based on their own goals [24]. Tasks chosen by users included using the television or a camera, remembering to take required objects when leaving the house, and basic ADLs such as table setting or making a sandwich [24]. In our own research conducting detailed interviews with people with dementia and their care partners, we identified a great deal of individual variation in what tasks were valued by individuals as well as idiosyncratic reasons for task incompletion and which steps within tasks needed more support [38]. Despite the technological challenges of an open-ended system in which people can choose their own tasks and prompts, this personalized approach appears to more closely match the needs of users within their everyday context.

This Research

A number of recent studies of home prompting systems for people with dementia have focused on implementing prompts via mainstream, tablet-based devices. Research indicates good potential for the usability of these systems such that people with dementia and their care partners can interact with a touch-screen tablet by, for example, advancing to the next step in a sequence via pressing an on-screen button [19]. However, a recent review concluded that general conclusions could not be drawn about the effectiveness of prompting technology for people with dementia because many studies were very small and did not have an experimental design with comparisons and control groups [11].

To address this gap, we conducted a series of 3 iterative studies aiming to advance assistive technology design by examining the potential of prompts to support people with dementia with 2 key aspects of ADL completion. First, people with dementia often experience loss of initiative and could benefit from technology that activates them to commence a task through effective reminders. Second, people with dementia experience difficulties with executive functioning, making multistep activities more difficult to perform and keep track of, so that complex tasks may need multiple prompts provided in a sequence to be completed successfully. The 3 studies integrated experimental design and both quantitative and qualitative methods and examined prompt modality (experiment 1), task breakdown (experiment 2), task initiation (experiment 3), and attention maintenance (experiment 3). At the conclusion of each study, we gained detailed user experiences and feedback to contextualize our findings and provide user recommendations for future technology development.

Ethical Considerations

All studies were conducted with approval from the Western Sydney University Human Research Ethics Committee (reference H14632). All participants provided extended consent for both primary data collection and secondary analyses of the research data. Additional proxy consent was obtained from family members in situations in which participants with dementia—through cognitive screening or specialist advice—were assessed to have reduced capacity to provide informed consent depending on their degree of cognitive impairment. In all three experiments, both participants with dementia and care partners were reimbursed (Aus $50 [US $33.74] per hour e-gift card) in recognition of their time and specialist expertise due to their lived experience of dementia. All methods were carried out in accordance with relevant guidelines and regulations. Data were deidentified for analyses and stored securely on Western Sydney University infrastructure.

Experiment 1

Methods

Participants

Participants were 11 people with dementia, 10 (91%) of whom were supported by a care partner to complete the research. Participants with dementia (n=5, 45% female; n=6, 55% male) ranged in age from 58 to 82 years, with an average age of 73 (SD 7.20) years. Participants who were care partners (10 female) ranged in age from 34 to 77 years, with an average age of 58 (SD 13.59) years. A total of 55% (6/11) of the participants with dementia spoke English as a first language, and 45% (5/11) spoke a language other than English. Participants with dementia had been diagnosed between 9 months and 9 years before the study, with an average of 3.5 years. The relationship of care partners to the participants with dementia included 50% (5/10) spouses, 40% (4/10) adult children, and 10% (1/10) siblings. Participants were recruited through care partner support groups, Dementia Australia, and the StepUp for Dementia Research participant database [39]. We did not formally record additional medical information regarding comorbidities beyond the participants' dementia diagnosis, but participants were required to have sufficient visual and hearing ability to be able to see and hear the iPad prompts as part of our inclusion criteria.

Design and Materials

Software for Prompt Delivery

We developed a method for remote data collection to accommodate restrictions on face-to-face research associated with the COVID-19 pandemic. A dedicated iPad app was developed to enable data collection in participants' homes. An iPad was issued to each participant, with reliance on collaboration between researchers and care partners who facilitated data collection with participants with dementia. Using the iPad app, we established 9 conditions to test what visual and auditory features would make prompts most useful. We varied prompts in a 3 (visual content: text instruction, iconic image, and photographic image)×3 (audio content: no sound, symbolic sound, and verbal instruction) experimental design. We also included 5 different tasks developed to sample a range of daily activities that a seated participant could complete with a single action (ie, not involving moving around the home). These tasks were (1) *drink some water*, (2) *brush your teeth*, (3) *wear a mask*, (4) *put on something warm*, and (5) *turn on the television*. The 5 different tasks were completed in each of the 9 conditions, resulting in 45 trials for each participant.

Visual Prompt Content

For the visual prompts, photo images representing each task were sourced from Unsplash (Getty Images [40]), and icon images representing each task were sourced from Flat Icon (Freepik Company SL; Figure 1).

Figure 1. Example item—the icon image for "Wear a mask.".

Auditory Prompt Content

For the auditory content, symbolic sounds were developed and recorded by the research team. Verbal instructions were recorded in an Australian-accented female voice as high quality, clearly presented audio clips.

Pilot-Testing

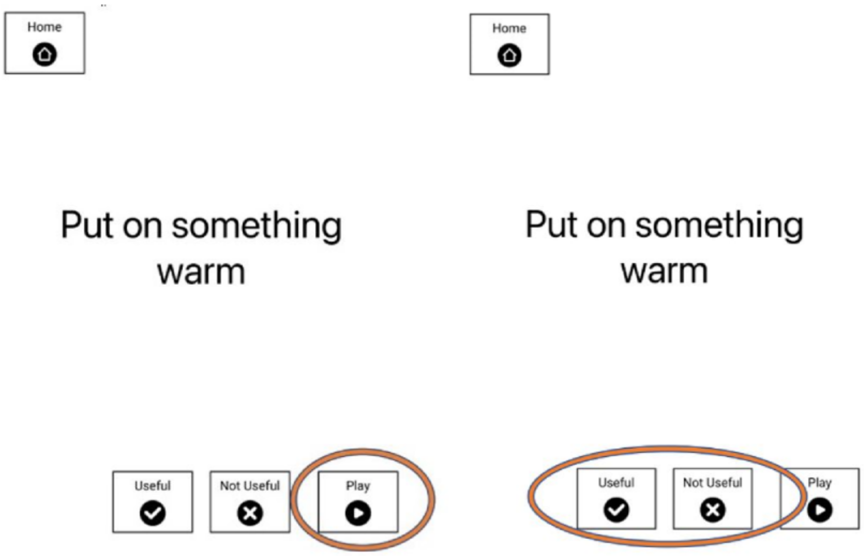
The associations among the images, sounds, and the target tasks were pilot-tested by conducting a survey of 55 Australian older adults (aged ≥65 years). We used the responses of these participants to refine our final stimuli selection by presenting a variety of stimuli and selecting the images and sounds rated as having the strongest association with the target task.

Measures and Scoring

Prompt Usefulness

Our key dependent variable was prompt usefulness. For each prompt, immediately following its presentation, care partners rated whether it was *useful* or *not useful* by selecting the appropriate button on the iPad (Figure 2). For a scoring of useful carers were instructed that this should be selected if the participant with dementia completed or approximated the target task (ie, initiated the task by selecting the correct target item from the table and then followed through by completing the prompted action with it). When tasks were not completed or the prompt could not be understood by the participant with dementia, carers were instructed to rate the prompt as not useful (Figure 2).

Figure 2. An example item for “Put on something warm” in the text and verbal instruction condition. The prompt screen included the option to press “play” to repeat the auditory content (either symbolic sound or verbal instruction). Carers rated the usefulness of each prompt by pressing the appropriate button.



Put on something warm

Put on something warm

Time to Respond

The time between prompt onset and the care partner indicating whether it was useful or not useful was recorded automatically via the iPad app. Response times were then compared across prompt conditions.

Care Partner Support

To understand the extent to which care partners were involved in supporting the participant with dementia in engaging with the prompts and completing tasks, the iPad app captured audio and video during each trial using the in-built camera. Independent coders scored the videos for verbal assistance from care partners at 3 time points (using the iPad, engaging with the objects on the table, and performing the action) and across 2 levels of assistance (*asking for attention* or *direct telling*). All videos were scored for the presence of support in the resulting 6 categories by 2 raters who were blind to the prompting condition. Agreement between raters was substantial (84.92%), and the ratings of the first rater were retained for analysis.

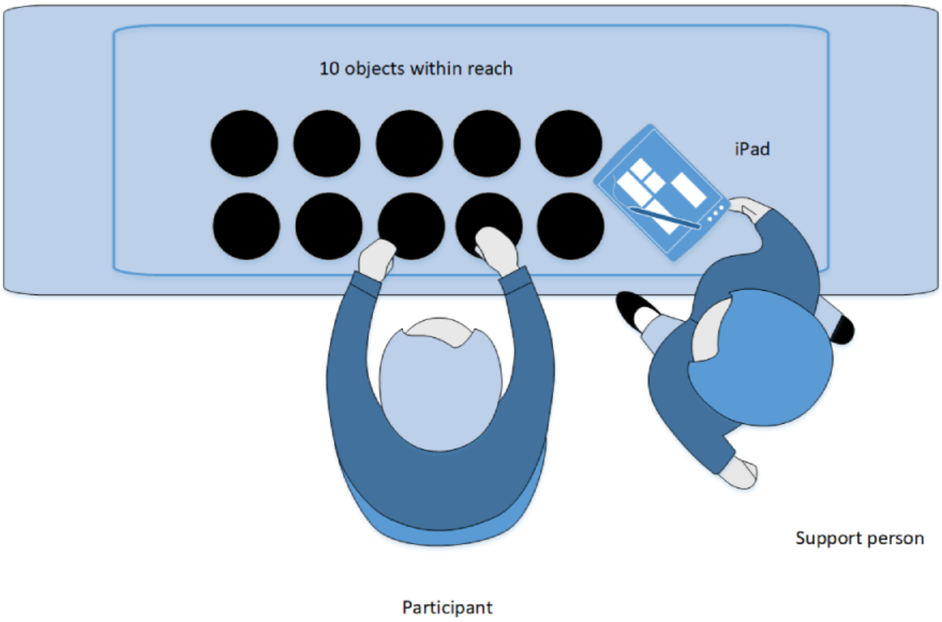
Procedure

Baseline

During an initial video call, participants were oriented as to the project. They provided informed consent and proxy consent where appropriate. If participants with dementia had not had a recent cognitive assessment with their health care provider, a Mini-Mental State Examination (MMSE) [41] was conducted to assess the cognitive status of participants with dementia and determine the consent pathway. Participants provided demographics, including age, gender, and cultural and language background, and information about their dementia diagnosis, including when it was received, by whom, and what type of dementia they were diagnosed with (if known).

Participants were given a detailed printed manual as well as verbal phone instructions about how to set up and conduct the tasks. Care partners were instructed that participants with dementia should sit comfortably at a table with 10 preselected objects in front of them within easy reach. Objects included 5 target objects (a glass of water, toothbrush, mask, an item of warm clothing like a scarf or woolen hat, and a television remote control) and 5 distractor objects (other familiar objects from around the home). The iPad was placed to the side of the participant with dementia to enable them to see and interact with it while being able to reach the objects on the table (Figure 3).

Figure 3. A visual representation of the at-home setup provided within the care partner manual, including positioning of the objects and iPad.



Experimental Phase

On each research participation day, care partners supported participants with dementia to work through a set of 5 prompts for the 5 target tasks. Each of the 5 task types appeared once each day in a different condition, with the condition associated with each task varying in a fixed random order. Across the whole experiment, each of the 5 tasks appeared in each of the 9 conditions, and conditions were spread across the 45 trials (Table 1). For each prompt, participants with dementia were to respond by selecting the appropriate object from in front of them and completing the task. There was a button labelled *play* that enabled care partners and participants with dementia to replay the symbolic sound or verbal instruction if they wished to have it repeated (Figure 2). Care partners were asked to allow participants with dementia to respond to the prompt themselves without assistance. For each prompt, care partners rated whether it was useful (the participant with dementia completed or approximated the task) or not useful (the participant with dementia did not complete the task) by selecting the appropriate button on the iPad (Figure 2). Once rated, the next task was presented on the iPad until the 5 tasks for that day were completed. This procedure was repeated over 9 separate sessions (typically one session each day for consecutive days) until all 45 trials were completed. The iPad automatically captured video and audio during the experimental sessions while the prompts were on the screen using the front-facing iPad camera. In the case of partial completion of the 5 tasks on a particular day, participants and care partners continued the tasks at their next session.

Table 1. The 9 experimental conditions for each of the 5 activity of daily living tasks[a].

Audio condition	Visual condition		
	Text instruction	Iconic image	Photographic image
No sound	Tasks 1-5	Tasks 1-5	Tasks 1-5
Symbolic sound	Tasks 1-5	Tasks 1-5	Tasks 1-5
Verbal instruction	Tasks 1-5	Tasks 1-5	Tasks 1-5

[a] Task 1: “Have a drink of water”; task 2: “Brush your teeth”; task 3: “Wear a mask”; task 4: “Put on something warm”; task 5: “Turn on the television.”

Experience and Feedback Interview

After completion of the 9-day experimental phase, a semistructured interview was conducted with both the participant with dementia and the care partner together. Questions included the following: “How did you and the person you care for engage with the system? What worked and what didn’t work?”; “What did you think of the images, sounds, and text?”; and “What would you use a system like this for in your daily life?” The interviews were approximately 15 to 20 minutes in duration. Due to restrictions on face-to-face interactions with participants, all interviews were conducted via web-based videoconference and recorded for transcription and analysis. The transcripts were checked and edited for accuracy. Transcripts were stored and analyzed by the research team in the NVivo qualitative analysis software (QSR International) using a coding rubric as a guide to code. A thematic approach was taken to identify, analyze, and interpret patterns of meaning [42].

Results

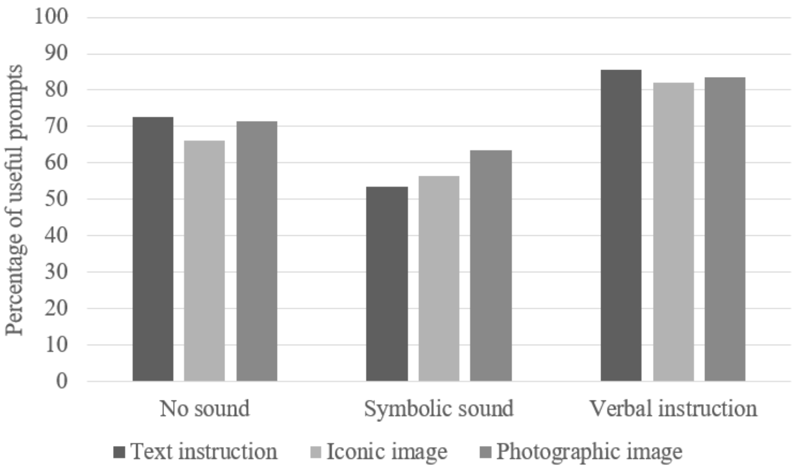
Prompt Usefulness

To determine what kinds of prompts were most useful, we first examined the frequency with which care partners responded *useful* versus *not useful* for each task type. A chi-square analysis indicated that prompt usefulness was significantly different across task types (χ^2_4=35.3; *P*<.001), with "drink some water" (79/100 trials, 79%), "brush your teeth" (80/100 trials, 80%), and "put on a mask" (82/100 trials, 82%) being more successful than "turn on the TV" (53/100 trials, 53%) and "put on something warm" (59/100 trials, 59%). These differences in usefulness may be due to the direct correspondence between the stimuli and the item in front of the participants with dementia that they were to select. For example, compared with the other target objects (glass, toothbrush, and mask), the link between the target objects for "turn on the TV" (television remote control) and "put on something warm" (item of clothing) was more abstract, without a direct correspondence between the visual prompt (eg, a television) and the item on the table (eg, the television remote control).

Participants varied in their stage of dementia and degree of cognitive impairment. Therefore, we examined any differences in prompt usefulness depending on dementia severity, which was self-reported by care partners as mild, mild to moderate, moderate, or severe. Self-reporting was also corroborated, where possible, through administration of the MMSE [41]. Data indicated a difference in prompt usefulness depending on the participants' dementia severity (χ^2_3=61.9; *P*<.001). Frequencies of prompts being rated as useful were comparable for participants who had mild (67/90 trials, 74%), mild to moderate (73/90 trials, 81%), and moderate (180/230 trials, 78.3%) dementia symptoms, and these participants found more of the prompts useful than did participants with severe dementia (33/90 trials, 37%).

Most importantly for our research questions, we examined what combinations of visual and verbal stimuli were the most effective in yielding useful prompts. Across tasks, the type of visual content made little difference to prompt usefulness. The most important prompt feature that impacted usefulness was the presence of the verbal instruction (compared to a symbolic sound or no sound). A chi-square analysis confirmed that the spoken verbal instruction was more useful than the other auditory conditions of a symbolic sound or no sound (χ^2_2=27.2; *P*<.001), whereas the different visual conditions (text instruction, iconic image, and photographic image) did not make a significant difference regarding prompt usefulness (χ^2_2=0.9; *P*=.65; Figure 4).

Figure 4. Percentage of useful prompts by prompt visual and auditory content.



Prompt Success Across Time

We examined whether there was a difference in prompt success across trials to see whether useful prompts were more frequent on later trials (indicating learning) or early trials (indicating fatigue). To achieve this, we compared the average day number (1-9) and the average trial number (1-45) for useful versus not useful prompts. This analysis indicated no significant difference in average day or task number of useful versus not useful prompts (t_{498}=0.85 and *P*=.20 vs t_{498}=0.93 and *P*=.18, respectively). This suggests no evidence that people found the prompts more or less useful with practice and experience.

Combining All Predictors

Given that there was wide variation in the usefulness ratings across participants and that participants contributed multiple trials to the data set, we followed up these trial-based analyses with a stepwise (forward, likelihood ratio) logistic regression, with predictors added in order of participant, degree of dementia, task content, day number (1-9), trial number (1-45), auditory condition, and visual condition. Usefulness on each trial was the binary dependent variable. This analysis yielded a model with 4 significant predictors, confirming a significant effect of auditory condition (*B*=0.37; *P*=.004) over and above the significant contributions of participant (*B*=0.068; *P*<.001), dementia severity (*B*=−0.55; *P*<.001), and task content (*B*=0.21; *P*=.006). There was no significant contribution of visual condition (*B*=.26; *P*=.61). Overall, auditory prompt content predicted prompt usefulness over and above participant variance, but visual prompt content did not.

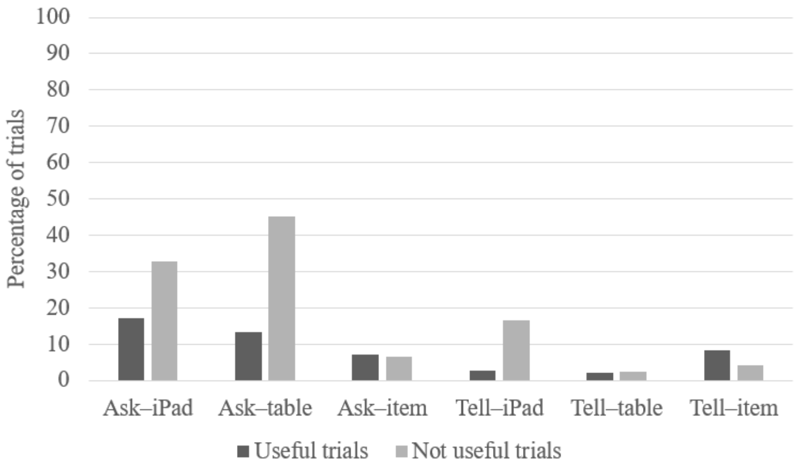
Time to Respond to Prompts

The time to respond to prompts was examined to understand which prompts elicited the quickest comprehension of information. In general, it took significantly longer for participants to select not useful (mean 30.70; SD 25.26 s) than useful (mean 19.19, SD 18.72 s; $t_{498}=5.62$; $P<.001$). This may be due to care partners giving participants with dementia more time to consider the prompt before declaring that it was not useful. We examined whether auditory or visual content resulted in a faster response by conducting a 3 (auditory content)×3 (visual content) ANOVA on response times for the 353 trials in which the prompt was useful. This analysis yielded no main effects or interactions between auditory and visual content on response time (F values of <0.93 in all cases; $P>.44$ in all cases). Overall, auditory and visual prompt features did not impact time to respond to prompts.

Care Partner Support

To understand how much care partners were involved in helping participants with dementia engage with the prompts and complete the tasks, independent raters scored the video recordings captured by the iPad during each trial for the presence of care partners providing additional verbal support or instructions. Care partners were observed giving assistance by *asking for attention* when they asked the participant with dementia questions such as the following: “what is on the iPad?”; “what is on the table?”; and “what do you do with it?” Care partners were observed to provide assistance through *direct telling* when they told the participant with dementia what was on the iPad (eg, “it’s a toothbrush”), what was on the table (eg, “see the toothbrush on the table”), and what to do with the item (eg, “now brush your teeth”). Across the categories of support, *asking for attention* and *direct telling* were much more likely in trials rated as not useful compared to useful (chi-square values of >13.1 in all cases; $P<.001$ in all cases; Figure 5). Support in drawing attention was more frequent, whereby care partners scaffolded the participant with dementia by sensitively drawing attention if the prompts alone were not successful. The lower frequency of the direct telling form of support suggests that the content of the prompts was useful for participants with dementia and could be understood and acted upon once their attention was drawn to the task (Figure 5).

Figure 5. Percentage of trials in which support was given by support type.



Experiment 2

Overview

In experiment 1, we focused on simple tasks that could be completed with a single object by participants seated at a table. This approach enabled us to compare the specific visual and auditory features of the tasks while holding other aspects such as complexity constant. In experiment 2, we extended our findings to more complex multistep tasks that were a better match for ADLs, which are likely to involve a sequence of interactions with multiple objects. We wanted to determine whether people with dementia would be able to follow a multistep task through to completion with an appropriate sequence of prompts, noting that, in experiment 1, care partners were involved in maintaining participants’ attention to the task.

Methods

Participants

Participants were 9 people with dementia, all of whom were supported by a female care partner to complete the research. All participants in experiment 2 had previously completed experiment 1. Participants with dementia (4/9, 44% female; 5/9, 56% male) ranged in age from 58 to 82 years, with an average age of 74 (SD 7.43) years. Participants who were care partners (4/9, 44% spouses; 4/9, 44% adult children; 1/9, 11% siblings) ranged in age from 34 to 77 years, with an average age of 61 (SD 13.31) years. A total of 44% (4/9) of the participants with dementia spoke English as a first language, and 56% (5/9) spoke a language other than English. Participants had received a diagnosis of dementia between 9 months and 9 years before, with an average of 3.5 (SD 2.79) years. We did not formally record additional medical information regarding comorbidities beyond the participants’ dementia diagnosis, but participants were required to have sufficient visual and hearing ability to be able to see and hear the iPad prompts as part of our inclusion criteria.

Materials

Software for Prompt Delivery

As with experiment 1, software development was conducted to produce an iPad app for displaying prompts and collecting data. An iPad was issued to each participant, with the reliance on collaboration between researchers and care partners to facilitate data collection with participants with dementia in their home.

Prompting Conditions

To examine the best way to break down prompts for multistep tasks, we selected 2 common everyday tasks (“wash and dry hands” and “make a sandwich”) that were relevant for all participants and in which the same set of steps to complete the tasks could be used for all participants. Care partners confirmed the suitability of the 2 tasks before participation. Care partners were issued a detailed manual together with verbal phone instructions to assist with the standardization and delivery of the experimental tasks in the participants’ homes.

Prompt Content

To develop a uniform set of custom-designed icons for prompts, we worked with a professional graphic designer to create visual stimuli that were simple and clear, used high contrasting colors, and included all relevant components of the task in the image (Figure 6).

For each of the 2 tasks, we developed 1-prompt, 3-prompt, and 7-prompt versions (Table 2). Each visual image was combined with a text instruction and a verbal instruction. The verbal instructions were recorded by the research team in an Australian-accented female voice. Stimuli were designed to include images, text, and audible verbal instructions so that prompt content represented the most useful condition from experiment 1. The iPad automatically captured video and audio during the experimental sessions while the prompts were on the screen using the front-facing iPad camera.

Figure 6. Visual stimuli for the 1-prompt version of the tasks.

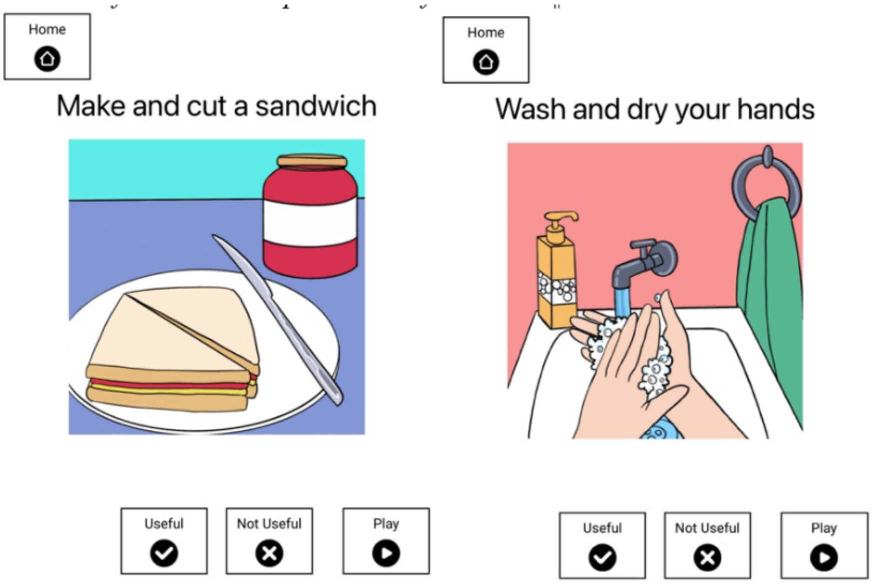


Table 2. Prompt conditions (1, 3, and 7 prompts) for the 2 tasks.

Daily task	Prompt condition		
	1 prompt	3 prompts	7 prompts
Wash hands	- Wash and dry your hands.	- Wet your hands under the water. - Wash your hands with soap. - Dry your hands.	- Turn on the tap. - Wet your hands. - Put soap on your hands. - Wash your hands with soap. - Rinse your hands. - Dry your hands. - Turn off the tap.
Make a sandwich	- Make and cut a sandwich.	- Get bread and fillings. - Put the fillings in the sandwich. - Cut the sandwich.	- Put 2 pieces of bread on a plate. - Butter 1 piece of bread. - Choose your fillings. - Put your fillings on the buttered bread. - Put the second piece of bread on the top. - Cut the sandwich. - Put the sandwich on the plate.

Measures

Prompt Usefulness

For each prompt, care partners rated whether it was “useful” or “not useful” by selecting the appropriate button on the iPad.

Task Quality

To understand the quality of task completion in the different prompting conditions, care partners completed a task checklist during the experimental task and noted any relevant observations. The task checklist itemized all 7 steps involved in the 2 tasks, and on each trial, care partners checked which steps were performed by participants with dementia in response to the 1-, 3-, and 7-prompt versions. As such, care partners could score that a prompt was “useful” overall (via button pressing on the iPad) but could also identify when some steps of the task may have been omitted (eg, using soap), especially during the more condensed prompting conditions.

Care Partner Support

As in experiment 1, we scored the video recordings of each trial for care partner involvement. Independent coders scored the frequency and type of verbal assistance from care partners classified according to 2 domains (asking for attention or direct telling). All videos were scored for the presence of support in the 2 categories by 2 raters who were blind to the prompting condition. Agreement between raters was substantial (86.9%), and the ratings of the first rater were retained for analysis.

Procedure

Baseline and Setup

During an initial video call, participants were oriented as to the project. They provided informed consent and proxy consent where appropriate. If participants with dementia had not had a recent cognitive assessment with their health care provider, an MMSE [41] was conducted to assess the cognitive status of the participants with dementia and determine the consent pathway. Participants were given a detailed printed manual as well as verbal phone instructions about how to set up and conduct the tasks. Care partners were instructed that participants with dementia would be prompted to complete 1 multistep task each day, either washing their hands or making a sandwich. Care partners were asked to indicate the usefulness of each step by pressing “useful” or “not useful” depending on whether participants with dementia understood the prompt and completed the action. In addition, care partners were asked to complete a checklist each day to indicate the quality of activity completion in each prompting condition.

Experimental Phase

On each research participation day, care partners supported participants with dementia in working through 1 of the 2 activities in each of 3 prompting conditions for a total of 6 experimental trials. Conditions and tasks varied in a fixed random order so that, across the whole experiment, each of the 2 tasks appeared in each of the 3 conditions. For each activity, participants first viewed a screen that stated what activity was scheduled for the day and how many steps it would have. Once participants pressed “start,” the prompt sequence began. Care partners were asked to allow participants with dementia to respond to the prompt themselves without assistance. For each prompt, care partners rated whether it was *useful* (the participant with dementia completed or approximated the task) or *not useful* (the participant with dementia did not complete the task) by selecting the appropriate button on the iPad. Once rated, the next step appeared on the screen, with a final screen to indicate when the activity was completed. The iPad automatically captured video and audio during the experimental sessions while the prompts were on the screen using the front-facing iPad camera. Care partners used a hard-copy notebook to record the checklist of completed steps and any other observations regarding each day’s task.

Experience and Feedback Interview

After completion of the 6-day experiment, a semistructured interview was conducted with both the participants with dementia and the care partners together using the same core questions as those for experiment 1. The interviews were approximately 15 to 20 minutes in duration. Due to restrictions on face-to-face interactions with participants, all interviews were conducted via web-based videoconference and were recorded for transcription and analysis.

Results

Prompt Usefulness

To examine the benefit of breaking down an activity into multiple steps, we first examined the frequency of useful versus not useful care partner ratings in each of the conditions.

The 7-prompt sequence obtained the highest ratings of useful for both the sandwich and handwashing tasks. However, usefulness ratings were high across steps in all conditions (Table 3). We also noted that washing hands appeared to reach maximum effectiveness after 3 prompts, with no additional benefit gained from the 7-prompt version. Separate chi-square analyses confirmed no statistically significant difference in frequency of useful versus not useful ratings for steps in the 1-step, 3-step, and 7-step conditions in the 2 different tasks (χ^2_2=1.2 and *P*=.54 vs χ^2_2=1.5 and *P*=.48, respectively).

Table 3. Percentage of “useful” steps in the 3 prompt conditions (1, 3, and 7 prompts) for the 2 tasks.

Daily task	Prompt condition, n/N (%)		
	1 prompt	3 prompts	7 prompts
Wash hands	9/11 (82)	28/32 (88)	71/77 (92)
Make a sandwich	9/11 (82)	26/33 (79)	67/77 (87)

Prompt Usefulness and Dementia Stage

We examined any differences in prompt usefulness depending on stage of dementia. Data indicated a difference in the frequency of prompts being useful versus not useful depending on participants' dementia severity (χ^2_2=26.8; P<.001). Participants with mild (80/88 steps, 91% useful) and moderate (102/109 steps, 93.6% useful) dementia had comparable results, whereas participants with more severe dementia found the prompts less useful (28/44 steps, 64% useful). In general, prompts in experiment 2 were more frequently rated as useful compared to those in experiment 1 regardless of participants' dementia severity. This was perhaps because experiment 2 used the most effective prompting condition identified in experiment 1, combining a visual prompt with both an audible verbal instruction and a written text instruction.

Task Quality

The task checklist and care partner observations from each day were analyzed to understand the quality of task completion in the different prompting conditions and gain feedback on how we had chosen to break down the tasks into steps and whether there were steps missing. Across all participants, care partners indicated that most steps were performed in all prompting conditions. However, there were individual differences in care partners' observations about which versions of the prompts were most effective. Some participants found that the 1-prompt condition was sufficient to support the participant with dementia in completing the activity. For example, some observations recorded in the 1-prompt condition included the following: "[participant with dementia] did it naturally, even rushed the steps," "Washing hands is something my mother knows very well, so she is able to perform it very easily when prompted," and "all instructions were performed." However, some participants mentioned that the 1-prompt sequence did not include enough instructions. For example, observations in the 1-prompt condition included the following: "[The participant with dementia] left tap running on a drip, [it] was not turned off properly," "I think the additional step 'eat your sandwich' may be beneficial as the sequence of steps does not state what to do with the sandwich once complete!" and "[participant with dementia] needed a prompt to find [the] hand towel."

The 7-prompt sequence worked well for many participants. For example, an observation in the 7-prompt condition was as follows: "all of the above steps are easy to follow." For some participants with dementia, the explicit instructions in the 7-prompt sequence encouraged them to stay focused on each step of the activity rather than rushing. For example, an observation in the 7-prompt condition was that the participant with dementia had "used more fillings" when making a sandwich compared to the 1- and 3-prompt conditions. Similarly, participants with dementia were observed by care partners to spend more time thoroughly washing their hands when following the 7-prompt sequence. However, for some participants with dementia, 7 prompts were too many. For example, observations in the 7-prompt condition were as follows: "At times...the 7 steps might have a few steps too many [as] mum was ahead of time doing the activity. She wanted to turn on [the] tap to rinse before the step was prompted" and "[participant with dementia]...pre-empts commands."

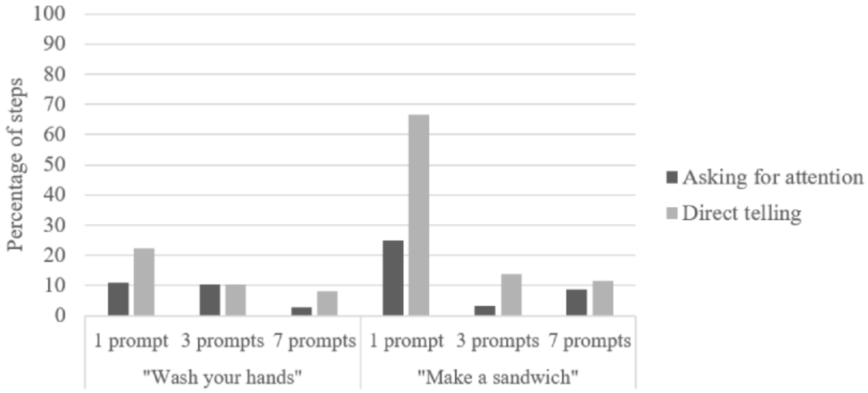
The completed checklists and observations made by care partners highlighted the personalization of prompts necessary to benefit each person. They also helped to contextualize the useful and not useful ratings, reflecting different degrees of quality or thoroughness in task completion. Overall, findings suggest that, for some participants with dementia, more granular prompt breakdown facilitated more thorough completion of the ADL. However, for others, the additional prompts may have caused confusion. Ideal task breakdown may also vary for different tasks. For example, some tasks familiar to the person with dementia may only need a single-step prompt, whereas less familiar tasks may need more explicit and finely grained multistep prompts, suggested by the different patterns between handwashing and sandwich making.

Care Partner Support

Similar to experiment 1, we measured the extent to which care partners used verbal statements to help participants with dementia notice and understand the prompts and complete the prompted tasks. Statistical analysis indicated that the frequency of both "asking for attention" and "direct telling" was relatively higher when the prompt was unsuccessful than when it was successful, indicating that care partners provided support when they perceived that it was needed (χ^2_1=10.7 and P=.006 vs χ^2_1=10.1 and P=.004, respectively), as in experiment 1. Substantially higher levels of support were provided in the 1-prompt condition, particularly for the less familiar task of making a sandwich (Figure 7), and this mostly involved direct instruction, unlike in experiment 1.

To examine the impact of condition given the association with prompt success and that participants contributed multiple trials to the data set, we followed up these trial-based analyses with a stepwise (forward, likelihood ratio) logistic regression, with predictors added in order of participant number, prompt success, task content, and number of prompts (1, 3, or 7). The presence of care partner assistance in the form of "asking for attention" or "direct telling" on each trial was the binary dependent variable for the 2 separate regressions. For "asking for attention," this analysis yielded a model with only 1 significant predictor, confirming prompt success as impacting the likelihood of drawing attention (B=1.71; P=.003). For "direct telling," this analysis yielded a model with 2 significant predictors of prompt success (B=1.27; P=.008) and number of steps (B=0.21; P=.02). The negative relationships indicate that tasks with fewer steps had higher frequencies of direct telling over and above the effect of prompt success. This provides evidence that breaking tasks down into more granular steps increased the independence of people with dementia in using the prompting system.

Figure 7. Percentage of steps in which care partners provided support by task type and condition.



Experiment 3

Overview

Experiment 3 aimed to follow up our observation in experiments 1 and 2 that care partners frequently supported participants with dementia in responding to prompts by drawing their attention or directly telling them what to do, especially at the outset of the task to draw attention to the iPad, consistent with the challenges that people with dementia experience with task initiation. In experiment 3, we addressed two key questions about how to better support people with dementia in independently initiating and completing ADLs: (1) what kind of auditory alerts are most effective for gaining people with dementia's attention so that they initiate a new task? (2) What kind of auditory alerts and what frequency are most effective for maintaining people with dementia's attention to complete multistep tasks? While various kinds of alerts (audio and vibration) have been found to be effective in gaining the attention of people with an acquired brain injury [43,44], little is known about the potential role of alerts in supporting people with dementia to initiating and accurately completing everyday tasks [45].

Methods

Participants

A total of 17 people with dementia were recruited for this study, including 16 (94%) who participated with a care partner and 1 (6%) person with dementia who participated alone. Participants living with dementia (n=6, 35% female; n=11, 65% male) were aged 58 to 90 years, with a mean age of 76 (SD 8.76) years. Care partner participants (15/16, 94% female; 1/16, 6% male) were aged 25 to 88 years, with a mean age of 61 (SD 18.89) years. In total, 65% (11/17) of the participants with dementia spoke English as their native language; 35% (6/17) communicated most of the time in a language other than English. Time since diagnosis ranged from 3 months to 9 years, with an average of 3 (SD 2.30) years. Care partners were 56% (9/16) spouses, 38% (6/16) adult children, and 6% (1/16) formal carers of the participants with dementia. We did not record additional medical information regarding comorbidities beyond participants' dementia diagnosis, but participants were required to have sufficient visual and hearing ability to be able to see and hear the iPad prompts as part of our inclusion criteria. The experiment ran over a 14-day period, and not all participants completed all trials. However, partially complete data were retained for analysis.

Materials

Software for Prompt Delivery

As previously, software development was conducted to produce an iPad app for prompt delivery and data collection, and an iPad was issued to each participant. Researchers and care partners collaborated to facilitate data collection with participants with dementia in their everyday home environment.

Coloring-In Activity

We designed a coloring-in activity to provide an experimental, multistep task that could be standardized across all participants. Our findings from experiment 2 emphasized the heterogeneity in the natural steps and sequence for completing ecological everyday tasks. Coloring pictures were selected from dementia-friendly coloring books, with a new picture provided each day in a physical printed booklet. We provided each participant with a coloring book and pencils with the same instructions and number of steps across all participants, enabling experimental control and an objective scoring system to determine task completeness and accuracy (Figure 8).

Figure 8. Example coloring prompt combining text, visual icon, and "Repeat" option for verbal instruction.

Colour the roses in red

Prompt Content

The prompt for each of the 6 steps was multimodal based on the most effective conditions from experiments 1 and 2, combining a text instruction, verbal instruction, and visual icon of the colored pencil that the participant was instructed to use. Participants pressed *repeat* on the iPad if they wanted to hear the verbal instruction again. Participants pressed *next* on the iPad to receive the next step in the coloring activity (Figure 8).

Auditory Attention Alerts

A melodic tone called "Blackberry Spirit" was used for both the initiation and the attention maintenance alerts. This tone was selected based on evidence that receiving a soft tone notification is preferred for receiving noncritical messages than notifications with loud tones, which are deemed more intrusive [46]. We judged Blackberry Spirit to have a soft tone with a "happy" emotional association. Verbal instructions were recorded in an Australian-accented female voice for both initiation ("You have a new activity on iPad. Press 'start' to begin") and maintenance ("When you have finished this step, press 'next' to continue") alerts.

Care Partner Notebook

In experiment 3, we asked care partners to sit in the next room during the experimental sessions and allow the participant with dementia to navigate the task and the prompts by themselves. To facilitate this and score the usefulness of the different prompts, care partners received a notebook with a series of questions to answer on each day of the activity, including recording whether they had provided assistance with initiating or completing the task, rating the participant with dementia's mood, indicating the other activities of the day, and recording any other observations or comments.

Procedure

Baseline and Setup

Care partners were given a detailed manual as well as verbal phone instructions regarding how to set up the at-home experimental task. Care partners were instructed to ensure that the participant with dementia was able to sit comfortably at a table, with the iPad, coloring-in book, and pencils within reach. The iPad was placed to the side of the participant with dementia to enable them to see and interact with it while being able to reach the objects on the table (Figure 9).

Figure 9. A visual representation of the at-home setup provided within the care partner manual, including positioning of the coloring task and iPad.

Task Initiation

At the beginning of each trial, an initiation alert played on the iPad. To test which initiation alert might be most useful for drawing the participant with dementia's attention to the iPad task, we adopted a 2×2 within-subject design with Alert Type as the first independent variable. The initiator alert was either the Blackberry Spirit tone alone (tone-only condition) or Blackberry Spirit followed by the verbal instruction (tone+verbal condition). The second independent variable manipulated whether the iPad screen repeatedly flashed bright white while the initiation alert was playing to add a visual cue for gaining attention. Care partners were asked to allow the participant with dementia to notice and initiate the task themselves but, if they did not, to then direct them to commence the task for the day by drawing their attention to the iPad. Care partners recorded in their notebook whether they had provided assistance for task initiation.

Task Maintenance

Following task initiation, participants with dementia were presented with a sequence of 6 prompts to complete that day's coloring-in activity. For each step, participants pressed *next* when it was complete and they wished to move to the next step. To examine whether alerts were useful for supporting participants with dementia to maintain focus and continue through the full sequence of steps in the activity, maintenance alerts were tested in a 2×3 experimental design varying 2 alert conditions (tone only vs tone+verbal) and 3 timing conditions (no alert vs 30-second interval vs 60-second interval). The resulting 6 conditions were presented in a fixed random order across days 2 to 13, with each condition appearing twice. Days 1 and 14 were always the no-alert condition to provide a baseline and a posttest of task completion. The iPad automatically captured video and audio during the experimental sessions while the prompts were on the screen using the front-facing iPad camera.

Experience and Feedback Interview

After completion of the 2-week experiment, a semistructured interview was conducted with both participants with dementia and the care partners together. Example questions included core questions from the previous experiments as well as some additional specific questions about the alerts, including the following: "Did the participant start the activity by themselves in response to the alert? Why or why not?" and "Did the alert during the task help the participant maintain focus?" The interviews lasted approximately 15 to 20 minutes. The interviews were conducted via web-based videoconference or in person and were audio recorded and transcribed for later analysis. Written transcripts were reviewed to identify common themes within and across participants.

Results

Task Initiation

We examined how often the participants initiated the task independently versus with assistance from their care partners by examining and coding the videos captured by the iPad and scoring the care partner reports recorded in their daily notebooks. Of the 210 initiation trials that had video data captured by the iPad, independent raters scored 91 (43.3%) trials as involving participants with dementia initiating the day's task themselves and 119 (56.7%) trials as involving support from the care partner to commence the day's activity. A total of 12.1% (29/239) of the presented trials were missing or could not be coded. Reports from care partners contrasted slightly with coded video results. Of the 204 trials with notebook entries, care partners reported that 129 (63.2%) trials involved participants with dementia initiating the day's task themselves and 75 (36.8%) trials involved support from care partners to commence the day's activity. Participants with dementia took between 1 and 299 seconds to initiate the task after the alert sounded. The average time taken to commence the task was 26 seconds. Taken together, these findings suggest that participants with dementia sometimes initiated the task themselves and sometimes relied on the care partner to do it for them. Coders also noted in the videos that participants with dementia were often seated at the iPad waiting for the task to commence and this may have influenced these findings.

To examine whether the nature of initiation alerts influenced the likelihood of trials being person with dementia initiated versus care partner initiated, we conducted 2 stepwise (forward, likelihood ratio) logistic regression analyses examining the impact of condition as well as accounting for participant-related variance. Predictors were added in order of participant, participant's dementia category, experimental day (1-14), alert type (tone only or tone+verbal), and screen flash (present or absent). Whether the task was initiated by the participant with dementia or by the care partner was the binary dependent variable for the 2 separate regressions, one using the independent video coding and the second using the care partner ratings of who initiated the task. A significant model emerged (χ^2_1=28.3; P<.001; R^2=0.169), with only 1 significant predictor of dementia category (B=−0.751; P<.001). These results suggested that the auditory and visual nature of the initiation alert had no impact on the likelihood of the participant with dementia initiating the activity independently and that people with more severe dementia were less likely to independently initiate the task. Both tone-only and tone+verbal alerts were similar in effectiveness, with no advantage of adding a voice to the tone and no impact of the additional visual cue of the flashing screen. Overall, initiation alerts were moderately effective, with participants with dementia independently initiating the task 43% to 63% of the time regardless of auditory and visual condition.

Task Maintenance and Completion

To assess the value of attention maintenance alerts, we scored participant performance on the coloring task by examining the coloring books and assigning each step on each task a score for *accuracy* (whether the correct color was used) and *completeness* (score from 1 to 5 indicating degree of coverage). Participants with dementia used the correct color on 78.97% (1093/1384) of the steps and the incorrect color on the remaining 21.02% (291/1384) of the steps. Participants received an average completeness score of 3.85 (SD 1.67), indicating 60% to 80% coverage on each step. However, the modal score was 5 (>80% completeness), which was achieved on 57.08% (790/1384) of the steps. Overall, these data suggest that participants with dementia could follow the prompts and complete the coloring task successfully and accurately, although their completion and accuracy varied across individuals and days. Participants with more severe dementia had lower accuracy and completeness scores than those with milder dementia. The average coloring step lasted for 378 (SD 297.65) seconds (just over 5 minutes), although this varied across participants and days.

Most importantly for our research questions, we examined whether the likelihood of participants with dementia pressing *next* independently, accuracy, completion, and time spent on each coloring step varied systematically as a function of the content and timing of maintenance alerts. We conducted 3 stepwise (forward, likelihood ratio) logistic regressions, with predictors added in order of participant number, dementia category, prompt presence (present or absent), prompt content (none, tone, or tone+verbal), and timing (none, 30 seconds, and 60 seconds) Binary dependent variables were whether participants with dementia pressed *next* independently (yes or no), accurate color choice (yes or no), and completeness (>80% or <80%) for 3 separate regressions. A fourth linear regression was conducted with the same predictors for the continuous dependent variable of time taken on each step (Table 4). Across dependent variables in all 3 logistic regressions, the only significant predictors were participant ID and dementia category. Overall, there were individual differences in independence and task completion, but these were associated with individual differences and task familiarity rather than with the presence, content, or timing of the maintenance alerts. The only exception was timing. The regression yielded alert type as a positive predictor of time spent on each step, indicating an advantage for sound+verbal trials, as well as alert trigger as a negative predictor, indicating an advantage for alerts at shorter intervals.

To better understand the impact of alert type and alert trigger on the time spent on each step, we compared mean time spent on each coloring step across conditions. A 1-way ANOVA across the 3 alert type conditions (none vs sound only vs sound+verbal) indicated no significant effect ($F_{2,\ 880}$=1.40; *P*=.25). A 1-way ANOVA across the 3 alert timing conditions (none vs 30 seconds vs 60 seconds) indicated a significant effect of timing ($F_{2,\ 880}$=9.43; *P*<.001). Follow-up comparisons indicated that participants with dementia spent significantly longer on steps that had maintenance alerts at 30-second intervals (mean 453.31 seconds; SE 15.36) than on steps that had no alerts (mean 371.18 seconds; SE 21.49; *P*=.006) and alerts at 60-second intervals (mean 364.35 seconds; SE 15.84; *P*<.001), with no significant difference between 60-second alerts and no alerts.

Overall, the findings from experiment 3 supported that people with dementia could accurately complete a sequence of multiple task steps supported by audiovisual prompts delivered on the iPad to both initiate and persist through a sequence of steps. Although there was some heterogeneity in whether people with dementia initiated the task independently and operated the iPad to move through the steps independently, we did not find clear evidence that the nature of auditory initiation or maintenance alerts made a difference regarding independent engagement with the prompts. Instead, individual differences, and particularly dementia severity, as well as experience with the task over the course of the experiment had a bigger impact. These findings suggest the value of iPad-delivered prompts as people with dementia could engage with them and use them to complete a sustained activity, with high rates of accuracy and completeness. We did find some evidence that maintenance alerts at 30-second intervals might help people with dementia persist with a task for longer. However, as people with dementia were supported to initiate the tasks approximately half the time regardless of alert condition, future work is needed to test alternative ways of initiating and maintaining attention if independent use of a prompting system without care partner support is a valued goal.

Table 4. Regression analyses predicting independent use, color accuracy, color completeness, and time spent on each step.

Dependent variable	Significant predictors	Model chi-square (*df*)	Model *R*	Model R^2	*P* value	Correctness (%)
Independent initiation	Participant ID, dementia (negative), and day (positive)	123.65 (3)	—[a]	0.185	<.001	66.4
Color accuracy	Participant ID, dementia (negative), day (positive), and step (negative)	85.54 (4)	—	0.134	<.001	80.8
Color completeness	Participant ID, dementia (negative), day (positive), and step (negative)	139.46 (4)	—	0.180	<.001	66
Time spent on each step	Day (positive), step (positive), alert type (positive), and alert trigger (negative)	—	0.235	0.055	<.001	—

A Synthesis of Experiences and Feedback Across all 3 Experiments

Overview

In all 3 experiments, we conducted detailed interviews with care partners alongside participants with dementia to discuss their experiences of the prompts and the tasks. We explored what participants found most useful about the prompting system and what features they would like to see in future assistive technology devices. As the questions and resulting themes were similar across all experiments, we present a synthesis of the interview findings in the following sections. These insights nuance our experimental findings and inform key recommendations for future assistive technology development.

What Aspects Did Participants Find Useful and Not Useful?

Care partners provided mixed reports on the usefulness of the prompting system. Most carers found the prompts to be useful to at least some degree. However, the perceived usefulness of the system varied according to the participants' dementia severity, consistent with our behavioral data. Participants in the early (mild) stages of dementia were less likely to report difficulties following the prompts and were able to complete the task independently. Care partners reported variability in participant mood and, therefore, the usefulness of the prompting from day to day (eg, "There are days he [enjoyed it]. There are days he [got] frustrated" [experiment 3]). Overall, findings highlighted the importance of customizability and personalization of the system to manage variability in preferences and abilities of people with dementia both across individuals and across time. Despite this variability, there were common themes regarding the benefits and challenges associated with the different prompts tested across the 3 experiments, which are detailed in the following sections along with care partner suggestions for further development and uses of a prompting system.

Useful Features

Care partner participants reported that the prompts were useful and practical and they generally liked the design of the visual pictures and icons (eg, "nice, simple pictures" [experiment 1]). Concerning auditory prompts (verbal instructions and symbolic sounds) in experiment 1, care partners reflected that the verbal instructions were more useful than the symbolic sounds as the association between the target object and action and the symbolic sound was more abstract, consistent with behavioral data. The verbal instructions were also perceived as helpful by care partners in later experiments:

> *The [verbal] instructions did [motivate him]. Yes, he would wait to hear "Colour the lady's hair green" or whatever. And then that was like "Oh, I have a task," and then he would do it.* [Experiment 3]

In experiments 2 and 3, some care partners found that the person with dementia's ability to complete the multistep tasks and associated activity improved over time and with repetition. This effect encouraged these care partners to continue with the activities at home. For example, as a result of watching her husband make a sandwich independently with prompts, one care partner (experiment 2) reported an intention to continue supporting him with prompts to prepare his own lunch instead of making it for him as she had done previously. Similarly, in interviews following experiment 3, some care partners reported that the person with dementia enjoyed the coloring in and they were continuing the activity at home:

> *Yeah and [Dad's] still doing it actually.... Now, when his carers come, they draw things or do writing, and he colours it in. So it started something that's entertaining for him. So that was very useful.* [Experiment 3]

In this way, participating in the research led to a focus on retained abilities and benefited day-to-day quality of life. It also demonstrated the potential for a prompting system to connect people with dementia with meaningful leisure activities in addition to the completion of ADL tasks.

In experiment 2, care partners observed that the granular nature of the prompts for the multistep tasks resulted in a more thorough completion of the ADL task, improving task quality in a way that was not always captured by our binary scoring of success. For example, several care partners reported that, with the support of the prompting system, the participant with dementia had used soap when washing their hands, a step usually omitted when not prompted, or had washed their hands more thoroughly. In addition, across experiments, participants reported that they appreciated the simple app interface and the ease of pressing the "home" button to return to the start. They also reported the value of having a dedicated device that only contained the prompting program ("without all that other stuff on it") to increase the simplicity of interacting with it.

Challenges

Some care partners reported that the need to locate buttons on the iPad was a mismatch with their family member's abilities due to their stage of dementia (eg, "So [the verbal instructions] part did motivate him. [but], pushing buttons and messages on the screen—no" [experiment 3]). Some care partners mentioned that the participant with dementia would have more success completing even simpler tasks if multiple, more granular prompts were given. For example, at times, even simple 1-step tasks needed multiple prompts to complete (eg, "He knows where the remote is, but has difficulty finding the right button to press" [experiment 1]). Similarly, in experiment 3, a care partner reported the following:

> *[The task] "colouring the leaves green" involves both finding the right colour pencil and identifying the correct part of the picture.*

This feedback suggests that the "right number" and granularity of steps may vary depending on the individual and the degree of support they need for a particular task.

Care partner responses indicated that the usefulness of the prompts was impacted by how well the prompt content matched an individual's experiences and preferences. For instance, one care partner in experiment 1 commented that the generic picture of the television was too old-fashioned and, therefore, was hard to recognize as referring to the participant with dementia's own television. These complexities highlight the need to personalize prompt content and structure to ensure that it matches the needs and experiences of the individual user.

Independent Use and Initiation by People With Dementia

Care partners of people with dementia in later stages generally expressed doubt about whether they would initiate and use a prompting device on their own:

> *I think maybe for somebody with very early dementia it might [be] useful, but I think for my mother's stage it's not so useful...it becomes just noise telling her to do something, and she's not able to grasp [what to do].* [Experiment 3]

An overarching theme from carer feedback across the experiments, consistent with our behavioral data, was that care partners felt the need to be involved in directing the attention of people with dementia to the iPad prompts. For example, carers noted that their presence was needed to provide repetitions of the prompt, break the prompt down into smaller steps, or focus the participant with dementia's attention. They also reported that participant with dementia found the initiation of the activity difficult and their ability to complete it was improved with scaffolding and support from the care partner. For example, some reported that screen-based prompts or activities were unsuccessful in capturing the attention of the participant with dementia, and others were unsure of whether the participant with dementia would understand the prompts and content on their own:

> *So it was that motivation to get started, and so I'm just not sure how it would work in practice. If she was alone, using the iPad, whether she would actually turn it on or not, I don't know.* [Experiment 1]

Despite these concerns, some care partners were more optimistic about people with dementia being able to use a home assistant device through strategies such as developing a routine of checking a device in the morning to orient themselves for the day or learning to use the prompts independently over time with practice and familiarity (eg, "It might take a few goes, but she would probably be able to do it on her own" and "by the end, she was able to do it much faster; at the beginning, where she was unsure she would look to me" [experiment 1]). Others also discussed whether the participant with dementia would advance to the next step without the care partner there to press the button and suggested considering a timed system that automatically advanced to the next prompt to reduce the demands. Participants with dementia also reflected on the anxiety of getting things wrong and a worry that the "machine" would break or freeze if they pressed the wrong thing. However, care partners observed that participants with dementia became less anxious and more accomplished with using the prompts with practice and repetition and enjoyed the opportunity to interact with technology. Although we were concerned with the time demands of the repeated experimental sessions, some participants expressed that the experiments were too short and the person with dementia was just becoming familiar and comfortable with the tasks at the point in which they ended:

> *Because at the beginning she's a bit nervous, so it's about getting used to the technology and it's hard to judge how well she's doing via the prompts. So, it's almost like, [the] last couple of days, where she's starting to get it, especially some of the similar ones that keep coming up like brushing your teeth, drinking water, the ones she could become familiar with. Towards the end the minute she sees it she knows what it is.* [Experiment 1]

Auditory Alerts as Attention Grabbers

Given that there was a great deal of variation in whether participants with dementia initiated the task and that it did not depend on the nature of the initiation alert in experiment 3, we sought to understand the reasons for this variation by asking care partners during interviews about whether the alerts were effective at grabbing attention for the participant with dementia. Interviews with care partners identified that a common reason given for participants with dementia not initiating the task was confusion related to understanding and interpreting the alerts and prompts:

> *When it first started...when it's buzzed...she knows something's buzzing...so she knows she needs to get started but then I think the first step she tries, and then I think she gets caught up and not know what to do. And also, like, I think it's a bit complicated for her in terms of that she doesn't know where to press, whether it's pressing on the colouring book or pressing on the iPad.* [Experiment 3]
>
> *But no, those alerts be it on the iPad or on the handheld, did not work [for mum]. It just didn't work.* [Experiment 3]

Suggestions for Future Device Development

Across experiments, care partners were given the opportunity to suggest improvements to the prompts and prompting system. Suggestions included ways of improving the hardware and user interface, such as the use of a larger device, potentially mounted or fixed in place so that it could not get lost or misplaced. They also suggested making the attention-grabbing prompts deliverable on a more portable device rather than requiring users to be in front of the iPad or noticing a new task from across the room. For example, several care partners suggested incorporating a wearable to bring the participant with dementia's attention to the task even if they were not in front of the iPad or so that reminders could be provided in nonhome locations (eg, taking medication while out at a friend's house). Such a wearable would be too small for the screen display to be useful but could emit voice instructions. One care partner participant suggested that videos or active prompts showing the movement and the action involved in a task would be helpful for people with dementia to copy compared to the static visual images that we tested. Finally, participants mentioned that the device could be voice activated rather than requiring a button press on the screen to interact with it and progress through tasks.

Suggested ADL Tasks for Prompting

On the basis of their experience of the prompting system, we asked care partners to reflect on what ADL tasks could be potentially supported using home prompting devices. Although we received a range of suggestions, common responses included health and self-care activities such as taking medication, drinking water, and eating; hygiene activities such as taking a shower and brushing teeth; and well-being and recreation, such as doing some exercise, listening to music, and calling a friend or family member. Care partners found our approach of breaking tasks into substeps useful and suggested that additional ADL tasks could be broken down and prompted in similar ways. Care partners also suggested having options to display (and schedule) set tasks for some days and not others or to orient people with dementia with a list of reminders each morning (eg, "today we are doing..."). Care partners also noted that even short periods within the day (eg, "20 minutes") while the person with dementia independently showers or shaves would be a valued source of independence and respite for both parties.

General Discussion

Principal Findings

We aimed to compare the usefulness of different features of tablet-based prompts to support people with dementia in completing everyday ADLs at home. Across 3 experiments, we found that people with dementia could engage with tablet-based prompts and use them to complete activities. Prompts were more useful for people with mild and moderate dementia compared to those with severe dementia, but even participants with severe dementia could understand and respond to prompts on most trials, particularly when prompts combined auditory and visual modalities. In experiment 1, we found that the most effective prompts included an auditory verbal instruction regardless of their visual content. In experiment 2, we found that breaking complex tasks into substeps could support task completion as well as task quality and independence. Although the ideal granularity of steps depended on the individual and the task, people with dementia were observed to need less support when there was more than a single prompt. In experiment 3, we found some benefit of auditory prompts for drawing and maintaining attention but no difference between a tone alone and a tone combined with a verbal call to action. Combined with feedback from care partners, these findings suggest that fully independent use of prompting technology may be a challenging goal and that different hardware choices beyond a touch-screen tablet may be better suited to this user group to facilitate attention and engagement. Regardless, a degree of independence and engagement supported by the prompting system was valued by both people with dementia and care partners even if care partners were involved at times in facilitating its use.

Prompt Modality

Our experimental research comparing different kinds of visual and verbal stimuli to each other found that the presence of an audible verbal instruction was associated with task success. The nature of the visual content, whether text, icon, or photo, did not appear to influence prompt usefulness over and above the presence of an auditory verbal instruction. This was consistent with care partner observations and feedback as well as with other studies that combined auditory and visual components when designing prompts, suggesting the particular effectiveness of direct verbal and text-based prompts [19]. Direct instruction, provided both verbally and visually via text, appeared to be the most effective, removing ambiguity about what the task was.

There was also evidence that prompting was more effective for people in early to moderate stages of dementia, with less success for those whose dementia was more severe, although even those with severe dementia could respond to the prompts at least half the time. However, gaining experience and familiarity with a prompting device during the earlier stages of dementia may enable people to continue using it as their dementia progresses. We did not find a learning effect in experiment 1, but regression analyses in experiment 3 suggested that the accuracy and completion of the coloring task increased across the 14 days. Participants also reported that they appreciated the prolonged experimental period that allowed people with dementia to overcome their initial anxiety and gain confidence and familiarity with the tasks. This is consistent with other research showing that those who were more successful responding to a prompting device used it for longer, over more days, and on more occasions [24], emphasizing the role of confidence building and successful use in motivating further use. A longer period of regular use may have even more advantages and may have boosted performance for those with more severe dementia, but future research is needed to examine this question.

Prompts for Complex Tasks

Generally, increasing the number of substeps within a task increased the success of the prompts and the likelihood of task completion and reduced the extent to which care partner support was needed. Observations indicated that the ideal breakdown varied according to the individual and their degree of cognitive impairment as well as with the task complexity and familiarity. These factors are likely to combine to make the optimal breakdown of steps idiosyncratic to the individual such that the ability to tailor or select and deselect substeps may be ideal for prompt usefulness. We did not identify any previous research examining the optimal granularity for breaking down tasks when providing prompts to people with dementia, although some of the prompting devices reported in previous literature did break tasks down into substeps. For instance, the COACH handwashing system provided 5 steps for washing hands [47]. We found that breaking tasks down into multiple steps could be critical for ensuring their completion and increased independence. For instance, one participant could not wash his hands independently because he would forget to turn off the tap, and others would neglect to use soap if not reminded. In cases such as these, single prompts may be insufficient or even counterproductive for task completion. However, the optimal granularity and the specific step content varied depending on the individual and the specific task, making personalization essential for success [24,48,49].

Grabbing and Maintaining Attention

Our analysis of the videos indicated that care partners were often involved in drawing the attention of people with dementia to the task and ensuring task completion. Moreover, although we trialed different methods for the system to gain and maintain attention, we did not identify a particular type of alert that made independent initiation and task maintenance more likely than another as the tone alone and the tone combined with a verbal call to action had similar outcomes. On the basis of feedback, auditory alerts were reported to be difficult to interpret for people with dementia even when accompanied by a verbal reminder. Future research is needed to test other ways to support people with dementia to notice and initiate the task and persist through the steps of complex ADLs. One suggestion from care partners was the inclusion of an associated wearable device to tell people with dementia when there was a new task. Other suggestions included using the person with dementia's name in the verbal call to action to gain and maintain attention across multiple steps, which was the approach adopted in a previous study [47]. Another study used a Bluetooth earpiece to directly provide verbal prompts to people with dementia wherever they were without relying on them being close to a device; however, this approach may not be suitable for all people with dementia

[21]. Further research is needed to determine how to support people with dementia to independently notice and initiate a task when prompted by a home-based system. However, we noted that care partners and people with dementia still valued the partial independence provided by the prompting system even when care partners scaffolded its use.

User Experiences and Avenues for Future Development

Generally, care partners were positive about the prompting system and the characteristics and content of the prompts. They had a range of specific feedback, some of which was idiosyncratic to the individual participant. Feedback that generalized across participants was the need for a custom, dedicated device, potentially including a wearable to enhance portability. Consistent with our analysis, care partners reported that success at the different tasks and usefulness of the prompts was impacted by how well the prompt matched an individual's experiences and preferences. Care partners reflected lack of certainty regarding whether such a system could be used independently, but both care partners and people with dementia valued the potential for independent use.

There was a range of specific recommendations that should be incorporated into future device development. This included the need for large display screens and large buttons. In addition, buttons should be clearly marked and kept to a minimum, and voice control may be more successful. Care partners suggested that the system may need multiple devices or screens in different rooms so that they could be in fixed, predictable locations and "plugged in" rather than needing to be charged. In addition, the system could be customized to deliver prompts automatically at set times. A recent review also noted the potential benefit of time-based prompts, especially as dementia progressed, but noted that the timing of transitions would need to be tailored and calibrated for the individual [11]. Overall, engagement remains a key challenge, particularly with remembering to use an assistive device and maintain attention to multiple steps in a sequence.

A major emerging consideration regards customizability and tailoring built into the prompting system [24,48]. We noted that much of the feedback about the usefulness of specific steps or prompts was idiosyncratic to the individual, their capacity, the specific task, and the home environment. It was challenging to generalize regarding the prompt content provided for people with dementia, and it varied depending on the individual and the task. Small mismatches between needs and expectations of the user and how the device behaves can render a system useless by creating confusion or uncertainty. Future development could focus on a technological solution that allows care partners or people with dementia to choose or edit the tasks and the steps that they want displayed to them (as in the study by Harris et al [24]). We also noted the wide range of content that care partners and people with dementia were interested in having supported through prompts. This included a focus on instrumental ADLs but also a focus on more meaningful activities, such as music listening, and facilitating social connection and reminiscing. Although much assistive technology development has focused on ADLs and safety [50], richer, meaningful activities are crucial for promoting positive quality of life for people with dementia and supporting relationships between people with dementia and care partners, and these should be considered in the development of prompting technology.

Limitations and Future Directions

Our research had a range of strengths, seeking generalizability by examining a set of prompts that were fixed and standardized across participants to examine how prompt features impacted their usefulness. However, this necessarily meant that the visual and auditory content of the prompts was generic rather than personalized. Although we made attempts to select the optimal content based on pilot-testing, it may have provided a poor match for some individuals, and this may have particularly disadvantaged the visual prompting condition in experiment 1. Future research is needed to examine whether there is more benefit from the visual prompt content when it is personalized to the individual, matching their own environment (ie, depicting their own television or their own bathroom sink) instead of being generic. Relatedly, we relied on care partners to indicate prompt usefulness. This meant that the research could be conducted in an ecological, everyday home setting over a long testing period rather than requiring the presence of researchers. However, carers may have been biased to support "good" performance and indicate that a prompt was useful when it was not. We deliberately framed our research questions regarding the usefulness of the prompts rather than the performance of people with dementia to reduce this bias, and we emphasized to participants that we wanted to know about prompts that were not useful just as much as those that were. However, future research could consider other ways of recording the outcomes of prompting, especially as pandemic-related restrictions on face-to-face testing have eased. Finally, we did not record detailed information about participants' comorbidities, including limitations to their mobility, vision, or hearing. These individual differences are likely to shape needs and what kind of prompting is best suited to whom, and this would be a fruitful avenue for future research.

Conclusions and Recommendations

Overall, our findings suggest promise for future development of assistive technology to support people with dementia and their care partners. Participants with dementia could become familiar with and use a touch screen–based prompting device to complete a range of activities, especially when prompted with a combination of verbal and visual information and when activities were broken down into more granular substeps. We found that participants with dementia responded to prompts more than half the time across experiments, including people with more severe cognitive impairment when prompts combined visual content with direct verbal instructions. Therefore, we recommend that future prompting technologies include both a direct verbal instruction alongside visual prompts to maximize task success and that they enable complex tasks to be broken down into customizable substeps. Care partners were often involved in scaffolding task initiation and drawing the attention of people with dementia to ensure task completion, and additional attentional alerts did not appear to influence this. Overall, people with dementia and their care partners are interested in assistive technology that is intuitive and able to be personalized for the individual to make it work for their needs and context, prompt valued tasks, promote independence and self-esteem, and enhance quality of life. Our findings highlight the value of working meaningfully with intended users within their everyday settings to understand the reasons why assistive technology is experienced as useful or not useful as well as the need to move away from one-size-fits-all solutions to support people with dementia.

Abstract

Background: Growing evidence suggests cognitive and social health benefits can be derived from digital storytelling for older adults with cognitive impairment. Digital storytelling apps offer the potential to serve as an on-demand, easy-to-access platform for enhancing cognitive abilities and promoting social well-being. Yet, despite the increasing quantity of such apps being available on the market, there is a gap in research investigating their quality.

Objective: This app review aims to assess the digital storytelling apps available in the Chinese market and evaluate them in accordance with the Mobile Application Rating Scale (MARS). The goal was to identify key features and evaluate the overall quality in the context of cognitively impaired users.

Methods: A systematic search was conducted in both the Google Play store (Google LLC) and iTunes store (Apple Inc), using English and Chinese keywords. Apps were chosen according to specific criteria that included features, including (but not limited to) memory capture, story saving, cue-based reminiscing, and the ability to share stories or memories with others. The MARS was used by 3 individual researchers to independently assess app quality across several domains, such as engagement, functionality, aesthetics, and information quality, for both Android and iOS apps.

Results: From an initial screening of 297 apps, only 9 (3%) met the criteria for detailed evaluation using MARS. The reviewed apps featured *capture memory*, *save*, *reminisce*, and *share* functions, which are critical in supporting cognitive functions and enhancing user engagement. The analysis revealed patterns in platform diversity and geographical distribution of developers, with apps available on both iOS and Android. Memoirs of Life and Memorize: Diaries, Memories, Notes, Ideas, Timelines, Categories (Fair Apps Mobile) had the highest mean MARS scores of 3.35, indicating strong engagement, functionality, and information quality, while the lowest score was 2.33. The overall mean score across all apps was only 3.03 (SD 0.60), highlighting significant variation, particularly in information quality. User feedback also showed considerable variability, ranging from 0 comments for apps such as Grand Storyteller (VarIT Inc) and PWI Storyteller (Project World Impact, LLC) to as many as 5361 comments for FamilySearch, which received extensive positive reviews. This wide range of user feedback underscores the importance of continuous improvement and user-centered design, particularly in enhancing information quality and content accuracy.

Conclusions: The systematic search and evaluation highlight the diverse capabilities yet variable quality of digital storytelling apps available within the Chinese market, reflecting user experiences, satisfaction levels, and efficacy in supporting cognitively impaired users. While some apps excel in engagement and functionality, others need significant improvements in information quality and user interface design to better serve those with cognitive impairments. Future research is recommended to investigate regional limitations and features that would result in more inclusive and effective digital storytelling apps.

KEYWORDS

mobile apps; digital storytelling; older adults; mobile phone; cognitive impairment

Introduction

Background

Storytelling, as a practice of therapeutic intervention, has been shown to empower people with cognitive impairment engaged in chronic disease self-management, facilitating recovery by allowing them to actively identify needs and knowledge gaps while fostering connections with peers who share similar experiences [1]. For instance, a storytelling-based intervention resulted in significant improvements in blood pressure [2] among older adults diagnosed with uncontrolled hypertension. Despite the demonstrable physical benefits, storytelling apps designed for people with cognitive impairment offer a range of mental health and general well-being benefits. First, these apps serve as powerful tools for memory enhancement, with empirical studies demonstrating positive improvements in long-term and short-term memory [3,4] as well as older adults recollection and improved cognitive functions via leveraging narratives and visuals [5,6]. By engaging users in personalized and meaningful activities, including story-editing activities [7] and story-sharing activities [8], these apps contribute to a sense of purpose and accomplishment, aiding positive psychosocial and cognitive recovery. In the context of communication and social interaction, these apps play a crucial role by facilitating meaningful connections between their caregivers (including spouses) [8,9], family members [10], and peers [11,12]. Moreover, emotional connections fostered through storytelling have been found to be integral in promoting overall well-being [13], mitigating symptoms of depression and anxiety [14], and even linking older adults with dementia to personal histories, thereby aiding memory recall. These systems are crafted to evoke memories, enhance communication, and foster social engagement by leveraging digital media technologies [15,16]. There are key differences between fictional storytelling and reminiscence-based storytelling, both of which have distinct impacts on cognitive, emotional, and social processes. Fictional storytelling, for instance, has been shown to enhance cognitive engagement by transporting individuals into the narrative, thus deepening their emotional involvement and promoting cognitive stimulation [17]. By contrast, reminiscence-based storytelling plays a crucial role in memory enhancement and emotional well-being, particularly among older adults, by encouraging the recall of personal memories and fostering a sense of identity and continuity [18]. The emotional processing involved in these 2 types of storytelling also differs significantly. Fictional storytelling often leads to the creation of new emotional experiences, while reminiscence-based storytelling is more likely to evoke past emotions, reinforcing a person's narrative identity [19]. In addition, the social benefits of reminiscence-based storytelling are well documented, with research showing that it can improve social interactions and contribute to overall well-being in older populations [15]. Research shows that individuals with cognitive impairments, including those with dementia, retain the ability to generate creative stories through structured programs. For instance, the TimeSlips program is an arts-based, creative storytelling initiative designed for people with dementia. In this program, participants collaboratively create stories using their imaginations and respond to staged pictures, guided by a facilitator [20]. This approach not only fosters creativity but also encourages meaningful social interactions among participants, highlighting their capacity to engage in generative activities despite cognitive challenges. This evidence supports the notion that even individuals with cognitive impairments can actively participate in creative storytelling, contributing to collective narratives and maintaining social connections. Thus, using the process of storytelling, these apps catalyze effective communication, supporting cognitive and psychosocial recovery, as well as enriching the lives of older adults with cognitive impairment.

Despite this potential, the plethora of storytelling apps available on the market—and their utility and efficacy for the cognitively impaired—remains woefully understudied. With a lack of concrete evidence regarding their quality, a need to fill this research gap emerges [21]. While the potential benefits for those with cognitive impairment are well understood in theory, the commercial digital storytelling apps available remain largely untested; instead, the academic focus has thus far been commercial software, primarily instant-messaging apps [22] and video editing software [7]. Given the uncertainty deriving from the plethora of available apps, consumers and older adults often turn to reviews and ratings on app stores or published on developer websites to inform their decision-making process [23]. However, reliance on such reviews brings forth the challenge of ensuring these apps are genuinely suitable for individuals with cognitive impairment. Indeed, despite the theoretical utility of such apps for older adults who are cognitively impaired, no specific measure or ranking system exists designed specifically for that user group. Extant consumer ratings were found to be poor indicators of clinical utility or usability, with a significant number of apps exhibiting potentially misleading and dangerous health information entered by users [21].

A scoping review explored studies related to digital storytelling apps published in 2023 [6], wherein only 1 study was found to have undertaken a randomized controlled trial, predominantly focused on academic apps that were not readily available in the commercial market [11]. A few exceptions were observed where commercial software, such as WeChat (Tencent) [22] and WeVideo (WeVideo, Inc) [7], were used. However, these commercial apps were used merely as auxiliary tools, limiting their capacity to support specific phases of the digital storytelling process. Bridging the gap between the lack of empirical proof of app utility and consumer reliance on potentially inaccurate reviews is crucial. An up-to-date and comprehensive review of apps offers an informative and much-needed benchmark in assessing the appropriateness and efficacy of digital storytelling apps, furnishing individuals and caregivers with valuable insights when selecting apps that genuinely cater to the unique needs of those with cognitive impairment. Simultaneously, this research aims to systematically review mobile apps for digital storytelling, evaluating their suitability for people with cognitive impairment. To do so, app quality is evaluated via an expert rating scale, delineating the features of the apps that received the highest scores.

On the basis of the extant body of academic literature [20,23], digital storytelling is conceptualized as comprising 4 components—*capture memory*, *save*, *reminisce*, and *share*—components which can be integrated into 2 prevailing theoretical frameworks: narrative psychology focuses on how individuals construct and understand their experiences through stories, making it particularly relevant for understanding the *capture memory* and *reminisce* functionalities. By contrast, life span developmental psychology emphasizes the importance of preserving memories and social connections at different stages of life, which aligns well with the *save* and *share* functionalities. The decision to use both theoretical approaches is grounded in their complementary nature. While narrative psychology offers insights into the personal and emotional aspects of storytelling, life span developmental psychology provides a broader context for understanding how these activities support cognitive and social well-being across the life span. These frameworks are epistemologically compatible, as both are concerned with understanding human development and behavior through the lens of memory and narrative. By integrating them, we can offer a more holistic understanding of how digital storytelling can be optimized for users with cognitive impairments.

First, narrative psychology studies how individuals construct and understand their experiences through stories. When translated to storytelling apps, this theoretical framework offers great potential for explaining the *capture memory* and *reminisce* functionalities. According to Bruner [24], people form and express their identity by recording and reconstructing their experiences. In digital storytelling apps, the *capture memory* functionality allows users to document life events through photos, videos, and text—transposing a cognitive function into a digital device. This not only helps users construct and understand their stories but also provides rich material for future reminiscence. In addition, narrative psychology emphasizes that individuals can better understand and construct their personal narratives by recalling and reflecting on past experiences [25]. In parallel, the *reminisce* functionality in digital storytelling apps allows users to revisit and reflect on their past, helping strengthen self-identity and promoting emotional health and social interaction [26].

Second, life span developmental psychology is focused on understanding how individuals handle and preserve memories at different life stages. This theoretical framework can correspond to and explain the *save* and *share* functionalities. Significant autobiographical memories shape an individual’s identity, reflect age-related themes of psychosocial development, and contribute to life satisfaction, particularly when these memories are emotionally positive [27]. In digital storytelling apps, the *save* functionality ensures that users can store their memories and stories indefinitely. This is especially important for older adults and individuals suffering from memory-related impairments, as it helps them maintain a sense of continuity in their personal history and narrative as memory declines.

In addition, life span developmental psychology emphasizes the importance of social relationships and emotional support at different life stages. By sharing personal memories and stories, users can enhance social connections and support [22]. The *share* functionality in digital storytelling apps also enables users to share their stories and memories with family and friends, catalyzing social relationships and maintaining social networks, thereby facilitating emotional support—which in turn helps improve psychological health and social well-being [13]. By integrating narrative psychology and life span developmental psychology, we can comprehensively explain the 4 functionalities—*capture memory*, *save*, *reminisce*, and *share*—offered by digital storytelling apps. These functionalities collectively promote cognitive functions, emotional expression, and social interaction, providing older adult-users with greater opportunities for social support, psychosocial betterment, and cognitive recovery. Using this integrated framework not only helps our understanding of the effectiveness of these apps but can also guide future app development to better serve users with cognitive impairments.

Objectives

This study evaluates the features and quality of digital storytelling apps tailored for individuals with cognitive impairment within the Chinese cultural context. The primary research question focuses on determining the overall effectiveness of these apps in supporting cognitive functions and enhancing user engagement. This study investigates the key features of digital storytelling apps that are designed to support cognitive abilities and stimulate user engagement among a research population of users who are cognitively impaired in China. In addition, the research will investigate how these apps may aid in reminiscence and potentially promote social interactions. Through a systematic analysis of these aspects, the study aims to identify the potential benefits and adaptability of digital storytelling tools in the context of cognitive impairment. The research questions are as follows:

1. What are the features of digital storytelling apps for users who are cognitively impaired?
2. What are the qualities of those apps?
3. What are the users’ recommendations for an effective and engaged digital storytelling app?

Methods

Search Process

A systematic search was carried out across China’s Apple Store (Apple Inc) and Google Play (Google LLC). The search encompassed a carefully selected array of keywords in both English and Mandarin, relevant to this study’s focus. These keywords include *storytelling*, *life memories*, *life stories*, *life review*, *reminiscence*, *mild cognitive impairment*, *dementia*, *cognitive impairment*, and *Alzheimer’s disease*. Multimedia Appendix 1 presents the search outcome.

In total, 3 research assistants systematically conducted the searches, downloaded all apps that fell within the inclusion criteria, and independently evaluated each one. For every app, 2 reviewers were assigned to evaluate its relevance; in cases of discrepancy, a thorough discussion ensued to reach a consensus. The Mobile Application Rating Scale (MARS) was then used by the research assistants to assign a score to each screened app.

App Screening

The inclusion criteria were as follows: (1) a smartphone-based app, (2) compatible with Android or iOS operating systems, (3) the language of the app should be either English or Chinese, (4) the app should have features that contribute to assisted storytelling or reminiscence for those with cognitive impairment, and (5) the app must be available for download in the China app store via iTunes and Google Play.

During the preliminary screening process, the following exclusion criteria were applied, with duplicates removed: (1) app content is merely for information, education, reference, or reading only (ie, no data entry capability); (2) the app only comprises treatment algorithms; (3) the app only supports media editing or saving; (4) original story creation is not supported; and (5) it was explicitly designed for use by clinicians only.

Android apps were downloaded (via the China Google Play store) and tested, capturing memory, saving memory, reminiscence, and sharing features using Huawei P30Pro phones equipped with Android (version 5.1.1; Harmony OS). Similarly, iOS apps were downloaded (via the China iTunes store). Android apps were rated and reviewed using Huawei P30Pro on Harmony OS and Samsung S9 using the Android system. Apple apps were rated and reviewed using iPhone 11 on iOS 13. Each app was tested in a real-world environment for no less than 20 minutes by 3 researchers and scored together after testing was completed. (the PRISMA-ScR checklist is attached in Multimedia Appendix 2).

Data Collection

A total of 9 digital storytelling apps were evaluated by the research team from December 17, 2023, all of which declared their potential to support individuals with cognitive impairments. During this period, each team member independently documented information gathered from extensive user reviews and feedback available in the Ratings and Reviews sections of the iTunes App store and Google Play platform for each app. The data were extracted and organized using Excel (Microsoft Corp), which allowed for systematic categorization and analysis of user feedback across multiple parameters relevant to our study. This tool facilitated the efficient management and analysis of the large volume of user-generated data. This included fun mental app details (such as its name, country of origin, developers, and user ratings), as well as more in-depth data, such as app description, first launch time, pricing, overall comments, and the number of user comments. Additional data captured include the app's stated aims, its main features, its target users, user experience, and interaction logic, as well as functionalities related to the cognitive support features of Capture Memory, Save, Reminisce, and Share mentioned earlier. User interface and visual design elements (such as color, imagery, and screenshots) were also recorded and analyzed.

Data Analysis

Textbox 1 details the analytic methods applied to the collected data; we used a methodological approach designed to focus on different aspects of digital storytelling apps. Thematic analysis was used to identify and report patterns or themes within the description of apps, summarizing key features and evaluating commonalities across apps [28]. Similarly, thematic analysis was used to categorize and interpret platform diversity, geographic origins of app developers, and app ratings, helping to ascertain the spread and focus areas of app development across different regions and platforms. Thematic was then used to systematically categorize specific features of digital storytelling apps, allowing a structured comparison of more nuanced functionalities, such as *capture memory*, *save*, *reminisce*, and *share*, highlighting how these features support cognitive functions and user engagement. Statistical analysis was conducted based on the MARS [29] ratings to evaluate app quality. Mean scores were calculated across 4 domains: engagement, functionality, esthetics, and information quality. MARS is a validated tool widely used in other studies to assess mobile health apps. MARS is structured as a Likert-type scale, with items rated from 1 (inadequate) to 5 (excellent) across 4 domains: engagement, functionality, aesthetics, and information quality [29]. MARS showed strong internal consistency and interrater reliability, offering a dependable approach for rating and comparing mobile apps [30,31].

Textbox 1. Data collected and type of analysis used.

Analysis and data collected

- Thematic analysis
  - Description of apps: platform diversity, geographical distribution of develope, and features of digital storytelling apps
  - User feedback and engagement
- Descriptive statistics
  - App rating and quality assessment of digital storytelling apps: Mobile Application Rating Scale rating

All collected data were collaboratively reviewed by the 3 research assistants to ensure accuracy, consistency, and impartiality in the final evaluation. The data analysis process was structured to ensure a comprehensive and accurate evaluation of the apps. Initially, key areas for app development and improvement were highlighted through data summarization using Excel, where the research team organized and extracted essential data points from the app stores. Following this, each research assistant independently analyzed the data, assessing the apps' features and performance.

The team engaged in group discussions to review the independently analyzed data to ensure consistency and minimize individual biases. Discrepancies were resolved through these discussions, leading to a consensus on the final data extraction. This collaborative approach not only enhanced the reliability of the findings by incorporating diverse perspectives but also provided a foundation for identifying areas where the apps could be further developed and improved.

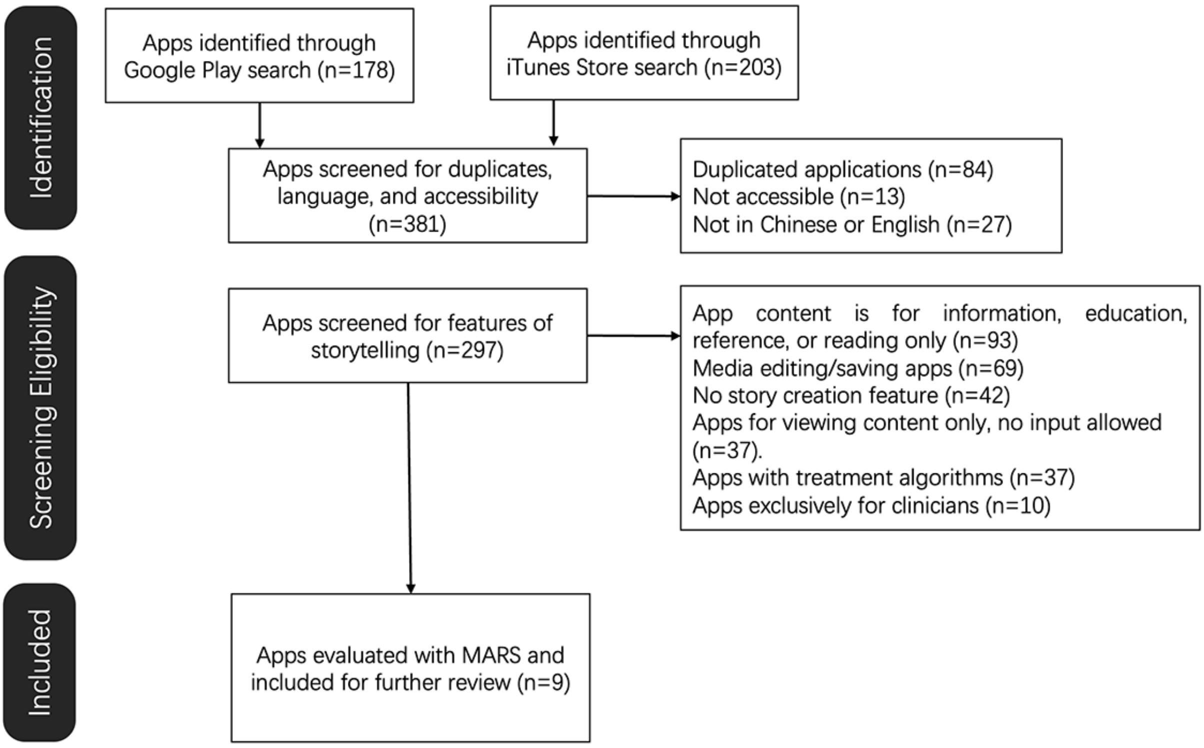
The research team used a detailed coding framework to systematically categorize feedback and MARS scores, ensuring a thorough and structured analysis. Regular cross-checks and validation steps were integrated throughout the review process to maintain data integrity and validity. Periodic meetings were also held to discuss emerging themes and refine the analysis methodology where necessary. This rigorous review process not only ensured the accuracy and consistency of the final evaluation, but also yielded comprehensive insights into the strengths and weaknesses of each app, thereby informing targeted recommendations for future app development vis-à-vis users who are cognitively impaired.

Results

Search Outcome

As depicted in Figure 1, Google Play yielded 46.7% (178/381) apps, while iTunes had a slightly higher yield with 53.3% (203/381) apps. After removing duplicates, the aggregate number of unique apps stood at 77.9% (297/381). The screening process then ensued, during which 4.3% (13/297) apps were found to be inaccessible; another 9.1% (27/297) apps did not offer Chinese or English language options. This filtration culminated in the inclusion of 9 apps that met all the stipulated criteria for further consideration.

Figure 1. Flow diagram of systematic search and selection of apps from the Google Play and iTunes stores. MARS: Mobile Application Rating Scale.



Overview of Digital Storytelling Apps

Table 1 provides an overview of the included storytelling and memory apps, detailing their platform compatibility, developer origins, user ratings, and feedback across both iOS and Android platforms.

Table 1. Overview of digital storytelling apps.

App name	Description	Country	Platform	Rating	Pricing	Number of comments
Story Dice: Story Telling	Game with 40 dice, 240 images, and unlimited stories. Mixed categories such as mystery or Star Wars.	Netherlands	Both iOS and Android	iOS: 4.6 and Android: 4.5	Free	iOS: 8 and Android: 0
Grand Storyteller	Create and share multimedia stories and convert stories into videos.	United States	iOS	No score provided	Free	—[a]
Memoirs of Life	Record daily life with documents, labels, and stickers. Add and edit photos.	China	Android	4	Free with membership	—
Spicy Memories	AI[b] selects and crops photos, sets time ranges, and shares photos as wallpapers or collages.	China	iOS	4.6	Free	245
PWI Storyteller	Share stories with nonprofits to help them tell their stories more effectively.	United States	iOS	No score provided	Free	—
Brief Memories of Photos	Simple Photo app groups photos with labels for easy retrieval.	China	iOS	3.6	Free	5
FamilySearch	Preserve and share family memories, create digital scrapbooks, capture important moments, identify relatives in photos, and sync across devices.	United States	Both iOS and Android	iOS: 4.9 and Android: 5.0	Free	iOS: 234 and Android: 47,400
Reminisce	Trivia game on American pop culture with categories such as television shows, movies, sports, history, and commercials.	China	Android	—	Free	—
Memorize: Diaries, Memories, Notes, Ideas, Timelines, Categories	Diary app for recording memories, thoughts, and events. Features include adding photos, voice notes, PIN[c] or fingerprint security, multiple themes, and backup or restore.	Unknown	Android	3.8	Free	3892

[a] Not applicable.

[b] AI: artificial intelligence.

[c] PIN: personal identification number.

All the apps included in our analysis are available (at least initially) for free, a common strategy used to increase user initial engagement without requiring a financial commitment. Only Memories of Life has a paid membership feature, which is necessary for users to export memories. Another shared aspect is their focus on storytelling or memory recording. This indicates a targeted market interest: users who are keen on documenting personal experiences, storytelling, or creatively engaging with content over periods. All these apps aim to preserve and share personal memories, stories, and experiences in a creative and engaging manner. They provide tools for users to manually record, organize, and share content, such as text, images, audio, and video. By and large, the apps are designed to be user-friendly and offer features such as tagging, categorizing, and integrating with other platforms for seamless sharing and retrieval of memories. They also emphasize personalization, enabling users to add their unique touches to their memories and stories.

Story Telling and Grand Storyteller, both encourage creative storytelling. The Story Telling app highlights its function of randomly displaying images, which prompts users to create imaginative stories. Story Telling uses dice with images to inspire the creation of fictional stories, encouraging users to craft narratives that are entirely imaginative and creative. The app's design promotes storytelling as a fun and interactive family activity, where participants use the random images provided by the dice to generate unique and inventive fictional stories. Grand Storyteller encourages detailed multimedia stories with text, images, audio, and video, which is perfect for documenting personal experiences and creating personalized audio storybooks. Memoirs of Life and Memorize both serve as digital diaries. Memoirs of Life is a simple app for documenting daily activities, moods, and thoughts with stickers and photos, whereas Memorize offers more features, including secure detailed memory recording with photos, voice notes, categories, tags, and themes, catering to a wide range of diary-keeping needs. Spicy Memories and Brief Memories of Photos function more like tools for organizing and curating photos.

Spicy Memories uses artificial intelligence (AI) to help users select and crop photos for rediscovery and sharing as wallpapers or photo collages. Brief Memories of Photos allows users to label photos for easy searching and revisiting, helping users efficiently manage photo collections. PWI Storyteller offers an innovative approach by connecting users with nonprofits, enabling them to share personal stories that organizations can use to promote their causes and engage audiences, fostering meaningful connections for social impact. FamilySearch helps preserve and share family memories by creating digital scrapbooks of important moments, enabling integration with other platforms for ease of access and sharing, making it ideal for documenting family heritage. The Reminisce app incorporates cultural elements by offering predefined story prompts that reflect various aspects of American pop culture, including African American heritage. This feature allows users to engage with culturally relevant content, which could include trivia about television shows, movies, sports, and historical events. In addition, users have the option to create their own stories, which provides a way to personalize their experience further. By integrating these elements, the app not only offers an engaging and educational platform but also allows users to explore and connect with cultural memories, potentially using their own photos to enhance and personalize the storytelling process.

Platform Diversity, Geographical Distribution of Developers, and App Ratings

The 9 apps sampled in this research exhibit significant diversity in terms of platform availability. About 44% (4/9) of the apps are exclusive to iOS, reflecting a preference (or perhaps a strategic decision) to target Apple's ecosystem, which is known for its more controlled user experience. In contrast, 22% (2/9) are exclusive to Android, which may cater to a broader user base given Android's larger global market share. Another 22% (2/9) are available on both iOS and Android, ensuring the widest possible accessibility. About 11% (1/9) of the total app's platform is unknown.

The geographical distribution of the app developers also exhibits significant variance, with China producing 33% (3/9) of the apps, reflecting significant input from Chinese developers in the app market. The United States is responsible for 22% (2/9) of the apps, demonstrating its continued influence in the global tech scene. About 11% (1/9) comes from the Netherlands, and the remaining 33% (3/9) have developers listed as global or unknown. All in all, this composition reflects a range of diverse or multinational development efforts.

About 67% (6/9) of the apps have a user rating of 4.0 or above, suggesting generally positive user feedback (where ratings are provided). Furthermore, 22% (2/9) of the apps have a high level of user engagement, with >200 comments on their respective platforms, highlighting significant interactive participation by users with those apps.

Features of Digital Storytelling Apps

The 9 sampled apps boast 4 principal functionalities: *capture memory*, *save*, *reminisce*, and *share* (Table 2). The *capture memory* feature allows users to take notes, snap pictures, or record videos directly through their smartphones, as well as upload existing media. The *save* function ensures that stories are not only displayed but also preserved for future access, transcending ephemeral experiences. *Reminisce* leverages these materials to facilitate the recollection of memories, enriching the user's reflective experience, such as via playback functionalities. Finally, *share* extends the reach of users' stories, enabling them to connect with a broader audience through digital or social media sharing. All apps incorporate reminiscence and outputting stories in the form of words or pictures.

Table 2. Comparative features of storytelling apps: capturing, saving, reminiscing, and sharing memories.

App	Capture memory	Save	Reminiscence	Share
Story Dice: Story Telling			✓[a]	
Grand Storyteller	✓	✓	✓	✓
Memoirs of Life		✓	✓	✓
Spicy Memories		✓	✓	
PWI Storyteller	✓	✓	✓	✓
Brief Memories of Photos		✓	✓	✓
FamilySearch	✓	✓	✓	✓
Reminisce			✓	
Memorize: Diaries, Memories, Notes, Ideas, Timelines, Categories	✓	✓	✓	✓

[a] Supported the features from the app.

Most apps (7/9, 78%) offer saving memories or stories, and 67% (6/9) apps support sharing the stories. About 22% (2/9) apps did not have *store memory stories* (Story Dice: Story Telling, and Reminisce), and 33% (3/9) did not have user tips (Grand Storyteller, Memoirs of Life, and Memorize: Diaries, Memories, Notes, Ideas, Timelines, Categories). Around 44% (4/9) apps provided memory themes (Grand Storyteller, PWI Storyteller, FamilySearch, and Reminisce). Grand Storyteller was unique in that it offered some broader story themes, which are illustrated by a cartoon picture and a sentence. PWI Storyteller is classified by some specific items or activities (potentially diseases for older adults-users) to determine the theme of the story. FamilySearch automatically determines the theme of memory through some very detailed guiding questions, whereby user answers influence the automated formation of stories. In *reminisce*, under each memory theme, an actual photo is in the foreground and questions about important life events are asked.

Table 3 synthesizes the findings from our analysis of the storytelling apps. The main columns in the table were created through thematic analysis of the features and functionalities identified across the apps. The "app community" column refers to the social features within each app that allow users to share their memory stories with others, fostering a sense of community. Memory Theme represents the categorization or thematic organization of the stories, which may be guided by the apps to help users focus on specific types of memories, such as childhood or significant life events. Classification denotes how the apps organize the content, whether by media type (text, photo, and video) or by chronological or thematic order. Usage Tips refers to the guidance or suggestions provided by the apps to enhance user engagement, such as best practices for creating and sharing stories or ways to use the app more effectively. These columns capture the core features shared across the storytelling apps. For instance, all the apps require users to upload and edit their memory-derived stories, providing materials for engaging in reminiscence. In addition, 89% (8/9) apps allow users to present their stories in multiple formats, such as text, photos, or videos.

Table 3. Shared features across storytelling apps.

App	App community	Memory theme	Classification	Use tips
Story Dice: Story Telling				✓[a]
Grand Storyteller		✓		
Memoirs of Life	✓		✓	
Spicy Memories			✓	✓
PWI Storyteller	✓	✓		✓
Brief Memories of Photos			✓	✓
FamilySearch		✓	✓	✓
Reminisce		✓		✓
Memorize: Diaries, Memories, Notes, Ideas, Timelines, Categories			✓	

[a] Supported the features from the app.

First, it can be seen that these storytelling apps all require users to upload their own memory-derived stories and use their own memories to edit and generate stories, providing materials for users to engage in reminiscence. Users can use the apps to browse through their own memory stories. Second, when using these apps (8/9, 89%), users can usually choose to present their memory stories in text, photos, or video form.

When engaged in creating their own memory stories, different apps use different methods for selecting the story's theme. For instance, Story Dice inspires users' creativity by letting them roll the dice in the app to create fictional stories, allowing users to invent characters, settings, and plots based on the outcomes of the dice rolls. Pela Memory uses AI technology to automatically select and crop photos uploaded by users to create collages. This kind of story generating method reduces the user's learning cost (which may be better suited for older adults who are cognitively impaired) and can guide users to pay attention to details in their photos that they have never noticed before, making user engagement with memory stories more fun and potentially aiding memory recall. In addition, these apps also differ in how they can classify user memories. There are 2 main ways of classification. One is to enable users to add tags themselves to classify their memories, whereby users edit memory classification tags manually, making it more flexible when using this kind of storytelling app. The other is that the app itself already has classifications, and users only need to add their own stories or photos under the preexisting classifications. This second approach may be more convenient and easier for cognitively impaired users to learn.

Quality Assessment of Digital Storytelling Apps: MARS Rating

To provide a systematic quality assessment, our research evaluated a sample of the available storytelling apps using the MARS across 4 domains: engagement, functionality, aesthetics, and information, culminating in an overall score (Table 4). The range of the mean score of MARS is 2.33 to 3.35, (SD 0.60). The reliability of the MARS was assessed using intraclass correlation coefficients (ICCs) across various categories. The results indicate that information quality demonstrated the highest reliability with an ICC of 0.81, suggesting substantial agreement among raters. Similarly, overall app quality also showed substantial reliability with an ICC of 0.71. The engagement category had moderate reliability with an ICC of 0.49, while the functionality and aesthetics categories exhibited fair reliability with ICCs of 0.37 and 0.38, respectively. The evaluation of digital storytelling apps using MARS yielded varied results across the 9 apps sampled, with scores reflecting different strengths and weaknesses regarding engagement, functionality, esthetics, and information quality. Memoirs of Life obtained a score of 3.6, 3.75, 3.3, and 2.4 over each of the domains, respectively, with a mean score of 2.33. Memorize: Diaries, Memories, Notes, Ideas, Timelines, Categories exhibited a slightly more consistent performance across domains, with scores of 3.4, 3, 3, and 2.9 (respectively), resulting in a mean of 3.06. Grand Storyteller emerged as a stronger contender for use by older adults who are cognitively impaired, with scores of 3.8, 3.75, 3.3, and 2.3 (respectively) and a mean score of 3.35. Spicy Memories and PWI Storyteller were found to be midrange, with mean scores of 3.18 and 3.05, respectively. Brief Memories of Photos and FamilySearch both demonstrated modest scores across all 4 domains, with a mean of 3.02 and 3.17 (respectively). Reminisce and Story Dice: Story Telling rounded out the evaluation, recording mean scores of 3.10 and 3.04 (respectively). The outcome of this assessment demonstrates the diverse capabilities and varying quality of digital storytelling apps currently available, reflecting a broad spectrum of user experiences and satisfaction levels.

Table 4. Average Mobile Application Rating Scale rating.

App	Engagement	Functionality	Aesthetics	Information	Scores, mean (SD)
Memoirs of Life	3.6	3.75	3.3	2.4	2.33 (0.77)
Memorize: Diaries, Memories, Notes, Ideas, Timelines, Categories	3.4	3	3	2.9	3.06 (0.70)
Grand Storyteller	3.8	3.75	3.3	2.3	3.35 (0.60)
Spicy Memories	3.4	3.5	3.7	2	3.18 (0.78)
PWI Storyteller	3	3.5	3.3	2.3	3.05 (0.53)
Brief Memories of Photos	3.2	3.25	3	2.3	3.02 (0.44)
FamilySearch	3.2	3.75	3.3	2.3	3.17 (0.61)
Reminisce	3.4	3.25	3.3	2.4	3.10 (0.46)
Story Dice: Story Telling	3	3.5	3	1.7	3.04 (0.22)

User Feedback and Engagement

User feedback and engagement across the digital storytelling apps reveal a diverse range of experiences and sentiments, which can be grouped into several key themes.

Overview of Comments

Despite the diverse range of comments, the overall comment across these apps is slightly positive, with 5231 positive reviews compared with 4280 negative ones. User feedback also showed considerable variability, ranging from 0 comments for apps such as Grand Storyteller and PWI Storyteller to as many as 5361 comments for FamilySearch, which received extensive positive reviews. This suggests a generally mediocre reception, with some apps, such as FamilySearch and Memorize, receiving high praise for their functionalities, while others, such as Spicy Memories, show room for improvement, particularly in user interface and flexibility. The diversity in feedback highlights the importance of continuous updates and improvements to meet user needs and enhance satisfaction, particularly for cognitively impaired users.

Ease of Use and User Interface

Users frequently mentioned the importance of a user-friendly interface. For example, Story Dice: Story Telling was generally found enjoyable, particularly for both adult and child users. However, criticisms arose regarding advertisements that could not be closed, which detracted from the overall user experience and could potentially confuse cognitively impaired users. Similarly, Spicy Memories faced criticism for becoming less user-friendly over time, as updates made the app more restrictive in editing options.

Content and Feature Satisfaction

Several apps received praise for specific features that enhance the user experience. FamilySearch garnered extensive positive feedback, with users appreciating its ability to collect and preserve family memories by adding photos, documents, and recordings to their family tree. This app also had the highest number of comments, indicating significant user engagement. By contrast, Brief Memories of Photos was highlighted for its effective tagging and organizing functionalities, though more detailed feedback was scarce.

Customization and Flexibility

Customization options were a point of contention for users. While Spicy Memories was praised for its innovative AI-driven features, such as rediscovering old photos and photo cropping options, users expressed dissatisfaction with the app's growing restrictions, reflecting challenges in balancing feature development with user flexibility. In addition, Memorize: Diaries, Memories, Notes, Ideas, Timelines, Categories received generally favorable reviews, particularly for its diary and note-taking functions, but users suggested improvements, such as enhanced data backup options, better security settings, and additional synchronization options.

Market Penetration and User Engagement

The level of user engagement varied widely among the apps. Grand Storyteller, PWI Storyteller, and Reminisce had no user comments available, which could indicate either low user engagement or limited market penetration. Memoirs of Life also lacked specific user feedback, making it challenging to assess user satisfaction or identify areas for improvement. The scarcity of comments for these apps suggests a relatively small target audience or recent entry into the market.

Discussion

Principal Findings

The principal findings from the evaluation of 9 digital storytelling apps using the MARS offer significant insights into the app landscape. Among the apps evaluated, Memoirs of Life and Memorize: Diaries, Memories, Notes, Ideas, Timelines, Categories scored the highest, with Grand Storyteller also performing well, indicating a balance in user engagement, functionality, esthetics, and information quality. Story Dice: Story Telling yielded the lowest mean score at 3.04, primarily due to its deficiencies in information quality. Apps with lower information quality scores are likely to struggle with user retention and credibility, which are critical for maintaining user interest. Users' feedback on specific app features and innovative features such as the photo classification functionality received positive feedback, contrasting with criticisms of Story Dice for its lack of innovation.

Apps, such as FamilySearch, have received extensive positive feedback and high user engagement, whereas others, such as Grand Storyteller, have received minimal feedback, highlighting market penetration inconsistencies and varying user interest levels. The geographical distribution of app developers, with significant contributions from China and the United States, indicates a global interest in digital storytelling technologies.

In summary, while certain apps set benchmarks for excellence in the digital storytelling domain, others lag, particularly in crucial areas, such as information quality. This disparity accentuates the need for ongoing improvements in app functionality and user interface to better cater to specific user groups, particularly those with cognitive impairments.

Features of Storytelling Apps

Traditional photo organization features on mobile devices often fall short of more complex or customizable sorting, making the structured and intuitive classification functions provided by storytelling apps highly beneficial [32,33]. These apps simplify the management of photos, offering a supportive user experience for the cognitively impaired. In addition, some apps incorporate AI to automatically generate photo albums and recall key life milestones, which can further support users in selecting appropriate materials for reminiscence [8]. This innovative use of technology simplifies data interaction as well as encourages sharing memories within social groups, which can improve social relationships and foster new connections, especially among older adults [34]. The effective use of AI and organization features in storytelling apps plays a crucial role in supporting cognitive functions and enhancing social engagement among users. AI can perform an automated role in curating, summarizing, linking, and presenting vast amounts of image data in a manner that is particularly helpful for the cognitively impaired. In this context, storytelling emerges as a fitting metaphor, adept at capturing and illustrating the narratives and insights hidden within the relationships among data scattered across various repositories. The difference, however, lies in the fact that commercial apps have introduced AI for automatic filtering and reminders.

In addition, helping users to share their memories or stories in a group by offering preset themes is also one of the ways to increase positive user engagement and, by extension, positive emotions. Such an approach is not only innovative but also instrumental in making complex data interactions more accessible and engaging for users, especially for older adults or those who are cognitively impaired. This underscores the untapped potential of commercial apps that could leverage AI to transform how we interact with and interpret image data, turning it into compelling and informative digital narratives that are particularly valuable in enhancing cognitive engagement among older adults. This form of sharing in a group, by contrast, can also support users in maintaining or enhancing their social relationships and making new social connections. Academic research has shown that the choice of story themes is limited, and there is little support for group activities [6,7], revealing a research and operational gap. Finally, the sample analyzed herein revealed how some apps focus on the entertainment value they provide. These apps often achieve this through some special interaction or interactive logic. For instance, by shaking the phone to simulate a dice roll, the app reads the contents of a photo album to automatically generate memories or to locate people nearby who have similar experiences, thereby encouraging face-to-face meetings or walks together.

Quality of Digital Storytelling Apps

The quality of these apps, as assessed using established methods such as the MARS, shows considerable variation. For instance, apps such as Memoirs of Life and Memorize: Diaries, Memories, Notes, Ideas, Timelines, Categories rank highly due to their comprehensive features and user-friendly interfaces, all of which are conducive to supporting cognitive functions [32,33]. In contrast, other apps may have lower scores due to less effective implementation of features or poorer information quality, aspects that are crucial for users who rely on accurate reminiscence triggers and social interaction support [35-37]. The effectiveness of digital storytelling apps, particularly within the Chinese cultural context and for individuals with cognitive impairments, such as dementia, reveals a high degree of potential yet varied outcomes [4]. This statistical approach provided a quantifiable measure of app utility and quality, facilitating objective comparisons. Thematic analysis was additionally used to gauge user feedback and engagement levels, a process that entailed an examination of user reviews to identify common sentiments, areas of satisfaction, and points of contention. This layer of analysis helps us to understand the user experience and the impact of app updates on user satisfaction.

These apps, which aim to engage users—especially older adults—often suffer from a gap in quality and a lack of specialized features. This results in an overall scarcity of intuitive and cognitively engaging apps, as is demonstrated by the limited user comments and a lack of engagement. These factors suggest a need for apps more tailored to specific user needs. Moreover, there is a clear oversight in the accessibility and practicality of these apps for public use, highlighting an urgent need for focused development and rigorous evaluation to enhance their relevance and effectiveness in promoting cognitive engagement. This finding is supported by various studies that demonstrate the benefits of digital reminiscence therapy, which can facilitate significant enhancements in cognitive function and emotional well-being among participants. Studies by Moon and Park [38], Mulvenna et al [39], Derbring et al [40], and Sarne-Fleischmann et al [41] illustrate how these interventions not only improve engagement and interaction among older adults and caregivers but also emphasize the importance of personalized digital systems in improving recall abilities among older adults who are cognitively impaired, especially among older adults with Alzheimer. Collectively, these findings provide an empirical basis to support the continued development and integration of digital storytelling tools in therapeutic and care settings, highlighting the potential of these technologies to significantly improve cognitive functions, emotional well-being, and interpersonal interactions, thereby enhancing the overall quality of life for cognitively impaired users. While this research has filled a gap in the academic literature, it has also revealed an important gap between empirical findings and commercially available solutions for the cognitively impaired.

Recommendations for Effective and Engaged Digital Storytelling

Synthesizing the user feedback indicates that there is a need for more interactive and personalized features in digital storytelling apps to improve engagement and effectiveness in cognitive and social support. Digital storytelling apps facilitate reminiscence and social interaction among users with cognitive impairment by providing functions that are both engaging and relatively easy to navigate. For instance, apps such as FamilySearch and Memoirs of Life offer functionalities that not only allow users to store and recall memories but also share these with others. This sharing capability is advantageous and yields therapeutic benefits, as it enables users to connect with family and friends, fostering social interactions that are vital for mental health and social well-being. Moreover, the integration of AI technologies in apps such as Spicy Memories enhances the curation and presentation of personal content, making it more accessible and engaging for users; this not only supports cognitive engagement through interactive reminiscence but also makes the apps easier to use and thus less burdensome for the cognitively impaired. Digital memory books that incorporate personal photos, videos, and narratives can improve the emotional and social well-being of older adults.

The strategies of these apps in terms of functionality are almost identical and offer little differentiation. For instance, some apps allow memories to be cataloged according to life events or specific topics, providing a structured approach (ie, timeline) to storytelling [11]. Moreover, there are apps that index memories by locations and dates, offering strategies to track recollections over time. These features enhance the user experience by simplifying the process of memory retrieval and organization, aiding in memory recall. In addition to the timeline organization strategy used in the reminiscence phase of digital storytelling, these apps offer significant potential for the integration of other stages and behavioral change strategies. These include setting behavior goals and outcome objectives, which can play a crucial role in structuring the storytelling process [42] and encouraging cognitive exercises. Specifically, in the reminiscence phase, the introduction of scaffolding techniques can significantly aid older users in recalling memories [43]. This could involve the use of guided questions or prompts that help in fleshing out stories more comprehensively. By incorporating such strategies, digital storytelling apps can become more than just tools for memory capture; they can actively assist users in weaving richer, more detailed narratives, thereby enhancing the overall storytelling experience for older adults.

Regarding story-sharing functionalities, in academic settings, sharing is found to be more oriented, toward family members and participants who are involved, which is understandable given the personal nature of photographs [14,44]. Narrating personal experiences and events offers a wealth of subjects for discussion and chances to establish connections with others [45]. Discussing our own life experiences is recognized as integral to forming relationships and is a primary method through which we pursue and establish connections with others. In this research, we observed distinct technical features across various storytelling apps, each designed to enhance the user experience in unique ways. Memoirs of Life stands out with its sharing capability, necessitates user login, and requires internet access for its functionality. PWI Storyteller similarly offers a sharing feature that requires internet access. A notable aspect of FamilySearch is its facilitation of family members sharing a common database, with the added advantage of memory sharing through networking. This app seamlessly synchronizes with FamilySearch, which facilitates a fluid experience across different devices by enabling users to pick up where they left off (a reduction in the necessary steps, thereby increasing accessibility for the cognitively impaired). Memorize offers a robust solution for journaling, with features for permanent storage, backup to Google's cloud storage, and the ability to import and export memories in different formats, including ZIP files. By contrast, some apps did not exhibit specific technical features.

Commercial apps offer several advantages in supporting story sharing, particularly for older adults or cognitively impaired users. A promising feature is the ability to invite family members to collaborate and edit stories together, fostering a sense of community and intergenerational connection [45]. Furthermore, research into the mediating effects of internet use reveals that it enhances the propensity of older adults to engage with their communities, partly due to the improvement in their subjective health perceptions [46]. By providing an easy and accessible platform for sharing personal narratives, commercial storytelling apps not only promote social interaction but also potentially improve the overall well-being of older adults, which is conducive to psychosocial and cognitive therapy.

Research Implications and Future Directions

This research identifies a need for more comprehensive studies that not only explore commercially available digital storytelling tools but also examine their adaptability and relevance for older and cognitively impaired users. Such studies should aim to address the usability challenges these apps often present and explore how AI-enhanced features can further support cognitive functioning, mental health, and social well-being. By focusing on these aspects, future research can significantly contribute to the development of digital storytelling apps that are more inclusive, effective, and tailored to meet the unique needs of this population segment. Ongoing research is needed to further explore the long-term effects of digital storytelling apps, the best practices for their design and usability, and how they can be integrated into broader dementia care strategies.

Strength and Limitations

This study offers an initial exploratory review of digital storytelling apps, assessing their quality and suitability through a newly developed multidimensional expert rating scale. This scale provides a comprehensive measure of app quality across 4 objective domains (engagement, functionality, aesthetics, and information quality) and incorporates a subjective aspect. These objective quality dimensions, which contribute to the overall app quality score, offer a quantitative means for comparative analysis and can set a benchmark for future research.

Nonetheless, this study has a few limitations. First, while the rating scale is effective in evaluating the current milieu of apps, it cannot replace the need for user-centered design and evidence-based practices in app development, especially within the health behavior sector. A significant limitation of this study is its geographic restriction to the Chinese market, meaning that apps that may be available in other regions have not been considered. This limitation may have resulted in the exclusion of potentially relevant apps that are not accessible within the Chinese market, thus limiting the scope of this review. Future research would do well to increase the geographic scope of analysis. Future studies should also focus on evaluating specific storytelling features and guided content within these apps, as there is currently no established standard for optimal storytelling practices or their efficacy in mitigating symptoms of cognitive impairment. This study did not establish a standard for optimal storytelling practices, particularly regarding the use of fictional versus reminiscence-based storytelling in digital apps for older adults. The differences between these 2 types of storytelling and their respective impacts on cognitive function remain underexplored. Future research should aim to delineate the cognitive benefits of each storytelling approach, particularly for older adults with cognitive decline.

Conclusions

This systematic search and evaluation of digital storytelling apps in the Chinese app ecosystem reveals a gap in the quality and features of these apps, particularly for users with cognitive impairment. Our findings, derived from an extensive search in both English and Chinese on the Google Play Store and iTunes Store, identified 297 unique apps, with only 9 (3%) meeting our criteria for further evaluation. The apps sampled herein and evaluated using MARS, exhibited varied levels of quality. Key functionalities such as capture memory, save, reminisce, and share were not uniformly present across all apps. The highest-rated apps were Memoirs of Life and Memorize: Diaries, Memories, Notes, Ideas, Timelines, Categories, indicating a balance in engagement, functionality, and information quality. However, overall, many apps reveal significant room for improvement, especially in the information domain (where user complaints were concentrated). This exploratory study lays the foundation for future research and development in digital storytelling apps, aiming to enhance user experience and effectiveness. The significance of these results lies in guiding the development of more effective digital storytelling apps to maximize their therapeutic potential with a focus on the cognitively impaired. In parallel, the findings emphasize the need for improved content accuracy, user interface design, and the integration of AI technologies to enhance cognitive support and user engagement by aiding in photo restoration and material selection.

Acknowledgments

The authors would like to thank all the master students, Zhouyang Li, Mingyang Zhang, and Mengyi Zhang, for searching and testing the apps.

Authors' Contributions

AAM and DZ conceptualized the study. DZ collected and analyzed the data. AAM directed several rounds of feedback and contributed significantly to the manuscript's writing and revision. AAM, WL, and DW supervised the project. All authors examined and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Remote programming enables physicians to adjust implantable pulse generators over the internet for patients with Parkinson disease who have undergone deep brain stimulation (DBS) surgery. Despite these technological advances, the demand for and attitudes toward remote programming compared with standard programming among patients with Parkinson disease are still not well understood.

Objective: This study aims to investigate the preferences and perceptions associated with these 2 programming methods among patients with Parkinson disease through a web-based survey.

Methods: A web-based survey was administered to 463 patients with Parkinson disease who have undergone DBS surgery. The survey aimed to assess the burdens associated with postoperative programming and to compare patients' attitudes toward the 2 different programming methods.

Results: A total of 225 patients completed the survey, all of whom had undergone standard programming, while 132 patients had also experienced remote programming. Among those who received standard programming, 191 (85%) patients required the support of more than 1 caregiver, 129 (58%) patients experienced over 2 days of lost work time, 98 (42%) patients incurred expenses ranging from US $42 to US $146, and 14 (6%) patients spent over US $421. Of the 132 patients who had used remote programming, 81 (62%) patients indicated a preference for remote programming in the future. However, challenges with remote programming persisted, including difficulties in obtaining official prescriptions, a lack of medical insurance coverage, and limited medical resources.

Conclusions: Postoperative programming of DBS imposes significant burdens on patients and their caregivers during standard programming sessions—burdens that could be mitigated through remote programming. While patient satisfaction with remote programming is high, it is imperative for clinicians to develop personalized programming strategies tailored to the needs of different patients.

Introduction

Deep brain stimulation (DBS) is recognized as a cost-effective, invasive treatment for patients with Parkinson disease [1]. DBS aims to regulate neural activity through controllable electrical currents generated by an implantable pulse generator (IPG) [2], which can be finely adjusted during programming sessions to optimize treatment effects [3]. However, the frequent long-distance travel required to access specialized medical centers often imposes significant costs and logistical challenges on patients [4], and may vary among different Parkinson disease subtypes [5].

Introduced as a viable alternative, internet-based remote programming first became operational in China in 2015. Its use expanded significantly during the COVID-19 pandemic, and it continues to be widely used, with over 10,000 sessions conducted annually [6,7]. Previous research has confirmed the satisfaction, necessity, and effectiveness of remote programming for patients with Parkinson disease with DBS implants [8-10]. However, most of these studies were conducted during the pandemic, when travel restrictions limited access to standard programming. With the lifting of COVID-19 restrictions, standard programming has resumed without these obstacles, prompting a reevaluation of the value of remote programming.

To explore the long-term value of remote programming, we conducted a comprehensive web-based survey focusing on patients with Parkinson disease who had received DBS. This study aimed to assess the burdens and factors associated with different programming methods and to compare patient attitudes toward each. The findings are intended to serve as an essential reference for specialized centers when making informed decisions about IPG selection prior to DBS surgery.

Methods

Study Design and Participants

A retrospective, cross-sectional, web-based survey was conducted from September 25, 2023, to October 15, 2023, following the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) guidelines and CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist [11,12]. A total of 463 patients are invited to participate through messages sent via WeChat (Tencent Co, Ltd), leveraging the platform’s extensive reach and accessibility. The message includes a brief overview of the study and an invitation link to the survey.

All participants met the following inclusion criteria: (1) diagnosed with Parkinson Disease and received DBS surgery at our center; (2) implanted with an IPG capable of a remote programming function, specifically from manufacturers SceneRay and PINS [13,14] (detailed information about the remote programming procedure can be found elsewhere [15]); (3) experienced at least one session of standard programming; and (4) was willing to participate in the survey.

In 2019, our center created a clinical database for patients with Parkinson disease to record the results of preoperative assessment and postoperative follow-up. The preoperative motor assessment of patients in this study was extracted from this database. The process of screening valid questionnaires and matching them with the database is provided in Multimedia Appendix 1.

Questionnaire Design

We developed a comprehensive 49-item questionnaire divided into five sections: (1) basic information (Q1-10: including name, age, gender, etc), (2) burdens of standard programming (Q11-19: exploring transportation needs, caregiver requirements per session, etc), (3) burdens of remote programming (Q22-29: detailing caregiver involvement and workdays lost per remote session, etc), (4) satisfaction with remote programming (Q31-43: assessing factors such as ease of use and therapeutic effects on a 5-point Likert scale, from strongly disagree to strongly agree), and (5) open-ended questions (Q46-49: eliciting views on the pros and cons of both programming methods). A preliminary test of the questionnaire was conducted with 12 patients to refine its content. The English version of the questionnaire is available in Multimedia Appendix 2. The cost was converted to US dollars, based on the exchange rate of US $1≈¥7.12.
