Our study has some limitations. Limitations were posed by the MedicAlert data set itself. First, missing incidents are also captured in data held by first responders (police, search and rescue organizations, paramedics, etc), and, because MedicAlert data are subscription-based data, there are inherent self-selection biases. Second, while inquiring about the data entry process at the MedicAlert subscribers' level, we discovered that a high percentage of data were stored raw (free-text fields) and not in analysis-ready format. Consequently, the available information did not allow us to categorize our data with the desired level of granularity. Third, the self-reported nature of the data caused missing data in some variables (eg, the use of de-escalation techniques to avoid missing incidents, whether a MedicAlert subscriber has special needs, and what constitutes a trigger for a missing incident). As the percentage of missing data in these variables was large (ie, >40%), we excluded them from the analyses as recommended in the literature [49]. The missing data will not allow for further comprehensive statistical analysis for these unmeasured confounding variables. Fourth, the database lacked some important outcome variables; for example, we were unable to determine for how long MedicAlert subscribers went missing, the response time (ie, time elapsed between the call to the hotline and the arrival of the first responders to assist a missing person) or the turnaround time of the missing incidents (ie, the time it takes to return a missing person to their residence). In summary, because this study used a secondary data source that had not been compiled for research purposes, we faced the same common limitations reported in other studies that use this kind of data source [50-52]. Notwithstanding these limitations, we believe that the results obtained in this study are very valuable for partially understanding the phenomenon of older adults with dementia and memory loss going missing in Canada. The data set used in this study represents a small portion of people living with dementia in Canada; by virtue of it being a paid subscription service, not everyone uses it. In future research, other sources of data also need to be considered (police and search and rescue data) to get a fuller picture of the prevalence of persons living with dementia who go missing.

Conclusions

In the data set used, missing incidents involved mostly female older adults living with dementia from an urban area (331/341, 97.1%). Overall, the majority of MedicAlert subscribers involved in missing incidents returned home safely (453/500, 90.6%). However, 9.2% (46/500) of the cases resulted in some form of minor or serious injuries and death. Of the 560 missing incidents, 126 (22.5%) were repeated missing incidents. This paves the way to more accurately describe the prevalence of missing incidents and their consequences and outcomes so that we can develop targeted intervention strategies to prevent missing incidents or locate missing persons.

Acknowledgments

This work was supported by the Search and Rescue New Initiatives Fund program, Public Safety Canada (22005). The authors thank Serrina Philip, Marria Khalid, Andrew Faller-Saunders, and Vanessa Vahedi for their help in data cleaning and the categorization process. The authors also thank Elea Thuilier for her help in conducting some of the data analyses. Finally, the authors thank the MedicAlert team for their help and support in understanding the MedicAlert database.

Conflicts of Interest

Abstract

Background: As the aging population in the United States continues to increase rapidly, preserving the mobility and independence of older adults becomes increasingly critical for enabling aging in place successfully. While personal vehicular transport remains a popular choice among this demographic due to its provision of independence and control over their lives, age-related changes may heighten the risk of common driving errors and diminish driving abilities.

Objective: This study aims to investigate the driving practices of older adults and their efforts to maintain safe and confident driving habits. Specifically, we sought to identify the factors that positively and negatively influence older adults’ driving performance and confidence, as well as the existing efforts put into sustaining their driving abilities.

Methods: We recruited 20 adults aged ≥65 years who remained active drivers during the recruitment from the greater New York area. Then, we conducted semistructured interviews with them to examine their perceptions, needs, and challenges regarding safe and confident driving.

Results: Our findings uncovered a notable disparity between older adults’ self-perceived driving skills and the challenges they face, particularly caused by age-related limitations and health conditions such as vision and memory declines and medication routines. Drawing on these findings, we proposed strategies to bridge this gap and empower older adults to drive safely and confidently, including fostering a realistic understanding of their capabilities, encouraging open dialogue regarding their driving, encouraging regular assessments, and increasing awareness of available resources.

Conclusions: This study uncovered a noticeable disparity between the perceived driving competence of older adults and the actual challenges they confront while driving. This divergence underscores a significant need for better support beyond the existing aid available to preserve older adults’ driving skills. We hope that our recommendations will offer valuable insights for practitioners and scholars committed to enhancing the overall well-being and quality of life for older adults as they age in their homes.

Introduction

Background

Due to the culture, lifestyles, and vast geography of the United States, automobiles play a crucial role in enhancing the quality of our daily lives by serving as the key to mobility, freedom, and independence. Driving holds particular significance for older adults in today’s aging society, as it enables them to maintain their socialization, independence, and mobility as they age [1-3]. The absence of driving can lead to isolation and depression among older adults [4], with consequent declines in both their physical and mental health [5-7]. Therefore, it becomes important to ensure that these drivers maintain and prolong their driving skills for independence, healthy aging, and overall quality of life.

According to the American Automobile Association, drivers aged between 60 and 69 years are considered the safest drivers in the United States [8]. Even drivers aged ≥80 years are involved in fewer car accidents per mile driven than younger drivers [9]. Furthermore, drivers in their 70s have lower rates of police-reported crash involvements per capita than middle-aged drivers [9]. Consequently, older adults can significantly contribute to our driving culture as some of the safest drivers. However, age-related changes can adversely affect the driving abilities of older individuals [10,11]. For example, as individuals age, they may experience shifts in reaction time, visual acuity, and cognitive processing, which can impair their capacity to drive safely [12,13]. Therefore, it is crucial for older adults to recognize that aging may increase the risk of safe driving and that they must be vigilant about signs indicating such changes and make efforts to maintain their driving capabilities.

Existing efforts to help maintain older adults' driving capabilities encompass programs focused on driver training, self-assessment tools, and regular health checkups [12,14,15]. However, little is known about the efforts that older drivers exert to cope with their aging-related changes and maintain their driving capabilities, let alone how they use any of these existing programs.

This study seeks to comprehend the current practices associated with daily driving experiences among older adults, providing insights into actionable and empirical implications to help older adults sustain their driving capabilities. Through semistructured interviews with 20 participants aged ≥65 years who were actively driving, we explored their perceptions of their driving abilities, identified the challenges they face while driving, examined strategies for managing these challenges, and assessed the efforts they put into maintaining their driving capabilities, if any.

Our findings revealed a significant disparity between the confident mindset that the participants held regarding their driving abilities and the challenges they encountered while driving. Although most participants expressed no immediate concern or effort about maintaining their driving proficiency and displayed overall confidence in their current capabilities, they acknowledged various challenges that negatively impacted their driving performance and confidence only when prompted about specific driving-related challenges. This highlights a significant disparity between the perceived need for support and the actual assistance required to uphold driving performance among older adults.

In what follows, we describe a review of existing related works, our study procedure, and key findings. We conclude this paper by discussing the implications for supporting the maintenance of older drivers' driving capabilities, along with addressing some limitations of this study.

This study aims to investigate the driving practices of older adults and their efforts to maintain safe and confident driving habits and to explore strategies that help older adults continue driving safely and confidently.

Literature Review

Driving and Quality of Life in Older Adults

The World Health Organization recognizes that maintaining mobility is fundamental to active aging, enabling older adults to remain engaged in various activities [16]. Loss of mobility, often stemming from the inability to operate a vehicle safely, can lead to activity restriction, physical deconditioning, and reduced social participation, significantly affecting an individual's health and overall quality of life [17]. In particular, impaired mobility has been identified as an early predictor of physical disability [18] and is associated with negative outcomes such as falls, loss of independence, institutionalization [19], and even mortality among older adults [20].

Undoubtedly, 1 key aspect of mobility for older adults is maintaining their driving privileges [21]. It is evident that the stage at which individuals change their driving behavior depends on various internal and external factors, such as personal circumstances and declining abilities [22]. Some individuals may abruptly cease driving due to external pressures or sudden events, while others who gradually restrict their driving likely do so in response to internal factors related to their abilities [21,23]. Those who prepare for driving cessation often have a combination of internal and external factors guiding their decision-making [24]. Research also highlights the profound impact of driving cessation on older adults' well-being. Several studies linked driving cessation to increased depressive symptoms [25,26] and identified it as a predictor of mortality risk [27].

Especially for many older adults in rural areas, driving remains critical for maintaining independence [8]. It aids daily living activities, supports familial responsibilities, and promotes community integration [23]. Even when facing physical and cognitive declines that may limit their ability to drive safely, some older adults continue to drive, as it contributes significantly to their self-confidence, well-being, and social connections [23]. As such, the relationship between driving and the quality of life in older adults is a critical aspect of aging, as it directly impacts their ability to lead dynamic and independent lives.

Physical, Cognitive, and Social Factors in Older Adults' Driving Capabilities

The overall physical health has been acknowledged as a crucial factor impacting older adults' ability to drive and respond effectively to unforeseen situations on the road [28]. Numerous studies have documented the correlation between health issues and the driving capabilities of older adults [2,23,29,30]. Generally, the findings indicate that health problems tend to increase with age, placing individuals with various health issues at a heightened risk for diminished driving performance. Specifically, vision impairments and physical limitations are found to be strongly associated with driving performance, albeit to varying degrees [31].

Cognitive abilities, including attention, memory, and executive function, are also critical for quick decision-making and multitasking, both essential for safe driving [28]. Several studies have underscored the crucial role of cognitive and neuropsychological factors in evaluating older adults’ driving capabilities. Factors such as processing speed, divided attention, visuospatial abilities, executive functions, psychomotor speed, and overall cognitive functioning have emerged as pivotal predictors of safe driving among older adults [31-33].

Social factors such as retirement and personal loss have also been found as triggers for driving anxiety among older drivers, thereby influencing their driving behavior [12,34]. These social circumstances can have immediate and long-term impacts on driving capabilities, highlighting the importance of preventive measures and interventions to address them [25].

Although age-related declines occur, older adults may not be aware of these changes or how they affect driving. Some older drivers fail to recognize their declines or overestimate their driving safety [24,25]. In this context, self-regulation and self-awareness play pivotal roles in how older adults adapt to these challenges, ultimately shaping their decisions and behaviors related to driving. Therefore, it is crucial to assist older adults with lower levels of health risk in increasing awareness of their health status concerning driving capabilities and taking preventive actions to maintain their ability to drive safely.

Existing Efforts to Help Maintain Older Adults’ Driving Skills

A systematic review of driver-training interventions for individuals aged ≥55 years, without any health-related impairments that prevent licensure, showed that interventions tailored to individual participants’ health conditions can positively impact driving ability and on-road performance [35]. Compared to the extensive studies on understanding factors that affect older adults’ driving performance, relatively few studies have explored the impact of tailored interventions on sustaining the driving safety of older adults. One exception is a randomized controlled trial that found tailored driving lessons reduced critical driving errors among older adults, acknowledging the need for longer-term follow-up and more extensive trials [28]. In addition, cognitive training, focusing on speed of processing and reasoning skills, demonstrated promising results, with a lower at-fault motor vehicle collision rate observed in older drivers who received training than controls [36]. These findings highlight the potential of personalized training interventions to enhance driving safety, sustain independence, and improve the quality of life for older adults, given the significance of driving mobility and the associated costs of declining driving capabilities.

In addition, driving simulator training has emerged as a useful tool to enhance driving skills in older adults for its effectiveness of attention training [24]. The implications of these interventions are found to be substantial in improving older drivers’ safety on the road [20]. Given the variability in older adults’ driving experiences, skills, and self-awareness, researchers argue that the strategies to help maintain older adults’ driving skills must be customized to address individual strengths and areas for improvement [37].

By delving deeper into the daily driving practices and concerns among older drivers, this research seeks to understand the complex interplay between aging, the challenges associated with driving, and the strategies to maintain mobility and safety. Through this investigation, the study aims to offer insights that can inform future interventions and policies to support older adults’ driving needs.

Methods

Ethical Considerations

The study was approved by the Rutgers Institutional Review Board (Pro2023001102), and informed consent was obtained from all participants before participating in the study. At the end of the interview, each participant was duly compensated with a US $30 Amazon gift card in recognition of their time and willingness to participate in the study.

Participant Recruitment

The recruitment of participants followed a systematic process aimed at ensuring a representative and ethically sound sample. To identify potential participants, the first author visited local libraries, senior centers, and low-income living facilities situated in the vicinity of the greater New York area. During our engagement with these facilities, the study’s objectives and purpose were comprehensively elucidated to the respective managers and supervisors. Upon their explicit approval and support, recruitment flyers were prominently displayed in the facility lobbies and on designated advertising boards.

The eligibility criteria for participant recruitment encompassed 3 primary requirements. First, participants had to be aged >65 years. Second, they needed to possess a valid US driver’s license, demonstrating prior driving experience. Third, they needed to be engaged in driving as part of their daily routine. This methodical recruitment approach ensured that our sample consisted of individuals who met the age criterion, had a documented driving history, and were healthy enough to sustain driving.

We recruited 20 participants, all of whom boasted substantial driving experience and maintained their active status as drivers (mean driving experience 51.1, SD 8.54 years). A gender distribution of approximately 70% (14/20) of female participants and 30% (6/20) of male participants was observed within the sample. The average age of our participants was 71.7 (SD 5.81) years. A breakdown of participant demographics is provided in Table 1 for further insight.

Table 1. Participant demographics and study duration (some participants included their learner’s permit periods in their years of driving experience; N=20).

ID	Age (years)	Gender	Driving experience (years)	Approximate driving frequency	Medical condition
P1	77	Woman	58	2 to 3 times a week	None
P2	65	Woman	50	Every day	None
P3	82	Woman	61	4 to 5 times a week	Cataract surgery
P4	77	Man	59	2 to 3 times a week	None
P5	73	Woman	50	Every day	None
P6	66	Woman	48	Every day	Survivor of breast cancer
P7	76	Woman	59	Every day	None
P8	73	Man	57	5 times a week	None
P9	83	Woman	59	2 to 3 times a week	None
P10	69	Man	52	4 to 5 times a week	Cardiac rehabilitation
P11	68	Man	32	Every day	None
P12	70	Man	52	Every day	None
P13	69	Woman	49	Every day	None
P14	73	Woman	55	Every day	None
P15	65	Woman	30	4 to 5 times a week	None
P16	67	Man	40	2 to 3 times a week	None
P17	74	Man	50	Every day	None
P18	84	Woman	60	5 to 6 times a week	None
P19	74	Woman	37	Twice a week	None
P20	68	Woman	40	Every day	None

Data Collection

The research methodology used in this study was carefully designed to investigate the perspectives that older adults had with their daily driving experiences, as well as the challenges faced by them in maintaining their driving capabilities.

A comprehensive interview protocol was crafted to facilitate in-depth discussions with the study participants. The protocol comprised a series of open-ended interview questions, ensuring a flexible and exploratory approach to data collection. The questions were purposefully designed to elicit a broad range of responses, enabling a comprehensive understanding of the participants’ experiences and perspectives.

The data collection process involved conducting in-person, semistructured interviews with each participant. These interviews were scheduled at a location of the participants’ preference to ensure their comfort and convenience. This approach facilitated candid and open conversations, allowing participants to express their thoughts and experiences freely. In addition to the interview responses, essential demographic information was gathered from each participant. This information encompassed details such as age, gender, prior health issues, and their level of familiarity and experience with technology. These demographic factors were considered in the data analysis to provide a comprehensive context for the study.

To maintain the integrity of the research, great care was taken to avoid any form of bias in the interview process. The questions posed during the interviews were constructed in response to the participants’ narratives and experiences, ensuring that the research did not unduly influence or guide their responses. This approach aimed to collect data that were a true reflection of the participants’ perspectives and challenges.

The duration of each interview session ranged from 30 minutes to 1 hour, depending on the depth and complexity of the participants’ experiences and responses. This flexible approach allowed for comprehensive data collection without imposing undue time constraints on the participants.

To ensure accuracy and a thorough analysis, all interviews were audio recorded. These recordings were later transcribed to create a written record of the interviews, which served as the basis for data analysis and the development of research findings.

Data Analysis

We used thematic analysis to identify and understand patterns across our interview data [38,39]. We began by open coding the data, which involved identifying and labeling key concepts. We then used axial coding to group related concepts into broader categories, which we called phenomena. Phenomena are recurring events, actions, and interactions representing people’s responses to problems and situations. Finally, we used selective coding to assemble the phenomena into a cohesive framework. We iterated all the steps until we achieved data saturation, signifying our thorough exploration of themes and patterns within the interview data. The goal of this step was to understand the relationships between the different phenomena and develop a comprehensive understanding of the interview data.

Results

Overview

The prevailing sentiment among our participants regarding their driving abilities was confidence in their abilities as good drivers. Consequently, a majority did not express any need or support for sustaining their driving proficiency, leading to consent among participants that such support was unnecessary. However, when probed about challenges related to their driving, several health-related issues emerged as factors adversely affecting their driving performance as well as their driving confidence. This dissonance between a confident mindset about driving and the escalating challenges encountered while driving among older drivers contributed to a significant gap between the perceived need for support and the actual assistance required to maintain their driving performance. Next, we first described how our participants perceived their current driving performance and the factors that positively contributed to their confidence in driving. Then, we reported a range of challenges that negatively affected driving performance. Finally, we concluded this section by describing the efforts aimed at maintaining driving capabilities. See Textbox 1 for a summary of our findings.

Textbox 1. A summary of themes and factors.

Factors positively contributing to older adults' driving confidence

- Active and independent driving
- Long-term, adaptive driving experience
- Physical fitness

Challenges older adults face in driving

- Vision challenges
- Memory decline
- Medication routines

Efforts to sustain driving

- Physical exercise
- Technology support: navigation systems
- Keeping focus undistracted while driving

Factors Positively Contributing to Driving Confidence

Active and Independent Driving

All participants reported that they were competent in their current driving skills. Several participants even expressed their pride in engaging in driving actively and regularly:

> *Driving is not a botheration for me at all. I would say 95% of the time, people want me to drive it because they feel I drive well and defensively.* [Participant 17]
>
> *I enjoy driving. It gives independence rights. I can go anywhere.* [Participant 11]

Participants mentioned several factors positively contributing to their belief that they were skilled and capable drivers.

As shown in Table 1, our participants exhibited a consistent trend of active driving, engaging in daily or near-daily driving activities. Daily routines involve driving for various purposes, including grocery shopping, medical appointments, and visits to family and friends. While local travel, covering short to moderate distances, was standard, participants also undertook occasional long-distance drives for special events or trips. Then, they expressed that these regular journeys contributed to their confidence in their driving skills. They attributed their confidence to the notion that by continuously driving, they were continually honing their abilities. The more they drove, the better they perceived themselves to be. For many, having a car and using it as their primary mode of transportation were testaments to their ongoing commitment to maintaining their driving skills:

> *I think driving skills improve on how often you drive. If you don't drive, then you never get improved. If you keep driving, then you will improve, and keep improving.* [Participant 18]
>
> *I have a car, I drive everywhere. And as far as possible, if I have to go anywhere within a certain radius, I prefer to drive rather than take public transportation.* [Participant 17]

Participants proudly emphasized their decades of solo travel on the road. This wealth of experience has undoubtedly contributed to a heightened sense of self-assuredness in their driving capabilities. These experiences, often marked by daily commutes, long-distance journeys, and even the foundational act of obtaining a driver's license, imbued them with a deep-seated belief in their driving proficiency:

> *I live alone. I gotta drive by myself. Driving myself is more accessible than using public transportation.* [Participant 20]

> *I drove from here to Dallas, and then back and forth a couple of times. Earlier, I used to drive for eight hours every day. So, I can drive with no problem.* [Participant 20]

> *When I was working, I used to get up early in the morning have a quick shower, and then drive down to work for the most part in my working career, I drove in excess of 50 miles every day.* [Participant 17]

Participants expressed that their ability to maintain their daily routines, even amid health challenges, reinforced their confidence in their driving skills. Whether running errands or embarking on longer trips, the participants frequently reiterated that they were accustomed to traveling alone. As such, this sense of independence in driving solo, sometimes despite challenges, strengthened their confidence in driving as skilled and independent drivers:

> *I'm good now. Yeah. I mean, I went through eight weeks of radiation. I drove myself every day. And that was not a problem.* [Participant 14]

> *My cataract surgery didn't go well. The doctors didn't correct my eyesight properly in my right eye. I use monocular vision. When the car gets too close, I will switch to my left eye by closing my right, allowing me to continue driving despite the challenge.* [Participant 3]

Long-Term, Adaptive Driving Experience

Our participants have driven for 51 (SD 8.54) years on average. This long-term period of driving contributes to fostering confidence to navigate the road effectively. Furthermore, these experiences have instilled a sense of resilience and adaptability, making them feel that driving in comparatively more spacious and less-congested locations is a breeze. This adaptability also positively contributed to their confidence in driving, as their driving skills are up to par, irrespective of the location:

> *I have traveled alone for the last 40 years.* [Participant 1]

> *I'm 77, and I got my driver's license when I was 18. So, I have been driving for 59 years.* [Participant 18]

> *I came to the United States for my graduate study. That's 1986. And I bought a used car. And I started driving regularly.* [Participant 20]

In particular, extensive driving experiences in different geographical characteristics positively influenced the development of adaptive driving experiences among our participants. Participants shared that they had experienced challenging driving environments throughout their lifelong driving experiences, such as driving along the bustling streets or the narrow and crowded roads of the city countless times. Participants expressed how their initial driving experiences in their countries of origin were marked by traffic congestion, narrow roads, and limited parking spaces. Their proficiency in handling diverse driving environments, from lifelong driving experiences in congested cities to more open rural areas, had bolstered their self-assuredness in driving:

> *Once you overcome that by driving in New York, you feel it's just a cakewalk everywhere driving.* [Participant 6]

> *I have no problem driving anywhere, no matter what kind of place it is, whether it's crowded or not because I have driven in India.* [Participant 16]

> *Driving is okay because you know, in Taiwan, the traffic is so bad. And the roads are so narrow. And the parking space is narrow. Up here all the roads are much bigger, and the parking space is bigger too. So, for me, it's easy.* [Participant 20]

Physical Fitness

The prevailing sentiment among our participants about their health conditions was positive. Participants said that their physical health remained in relatively good shape and did not mention any significant health issues. While some participants mentioned minor challenges in their physical condition, such as feeling weaker or less energetic, all of them said that these challenges did not hinder their driving capabilities much. Only a couple of participants shared specific health concerns, such as vision problems due to unsuccessful cataract surgery, or concerns relating to survivors of cancer or those undergoing cardiac rehabilitation. Unsurprisingly, therefore, we found that participants' good health conditions and physical fitness positively affected their perception of being adept drivers. As such, the absence of health issues and mobility challenges contributed to building a sense of self-confidence about driving skills:

> *At the moment, I feel comfortable driving and I don't have any health conditions. That should not be a problem for me driving.* [Participant 8]

> *I can see that my heart lot better after I retired because doing activities and stuff like that. Before I used to work longer hours and I was always tired. But now I have a lot of energy and I can do myself a lot of different things.* [Participant 15]

In addition, a positive perception of overall health conditions led them to believe that their driving abilities could endure for a considerably prolonged period. They associated good health and overall energy levels with their potential to drive effectively, even after retirement:

> *I think I still can drive for the next 20 years because I always believe we have good genes because my dad's life is 100.* [Participant 20]

> *Serious conditions like diabetes or any other conditions may disturb driving, but regular vision or something muscular isn't stopping driving.* [Participant 3]

Challenges Faced in Driving

Overview

While our participants generally held positive perspectives regarding their driving capabilities, a contrasting reality emerged when we delved into the challenges that they encountered while driving. Participants reported a range of challenges stemming mostly from individuals' health conditions and physical declines due to aging, which echoes much prior work [2,19,20,31,32,40,41].

Vision Challenges

Among the challenges frequently highlighted by the participants, aging-related vision issues emerged as a prevalent concern. These included conditions such as nearsightedness, presbyopia, sensitivity to light and glare, and cataracts. The aging process often introduces visual impairments that might significantly impact safe driving [19,41]. Participants acknowledged the obstacles posed by these aging-related vision issues, even when using corrective eyewear. In particular, night driving emerged as a significant challenge for our participants due to reduced visibility caused by inadequate lighting and distracting glares. This discomfort significantly contributed to having a fear of driving at night among our participants. The disruptive effect of the lights from incoming cars was a recurring theme, with participants describing it as "very difficult" and sometimes "blinding." Consequently, participants stated that they voluntarily restricted their driving activities to daytime hours and, in emergencies, reluctantly ventured out at night:

> *I thought I just needed a new eyeglass prescription (for driving? Or in general?), but apparently, I was starting to develop a cataract, so I'm not comfortable driving at night.* [Participant 10]
>
> *When I drive during the night, it looks like the light from across the car is coming too quickly. It's as if you cannot see, and you are suddenly blinded.* [Participant 15]
>
> *I can see clearly in the morning. Probably my, my eyes are aging for the night. I don't drive at night.* [Participant 13]

While various vision changes can influence driving abilities across different age groups, cataracts were mentioned as a significant concern that is directly connected to aging. Participants mentioned issues relating to the development of cataracts as they aged, often noting that they might not immediately recognize their onset:

> *The only issue I have with driving now is night driving, and it's a curious issue. I had a cataract, and I went for surgery, but it didn't go well.* [Participant 3]

Memory Decline

We confirmed that memory decline in older adults is another critical factor significantly influencing their ability to drive safely and confidently. Participants mentioned how memory decline has negatively impacted their driving experiences and heightened concerns about their safety on the road. They expressed a general feeling of reduced alertness in older age compared to their younger years. Although they lacked quantitative data to confirm a decline in their reaction time, they acknowledged a perceptible change in their level of alertness while driving. This sense of reduced alertness can significantly affect their ability to respond promptly to unexpected events on the road, potentially compromising safety, which echoes prior work [35]:

> *I feel that reaction time is slower. But I haven't tested my reaction time.* [Participant 3]

One recurrent concern regarding memory decline among participants was a diminished awareness of their surroundings, particularly when changing lanes or responding to vehicles approaching from the side. Memory lapses were particularly concerning at intersections and stop signs. Participants admitted to being more forgetful when it came to looking both ways and ensuring that there were no oncoming cars. Such lapses in memory can lead to critical oversights and increased risk at intersections, which are the common sites for accidents:

> *I've become a little less likely to notice a car that's coming up on one side while I'm about to change lanes. Also, when I come to a stop sign, I'm a little bit more forgetful to look both ways and make sure there are no cars coming. I don't have any quantitative evidence that there's a decline in my reaction time, but I just don't feel quite as alert as I did 10 or 20 years ago.* [Participant 8]

Medication Routines

Participants mentioned the increasing need for taking medication in their daily routine as a factor negatively influencing their driving abilities. As they confronted more health issues as they aged, participants relied on a more complex regimen of medications to manage various ailments. In particular, we identified the necessity for our participants to take multiple medications daily, often comprising pills for conditions such as high blood pressure, high cholesterol levels, and heart problems. These medications, while vital for health management, can lead to immediate physical discomfort and limitations. For instance, certain blood pressure medications can cause a significant drop in blood pressure upon ingestion, rendering individuals unfit to drive for a specific period, typically an hour. This medication routine apparently translated into challenges and constraints regarding safe driving and might necessitate meticulous planning around medication schedules, often hindering spontaneous travel. Participants emphasized the importance of understanding these risks and the necessity for stringent precautions to prevent any accidental mishaps on the road:

> *I do have heart problems. I take about six pills in the morning. Because some of them are for blood pressure. And then I take three pills at night. So, when you first take the blood pressure pills, they lower your blood pressure very strongly. So, you're not supposed to drive for like an hour.* [Participant 10]
>
> *I have a friend who takes insulin every day; when insulin is shot, you go into a coma, and you cannot*

> *control that car, then I think you really should be clear about driving.* [Participant 18]

Efforts to Sustain Driving

Overview

The participants highlighted the challenges that adversely affected their driving performance; however, most of them did not exert much effort to overcome or address these challenges. Some participants mentioned that they were not aware of any available resources or support to remedy the challenges, while others expressed the belief that they did not need any assistance:

> *I didn't even know something like the resources existed. So, I never thought of that. Is there anything like that?* [Participant 16]

Only a few participants mentioned that they had adopted efforts to maintain their independence, mobility, and safety on the road. They exhibited resilience and resourcefulness in addressing the obstacles posed by health conditions, medication, and aging-related discomfort. The efforts included doing physical exercise, using technology support for navigation, and keeping undistracted focus while driving.

Physical Exercise

Physical exercise emerged as a crucial strategy among our participants to counteract the physical limitations associated with aging and health issues that negatively influence their driving abilities. Participants emphasized the positive influence of regular physical activity on their overall health and specifically on their driving ability. For them, the incentive to exercise stemmed from health-related wake-up calls, such as heart attacks, muscular pains, and so on. These experiences prompted them to adopt a proactive approach to their well-being. Participants acknowledged that engaging in physical activities, such as doing physical exercises and playing sports, vastly helped maintain their driving capabilities, as it improved reflexes and hand-eye coordination. As such, the connection between physical exercises and driving was emphasized as an avenue for honing the reflexes and cognitive skills required for safe and efficient driving:

> *Many times, the number of games you play helps you to be reflexive, and in my case, I play sports that reflect it. It's hand-eye coordination and also keeps you fit. This helps me to drive better.* [Participant 18]
>
> *That's why I'm trying to do a lot of exercise. That's where my muscles don't get lost and get stronger and stronger. We have a good Senior Center exercise program over there. That helped me a lot.* [Participant 15]

Importantly, some participants found community resources invaluable in their quest for physical fitness. Senior center exercise programs were particularly commended for providing structured and accessible opportunities for exercise. These programs offered guidance, camaraderie, and a supportive environment that motivated older adults to stay active:

> *I'm trying to do a lot of exercise. We have a good exercise program at the senior center. That helped me a lot.* [Participant 15]

Technology Support: Navigation Systems

One of the most remarkable and transformative aids in the driving endeavor has been the adoption of GPS and navigation systems. This technological innovation has become an indispensable tool, significantly enhancing the safety and confidence of not only our participants, older drivers, but all individuals behind the wheel. Participants expressed a heavy reliance on GPS devices and navigation systems to bolster their driving capabilities. Some participants were using traditional stand-alone GPS devices, considering them to be highly reliable, while others were using a mobile navigation app, such as Google Maps:

> *I have a very old navigator. I still use that to navigate. I plug in that older one. It's kind of more reliable.* [Participant 13]
>
> *I can use Google Maps and Waze maps, just to feel confident, and I have GPS on my car also. I always put GPS on my car if I had to go someplace, even my sister's house.* [Participant 15]

Before starting the journeys, participants described their predrive routine, which often includes a preliminary check of routes and traffic conditions using Google Maps or other mobile mapping services. This proactive approach gives them a sense of preparedness and certainty about their route, reducing the stress of driving in unfamiliar locations:

> *Before I drive to a place, I prepare in advance; I use Google Maps at home and on the computer.* [Participant 10]

Participants emphasized that the integration of GPS functionalities into modern vehicles has been a game changer. These systems not only presented navigation instructions and route information but also provided a wealth of supplementary data about the car's performance and its surroundings. This additional information enriched the overall driving experience, addressing sensory limitations by offering extra visual cues and audible directions. For example, signage recognition on the dashboard, even when exterior signs might be challenging to discern, provided an additional layer of safety information and reassurance to our participants:

> *Even though I cannot see the sign outside, I'm able to see it on the map in my dashboard, and then it tells me, like the stop signs, exits.* [Participant 16]
>
> *Now you can get a whole display. And you get so much more information about your car than you ever could before.* [Participant 3]

While these technical innovations are not exclusively advantageous for older drivers, our participants undeniably derived significant benefits from using these technologies, which enhanced their driving performance.

Keeping Focus Undistracted While Driving

For many of our participants, driving has become a singular task that demands their full attention. Since the act of driving itself has its inherent cognitive demands, our participants considered remaining mentally agile crucial for maintaining driving capabilities. Therefore, to focus solely on the road while driving, some participants deliberately minimized distractions by actions such as turning off the radio or refraining from engaging in lengthy conversations with passengers. They consider this a necessity, recognizing that their vigilance on the road is a key factor in their continued safe mobility. This deliberate choice reflects their understanding that maintaining their attention span while driving is crucial for their driving performance and safety:

> *I don't turn the radio on. Attention spans should go to driving. And I have other things like even passengers talking to me. I tell them, you have your conversations. I have mine because I must pay attention to the road.* [Participant 13]
>
> *The more you talk, the more active you are, yeah, otherwise I can fall asleep.* [Participant 16]

Discussion

Principal Findings

Our findings demonstrate a significant disparity between self-perceived driving competence among our participants and the challenges they currently face, which are adversely affecting their driving abilities. Our participants consistently expressed confidence in their driving abilities, either contrasting with or regardless of the actual aging-related difficulties. While it is encouraging that older drivers maintain this confidence, the negative consequences of these perceptual gaps are far-reaching and can directly affect driving safety.

The lack of awareness or denial of their limitations can increase the risk of accidents and compromise overall driving safety [34]. For example, when older adults underestimate the significance of their vision challenges or believe that their adaptability can compensate for memory lapses, they may forego necessary medical evaluations and interventions crucial for their safety on the road [1]. Furthermore, the overreliance on a perception of good health and physical fitness can lead older drivers to disregard the potential effects of aging-related physical changes on their driving skills. This can result in underestimating the risks associated with physical discomfort and the need for medication. Therefore, this gap needs to be addressed adequately to help older adults maintain their ability to drive safely and confidently for longer periods.

The self-assurance of older drivers, often stemming from their extensive driving experience and desire for independence, may cause them to hesitate in recognizing limitations imposed by aging-related health factors that affect their driving abilities. This can result in overconfidence and a delay in taking proactive measures to address their challenges. By bridging the gap between subjective confidence and objective impediments, we can reduce the risk of a false sense of security and promote timely decisions for preventive actions while respecting their need for independence and mobility. While numerous prior works have compared older drivers' self-assessed driving skills to those of drivers in other age groups [22], no study to our knowledge has examined older adults' self-assessed driving skills specifically in light of the challenges they experience while driving, which we believe as a key contribution of our work.

In the following sections, we propose several potential solutions to close this perceptual gap based on our findings on the challenges and practices older drivers might face. These include fostering a realistic understanding of their capabilities, encouraging open dialogue about aging and safe driving, promoting regular assessments, and increasing the awareness of available resources.

Foster a Realistic Understanding of Older Drivers' Capabilities

With age, physiological changes inevitably affect various aspects of driving; however, older drivers may not always recognize these changes or may underestimate their impact on their driving abilities. Therefore, the first step in bridging the gap is to cultivate a realistic understanding among older adults regarding their capabilities and their direct impact on road safety and overall well-being. Understanding their capabilities realistically can allow older drivers to make informed decisions about their driving habits. Furthermore, it empowers them to recognize when adjustments may be necessary, such as limiting driving during certain times of the day or in adverse weather conditions or seeking alternative transportation options when needed. By embracing their limitations and taking proactive steps to address them, older drivers can continue to enjoy the freedom and mobility that driving provides while minimizing the risks associated with age-related changes.

As our findings demonstrated, many older adults may not fully comprehend how age-related changes can directly affect their driving abilities. One way to solve this problem is to provide education tailored specifically for older drivers so that we can emphasize the importance of acknowledging and adapting to age-related changes in a positive and constructive manner. This education can include information about common age-related declines in physical and cognitive functions, such as diminished vision or slower reaction times, and how these changes can affect driving safety.

Encourage Open Dialogue for Aging and Safe Driving

Families and friends serve as invaluable resources for discussing sensitive topics in positive and constructive ways. In this regard, having an open dialogue for safe driving with families and friends can provide a platform for older adults to openly address their concerns, challenges, and experiences related to aging and driving. Family members and friends can play a crucial role in recognizing the changes in driving abilities and discussing potential solutions, such as driving assessment programs or alternative transportation options.

Open dialogue can take place within various settings, such as community groups, senior centers, or health care facilities, and can involve discussions with peers, family members, and health care professionals. By encouraging open communication, older drivers can gain valuable insights, support, and advice from others who may have faced similar situations or challenges. Moreover, open dialogue can help to destigmatize discussions around aging and driving, breaking down barriers that may prevent older drivers from seeking assistance or support. Many older adults may feel reluctant to acknowledge age-related changes in their driving abilities due to fears of losing their independence or being perceived as incapable [22,42]. By fostering an open and supportive environment, older drivers can feel more comfortable expressing their concerns and seeking guidance without judgment.

In addition, open dialogue promotes education and awareness about the importance of safe driving practices as individuals age. This includes discussions about the potential effects of aging on driving abilities, such as changes in vision, hearing, reaction time, and cognitive function. By raising awareness of these issues, older drivers can better understand the importance of regular self-assessment, professional evaluation, and ongoing monitoring of their driving skills.

Encourage Regular Assessments

A structured and standardized approach to providing older drivers with realistic insights into their driving abilities and identifying areas that may require improvement or modification can be achieved through regular assessments. This can include assessments of vision, reaction time, cognitive function, and physical mobility. As individuals age, changes in physical and cognitive abilities can occur, which may impact their driving skills. By undergoing periodic evaluations of their driving abilities, older drivers can stay informed about any changes in their capabilities, address emerging challenges proactively, and continue to enjoy the freedom and mobility that driving provides while ensuring the safety of themselves and others on the road.

Furthermore, regular assessments can empower older drivers to stay informed about any changes in their capabilities, take proactive steps to address any emerging challenges, identify potential areas where they may need to adjust their driving habits, and ensure their safety on the road. For example, if an assessment reveals changes in vision or reaction time, older drivers can take measures such as adjusting their driving habits, seeking additional training or support, or even considering alternative transportation options when necessary. Moreover, regular assessments can provide peace of mind for older drivers and their families, knowing that they are actively monitoring their driving abilities and taking steps to maintain their safety [10]. It can also serve as a preventative measure, helping to identify any potential issues before they escalate into more significant concerns.

Increase the Awareness of Available Resources

There exist useful resources and support tailored to addressing the needs of older drivers with their driving skills and overall health conditions [12,14,15]. For instance, the New York State Office for the Aging has the Older Driver and Pedestrian Safety Project, which offers a handbook for families dealing with the issue of an older driver at risk. The state of New Jersey also provides several resources for older adults who drive, including programs to improve driving skills, assessments to evaluate driving capabilities, and services for drivers with medical conditions. In addition, most other states offer similar programs to support capacity-building initiatives for older drivers. Our findings, however, show limited awareness about available resources and support systems designed to enhance their driving safety and skills. Despite the resources and support systems available for older adults, none of our participants were aware of or had used any of these resources. The lack of awareness about resources can impede their ability to adapt to changing conditions and acquire the knowledge and tools necessary to drive safely as they age.

Increasing the awareness of available resources is crucial for older drivers as it provides them with access to support, information, and services that can enhance their driving safety and overall well-being. Awareness of available resources ensures that older drivers are informed about the various programs and organizations dedicated to promoting safe driving practices among older adults. This includes community-based programs; government agencies; nonprofit organizations; and health care facilities that offer services tailored to the needs of older drivers, such as driver education courses, vehicle safety checks, and mobility assistance programs. By increasing the awareness of these resources, older drivers can proactively seek assistance and support when needed, whether it is addressing age-related changes in their driving abilities, exploring alternative transportation options, or accessing adaptive driving equipment and technologies. This empowers older drivers to take control of their driving safety and make informed decisions that prioritize their well-being.

Moreover, the awareness of available resources helps to combat social isolation and promote social connectedness among older drivers. Many of the resources available to older drivers also provide opportunities for social interaction, peer support, and community engagement, which can have positive effects on mental and emotional well-being. By participating in group activities, support groups, or educational workshops, older drivers can connect with others who share similar experiences and concerns, reducing feelings of isolation and loneliness.

Limitations

Our findings must be evaluated in light of several limitations. First, our sample size was small, and all participants were recruited from the greater New York area. Second, most participants were considerably healthier than average older adults. We believe this is because older adults with health issues that prevent them from daily driving might have been naturally excluded due to an inclusion criterion requiring them to be actively engaged in driving as part of their daily routine at the time of recruitment. However, since we focused on studying older adults who drive daily, having a healthier participant pool was inevitable. Consequently, our participant pool may not accurately represent the broader aging population. While we believe that our findings offer valuable insights into understanding current practices and perspectives on older adults' driving practices, further research is necessary to explore how older adults from different sociocultural-technical backgrounds or residing in other regions (eg, rural areas) might perceive this topic differently.

Conclusions

To many older adults, driving is essential for maintaining mobility and independence for aging in place. The absence of driving can significantly affect the overall quality of life of older adults, which results in declines in both their physical and mental health. Therefore, it is important to ensure that these older drivers prolong their driving skills for independence, healthy aging, and overall quality of later life. This study investigated the daily driving practices of older adults and uncovered a noticeable gap between their perceived confidence in driving abilities and the challenges they encountered on the road. This disparity calls attention to a significant need for support that surpasses the actual assistance currently available to maintain driving performance among older adults. Drawing from our findings, we discussed actionable implications and empirical interventions aimed at sustaining older adults' driving capabilities. We are hopeful that these suggestions are valuable for practitioners and researchers focused on enhancing overall well-being and quality of life in later stages toward facilitating aging in place.

Abstract

Background: Case managers for persons with dementia not only coordinate patient care but also provide family caregivers with educational material and available support services. Taiwan uses a government-based information system for monitoring the provision of health care services. Unfortunately, scheduling patient care and providing information to family caregivers continues to be paper-based, which results in a duplication of patient assessments, complicates scheduling of follow-ups, and hinders communication with caregivers, which limits the ability of case managers to provide cohesive, quality care.

Objective: This multiphase study aimed to develop an electronic information system for dementia care case managers based on their perceived case management needs and what they would like included in an electronic health care app.

Methods: Case managers were recruited to participate (N=63) by purposive sampling from 28 facilities representing two types of community-based dementia care centers in Taiwan. A dementia case management information system (DCMIS) app was developed in four phases. Phase 1 assessed what should be included in the app by analyzing qualitative face-to-face or internet-based interviews with 33 case managers. Phase 2 formulated a framework for the app to support case managers based on key categories identified in phase 1. During phase 3, a multidisciplinary team of information technology engineers and dementia care experts developed the DCMIS app: hardware and software components were selected, including platforms for messaging, data management, and security. The app was designed to eventually interface with a family caregiver app. Phase 4 involved pilot-testing the DCMIS app with a second group of managers (n=30); feedback was provided via face-to-face interviews about their user experience.

Results: Findings from interviews in phase 1 indicated the DCMIS framework should include unified databases for patient reminder follow-up scheduling, support services, a health education module, and shared recordkeeping to facilitate teamwork, networking, and communication. The DCMIS app was built on the LINE (LY Corporation) messaging platform, which is the mobile app most widely used in Taiwan. An open-source database management system allows secure entry and storage of user information and patient data. Case managers had easy access to educational materials on dementia and caregiving for persons living with dementia that could be provided to caregivers. Interviews with case managers following pilot testing indicated that the DCMIS app facilitated the completion of tasks and management responsibilities. Some case managers thought it would be helpful to have a DCMIS desktop computer system rather than a mobile app.

Conclusions: Based on pilot testing, the DCMIS app could reduce the growing challenges of high caseloads faced by case managers of persons with dementia, which could improve continuity of care. These findings will serve as a reference when the system is fully developed and integrated with the electronic health care system in Taiwan.

Introduction

The global population of persons living with dementia currently exceeds 55 million. The progressive decline in cognitive impairment and symptoms associated with dementia has a significant impact on the quality of life for patients and families [1] and a global economic cost of US $1.3 trillion [2]. Nearly 50% of the health care costs for persons with dementia stem from informal caregivers such as family members or close friends [2]. Case managers for persons living with dementia who are cared for by informal caregivers provide comprehensive information on medical treatment, caregiving techniques, and social resources, and face additional challenges when providing services for persons with early onset dementia [3]. Case management for these patients involves coordinating assessments, follow-up evaluations, and care, which requires providing caregivers with information about navigating support services available to the patient, as well as the caregiver [3-5].

Taiwan initiated “Long-Term Care 2.0,” which prioritizes dementia care, and within this framework, the focus is on enhancing case management by providing consultations, advice, and support on a regular basis. By 2025, the targeted goal for the percentage of persons living with dementia receiving care facilitated by case managers will exceed 80% [6]. Case management encompasses the coordination and linking of care service resources, which requires case managers to provide regular comprehensive and continuous care services, including monthly consultations, referrals, and service resources, which is based on the severity of dementia, their caregiving needs, and input from caregivers [7]. Currently, each dementia care case manager oversees a caseload with a minimum of 150 patients, which can sometimes exceed 300.

Case managers at community-based dementia care centers use the Dementia Care Service Management System, offered by the Ministry of Health and Welfare, for registration of cases and medical expense reimbursement [7]. However, there is no electronic health care system for managing follow-ups, and integration of health care with health education information is lacking. This leads to duplicate assessments, discontinuities in health education interventions, and the inability to provide timely services. Case managers with no experience or knowledge about certain aspects of dementia care are impacted by the lack of an accessible health education database, requiring them to spend time conducting internet-based searches or reading paper-based health education brochures, which affects their efficiency and confidence [8]. The absence of an established robust information support system that can facilitate data management and easy access to information and education material on dementia care leads to inefficient service and impedes the ability to provide continuous and high-quality case management.

IT in the form of mobile apps, internet-based interventions, and eHealth has been demonstrated to provide support for caregivers of persons with dementia. Mobile apps have been demonstrated to benefit family caregivers of persons living with dementia to help manage their relative’s disruptive behaviors [9] and reduce caregiver burden [10], and an internet-based supportive intervention can reduce caregivers’ depressive symptoms and stress and increase self-efficacy [11]. A systematic review found that eHealth benefited health care staff in long-term care facilities by providing remote consultations for comprehensive assessments and decision-making [12]. Therefore, it should be feasible to facilitate dementia case management with an IT-based support app.

A decision support mobile app for dementia care case managers was designed to increase confidence in their management role. Although overall confidence did not improve compared with a control group, case managers highly recommended the use of the app [8]. This finding and those of studies on caregivers of persons with dementia suggest electronic health care could have significant benefits for dementia care case managers. However, there is no available technology system for case managers in Taiwan. Therefore, this study aimed to develop an IT-based support app to meet the needs of dementia care case managers in Taiwan. We believe the availability of an app that streamlines the organization of case managers’ responsibilities could improve the quality of care provided to persons living with dementia and their family caregivers in Taiwan.

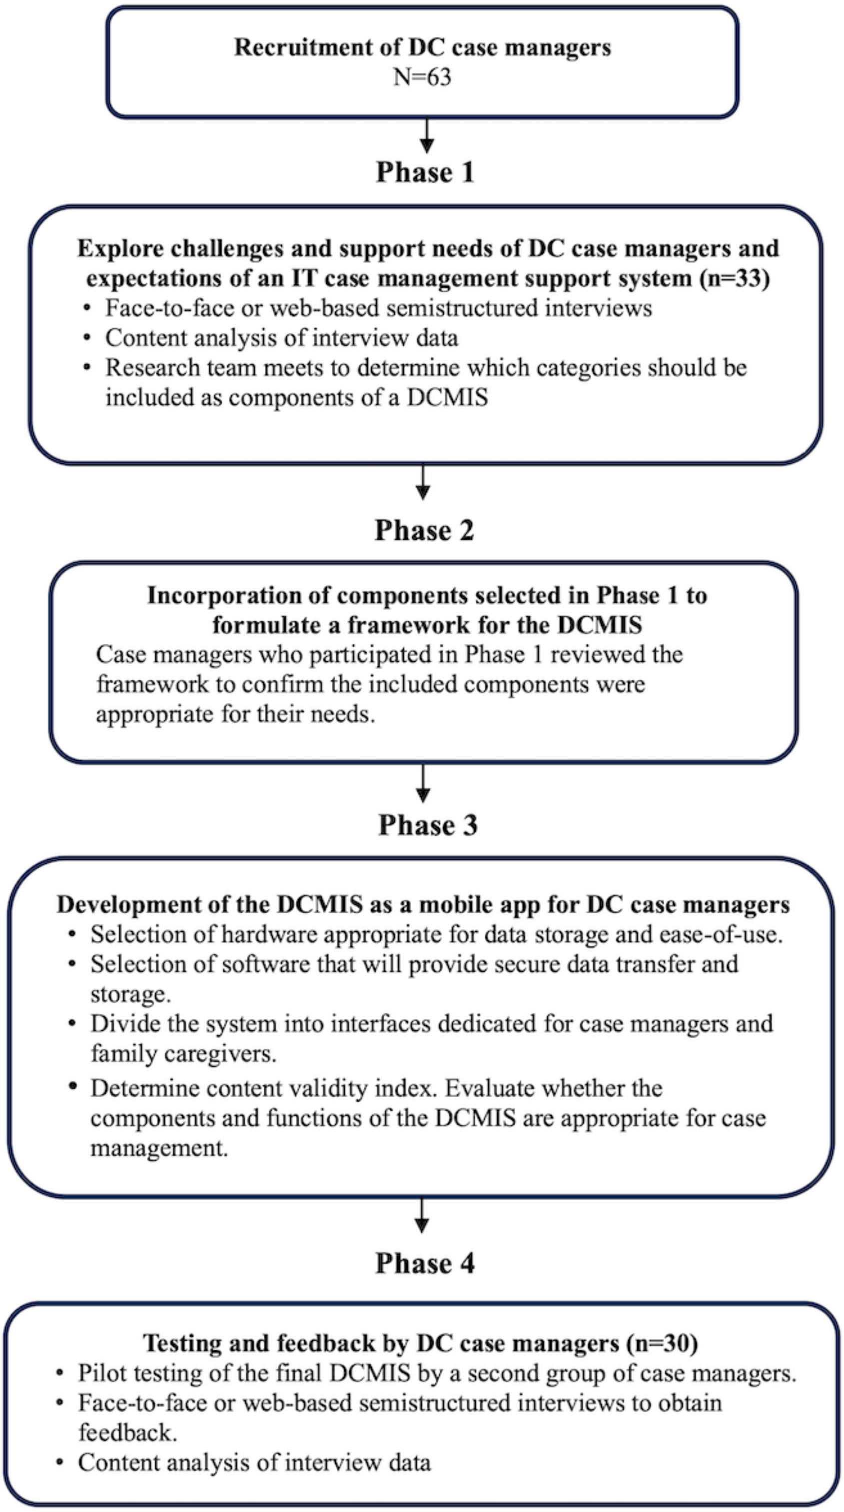
Methods

Study Design

This study was conducted between November 2020 and May 2023. The design of the study was implemented in four phases: phase 1 explored dementia care case managers’ perceived needs and their perspectives about IT support systems for dementia case management; phase 2 formulated the framework of a dementia case management information system (DCMIS) based on the findings of phase 1; phase 3 designed and developed the DCMIS for use as a mobile app and evaluated the validity of the system; and phase 4 pilot-tested the DCMIS app with dementia care case managers (users) and collected user feedback. Figure 1 provides an overview of the study design.

The study is registered at ClinicalTrials.gov (NCT05131789).

Figure 1. Overview of the study design. DC: dementia care; DCMIS: Dementia Case Management Information System.



Recruitment of DC case managers
N=63

Phase 1

Explore challenges and support needs of DC case managers and expectations of an IT case management support system (n=33)

- Face-to-face or web-based semistructured interviews
- Content analysis of interview data
- Research team meets to determine which categories should be included as components of a DCMIS

Phase 2

Incorporation of components selected in Phase 1 to formulate a framework for the DCMIS

Case managers who participated in Phase 1 reviewed the framework to confirm the included components were appropriate for their needs.

Phase 3

Development of the DCMIS as a mobile app for DC case managers

- Selection of hardware appropriate for data storage and ease-of-use.
- Selection of software that will provide secure data transfer and storage.
- Divide the system into interfaces dedicated for case managers and family caregivers.
- Determine content validity index. Evaluate whether the components and functions of the DCMIS are appropriate for case management.

Phase 4

Testing and feedback by DC case managers (n=30)

- Pilot testing of the final DCMIS by a second group of case managers.
- Face-to-face or web-based semistructured interviews to obtain feedback.
- Content analysis of interview data

Participants

Case managers overseeing the coordination of care for persons with dementia at community-based facilities were recruited through purposive sampling from 28 facilities from shared dementia care centers and dementia care community service sites in Taiwan. Case managers were included if they met the following criteria: age 20 years or older, proficient in Mandarin or Taiwanese, and currently employed in one of the above dementia care facilities. There were no exclusion criteria. A total of 63 case managers were recruited to participate.

Development of the DCMIS

Phase 1

During phase 1, semistructured interviews were either face-to-face or internet-based, using Google Meet, based on the preference of each participant. All interviews were conducted with one of two members of the research team (CYK and YLS). Questions followed a semistructured interview guide developed through discussions with members of the research team (Textbox 1). Interviews were recorded and transcribed verbatim. Analysis of interview data was conducted by three members of the research team (CYK, YLS, and HLH) using thematic analysis. Members of the research team met to discuss the findings and determine what identified components were described with the highest frequency by case managers. Any disagreements about what should be included or excluded were discussed and revised until a consensus was reached. Case managers who participated in phase 1 were invited to review the included items to determine whether the components of the DCMIS were relevant to the needs they expressed during the interviews.

Textbox 1. Semistructured interview guide for phase 1: perceived challenges and IT needs of dementia care case managers.

Duration, responsibilities, and experiences of being a case manager

- How long have you been working as a dementia case manager?
- What are the main responsibilities in your role as a case manager?
- How do you feel about the process of performing your duties?

Factors influencing job performance

- What factors influence your performance as a case manager?
- Are there any resources available that could improve your performance as a case manager?

Barriers to fulfilling the responsibilities of a case manager

- Are there any aspects of being a case manager that you find challenging?
- (If yes): What type of assistance would help you navigate the challenge or challenges?

Availability of IT systems

- Do you use any IT system to support your work as a case manager?
- How does this help you with your work?
- Do you feel comfortable or uncomfortable using the system?

IT systems that could improve case management for persons with dementia

- Looking ahead, would you consider using an IT system to assist you in your role?
- Why would you be willing or not willing to use an IT system for support?
- Do you have any suggestions for such a system or the specific type of assistance you would hope would be provided?

Regarding this interview, do you have any other thoughts or ideas you would like to share or discuss?

Phase 2

Phase 2 involved formulating the framework of the DCMIS based on the components identified during phase 1. Dementia care case managers who participated in phase 1 were invited to review the components of the app to confirm whether they were appropriate and functional for case management of persons with dementia.

Phase 3

Phase 3 focused on the development of the DCMIS as a mobile app, which involved an interdisciplinary team comprised of an associate professor from the Department of Computer Science and Information Engineering, two IT engineers, and two experts in dementia care.

The DCMIS operating system was designed to use Microsoft Windows Server 2019 and was based on the LINE (LY Corporation) instant messaging platform. LINE is the most commonly used instant messaging app among Taiwanese, accounting for 77.56% [13]. We used the LINE messaging application programming interface to develop a LINE bot, which requires a webhook URL to receive webhook payloads from the LINE platform. For this purpose, we opted for a secure unified Ingress platform, ngrok [14], which is a proxy server enabling the creation of an HTTP/HTTPS server with a simple command. The ngrok platform was used to establish a secure tunnel with localhost on our local machine, allowing locally running services to be securely accessed over the internet through this tunnel. All responses from the bot server to users are programmed using Python codes stored in an Amazon Elastic Compute Cloud (EC2) virtual machine. The response content can be either text or a hyperlink. It was important that information entered by the users be secure and have cross-platform connectivity; therefore, Hypertext Preprocessor (PHP) scripting language was used, which allows the hyperlink to direct users to a web page where they can securely complete forms such as detailed patient information. The open-source database management system, MySQL, was configured to use the EC2 server for storing user information, patient data, questionnaire items, scoring correspondence tables, and any other needed data. To enhance network security on the EC2 virtual machine, all unnecessary ports were closed and connections for program updates were made using the default remote desktop protocol, which uses a 2048-bit SSH-2 RSA key pair for security. Database security was further enhanced by removing default accounts and using nonroot accounts, applying secure hash algorithm-1 encryption for sensitive data, and scheduling automatic backups.

During this development phase, biweekly meetings were conducted to assess progress, address challenges, and resolve system errors. We also sought consultations with software experts when necessary and feedback from the phase 1 case managers to ensure the DCMIS included all user needs.

Following the development of the DCMIS, four experts in dementia case management were invited to evaluate whether the content of the components and functions of the system were appropriate for case management. Each component was evaluated on a 4-point Likert scale: 1=very inappropriate; 2=inappropriate; 3=appropriate; and 4=highly appropriate. The content validity index (CVI) was calculated as the sum of the scores for each item divided by the number of experts. None of the items had a CVI ≤2, thus none were excluded. Although experts proposed renaming the case management function labeled, “Add/Select Case” to “Case List,” discussions with the research team believed these changes would not impact usability, and no change was made. The CVI for all components was > 0.9, indicating all were acceptable [15,16].

Phase 4

A second group of dementia care case managers participated in using the DCMIS. They then provided feedback on their experiences through face-to-face interviews as described for phase 1, but interviews were guided by a second semistructured interview guide (Textbox 2).

Textbox 2. Semistructured interview guide for phase 4 for case managers’ feedback about using the dementia case management information system (DCMIS) app (n=30).

Experience of using the DCMIS for case management

- What was your overall impression of the app?
- Could you please share your opinions or reactions about the functionality of the components including in the DCMIS?

Impact of the DCMIS on case management

- Do you think the DCMIS with have a positive impact on your work as a case manager?
- Can you tell me more about that?

Changes or modifications needed for the DCMIS

- Do you think there are any additional functions or modifications that should be made to the DCMIS to improve case management?
- Why do you think these are needed?

Other variables about the DCMIS

- Are there any factors that might influence whether you use the DCMIS?
- Could you explain why?

Do you have any other thoughts, ideas, or recommendations about the DCMIS app you would like to share?

Data Collection and Analysis

The collection of interview data and thematic analysis of transcribed interviews were conducted concurrently. Interview data were analyzed with thematic analysis using the method described by Braun and Clark [17]. During phase 1, text was identified to understand the key categories that described case managers’ experiences and perceived needs. During phase 4, text was identified that described the case managers’ experiences of using the DCMIS. For both phases, text was analyzed line-by-line to identify the experiences of the dementia care case managers and coding of the identified text was used to generate the key categories to provide an understanding of the experiences of the case managers [17,18]. The rigor of the interview data was maintained by the credibility of the data, which occurred by allowing other members of the research team to provide feedback about the validity of the analyzed data, and by dependability, which occurred by maintaining an audit trail of the process of data collection and analysis. Confirmability of the findings was provided by peer debriefing sessions; transferability was ensured by comparing the quantitative data with existing research on dementia case management [18].

Ethical Considerations

This study was approved by our institutional review board (phase 1: IRB 202000902B0; phases 2-4: IRB 202100914B0). All case managers were informed of the study’s purpose, procedures, and potential risks before participating. Informed consent was obtained in writing from all participants. The data were anonymized, no personal identifiers were used in the analysis or reporting of the data, and participant confidentiality was strictly maintained. As a token of appreciation, all participants who completed the interview received a US $6 gift voucher.

Results

Participants

A total of 63 case managers were recruited to participate. Phase 1 included 33 case managers with a mean age of 36.7 (SD 10.9; range 23-63) years, most were female (n=29, 88%), and most (n=32, 97%) had a bachelor's degree or higher. The average duration of employment as a dementia care case manager was 28 (SD 19.2; range 6-108) months. Phase 4 included 30 case managers with a mean age of 38.4 (SD 11.5; range 24-62) years, most were female (n=26, 87%), and most had a bachelor's degree. The average duration of employment as a dementia care case manager was 43 (SD 35.6; range 4-156) months.

Phase 1

Overview

Analysis of the interview data indicated that the challenges faced by dementia care case managers were high caseloads and a lack of support services. These were the result of increases in the number of persons with dementia, the time required to enter large amounts of patient data and administrative paperwork, and a lack of support services for themselves, as well as for persons with dementia and their family caregivers. The results of the analysis of the interview data are summarized in Textbox 3. The following information was provided when participants from phase 1 (P1) were asked about what challenges acted as barriers to fulfilling their role as a case manager.

Textbox 3. Challenges and IT needs for case managers (n=33).

Challenges

- High caseload numbers and concomitant increases in paperwork
    - Difficult to keep track of cases
    - Missed follow-ups
- Support services disorganized and complicated to navigate
- Absence of an established health education database
    - Additional time spent searching for material
    - There is no source of material for caregivers
    - No digital database requires carrying large amounts of hard copies
- Little internet-based sources for health education and case management
- Lack of remote data access about patient information

IT needs

- An integrated system with a user-friendly input mechanism
- A comprehensive database of available resources
    - Type and description of dementia care services
    - Type and description of support services
- A detailed health education model
- A communication system to improve patient handover
- A reminder function to identify cases needing assessments or follow-ups
- An itemized list of available dementia education materials for family caregivers

Challenges

One barrier mentioned by nearly all case managers was the significant increase in the size of their caseload. They also mentioned that manpower has not increased accordingly, and therefore, they often miss follow-ups, and the amount of paperwork has increased. Some case managers expressed feelings of powerlessness. One case manager contemplated resigning, saying:

> *Due to the large number of cases, it is impossible to track every case and understand their current status. I feel guilty about this. I have been angry with myself; at one point I considered resigning.* [P1.CM01]

A second barrier mentioned was the absence of a system that lists and describes available support services that address the care needs of persons with dementia. Several case managers mentioned this challenge. The following comment was typical:

> *To be honest, I'm not very familiar with community resources because there are so many types of services.*

> *There are dementia community service sites, long-term care stations, daycare services, small-scale multi-functional services, and respite care services. These things are just too diverse.* [P1.CM16]

Other comments included the following:

> *I'm not familiar with tasks like identification and certification of a disability or hiring a foreign caretaker. I need to study the application procedures and the required documents, which means considerable time spent searching for information.* [P1.CM04]

Case managers also found the lack of a health education database added to their frustration and inability to help patients navigate the system. Case managers described the need to invest additional time searching for health education information for themselves, as well as for patients and family caregivers. Another case manager mentioned family caregivers also found it challenging to obtain relevant information on their own, saying:

> *Some family caregivers don't know where to find these resources and have already begun caring for a family member with dementia (without any information).* [P1.CM26]

The absence of internet-based sources of information about support services and health education material meant that case managers needed to carry large volumes of hard copies. One case manager said:

> *My colleague prints out all the health education materials and case information and puts them in a folder for easy access, but I feel it's inconvenient to carry the folder around for work.* [P1.CM21]

Information Technology Needs

All participants agreed that an IT system would be useful for addressing some of the challenges that were barriers to fulfilling their role as case managers. Making patient data available internet-based would reduce the time required for case management. Although all case managers used the IT systems provided by the government, they expressed frustration that these were not adequate for supporting most of their case management tasks. Some case managers used available software spreadsheets to meet their needs. One participant provided the following description:

> *I believe effective case management requires multiple reminders. These are used as prompts for tracking specific cases on a given day, identify individuals requiring reassessment, and specifying the focus of the current follow-up. I have 20 individuals needing follow-up today. Without the use of an Excel spreadsheet, I would not know which patients will be present.* [P1.CM02]

When asked what should be included in an IT system designed specifically for dementia care case managers, first and foremost was the need for a user-friendly input mechanism. Regarding the components that should be considered, the following were mentioned most frequently: a comprehensive database of resources listing and describing available types of dementia care and support services, a detailed health education module, and a shared platform that would allow communication between team members, which could improve patient handover. Additionally, many case managers emphasized the necessity of reminder functions for efficient case follow-up. One participant explained:

> *At times, due to the demanding nature of our responsibilities, we may overlook pending tasks. With a reminder function, we would be able to identify cases yet to be assessed.* [P1.CM17]

Case managers also believed a health education component should be available, which could be provided to caregivers. Several suggested constructing a needs-specific list of available materials within the areas of dementia care. Case managers could then check a box to indicate materials of interest, which would make it easier to access educational material appropriate for caregivers of their cases. A case manager provided the following example:

> *If a case manager has a client with dementia who is exhibiting behavioral problems, they could check a box next to 'behavioral problems' to generate a list of available educational material that could be provided to the caregiver.* [P1.CM20]

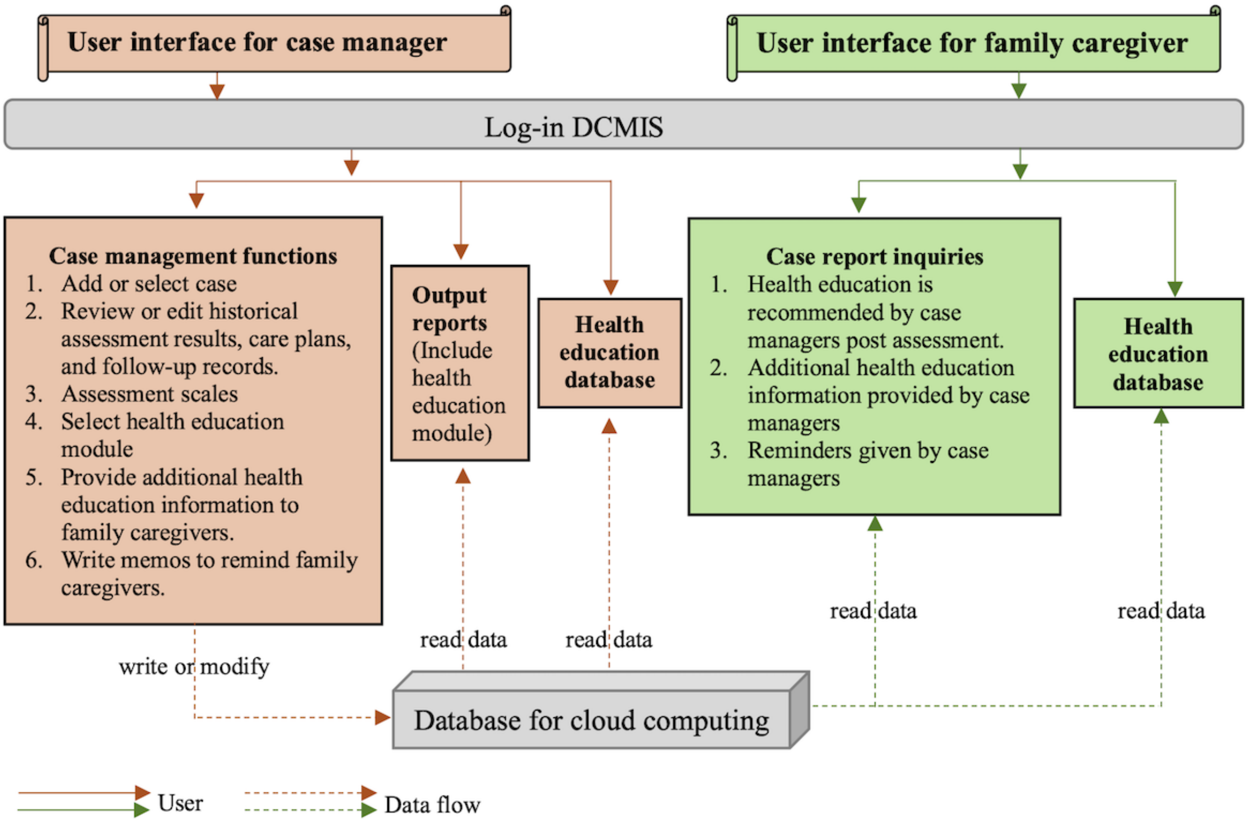
Phase 2

Based on the challenges and needs expressed by dementia care case managers, a framework for the DCMIS was developed. Because interview data showed case managers believed that there should be a component of the DCMIS that could be used by caregivers, the framework included an interface for case managers, as well as one for caregivers. A diagram of the framework of the DCMIS is shown in Figure 2, which includes a schematic of the case manager interface and theoretical interactions with a family caregiver interface.

The case manager interface was comprised of three blocks: case management functions, such as assessments, care plans, and reminders; output reports; and a health education database. The assessment block incorporates comprehensive assessment scales. When conducting case management, case managers can select relevant scales based on the needs of physical and mental assessments for the individuals or caregivers, for example, activities of daily living, brief version, and Chinese version of the Zarit Burden Interview (sCZBI-12). The care management follow-up block incorporates a case management database encompassing patient and family caregiver information, historical assessment results, care plans, and follow-up records. Case managers can review each case, provide care plans, and provide timely reminders for follow-ups. Historical case management data can be exported into reports for review or modification and synchronized with the caregiver interface, which has not yet undergone any clinical trials. The health education database integrates the research findings on dementia [19-24] and existing service resources, which incorporate an introduction to the different stages of dementia, treatments and care, family caregiver support, existing care resources, other chronic disease care, and common health issues. Dementia care case managers can directly select and query the required information from a database. Alternatively, after conducting case assessments, the system automatically and synchronously provides corresponding health education suggestions.

Each block of the case manager interface was designed to facilitate communication with their cases through a family caregiver interface. Although not yet tested with caregivers, the theoretical schematic is included in Figure 2, illustrating how family caregivers will be able to receive health education information, reminders, and follow-up records from the dementia care case managers. Additionally, caregivers will be able to autonomously search for relevant health education content using keywords. Given the prevalence of foreign caregivers hired to provide care for persons with dementia, specific health education materials will include versions in the languages of these caregivers.

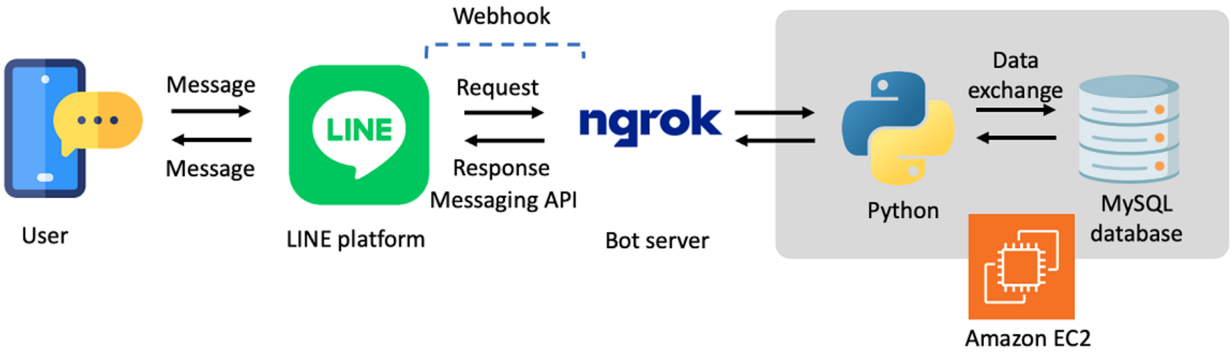
Figure 2. The framework of the DCMIS. DCMIS: Dementia Case Management Information System.



Phase 3

The final architecture of the DCMIS is shown in Figure 3. The use of the LINE mobile app, which is widely used throughout Asia [25], offers portability and freedom from environmental constraints. Case managers download the app to their smartphones, enabling them to perform assessments, health education, and case management. Further clarification and guidance about the use of the app were provided through instructional videos and user manuals.

Figure 3. The final architecture of the DCMIS. API: application programming interface; DCMIS: Dementia Case Management Information System.



Phase 4

Overview

Analysis of interview data with case managers following pilot testing of the DCMIS app indicated that the overall experience was positive because the operation was user-friendly with only a few barriers. Three categories describe case managers' user experiences using the DCMIS app: positive impact, facilitators of use, and barriers to use. Although the focus of pilot testing the DCMIS app was to get feedback about the interface for case managers, when asked if they had anything additional that they would like to share, case managers offered opinions about the caregiver interface, which involved two categories: anticipated benefits and anticipated difficulties. Components of these five categories are summarized in Textbox 4. Some of the specific comments from participants during the phase 4 (P4) interviews are provided below.

Textbox 4. Case managers experiences of pilot testing the dementia case management information system app and their opinions (n=30).

Case managers' experiences

- Positive impact
  - User-friendly operation
  - Enhanced accessibility of patient data
  - Ease of tracking and recording data in real time
  - Simplified interface and logical procedures
  - Reduction in searching for paper-based educational materials
- Facilitators of use
  - Components are time-saving solutions for high caseloads
    - Digital assessment tools
    - Streamlined case management
    - Comprehensive health education database
  - Improved delivery of patient care and availability of information for caregivers
    - Automated reminders enhanced follow-ups
    - Improvements in handovers
    - Comprehensive care information about the trajectory of dementia
- Barriers to use
  - Lack of integration of the DCMIS with the government operating system, which may increase redundancy
  - Availability of the DCMIS as only a mobile app
    - Some case managers preferred using a desktop for data entry; no desktop option
    - Caregivers might view using a mobile app during consultations as impolite or unprofessional

Case managers' opinions about the caregiver interface

- Anticipated benefits
  - Information about the experience of living with dementia
  - A better understanding of caregiving needs for persons living with dementia
  - The ability to access educational material at a time convenient for the caregiver
- Anticipated difficulties
  - Older caregivers might find it challenging to use a mobile app independently
  - Some caregivers prefer being provided with information rather than searching themselves
  - Oral- or paper-based health educational material might be desired by older caregivers

Positive Impact

Incorporating the DCMIS into a mobile app enhanced accessibility to patient data by enabling case managers to seamlessly access and track case information and record data in real-time without temporal or spatial constraints. In addition to the ease of use, the simplified interface and logical procedures were the key factors influencing case managers' readiness to embrace the system. All case managers viewed that eliminating the need to search for supplementary paper-based health education materials reduced their workload considerably. One case manager appreciated being able to perform case management more easily:

> *I feel the app is very convenient. The ability to use my mobile phone with LINE allows me to perform tasks like record keeping and track the status of my cases anywhere, which reduces my workload tremendously. I don't need to bring paper copies with me anymore! Most of my important work as a case manager is away from the office. The app allows to conduct record keeping away from my desk. I think it is very helpful.* [P4.CM11]

Another case manager described why the app was easy to use:

> *The interface is clear, so it's easy to use. Although it took a little time to for me to adjust, when I became familiar with the interface, I understood the logic of it. Once this happened, it was very convenient to use. Including the ADL function is really a time-saver because it calculates the ADL score, which is not always simple.* [P4.CM03]

Facilitators of Use

Case managers reported that the DCMIS would facilitate significant savings in time. They felt the digital assessment tool had a positive impact on work efficiency, which would streamline case management when caseloads were high. The comprehensive health education database was also seen as a time-saving component because it would facilitate searching through stacks of documents and brochures. The generation of corresponding educational modules postassessment content was also considered a time-saver with real-time information delivery to family caregivers ensuring information was received without a delay and the generation of automated reminders from case managers to caregivers would enhance effective case follow-up. One case manager commented on the expectation that the app would improve handovers:

> *I find the presentation format of the output reports very clear. It systematically organizes and presents data and provides a transparent record of actions during the service process.* [P4.CM21]

Another case manager thought that the DCMIS app addressed the complexity of management:

> *Dementia care issues vary at each stage and every condition is unique. This system provides comprehensive care information covering the entire disease trajectory. This includes information that can be shared with family caregivers, which is highly beneficial to our work.* [P4.CM04]

Barriers to Use

One barrier to use that was expressed by some of the case managers was the lack of integration between the government's operating system and the DCMIS. This was a concern because monthly entries into the government system are required for the registration of cases and reimbursements for services delivered. Case managers saw a potential for duplication of efforts if the systems were not integrated. One case manager said:

> *If the DCMIS is not integrated with the Ministry of Health and Welfare's system, my data will need to be entered a second time, which will add redundancy to the system.* [P4.CM28]

The second barrier was that the DCMIS was only available in a mobile version. Some case managers mentioned they preferred a larger desktop system over a small mobile app. Not only was size a consideration, but they also believed that operating a mobile app while simultaneously engaging in clinical responsibilities or having a conversation with a caregiver might have a negative impact on their image as a professional. This was voiced by one case manager, who said:

> *If we are constantly looking at our mobile phones during a consultation, would the family caregivers perceive us as impolite?* [P4.CM13]

Anticipated Benefits for Family Caregiver Users

Case managers mentioned that the DCMIS could enable family caregivers to better understand the experience of dementia for their family members. One case manager said:

> *It could provide family caregivers with information about the current condition of their family member with dementia, which could provide caregivers with a better understanding of the caregiving tasks required.* [P4.CM26]

Another case manager said:

> *Family caregivers can simultaneously access caregiving recommendations or health education information on their mobile phones, which be convenient to reading during their free time.* [P4.CM22]

Anticipated Difficulties for Family Caregiver Users

Some case managers expressed concern that family caregivers might not be able to access and read health education information using an app without the help of someone else. One case manager believed older caregivers might find it challenging to use new technology, saying:

> *I think sometimes family caregivers prefer having information provided to them directly rather than having to do a search themselves, unless they are particularly diligent.* [P4.CM03]

Another case manager had the same concern, although they thought caregivers who were younger would be more willing to use the app:

> *The DCMIS interface may be suitable for younger or middle-aged caregivers familiar with mobile phone use. However, oral- or paper-based health education may be more appropriate for older adult caregivers.* [P4.CM14]

Discussion

Principal Findings

Development of the DCMIS app for dementia care case managers used a multistage process. The framework was designed to meet the needs of case managers, which was guided by the literature on eHealth, as well as qualitative interview data from 33 experienced case managers. The components of the app were examined for content validity and the usability of the app was pilot-tested with hands-on use by 30 case managers. Qualitative interview data provided feedback about functionality and how well the available components aligned with the assistance needed by case managers to benefit their job responsibilities.

The effectiveness and usability of the newly developed eHealth system increases when feedback is obtained from stakeholders who will be the primary users [26-28]. We explored the opinions of case managers regarding not only the type of help the DCMIS should provide but also what they expected in an eHealth app. Firsthand experience of case managers and qualitative interviews following sustained use of the app confirmed the app was feasible for use in a clinical setting.

The incorporation of the LINE messenger app into the system enhanced usability. Most people in Taiwan are already familiar with how to connect to the internet via their mobile phones through LINE messenger, which allows rapid exchange of information and services including text, images and video sharing, and searches [29-31]. This familiarity with LINE further enhanced usability because it was easy for case managers to record, query, and share information. The health education database incorporated into the DCMIS addressed case managers' concern about the problem of time wasted when they needed to manually search through paper-based reports for information on dementia. Finally, the feature of separate interfaces for case managers and family caregivers was designed to allow synchronization of results of assessments and related health education measures allowing caregivers immediate access to patient information before meeting with the case manager. System feedback and individualization are functionalities strongly supported by participants [28,32].

Many of the available platforms have similar functions; however, their applications differ from the DCMIS app for dementia care case managers. Several apps provide support for family caregivers of persons with dementia [9-11,33], video consults and decision support tools to help dementia care nurses and case managers care for persons with dementia in residential care facilities [12], and internet-based training and support for informal dementia carers [28]. An app with similar functions to the DCMIS app is available in Taiwan but its purpose is to provide nurses with tracking information related to location and fall detection for persons with dementia residing in nursing homes [34]. By contrast, the DCMIS app was developed to streamline the work performed by dementia care case managers with a design focused on making it easier to implement dementia case management practices and improving the quality of care for persons with dementia.

The ability of the DCMIS app to help with tracking assessments, care plans, and follow-up reminders, and the inclusion of a health education database will allow integration of the platform with other health systems in Taiwan. Future expansion of the DCMIS to other health care facilities should increase the efficiency of scheduling patient assessments, follow-ups, and receiving test results that require an exchange of information between dementia care case managers and dementia care medical centers, community-based clinics, or home health care providers. Dementia and health care–related assessment tools for behavioral problems, sleep quality, frailty, nutrition, and activities of daily living can be reviewed and associated health education suggestions can be generated. The design of the DCMIS app makes it easier to manage large case numbers by including reminders about when patients need critical assessments or follow-ups so that appointments are not missed. This function will be essential during periods of unexpected reductions in manpower, as occurred during the COVID-19 pandemic. A loss of manpower results in a higher-than-normal caseload, and this reminder function minimizes errors that occur when appointments and follow-ups are paper-based.

The DCMIS app enables case managers to complete multiple tasks on one platform, thus enhancing work efficiency. It is hoped that the system will eventually include an interface with a caregiver app, which will further increase continuity of care. Case managers' concerns that older caregivers of persons with dementia might find it difficult to interact with case managers via an app suggests it will be important to ensure user-friendliness for all ages and abilities when the caregiver app is launched. It is believed this issue will be ameliorated by alterations in the design through interdisciplinary collaborations [35]. Future applications could also include training of current case managers or nursing students.

Limitations

This study had several limitations. First, as mentioned, integrating the DCMIS with the government's operating system to avoid redundancy might not be achievable due to the barriers of integrating the system with Taiwan's IT system, which is based on financial reimbursements. This is in sharp contrast to the DCMIS, which was developed as a tool to improve case management and improve continuity of care. Second, the current DCMIS is only available as an app for mobile phones; it is unclear when it will be available for desktop computers. The convenience of simultaneous assessment and recording was appreciated by some case managers but others were concerned the use of the mobile app might be perceived as disrespectful. Future designs should consider user-friendliness and diversity to align with individual preferences and use habits. Finally, family caregivers were not included in any of the phases for input into their needs or pilot testing of the app and providing feedback, which was due to lack of time and manpower. Future research should include family caregivers to promote better alignment of the DCMIS with their needs.

Conclusions

The growing aging population and increase in the number of persons with dementia present a global challenge to the adequacy of care resources. The availability of a case management app could improve the management of health care for persons with dementia by improving efficiency when managers are faced with high caseloads. Participants who reacted positively to the DCMIS app did so because it was easy to use, and they perceived their caseloads were easier to manage. Our findings suggest that the incorporation of eHealth could enhance efficiency for case managers and improve the quality of care provided to persons with dementia. Our findings can serve as a reference for future research on the development and application of eHealth systems for other case managers. However, a large-scale clinical trial with a larger number of dementia care case managers and multiple health care systems will need to be conducted to quantitatively assess the effectiveness of the DCMIS app on case management outcomes including improvements in patient care and support for family caregivers.

Abstract

Background: Population aging affects society, with a profound impact on daily activities for those of a low socioeconomic status and with motor impairments. Social assistive robots (SARs) and monitoring technologies can improve older adults' well-being by assisting with and monitoring home activities.

Objective: This study explored the opinions and needs of older adults, including those with motor difficulties and of a low socioeconomic status, regarding SARs and monitoring technologies at home to promote daily activities and reduce sedentary behaviors.

Methods: A mixed methods approach was used, with 31 older adults divided into 3 groups: those of a low socioeconomic status, those with motor difficulties, and healthy individuals. Focus groups were conducted, and they were analyzed using thematic analysis. Perceived mental and physical well-being were assessed using the 12-Item Short Form Health Survey, and attitudes toward robots were evaluated using the Multidimensional Robot Attitude Scale.

Results: The results identified 14 themes in four key areas: (1) technology use for supporting daily activities and reducing sedentary behaviors, (2) perceived barriers, (3) suggestions and preferences, and (4) actual home technology use. Lower perceived physical well-being was associated with higher levels of familiarity, interest, perceived utility, and control related to SARs. Lower perceived psychological well-being was linked to a more negative attitude, increased concerns about environmental fit, and a preference for less variety. Notably, older adults from the low–socioeconomic status group perceived less control over SARs, whereas older adults with motor difficulties expressed higher perceived utility compared to other groups, as well as higher familiarity and interest compared to the low–socioeconomic status group.

Conclusions: Participants indicated that SARs and monitoring technologies could help reduce sedentary behaviors by assisting in the management of daily activities. The results are discussed in the context of these outcomes and the implementation of SARs and monitoring technologies at home. This study highlights the importance of considering the functional and socioeconomic characteristics of older adults as future users of SARs and monitoring technologies to promote widespread adoption and improve well-being within this population.

Introduction

Background

Population aging is a significant phenomenon with far-reaching implications for both the economy and society. Worldwide, older adults constitute approximately 13% of the population, with this proportion increasing by 3% annually [1], whereas projections for the United Kingdom suggest that, by 2050, a quarter of the population will be aged ≥60 years [2]. This demographic shift introduces new challenges, notably, a heightened need for health and social services [2] as aging is associated with a reduction in physical and cognitive functioning and an increase in frailty conditions [3-5]. Frailty conditions lead to a reduction in an older person's ability to carry out activities required to live independently, known as activities of daily living (ADLs) [6,7]. To counteract this, there is a global increasing interest in age-friendly environments that may include social or technological innovations [8] that support older adults in remaining independent in their daily lives. In this paper, "daily activities" refer to ADLs. These activities can be physical, such as those needed to manage physical needs, or complex, referring to tasks necessary for independent living within the community [8].

The ability to perform ADLs tends to diminish gradually starting from late middle age and during seniority [9,10] due to a reduction in fundamental physical abilities [11-13]. One method of promoting healthy aging and independence in older age is maintaining an active lifestyle [14]; however, older adults often find themselves spending most of their time engaged in sedentary behaviors [15]. Increased sedentary behavior is associated with a higher risk of mortality and adverse health outcomes [16]. In contrast, the performance of daily physical activities is reported to be linked with various indicators of well-being, including improved mental health [17], reduced risk of chronic diseases [18], a reduction in long-term assistance needs [19], reduced hospitalization rates [20], reduced carer burden [21], and reduced mortality [22]. Thus, national and international recommendations suggest decreasing older adults' sedentary time and increasing time spent in physical activities [23].

In addition to declining physical abilities, factors such as lifestyle, health indicators, social isolation, and socioeconomic status—including household income—can affect the ability of older adults to perform daily activities [24]. Within the socioeconomic context, higher socioeconomic status is associated with better health status [25] and decreased frailty conditions [26], and notably, a lower socioeconomic status is linked to a greater need for personal, instrumental, and environmental support [27]. Therefore, individuals of a low socioeconomic status may have specific needs that ought to be considered when designing interventions to promote healthy aging.

There is a current trend of interventions aimed at improving quality of life for older adults consisting of adapting their environment to enable them to live as independently as possible for as long as possible, known as "aging in place" [28]. Aging in place refers to older adults' capacity to remain in their own homes and communities securely, independently, and comfortably irrespective of their age, financial resources, or functional limitations [29]. Through these interventions, support is provided to enhance the well-being and independence of older individuals while reducing health care costs [30,31]. Importantly, because of the high levels of variation among the older population, care provision needs to encompass a wide range of options, with home-based technology serving as a potential tool to reduce the daily burden on primary carers [32]. Within this framework, smart home technologies, such as monitoring systems and social robots, offer promising solutions for helping older adults maintain independence and age in place, particularly in the context of an aging population and a shortage of care workers [33]. The literature indicates that the integration of home modification strategies into smart homes to monitor daily activities and health is viewed as a key factor in enabling successful aging in place [34]. Systems incorporating these technologies use artificial intelligence models to understand older adult users and make informed decisions, with a primary focus on activity assistance and recognition [35].

Social assistive robots (SARs) have proven to be a valid method of supporting older adults and people with clinical conditions [36,37]. The literature indicates a strong interest in understanding the psychological dimensions of human-robot interaction [38]. SARs offer significant potential to improve the quality of life of older adults by providing physical assistance with ADLs [6,39] and carrying out cognitive assessments [40], which are fundamental aspects of supporting "aging in place" solutions [41,42]. The use of these technologies to promote the well-being and healthy behaviors of older adults has increased in recent years. However, it has been noted that their design may not adequately meet the diverse needs and capabilities of all users due to the current limitations in involving individuals with varying characteristics and of various socioeconomic backgrounds in a user-centered design framework [43]. Older adults often embrace robots, sometimes more than their younger counterparts [44]. However, these relationships between older adults and robots are often complex, with the acceptability of robots differing based on financial availability [45], previous experience [46], and perceived usefulness [6]. Discrepancies between the needs of users and the solutions currently provided by SARs have the potential to diminish their adoption [47]; however, acceptability could be improved by tailoring them to users' needs and issues [48].

Alongside SARs, other technologies can be used to detect specific activities taking place within a designated room [49], allowing for the adoption of more specialized care and home adaptation strategies [50]. One strength associated with these technologies is their capacity to provide objective measurements within the domestic environment [51], thus informing decision-making among statutory providers, family carers, and older people. Various types of sensors, both environmental and wearable, have been widely used in the literature to evaluate and recognize older adults' daily activities [52]. Smart home systems have been widely used to assess daily activities. The most common methods involve environmental technologies, with infrared motion sensors and contact sensors being the most frequently used [53]. Data collected from sensors can be used to detect routines, identify deviations from typical daily activities [54], and monitor potential health issues [34]. Given their potential in the assessment of daily activities and various health-related issues, monitoring technologies installed in older adults' homes play a crucial role in the aging-in-place framework [34] and prompt a discussion on the significance of incorporating users' opinions to enhance the design and usability of these sensors [52].

Objectives

This study aimed to understand the perspectives of older adults regarding the use of SARs and monitoring technologies in their domestic environment to reduce sedentary behavior and promote daily physical activities. In addition, through the inclusion of older adults with motor difficulties and those of a low socioeconomic status, this study aimed to recognize the considerable role that these aspects play in influencing individuals' daily activities, needs, and well-being.

Methods

Study Design

This study used a mixed methods approach, with qualitative data gathered during focus groups and quantitative measures collected through the questionnaires described in the Measurements section. This study used a parallel design in which the collection of both quantitative and qualitative data occurred simultaneously but the data were analyzed separately [55]. This design aimed to create distinct sets of data that informed each other and were later integrated to provide a more comprehensive understanding of the overall topic. The questionnaires were web-based, and reporting of these methods and results was in line with the Checklist for Reporting Results of Internet E-Surveys [56] (Multimedia Appendix 1).

Procedure

This study included older adults from the United Kingdom recruited from June 2023 to September 2023. Participants were contacted through social media, email lists and advertisements from charity groups, care homes, and universities. To be eligible for this study, all participants had to be aged ≥65 years. Participants were divided into three groups according to the following criteria: (1) older adults with a relatively low income, as defined by the most recent UK statistics [57], were considered as the *low–socioeconomic status group*; (2) older adults with reported motor difficulties and needing physical support to move were considered as the *motor difficulties group*; and (3) older adults not in relative poverty, without physical difficulties, and able to live independently were considered as the *healthy group*. Participants were asked to complete an online survey at their own pace and then invited to take part in one of the focus groups. The survey collected demographic information, health information, and responses to the questionnaires described in the Measurements section. Focus groups were planned as qualitative data collection that included participants' reported experiences, with ongoing analysis conducted until saturation was achieved [58]. Focus groups were used as a qualitative research technique due to their advantages in fostering interaction to generate ideas and gain deeper insights into participants' beliefs, attitudes, motivations, and perceptions [59]. This approach allows for a shared understanding of daily life and encourages the use of everyday language. The diverse responses provide a richer understanding of the topic, enabling connections to be made and participants' viewpoints to be continually re-evaluated [59]. These methods were used to obtain both qualitative and quantitative data from participants. A total of 40 participants joined the study. In total, 22% (9/40) of the participants withdrew for various reasons, resulting in 31 participants who remained involved.

Ethical Considerations

Before taking part in the study, participants were provided with information regarding the study and asked to sign an informed consent form. This study was approved by Nottingham Trent University Institutional Human Research Ethics Committee (ID 1726544) and was conducted according to the principles established by the Declaration of Helsinki. The participants were reimbursed for their travel expenses. Data were anonymized.

Focus Group Structure

Participants engaged in focus groups comprising 6 to 8 individuals to explore how SARs and monitoring technologies could support older adults in reducing sedentary behavior and enhancing their daily activities. Before the discussion and instructional phase, participants were informed about the focus groups' objectives and discussion rules. A presentation was organized to introduce the 3 main topics: ADLs, SARs, and monitoring technologies. Daily activities could range from the basics to more complex activities, leading to a distinction between basic and instrumental activities [60,61]. For instance, basic daily activities encompass bathing, feeding, or mobility, whereas instrumental activities comprise tasks such as housekeeping or managing medications and finances [62,63]. Basic and instrumental ADLs were presented through a Microsoft PowerPoint presentation, followed by a live demonstration of various SARs, as depicted in Figure 1A. The showcased SARs—NAO, Pepper, MiRo-E, and TurtleBot 4—represented a diverse range of types, functions, dimensions, movements, and characteristics. The rationale for selecting these robots was to provide participants with examples of widely used SARs, showcasing the widest possible range of variations and features. This selection aimed to enable participants to provide concrete ideas and associations related to these technologies during the focus groups. NAO and Pepper were chosen as humanoid robots, both equipped with a variety of sensors and hands capable of gripping objects. However, they differ in dimensions (58 and 120 cm, respectively), types of interaction, and movement style. A key difference is the ability of Pepper to interact using a tablet on its chest, which is not a feature of NAO. Similarly, Pepper has built-in omnidirectional wheels to maneuver itself, whereas NAO is able to walk in a more human fashion due to having legs and feet containing specific motors and joints. MiRo-E was selected to showcase a more minimalistic appearance with an animal-like design. TurtleBot 4 was chosen as an objectlike robot with a design similar to those commonly used at home. It features a differential drive base and sensors for perception, offering versatility. The research team described each SAR's main features and functions, allowing participants to interact with the SARs during the session. Monitoring technologies were explained through a PowerPoint presentation, accompanied by a physical display of various sensor types to participants (Figure 1B), including ultrasonic, light detection and ranging, pressure sensor, and Xsens. The presentation aimed to equip participants with sufficient information to offer coherent suggestions on the topic and provide a more tangible understanding of the current capabilities of SARs and monitoring technologies. The presentations typically lasted between 20 and 30 minutes in total. This segment was followed by the focus group discussion, which took the form of a semistructured interview. Participants were asked about challenges they face in their daily activities, how SARs and monitoring technologies could assist them in reducing sedentary behavior and in daily activities, and their suggestions and concerns regarding the use of SARs and monitoring technologies in the home. The discussions were audio recorded and then transcribed verbatim. The focus groups typically lasted approximately 90 minutes (range 83-101 minutes) with a 15-minute break.

Figure 1. (A) Social assistive robots. From left to right: NAO, MiRo-E, Pepper, and TurtleBot. (B) Monitoring technologies presented to the participants before the discussion. From left to right: light detection and ranging, Xsens, pressure sensor, and ultrasonic sensors.

Measurements

The 12-Item Short Form Health Survey [64], a short form of the Medical Outcomes Study 36-Item Short Form Health Survey [65], is a 12-items questionnaire that assesses people's perception of their general health according to physical and mental health components. A norm-based standardized score is calculated [66] leading to a physical component score and a mental component score.

The Multidimensional Robot Attitude Scale (MdRAS [67]) is a questionnaire developed to assess people's attitudes toward domestic robots investigating 12 dimensions: familiarity, interest, negative attitude, self-efficacy, appearance, utility, cost, variety, control, social support, operation, and environmental fit. The questionnaire is composed of 49 items on a 7-point Likert scale and reflect people's expectations regarding future interactions with real SARs.. Participants were provided with images of SARs before completing the questionnaire.

Thematic Analysis of Focus Groups

The focus groups underwent a comprehensive thematic analysis following an inductive approach [68] using NVivo (QSR International). This method encompasses several key phases, beginning with familiarization with the data followed by the generation of codes, linking these codes to overarching themes, and subsequently reviewing and defining these identified themes. The final step involves compiling a comprehensive report summarizing the outcomes of the analysis. The fit between the codes and statements was reviewed in a series of research team meetings after each focus group during which codes were revised leading to possible changes, splitting, or conceptual expansions [69,70]. The reliability of the codes was then assessed through cross-coding comparison with a small portion of the overall transcripts. To this end, 2 independent research team members who had not previously been involved in the coding processes were introduced to the coding manual and asked to independently code a sample of 10% of the transcripts, indicating strong agreement between the two coders (k=0.81). Codes were then grouped and refined into themes during a series of meetings, and a final report was compiled. Saturation was considered achieved based on a code frequency count approach, with a stopping criterion established as a new information threshold of ≤5% [58].

Statistical Analysis of Questionnaires

The statistical analysis should be interpreted with caution due to the small sample size and further evaluated in future studies. A preliminary Shapiro-Wilk test was conducted, indicating that the data did not follow a normal distribution; therefore, nonparametric techniques were used. To assess differences in scores related to physical (physical component score) and psychological (mental component score) well-being measured using the 12-Item Short Form Health Survey, as well as attitudes toward domestic robots assessed using the MdRAS, the groups were compared using the Kruskal-Wallis test. If a significant result was obtained, pairwise comparisons were then further evaluated using the Dwass-Steel-Critchlow-Fligner test. In addition, Spearman correlations were performed to evaluate associations between the physical and psychological dimensions and the various attitudes toward domestic robots.

Results

After presenting the characteristics of the participants and groups, this section presents the results of the thematic analysis followed by the quantitative statistical results and their joint outcomes.

Participants

A total of 4 focus groups were conducted with 31 participants divided into 3 groups: low–socioeconomic status individuals, individuals with motor difficulties, and healthy individuals. The groups were balanced regarding age (χ^2_2=2.7; P=.25) and sex (P>.99; Fisher exact test). The groups showed no differences regarding psychological well-being (χ^2_2=1.7; P=.43); however, significant differences were found on physical well-being (χ^2_2=19.7; P<.001), where the group with motor difficulties showed lower scores compared to the low–socioeconomic status group (W=−5.34; P<.001) and the healthy group (W=−5.47; P<.001). Group statistics are reported in Table 1.

Table 1. Description of the participants who took part in the focus groups (N=31).

Variable	Healthy group (n=10)	Motor difficulties group (n=10)	Low–socioeconomic status group (n=11)	Statistical test	
				Chi-square (*df*)	*P* value
Sociodemographic characteristics					
Age (y), median (IQR)	75.5 (70.8-80.3)	71.5 (68.3-75.5)	69.0 (68.0-75.5)	2.7 (2)	.25
Sex, n (%)				—[a]	>.99[b]
Male	4 (40)	4 (40)	4 (36)		
Female	6 (60)	6 (60)	7 (64)		
Health-related characteristics					
PCS-12[c] score, median (IQR)[d]	52.8 (50.2-53.7)	31.7 (22.2-35.5)	52.7 (51.0-54.0)	19.7 (2)	<.001
MCS-12[e] score, median (IQR)	58.7 (51.4-59.4)	59.1 (39.9-60.7)	55.7 (49.3-58.3)	1.7 (2)	.43

[c] PCS-12: physical component score of the 12-Item Short Form Health Survey.

[d] The group with motor difficulties had a significantly lower score on the PCS-12 than the other 2 groups.

[e] MCS-12: mental component score of the 12-Item Short Form Health Survey.

Thematic Analysis of Focus Groups

Overview

The thematic analysis resulted in a total of 14 themes divided into 4 key areas: (1) use of technology to support daily activities and reduce sedentary behaviors, (2) perceived barriers, (3) suggestions and preferences, and (4) actual use of technology in the home. Saturation was achieved. For each theme, we report in Table 2 the percentage of related statements made by each group. In the following sections, the type of user who made each comment is indicated in brackets next to the quotes. The full list of comments by participants for each theme is available at the online repository [71]. In addition, for each theme, it is indicated whether it relates to SARs, monitoring technologies, or both.

Table 2. Joint table of qualitative and quantitative results. Percentages and absolute frequencies of a theme are reported for each group. Quantitative dimensions with common concepts are reported for each theme.

Theme	Group, n/N (%)			Quantitative attitude
	Healthy individuals	LSE[a]	MD[b]	
Use of technology to support daily activities and reduce sedentary behaviors				
Managing daily activities	13/36 (36)	11/36 (31)	12/36 (33)	—[c]
Motivating and stimulating older adults	6/26 (23)	8/26 (31)	12/26 (46)	Familiarity[d]
Providing physical assistance	7/33 (21)	3/33 (9)	23/33 (69)	—
Continuous monitoring of health, safety, and activities	15/45 (33)	11/45 (25)	19/45 (42)	—
Perceived barriers				
Social support	9/36 (25)	19/36 (53)	8/36 (22)	Familiarity[d]
Personal factors	17/52 (33)	22/52 (42)	13/52 (25)	Self-efficacy, negative attitude, and social support
Economic factors	5/18 (28)	9/18 (50)	4/18 (22)	Cost
Privacy	5/15 (33)	7/15 (47)	3/15 (20)	—

Actual use	13/38 (34)	14/38 (37)	11/38 (29)	Utility[f]

[a] LSE: low socioeconomic status.

[b] MD: motor difficulties.

[c] No common concepts between the quantitative dimensions and the theme.

[d] The MD group showed significantly higher scores than those in the LSE group (*P*=.005).

[e] The LSE group showed significantly lower scores than those in the healthy group (*P*=.02) and the MD group (*P*=.001).

[f] The MD group showed significantly higher scores than those in the healthy group (*P*=.01) and the LSE group (*P*=.003).

Use of Technology to Support Daily Activities and Reduce Sedentary Behaviors

Managing Daily Activities (SARs and Monitoring Technologies)

Participants reported that SARs and monitoring technologies could support older adults in managing their daily activities, which could help in reducing sedentary behaviors through reminders to be active or suggesting specific exercise routines and physical activities:

> *I wouldn't want it to do anything physical...but I think mentally it could be good, you know, as a reminder thing. Like, doing some exercises or something like that, yeah.* [Healthy individual]

> *...well one of the things we could potentially look at doing would be to get a robot doing a kind of exercise routine with people.* [Healthy individual]

Alternatively, they may be a useful reminder of specific events or activities, medications, and maintaining social connections:

> *...a diary and, you know, you wake up in the morning and think "have I got anything today?" you know, you could ask...or press a button, "what's on today?"* [Low–socioeconomic status individual]

> *...It could remind me, you know, "you need to call your aunty" or I think, if you could ask it, as I've said before, like a diary. You'd be able to go out, maybe to your garden, you know, and maybe it would do a conversation. Or "you need to take medicine."* [Individual with motor difficulties]

Motivating and Stimulating Older Adults (SARs)

Participants reported that a possible consequence of using SARs was that they could make people lazier:

> *...the thing that worries me is that it could encourage you to become lazy It would be too easy to do nothing.* [Low–socioeconomic status individual]

However, it was suggested that the way in which SARs are implemented could have the opposite effect:

> *...the other issue, of course, is that they can encourage people to occasionally get up and do something rather than just sit.* [Low–socioeconomic status individual]

The activities suggested by SARs do not necessarily need to be physical but they can also involve other types of tasks:

> *I have a (older adult) friend whose main activity is jigsaw puzzles...I'm wondering whether something like this sat on the table next to him wouldn't actually place the piece for him, but would point out the piece and where it might go.* [Low–socioeconomic status individual]

This may be especially true if motivation to complete daily activities is limited:

> *...sometimes, if I'm not very well I don't always want to get out of bed...but maybe extra support...would help.* [Individual with motor difficulties]
>
> *...to me it would have to, sort of, push you type of thing.* [Individual with motor difficulties]

Providing Physical Assistance (SARs)

Older adults indicated that SARs were suitable aids designed to offer physical support in some scenarios—"...so when you can't walk, it would walk for you, you know, but you'd be inside it or walking with it" (individual with motor difficulties)—or provide assistance in daily tasks requiring more strength than older adults may have, such as shopping, or tasks requiring grip strength—"I can drive in car and fetch shopping but its getting all the bags from the car" (individual with motor difficulties) and "I think the robot is beneficial because they can open things. Things like gripping and holding. That's something that deteriorates with age" (individual with motor difficulties)—which could foster their independence:

> *...maybe it could help to be a bit more independent. I don't need to have another person 24/7, but it could be a device that can help me with some tasks everyday.* [Low–socioeconomic status individual]

Continuous Monitoring of Health, Safety, and Activities (SARs and Monitoring Technologies)

Participants expressed that a strength of SARs and monitoring technologies is that they can support continuous care for older people:

> *...the side of looking after someone who does need 24/7 care, it's a good thing. But there are a lot of things to take on board.* [Low–socioeconomic status individual]

This could assist carers in monitoring older adults' whereabouts:

> *...she can have a tracking device just popped in her bag, and then with a smart phone someone can always know where she is. I think that might be a good idea. I mean, she lives on her own independently, but at least you can keep an eye on them.* [Individual with motor difficulties]

In addition, it could provide peace of mind for carers overnight:

> *I think there are benefits for carers in terms of if you are a carer, say at night time...Because it's actually really difficult if you're a carer. You never really sleep. You're constantly on the alert in case the person you're looking after is needing help.* [Individual with motor difficulties]

According to participants, the monitoring systems should encompass emergencies and risky situations alongside general monitoring for the benefit of both older adults and carers:

> *...you would know that she's just safe. Or if something did happen, you'd know to go over to them.* [Individual with motor difficulties]

Social Support (SARs)

Participants emphasized that loneliness is a significant problem for older adults:

> *...if you're looking at really old people that you're trying to help, they probably wouldn't have a lot of interaction. That's what I find. They don't have an awful lot of interaction.* [Low–socioeconomic status individual]

Consequently, SARs were identified as potential social partners to alleviate loneliness:

> *...you could say, well yeah I want to talk about [this topic] and it already knows about it so it can have a discussion, you see that? That would be very helpful.* [Individual with motor difficulties]

This could also be in addition to other daily tasks:

> *...it could be while you're doing something as well, because it can follow you, so if you're having a conversation, the cameras are pointed at you, so you can keep up with you and stuff.* [Individual with motor difficulties]

However, some participants expressed reservations about SARs replacing human interactions:

> *I don't know if these would ever get to that point...It couldn't ever be human, obviously.* [Individual with motor difficulties]

Moreover, an additional feature reported by participants related to loneliness was supporting older adults' social connections and communication with others:

> *...if we had something like, say, Pepper, which has a screen on it as well. Or like the Turtle one back here that could almost be like a video conferencing robot.* [Low–socioeconomic status individual]
>
> *...we can have an exchange by texting...that's quite a useful thing... [Healthy individual]*

Perceived Barriers

Personal Factors (SARs and Monitoring Technologies)

The discussion highlighted various personal factors among participants that could pose challenges in using technologies and staying active. According to participants, personal motivation emerged as a crucial factor in maintaining activity levels:

> *I think it's a bit dependent on yourself isn't it, really. It's how much you want to keep going.* [Individual with motor difficulties]

Many participants identified physical difficulties as significant barriers that arise with aging and highlighted specific daily challenges:

> *It's the ageing body, it gets harder. Physical activity gets harder, and you have to push yourself more. It's quite easy when you're 20 to go and run, but it's harder when you're old.* [Individual with motor difficulties]
>
> *I have trouble cleaning me windows and that; changing the bed because I get dizzy and lose my balance.* [Individual with motor difficulties]

In addition to physical challenges, participants discussed perceptual issues and cognitive difficulties:

> *Sight deteriorates. Even with glasses, it can still be a problem when you get older.* [Healthy individual]
>
> *I tend to just forget things until someone else tells me that I should do something.* [Low–socioeconomic status individual]

These factors may act as barriers, adding to the difficulties in adapting to and familiarizing themselves with new technologies:

> *Just as we're older, um, we would find it more difficult to understand what we have to do.* [Healthy individual]

Participants also observed that these challenges may lead to stress due to cognitively demanding situations, a possible sense of lack of control, or fears of technology breaking down:

> *I can't handle too many things at once sometimes. I'm afraid it overwhelms me.* [Healthy individual]
>
> *It's got to be under my control.* [Low–socioeconomic status individual]
>
> *I'd be worried if it would break down. I'm always worried that my computer is not going to fire up or something. So I'd certainly been concerned about having one of these in the house.* [Low–socioeconomic status individual]

Participants acknowledged the need for support in using these technologies:

> *I would need help, obviously. Sons, daughters, anybody, but yes I would definitely.* [Healthy individual]

Economic Factors (SARs and Monitoring Technologies)

Participants expressed concerns about the cost of these technologies:

> *...one thing is, well to me, what's the cost of these things going to be?* [Individual with motor difficulties]
>
> *...just how much is it going to cost, I can imagine it would be quite an expensive luxury.* [Low–socioeconomic status individual]

This suggests that the affordability of such technologies is a crucial factor to consider, raising questions about potential financial support or subsidies:

> *...but how would that be financed? Because I mean, a lot of old people, they hardly have money to pay their bills and put food on the table.* [Low–socioeconomic status individual]

Interestingly, participants suggested rental periods as a possible solution, expressing the following idea:

> *...the ideal thing would be able to ring a robot center and say, "oh right, I'm at so-and-so address, send me a robot" and then have it for a day.* [Individual with motor difficulties]

Privacy (SARs and Monitoring Technologies)

The participants' statements underscored significant apprehensions surrounding the privacy implications of SARs and monitoring technologies. Concerns regarded the extent of personal information collected, questioning its storage, custodianship, and the entities involved:

> *...how much personal information, and how much is collected—where is it and who is dealing with it? That's another story, and that's a thought.* [Individual with motor difficulties]

For instance, participants pondered the potential future uses of these data:

> *How is it used in the future? How is your life insurance, health insurance, going to use this?* [Individual with motor difficulties]

The discussion highlighted the importance of consent in the context of tracking individuals, emphasizing that individuals must willingly agree to be tracked:

> *...they have to agree to it. You can't track somebody if they don't want to.* [Healthy individual]

Spatial Issues (SARs)

Older adults emphasized practical considerations and challenges associated with the deployment of these technologies within households, particularly in the context of navigating physical spaces:

> *...you'd have to have the room, like space, as well around your house for it to go in different rooms.* [Low–socioeconomic status individual]

Participants highlighted the need for obstacle detection and avoidance mechanisms to prevent collisions and property damage:

> *...well, it needs to sense, I suppose, where the barriers are...it would need to be able to get over them without tripping or getting stuck in a certain place or whatever. Yeah, so I think that is something you need to consider and think about. And of course, every house is different.* [Individual with motor difficulties]

> *...be able to sense objects around him so that, you know, it doesn't run into tables and break things.* [Healthy individual]

Suggestions and Preferences

Number of Devices (SARs and Monitoring Technologies)

Participants discussed their preferences concerning the number of SARs and monitoring technologies at home. Divergent opinions emerged during the conversation, with some participants expressing a preference for all-encompassing, multitasking SARs or single monitoring sensors:

> *If they're going to get one it's got to do everything.* [Low–socioeconomic status individual]

However, a consensus on this viewpoint was not reached as other participants advocated for a more specialized approach, suggesting different technologies for distinct tasks:

> *I'm not sure it would be a single robot. You know, I think with everything we've got...you can't have one that does everything, and that certain tasks are done by certain pieces of technology, you know.* [Healthy individual]

A nuanced perspective emerged, arguing that the ideal number of SARs and monitoring technologies should be contingent upon an individual's specific circumstances, such as the following:

> *It's like having a sensor in the living room in case you fall. But if you fall in the hallway, you haven't got one, have you? So, depending on how badly you are or how incapable you are of doing things. It would depend on obviously the size of the house or the room. If you're in a one-bedroom flat and it's all on ground level you don't need that much, do you? It depends on the situation of the particular person.* [Healthy individual]

Physical Characteristics (SARs)

Participants expressed a range of opinions regarding the physical characteristics of SARs, demonstrating diverse preferences and considerations. Some participants favored humanoid robots, appreciating the humanlike features:

> *I like that one as well [Pepper]. Its more connected to you as a human. You know, you feel like you could talk to it and it understand you more because it looks at you.* [Healthy individual]

In contrast, others leaned toward nonhumanoid designs, emphasizing their distinct robotlike appearance:

> *...it [TurtleBot] looks more like a robot than the others. It's much more like an object.* [Healthy individual]

Practical considerations emerged as a unifying theme among participants, with agreement that the design of SARs should be task oriented:

> *...well it depends on what the task is its doing, doesn't it? I mean, we assume a robot is in the form of a human being, but a lot of robots aren't.* [Individual with motor difficulties]

> *...the consensus is that they don't need to be humanoid. A box on the decks...could be quite configurable depending on who you are and what you want it to be. But there are limits...that's why there might be a range of robots in a different environment.* [Individual with motor difficulties]

Participants also expressed a preference for smooth movements, emphasizing the importance of versatility in motion:

> *...it would have to move in every direction. Spin round, bend forward, reach up.* [Individual with motor difficulties]

An additional concern raised was discomfort with SARs staring, particularly when not interacting, highlighting the importance of social cues and behaviors in shaping participants' comfort levels:

> *...well it just tends to stare at you a lot, and even when you're not talking to him, his hands and arms and that are moving and it makes you think "oh, well what's he going to do?"* [Low–socioeconomic status individual]

Regarding animal-like SARs, participants expressed the view that, if SARs are to have animal-like characteristics, they should be realistic, featuring fur and tactile qualities:

> *...it would need to have fur, erm, and be a bit more tactile.* [Low–socioeconomic status individual]

However, despite this acknowledgment of realism, participants tended to dislike the animal-like designs:

> *...well just because it's a cute little thing that's all—it's more like a distraction.* [Individual with motor difficulties]

Participants also acknowledged that, while petlike robots could offer more than just the companionship of a dog or cat, they might be perceived more as toys:

> *...it gives them more than just a, you know, dog or cat, so I think there is some good but I think it would be more of a, um, well a toy perhaps.* [Low–socioeconomic status individual]

In fact, a noteworthy trend among older adults was the expressed preference for SAR designs that differed from toys:

> *It sort of looks like a toy [NAO], don't it? I would imagine if that's the same size a pepper, it would be more robotic, a bit more visual that it's a robot more than a toy—only because of its size.* [Individual with motor difficulties]

This characteristic was deemed important as participants expressed the view that SARs should not resemble toys and should not be perceived as such by adults:

> *I think they can be nice, and cute, and not scary for children—they are like toys but they are not to us.* [Individual with motor difficulties]

Personalization and Remote Control (SARs)

The focus groups provided valuable insights into participants' preferences and expectations for the customization of SARs. Participants emphasized the importance of adjustable volume, particularly for individuals with hearing difficulties:

> *...well something where you could turn it up, since I'm a bit deaf. There is those that are hard of hearing.* [Low–socioeconomic status individual]

The participants discussed the idea of customizable voice options, for instance, allowing users to choose between different genders and accents:

> *...yes, and then you can select whether you want a ladies voice or a gent, or a softer voice—American accent, Australian accent.* [Individual with motor difficulties]

This suggestion reflects the importance of the diverse preferences that users may have regarding the characteristics of SARs. In fact, the concept of customizable interactions based on individual preferences was also brought up:

> *I think this is something that can be customized, for some people who really love the interaction and then for those who don't. If you like someone staring into your eyes it can do that but otherwise it can be a bit sideways maybe.* [Healthy individual]

Similarly, a participant stated the following regarding the information used by SARs to enhance user experience:

> *...it would give you information on what's happening. But I suppose you would have to get used to it, wouldn't you—customize him to your way of thinking.* [Individual with motor difficulties]

Participants highlighted the convenience of voice activation over buttons, aligning with the idea of making SARs user-friendly and accessible, allowing for multitasking and seamless interaction:

> *A voice activation would be easier. I'm not good with buttons.* [Individual with motor difficulties]

> *...it allows you to multitask, you know. You could be getting ready for work and you can chat at the same time, you know, "what's the weather today?" you know, and you can still be getting ready.* [Healthy individual]

In addition, some participants raised concerns about batteries and expressed a preference for SARs with the capability to recharge themselves:

> *...if you've got someone with Alzheimer's or limited ability to move, you'd need them to be self-charging.* [Low–socioeconomic status individual]

Use (Monitoring Technologies)

The discussion on monitoring technologies addressed wearable and environmental sensors. Participants highlighted the advantages of wearable sensors, noting that they can be used wherever the person is located:

> *I think it would be useful to wear something because then it doesn't matter where you are, it will pick you up.* [Healthy individual]

However, concerns were raised about the potential for losing these sensors or forgetting to put them on:

> *...you still might lose it somewhere. Might end up wandering into our storage cupboard!* [Low–socioeconomic status individual]

> *I'd probably forget to put it; I don't have a good memory so I'd probably forget to put it on.* [Low–socioeconomic status individual]

In contrast, these concerns did not apply to environmental sensors:

> *Something wearable is always with the person as long as they remember to put it on, but something in the room is always there, you know.* [Healthy individual]

Overall, participants reached a consensus that using both types of sensors would be more beneficial:

> *If you take it off because you've been in the bath and then forget to put it back on, it's not helpful. If you have both, then if you fall or something, it would serve both purposes.* [Healthy individual]

Importantly, participants stressed the need for strategic placement of environmental sensors, prioritizing areas of higher risk for older adults:

> *...the bathroom is a really bad place to fall because there's a lot of hard surfaces and if you slip on a wet patch or something, then you're more likely to injure yourself.* [Individual with motor difficulties]

> *...on the stairs. I think it's a good thing. Because if you, I think you're on that surface, you're more likely to fall.* [Individual with motor difficulties]

Participants also suggested that familiarity with sensor technology could contribute to its acceptance and integration into daily life:

> *I mean, if you've got a burglar alarm in your house, you've got sensors like that. I don't look at mine. Once they're there you should get used to it.* [Low–socioeconomic status individual]

Actual Use (SARs and Monitoring Technologies)

Some participants conveyed both their efforts and enthusiasm to keep up with technology:

> *I always try to keep up to date with technology. I've got two sons who ensure that they do keep up to date with it. Otherwise, there's a gap between the two generations.* [Low–socioeconomic status individual]

> *...yes I would use it, definitely, because I like, you know, I like new technology.* [Individual with motor difficulties]

However, others expressed difficulty in doing so and a reluctance to embrace new technology:

> *I don't think our generation is capable of doing it now. I think we're too old.* [Low–socioeconomic status individual]

The belief in the future prevalence of these technologies was a common sentiment among participants, drawing parallels with other technologies:

> *I think these things are already, kind of, with us and probably are only going to increase as technology, you know, the rate at which technology has happened is, you know, only going to continue along that upward arc, I think.* [Healthy individual]
>
> *I think even if you think about phones. Not that long ago no-one had them and yet now people don't go anywhere without them.* [Individual with motor difficulties]

They also speculated about the integration of SARs and monitoring technologies into health care:

> *...it is something that, you know, in the future, hospitals—doctors, physios, occupational, you know, people—will recommend and prescribe something like this.* [Low–socioeconomic status individual]

Importantly, participants emphasized their willingness to embrace the use of SARs and monitoring technologies if they proved helpful and could be incorporated into daily tasks:

> *...if I needed help I would use it.* [Individual with motor difficulties]
>
> *I'd want a robot to help me with all the things I need to do if I found I couldn't do them myself. I would be reluctant, and probably a bit resistant but I'd want it to help me.* [Healthy individual]
>
> *I could see them being very helpful to lots of people—to be helpful it's got to do the things you want it to do.* [Healthy individual]

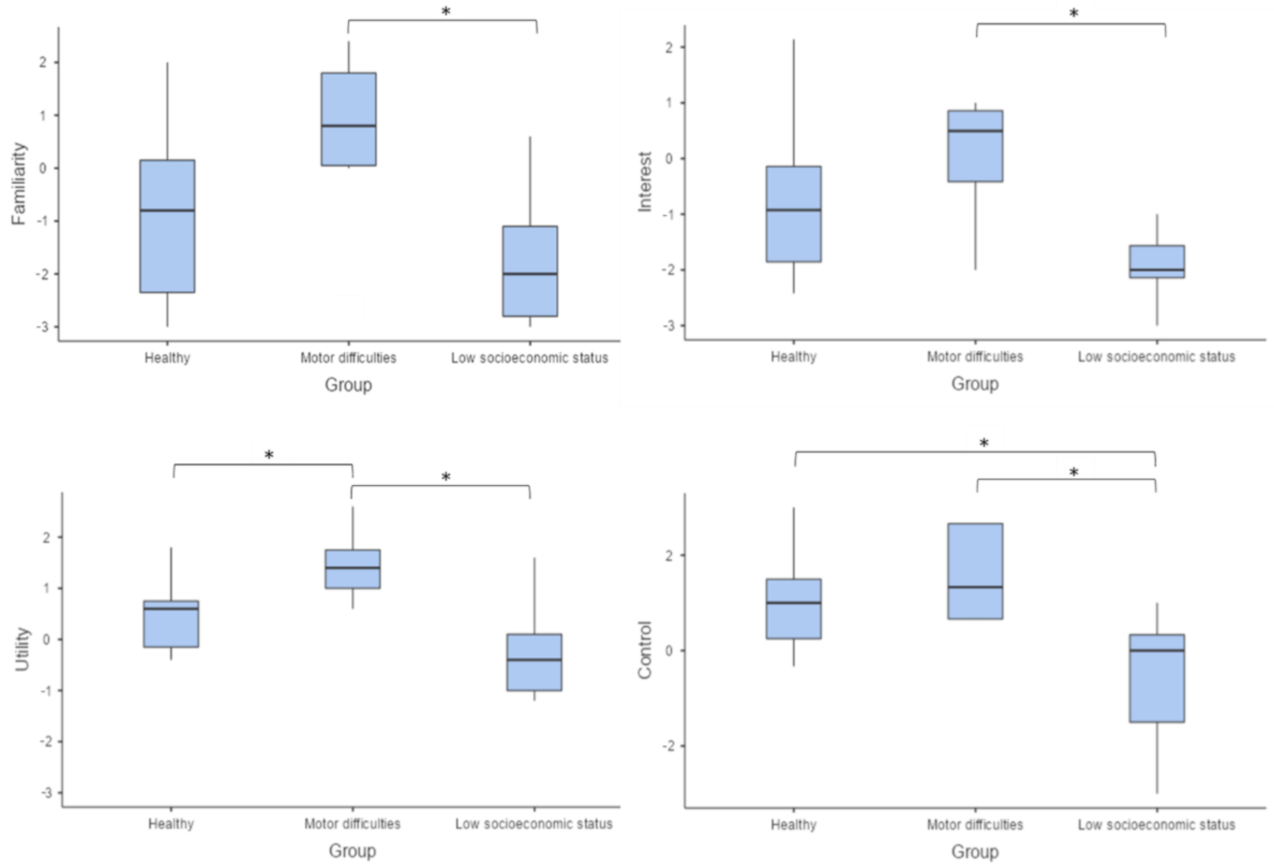
Statistical Analysis of Questionnaires

Spearman correlations indicated that older adults' perceived well-being was associated with attitudes toward domestic robots, assessed using the MdRAS. Specifically, physical well-being was significantly associated with the sense of familiarity with (r=−0.409; P=.02) and interest in (r=−0.381; P=.03) SARs, as well as with perceived utility (r=−0.592; P<.001) and control (r=−0.559; P=.001). This suggests that, as a person perceives lower physical well-being, they report higher levels of familiarity, interest, perceived utility, and control related to SARs. Psychological well-being was significantly associated with a negative attitude toward SARs (r=−0.397; P=.02) and environmental fit (r=−0.394; P=.02), indicating that lower perceived psychological well-being is linked to a higher negative attitude and increased concerns for environmental fit. In addition, psychological well-being was positively associated with variety (r=0.553; P=.001), suggesting that people with lower psychological well-being prefer less variety in domestic SARs.

The group comparison revealed significant differences in the dimensions assessed using the MdRAS: familiarity (χ^2_2=10.8; P=.005), where the group with motor difficulties showed higher perceived familiarity with SARs than the low–socioeconomic status group (W=−4.39; P=.005); interest (χ^2_2=12.0; P=.003), with the group with motor difficulties showing higher interest in SARs than the low–socioeconomic status group (W=−4.60; P=.003); utility (χ^2_2=14.5; P<.001), where the group with motor difficulties showed higher perceived utility of the SARs than the healthy (W=−3.88; P=.01) and low–socioeconomic status (W=−4.69; P=.003) groups; and control (χ^2_2=13.2; P=.001), where the low–socioeconomic status group perceived less control over SARs compared to the healthy group (W=−3.67; P=.02) and the group with motor difficulties (W=−4.91; P=.001). A graphical representation is shown in Figure 2.

Table 2 is a joint table of the qualitative and quantitative analyses. The results show that the group with motor difficulties showed significantly higher scores than the low–socioeconomic status group on the familiarity dimension assessed using the MdRAS, indicating a greater interest in using SARs for the related qualitative themes of motivation and social support. In contrast, participants from the low–socioeconomic status group reported lower perceived control over using SARs at home, highlighting that addressing the needs reported for personalization and remote control features may affect their acceptance. Although participants expressed a willingness to use these technologies if they were beneficial, the utility dimension of the MdRAS indicates that the group with motor difficulties perceived SARs as more useful, suggesting that they may have a higher acceptance of this technology.

Figure 2. Box plot of the groups' scores on the familiarity, interest, utility, and control subscales of the Multidimensional Robot Attitude Scale indicating the groups' attitudes toward domestic social assistive robots. *P<.05.



Discussion

Principal Findings

The aim of this mixed methods study was to understand how healthy older adults, alongside those with motor difficulties and of a lower socioeconomic status, perceive the usefulness of SARs and monitoring technologies in the home to reduce sedentary behavior. This study identified key themes across 4 areas: the use of technology to support daily activities and reduce sedentary behavior, perceived barriers, preferences, and actual home technology use. In terms of using these technologies to assist with daily activities, participants highlighted their potential to help manage tasks, motivate and engage users, provide physical assistance, monitor health, and ensure safety. Perceived barriers included the need for social support, personal and economic limitations, privacy concerns, and spatial constraints. Suggestions focused on preferences for how many technologies they would like at home, desired features for SARs, the need for personalization and remote control, and how monitoring technologies should be used. Importantly, participants indicated that they would adopt these technologies if they effectively addressed their specific needs. These themes reflect how older adults suggest using these technologies to support their daily activities, as well as their preferences and concerns that should be addressed in the design and implementation of these solutions. Importantly, socioeconomic status and motor difficulties influenced perceptions. Older adults from lower socioeconomic backgrounds felt less control over SARs, highlighting the need to carefully consider these factors when designing for this group. In contrast, older adults with motor difficulties found SARs more useful, indicating that this group may have higher expectations and motivation to use such technologies. Notably, lower physical well-being was associated with greater interest in, familiarity with, and control over SARs, whereas lower psychological well-being was linked to more negative attitudes and concerns about environmental fit. Overall, this study underscores the importance of tailoring SARs to the specific needs of older adults to encourage adoption and improve their well-being.

Thematic analysis of the focus groups resulted in 14 themes outlining perceived needs and overall opinions on how these technologies may be used within older adults' domestic environment. Participants indicated that SARs and monitoring technologies could help reduce sedentary behaviors by assisting in the management of daily activities and through providing motivation and stimulation. Many of the suggestions involved providing reminders, establishing routines or programs, and monitoring levels of sedentary behavior. The management of daily living activities poses a challenge for older adults and especially for health care professionals. Enhancing older adults' ability to manage these activities has a significant impact on overall daily living [72].

Motivation is a key element when considering engagement in any physical activities, for instance, through highlighting potential benefits that the activity may entail [73]. When involved in the design of interventions or products to support physical activity, older adults tend to emphasize this motivational aspect [74]. Therefore, designing SARs and monitoring technologies aimed at motivating older adults to participate in physical activities could serve as a viable solution to mitigate sedentary behaviors at home. The combined results indicate that the group with motor difficulties scored significantly higher than the low–socioeconomic status group on the related quantitative measure of Familiarity, suggesting that this specific group has a greater interest in using SARs in relation to activity motivation.

In addition, older adults indicated that they viewed SARs as potential aids in providing physical assistance. Aging is characterized by a reduction in people's physical strength and, thereby, a reduction in their capacity to perform ADLs [11,12]. Technologies could assist older adults with various tasks, catering to a wide range of specific needs such as helping with opening jars (perhaps to support cooking), transporting weights (eg, groceries), or physically assisting older adults (eg, help with walking). This was particularly important for the group with motor difficulties, who made most of the statements related to this theme.

A key perceived benefit offered by these technologies is their ability to monitor older adults' health conditions, safety, and daily activities continuously, including overnight, which can be a particularly stressful time for caregivers. Risky situations such as falls are common in this population, especially in relation to gait during daily activities [75]. Thus, these are important strengths and considerations that monitoring technologies and SARs should address to support older adults at home. It is worth noting that the group with motor difficulties made a slightly higher proportion of statements related to this theme. We can assume that this aspect was of particular interest to them.

Loneliness is a reported issue among older adults [76], with previous work suggesting that socializing and communication are considered important daily activities for older adults [60]. This can be especially prevalent in groups of a low socioeconomic status [77], which was highlighted during our discussions with this group through their ideas of using SARs for social support. Finding solutions to cope with this condition may be challenging [78]; however, it has been suggested that SARs may reduce feelings of loneliness in older adults residing in care facilities [79] or enhance their social interactions [80]. Participants indicated a willingness to interact with SARs to alleviate loneliness or expressed interest in integrated functions that could enhance their social network. Participating in group activities and discussions has been shown to be beneficial for older adults' social [81] and cognitive functioning [82]. Using SARs to facilitate this and as a tool for cognitive stimulation and discussion may be beneficial for older adults experiencing loneliness, which is one of the key future directions for research in this area. In this case, it is important to note that the group with motor difficulties presented significantly higher quantitative scores than the low–socioeconomic status group. This suggests that the group with motor difficulties find SARs more engaging in this role.

Several of the reported barriers to technology use for activity monitoring among the older population were related to personal factors such as personal motivation, with participants underscoring the significance of individual desire in maintaining activity levels regardless of technological intervention. Previously discussed physical challenges associated with aging, such as diminished strength and mobility, were also identified as notable obstacles alongside perceptual issues, such as deteriorating sight, and cognitive difficulties, such as forgetfulness. Moreover, cognitive challenges were expressed in concerns about the capacity to comprehend and effectively use these technologies, which may be perceived as overly complicated. Fear of technology breakdowns and a desire for control over the technology were expressed by many participants, indicating that the design and application of these technologies should be as user-friendly and simple as possible, thus avoiding additional cognitive demands and stress. Using these new technologies will subsequently require a learning process and dealing with issues such as software updates; this can pose cognitive and perceptual challenges to older adults [83], leading to increased stress as individuals adapt to these changes [84]. Participants acknowledged the need for support in using these technologies, suggesting that various forms of support should be considered as potential solutions. Future research should concentrate on addressing these challenges and determining the most effective solutions to facilitate older adults' use of technologies.

When discussing the introduction of new technologies with end users, economic and privacy concerns are often raised [6,85]. Therefore, these should be carefully considered when making decisions about the selection and deployment of SARs and monitoring technologies. There was also a common emphasis on the importance of smooth movement within an environment, with participants also recognizing potential limitations due to physical space availability. This is of increased concern within a domestic environment, which could restrict the movement and subsequent usefulness of SARs. These considerations should be addressed before introducing SARs into the home environment to ensure a suitable fit.

Discussions regarding the number of sensors and SARs to use in one setting were pragmatic, indicating that the number of sensors and SARs should depend on the individual circumstances. This was also true when discussing the preferred characteristics of SARs; however, some similarities emerged, such as the reduced acceptance of animal-like robots and suggestions to avoid SARs that could be perceived as toys. Moreover, a preference for personalizing certain characteristics and being able to control SARs remotely was expressed. In this regard, the quantitative analysis indicated that participants from the low–socioeconomic status group tended to feel that they had less control over the use of SARs at home. This suggests that addressing this need could be a crucial consideration during the design process for this group. Interestingly, participants accepted both environmental and wearable technologies. Despite reporting the common strengths and weaknesses associated with each type of sensor [60], they indicated that using both types would be beneficial. It is important to use sensors in situations or areas in which there is a higher risk for older adults, such as those where falls are more probable. Finally, participants indicated that they would use SARs and monitoring technologies if they were perceived as helpful, confirming previous results [60]. Notably, quantitative results indicated that the group with motor difficulties had a higher perception of the utility of SARs at home, suggesting that they tend to view this technology as more helpful compared to the other groups.

These results align with other evidence suggesting SARs as potential tools to provide coaching, monitoring, and companionship [86] and promote changes in daily routines [87]. In addition to other important key points emerging from the analysis, considering 3 different groups characterized by different socioeconomic levels and physical difficulties further developed our understanding of the perspectives on these technologies within a wider category of older adults. Perceived physical and psychological well-being are associated with various dimensions regarding SARs. When an older adult perceives themselves as more physically impaired, they are more likely to feel a sense of familiarity with and interest in SARs. This perception is coupled with the perceived utility and the ability to control SARs. On the other hand, if an older adult perceives a lower psychological wellness, they may have more reservations about SARs due to a general negative attitude and concerns regarding the environmental fit of the SARs. Interestingly, this was associated with less interest in SAR variety. Several factors, as indicated in the literature, are associated with the intention to use SARs or their acceptability among older adults [88,89]. However, to the best of our knowledge, this is the first study indicating that specific well-being domains—psychological and physical—play a pivotal role in attitudes toward SAR use at home. This is noteworthy considering that most SAR use is related to health [88]. Group comparisons also yielded interesting insights, largely aligning with the associations discussed. The group with motor difficulties perceived SARs as more familiar and expressed greater interest than the low-income group. In addition, the group with motor difficulties considered SARs to be more useful compared to the other groups. On the other hand, participants of a low socioeconomic status indicated less perceived control over SARs compared to the other groups. This aligns with a recent survey indicating that people of a low socioeconomic status are less supportive of technologies and SARs [90]. In this regard, our results suggest a connection with the perceived barriers associated with these technologies as the participants from the low–socioeconomic status group tended to report the highest percentages of statements related to all the perceived barriers identified in the analysis, including personal factors, economic considerations, privacy concerns, and space issues. This suggests that, for this specific category, it may be crucial to demonstrate the usefulness of SARs and monitoring technologies and address older adults' needs. Importantly, older adults with physical difficulties had more positive attitudes toward SARs at home compared to the other groups. These insights highlight their tendency to be more accepting of SARs in their homes for support, aligning with the findings obtained from the thematic analysis.

Limitations

Despite yielding interesting results, this study has certain limitations. The limited sample sizes of the 3 groups for quantitative analysis represent a limitation of the study; thus, the statistical results should be interpreted with caution. Therefore, the results of the quantitative statistical analysis need to be replicated, and future studies should confirm these findings with larger sample sizes. Demographic variations and characteristics specific to older adults may influence their needs and opinions. For instance, our results suggest that psychological well-being significantly influences attitudes toward SARs. Therefore, future studies should encompass older adults with psychological difficulties, such as depression, for a more comprehensive understanding. Cognitive and sensory challenges among participants were not evaluated, which should be considered for future research. This study did not consider other demographic characteristics of older adults, such as gender and ethnicity, which should be included in future studies.

Conclusions

The participants indicated that SARs and monitoring technologies could help reduce sedentary behaviors and assist in the management of daily activities. This study highlights the importance of considering the functional and socioeconomic characteristics of older adults as future users of SARs and monitoring technologies to promote widespread adoption within this population and improve well-being. Older adults with different characteristics and backgrounds may have varying attitudes and needs, which the design and implementation of technologies should take into account.

Acknowledgments

This work was supported by the Engineering and Physical Sciences Research Council and the National Institute for Health and Care Research (grant EP/W031809/1; Intelligent Multimodal Assessment and Coaching Through Identification of Vulnerabilities in Older People project). The funding sponsors had no role in the design of the study; the collection, analyses, or interpretation of the data; the writing of the paper; or the decision to publish the results.

Data Availability

The datasets generated during and analyzed during this study are available in the Zenodo repository [71].

Authors' Contributions

RV, MZ, ADN, and DM contributed to conceptualization. Methodology was designed by RV, SM, HM, SFD, and DM. All the authors contributed to formal analysis. Resources were provided by MZ, HM, SFD, ADN, and DM. Data curation was managed by RV and NC. The original draft of the manuscript was written by RV, NC, MS, and KA-B. RV and NC contributed to visualization. Supervision was provided by SM, MZ, ADN, and DM. Project administration was handled by SM, HM, SFD, and DM. Funding was secured by SM, MZ, ADN, HM, SFD, and DM. All the authors contributed to writing, review, and editing.

Conflicts of Interest

None declared.

Abstract

Background: With the growing proportion of Canadians aged >65 years, smart home and health monitoring technologies may help older adults manage chronic disease and support aging in place. Localization technologies have been used to support the management of frailty and dementia by detecting activities in the home.

Objective: This systematic review aims to summarize the clinical evidence for in-home localization technologies, review the acceptability of monitoring, and summarize the range of technologies being used for in-home localization.

Methods: The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) methodology was followed. MEDLINE, Embase, CINAHL, and Scopus were searched with 2 reviewers performing screening, extractions, and quality assessments.

Results: A total of 1935 articles were found, with 36 technology-focused articles and 10 articles that reported on patient outcomes being included. From moderate- to high-quality studies, 2 studies reported mixed results on identifying mild cognitive dementia or frailty, while 4 studies reported mixed results on the acceptability of localization technology. Technologies included ambient sensors; Bluetooth- or Wi-Fi–received signal strength; localizer tags using radio frequency identification, ultra-wideband, Zigbee, or GPS; and inertial measurement units with localizer tags.

Conclusions: The clinical utility of localization remains mixed, with in-home sensors not being able to differentiate between older adults with healthy cognition and older adults with mild cognitive impairment. However, frailty was detectable using in-home sensors. Acceptability is moderately positive, particularly with ambient sensors. Localization technologies can achieve room detection accuracies up to 92% and linear accuracies of up to 5-20 cm that may be promising for future clinical applications.

Introduction

The proportion of Canadians aged >65 years is growing, from 7 million in 2020 to an estimated 9.5 million (23% of the population) by 2030 [1-3]. With the ratio of adults aged 15-64 years to persons aged 65 years and older halving from 7.2 in 1980 to 3.6 in 2020, the question of how to maintain a sustainable health care system in the face of these changing demographics remains a top priority [1]. Transforming care processes by using digital platforms and remote monitoring tools may be able to address our increasingly older population and lead to higher life expectancies [4]. Smart home and health monitoring technologies have been touted as the future of managing chronic diseases and allowing people to age in place and live within the comfort and familiarity of their own homes for longer [5-8].

Aging is often accompanied by a gradual decrease in physical and mental capacity [9,10]. In-home monitoring technologies have been used to support older adults to age in place by detecting and managing worsening physical and cognitive decline [7,8,11-19]. Wearables, including accelerometers and gyroscopes, have been used to monitor postural transitions [20] and provide yearly gait speed assessments [21], while weight scales and grip balls have been used to monitor changes in weight and grip strength [22]. Actigraphy has been commonly used in cross-sectional studies on physical activity and gait alongside ambient sensors [13] and to monitor behavioral changes such as agitation and aggression [12,16].

In order to identify appropriate interventions for aging in place, technologies need to first identify body postures and positions that can be reliably interpreted as a functional activity of daily living. While actigraphy can give some quantitative idea of the amount of movement happening, it lacks contextual data that could allow for targeted interventions and improved interpretation of activity data [15,23-25]. Localization technologies are key to providing context that helps with reliable interpretation of what activities are being done. Ambient monitors, including infrared sensors and magnetic door contact sensors, can detect which room a resident is in, determine if they are cooking elaborate or simple dishes, or identify if they are doing self-care activities such as mopping or laundry. This context may be a more sensitive factor in the early detection of dementia, cognitive decline, or increased risk of falls among older adults [26-28]. Wearable tags using wireless technologies such as Bluetooth or Wi-Fi can also be used to localize residents in their homes, offering 1.5-5 m, or room-level accuracy that can help with interpreting what activities are being done [29,30]. More modern technologies, such as ultrasound or ultra-wideband (UWB) localization, provide higher level accuracies that are more useful for detecting functional activities. Detection of basic activities of daily living (personal hygiene, grooming, dressing, and toileting) and instrumental activities of daily living (managing finances, food preparation, and housekeeping laundry) are critical for effective functional assessment.

Other systematic reviews on indoor localization have focused on the technical measures of accuracy or the range of technologies that could be used to detect activities with localization techniques [31,32]. The focus of this review is to review currently available localization technologies being used for clinical purposes, including the acceptability of devices and measurement of clinical outcomes or diagnoses.

The primary objective of this study is to systematically review the clinical evidence for indoor localization technologies to support in-home monitoring of older adults. Secondary objectives include the following: to review the acceptability of in-home positioning technologies and to summarize the range of localization technologies being developed.

Methods

Review Registration and Search Strategy

This systematic review protocol was registered with PROSPERO (ID: CRD42022339845) and follows the methodology of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [33]. The PRISMA checklist can be found in Multimedia Appendix 1.

The search was completed on May 19, 2022, with inclusion criteria displayed in Textbox 1. The search strategy can be found in Multimedia Appendix 2. The search strategy included search terms for the older adult population undergoing in-home positioning or monitoring systems as their intervention. Keywords related to older adults included “Aged,” “Senior,” “Over 65,” or “Aging,” while terms on the setting included their home or house. For the technologies, terms included the purpose of monitoring (“Positioning” or “Localization”) and specific types of technologies, including wireless trackers (Bluetooth, Wi-Fi, UWB, or Zigbee), wearables (accelerometers or gyroscopes), camera, and audio systems. The search did not include comparator groups or outcomes to improve the sensitivity of the search. We included studies that had at least 4 patients to improve the sensitivity of the search. Articles focused on measuring life spaces outside the home (travel to appointments, shopping centers, or recreation centers) were excluded. Studies using wearables were only included if assessed within a home setting.

Textbox 1. Inclusion and exclusion criteria.

Abstract inclusion criteria

- Older adults (65+)
- Monitoring technology
- In-home setting
- Sample size >4 patients

Full-text inclusion criteria

- All abstract inclusion criteria
- Positioning system

Exclusion criteria

- Care centers (assisted living, long-term care, hospital, etc)
- Conference abstracts
- Reviews and study protocols
- Non-English

Study Selection, Extraction, and Quality Assessment

MEDLINE, Embase, CINAHL, and Scopus were searched, and articles were deduplicated. Abstract screening, full-text screening, data extraction, and quality appraisal were completed by 2 reviewers: the first author (AC) and 1 of 4 secondary reviewers (SP, BC, LQ, and JC). Reviewers were trained with 10 test abstracts and full-text articles, and then concordance was reviewed. At each stage, interrater agreement was calculated using the κ coefficient calculated by the following formula:

where Pr(*a*) represents the actual observed agreement and Pr(*e*) represents the chance agreement [34]. Disagreements were resolved by having both reviewers reassess articles for 2 additional rounds, and then the article was discussed to reach a consensus.

Data extraction included article demographics (country and year published), study design (clinical, usability, or technical study), population characteristics (age, gender distribution, clinical diagnoses, and comparators), types of localization interventions (wearable or ambient, data transmission, technology readiness level, and data analytics methods), and outcomes (types of activities monitored, clinical assessments and outcomes, acceptability, and reliability). Data were compiled into summary tables, presenting the population, technological intervention, and clinical outcomes of each study.

To assess risk of bias, the JBI checklist for case series critical appraisal tool was used, as we did not expect any high-quality randomized controlled trials related to in-home monitoring [35]. Criteria for appraisal were predetermined: studies with 7 or more "Yes" ratings were considered high quality, studies with 4-6 "Yes" ratings were considered moderate, and studies with fewer than 5 "Yes" ratings were considered low quality. No meta-analysis was planned, as we did not expect to find high-quality quantitative studies that would allow for heterogeneity to be assessed. Instead, the outcomes from each study were presented individually.

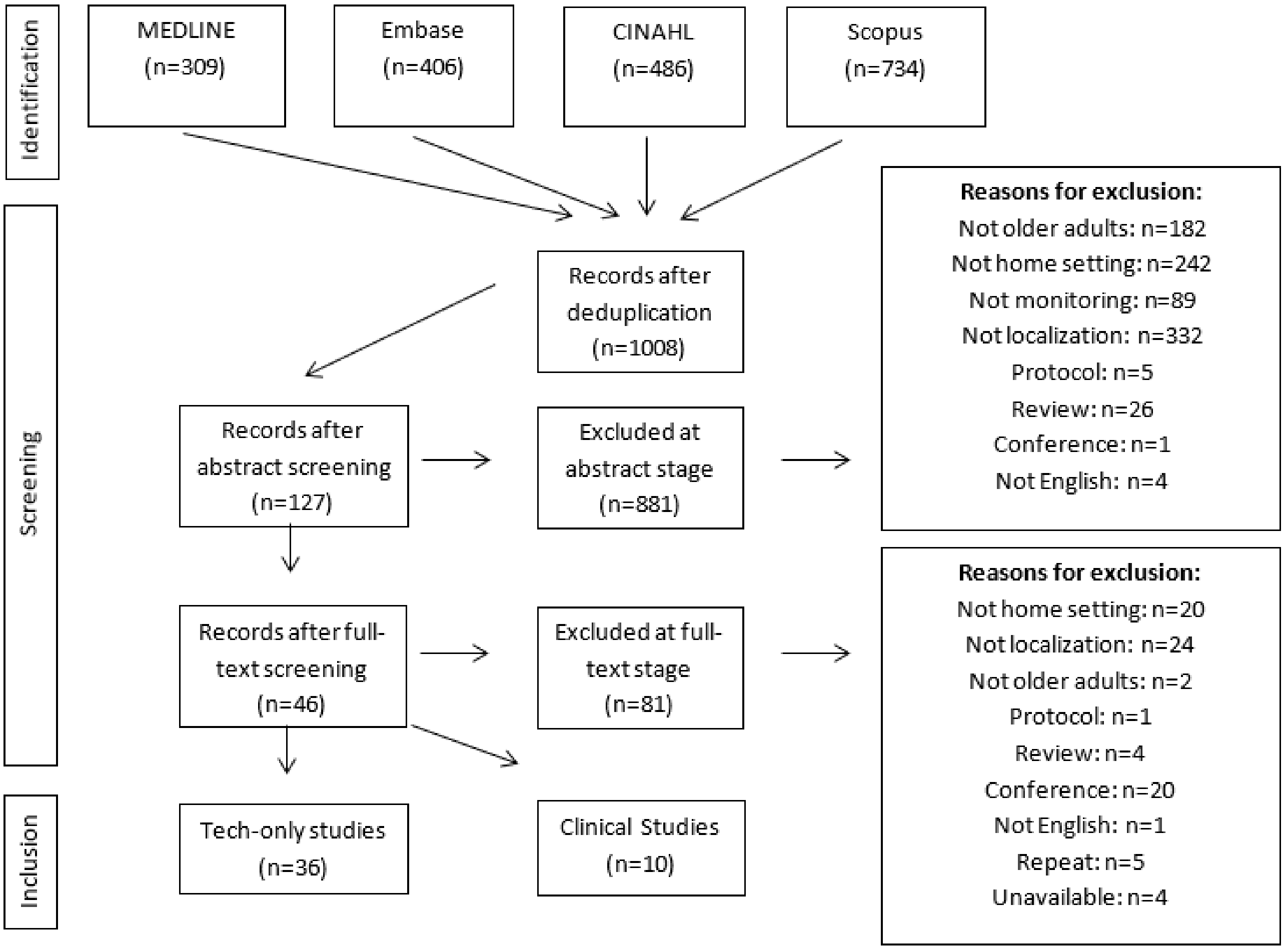
Clinical outcomes were summarized in summary statements, with only moderate- or high-quality studies considered. Evidence was summarized as positive if the majority of studies showed positive results, negative if the majority of studies showed negative results, and mixed if neither had a majority.

Results

Search Results

During the initial search, 1935 articles were found, with 1008 unique articles after deduplication. After abstract screening, 127 articles remained. After full-text screening, 46 articles were included in the final extractions: 36 technology-focused articles and 10 articles that included relevant patient populations. Agreement between reviewers at the abstract screening stage was 94.9% with a κ of 0.77, and agreement for the full-text screening was 95.8% with a κ of 0.71. Quality assessment agreement was 76% with a κ of 0.51. The PRISMA flowchart in Figure 1 maps out the excluded articles.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart showing included clinical studies (n=10) and technology-only studies (n=39).



Studies With Clinical Population

Table 1 displays the baseline characteristic for the 10 papers that included relevant patient populations. In total, 7 studies were conducted since 2019. In total, 5 studies were from North America, 3 from Europe, and 2 from Asia. In total, 2 studies were descriptive studies of the technology, 4 studies had a mixed design and qualitative study design, 2 had qualitative study designs, 1 was a mixed study with qualitative and quantitative outcomes, and 1 focused on quantitative outcomes. Only 1 study had more than 25 participants. In total, 8 studies had more female than male participants.

All studies had patient populations that included older adults, although only 7 specifically reported population characteristics. In total, 4 studies included older adults living at home with nonspecific functional challenges, 2 focused on adults with mild cognitive impairment or dementia, and 1 focused on older adults with frailty. Half of the studies (5/10, 50%) were considered low quality, 3 (30%) were considered moderate quality, and 2 (20%) were considered high quality.

Table 2 shows the technologies and localization methods used in the included studies, their setting, and the duration of monitoring. From a technology perspective, 2 used solely an ambient sensor design, 5 combined ambient sensors with wearables, and 3 used wearable-only designs. Ambient sensors included temperature sensors, magnetic door sensors, infrared motion sensors, light switch sensors, pressure detectors, and lidar sensors. Wearables included inertial measurement units (IMUs), electrocardiograms, heart rate meters, and wearable wireless tags (Wi-Fi or Bluetooth low energy). Of the 10 studies, 7 (70%) included technologies of unknown brand or model (3 only used non-branded devices), while 3 (30%) listed the brands of devices used.

Most studies (7/10, 70%) were done in the home setting, with 2 in a home-like laboratory setting and 1 in a laboratory setting. Studies in the laboratory-home involved monitoring sessions lasting between 1 hour and 7 days [28,29,41], while home-based monitoring ranged from 3 weeks to 18 months.

Table 3 displays the outcomes from studies that included patient populations. In total, 7 included technical outcomes, 6 included usability and acceptability outcomes based on patient or clinician surveys or interviews, and 3 included clinical outcomes. Room detection accuracy ranged from 50% to 88% across 3 studies [27,28,30], while 1 study reported failure rates of >15% for motion detectors and servers installed in the home [36]. One study reported linear accuracies of 1.5-2 m using wireless sensor networks within the home [29].

Table 1. Baseline characteristics from the included clinical papers.

Author (year)	Country	Design type	Participants, n	Female	Age (years), mean (SD; range)	Population	Category of technology	Quality

Table 3. Outcomes from studies that included patient populations.

Author (year)	Category of technology	Outcomes measured	Technical outcomes	Qualitative outcomes	Clinical outcomes	Quality

Hu et al (2016) [36]	Ambient	- Survey: ease of installation, acceptability of sensors, instructions efficiency, device failure rates	- Failure rate:
			  - <15%: motion detectors and temperature sensors
			  - >15%: door sensors, servers, and relays
				- Ease of use: 2.9 out of 4, high
				- Concerns with devices: 1.6 out of 5, low concerns
				- Instructions efficiency: 80.95%, yes
					N/A[a]	Low

Rahal et al (2008) [28]	Ambient	- Localization accuracy	- Combined: 85% room detection accuracy - Accuracy for each device: 1. 88% 2. Not measured 3. 50% 4. 77% 5. Not measured	- N/A	N/A	Low
Shin et al (2021) [37]	Ambient and wearable	- Patient interviews: adaptive behaviors at home	- N/A	- For difficult activities, patients most often give up on them or perform slowly - Home adaptations are rarely implemented due to cost - High fall–risk locations are avoided	N/A	Moderate

Pais et al (2020) [38]	Ambient and wearable	- Survey: satisfaction with devices	- N/A	- Ambient sensors:
				  - Older adults: 81.6% positive
				  - Caregivers: 80% positive
				  - Nurses: 69% positive
				- Wearable sensors:
				  - Older adults: 72.2% positive
				  - Caregivers: 60% positive
				  - Nurses: 49% positive
					N/A	High

Lach et al (2019) [27]	Ambient and wearable	- Measurement of activity levels and sleep duration
		- Patient interviews: Patient experiences with monitoring
			- Activity:
			  - Self-reported activity and sensor activity correlate
			  - Actigraphy did not
			- Sleep:
			  - Self-reported: 492 min

[a] N/A: not available.

For studies that included usability and acceptability outcomes, surveys from 3 studies [29,36,38] showed positive results. One study focused on ease of setup of a smart home in a box design and found high ease of use, few concerns with devices, and highly efficient instructions [36]. Another found the highest satisfaction among older adults, followed by caregivers, and the lowest satisfaction with nursing staff [38]. One study found an average system usability scale score of 62.8, indicating below average usability [29]. Interview results from 4 studies [27,37,39,40] found improved safety and security with devices, but there was some perceived physical intrusiveness to ambient devices [39], and some patients changed their behavior due to monitoring [27]. One study found a tag-based system was highly acceptable [40].

Lastly, regarding clinical outcomes, 1 study provided qualitative observations on why patients behaved in certain ways in their home, finding certain activities are performed slower and some areas in the home are avoided, including staircases to avoid falls, depending on their functional level [37]. One study found no difference in behaviors between residents with mild cognitive impairment and those who were cognitively healthy, based on continuous monitoring of sleep and identifying frequency of forgetting to do activities [39], while another study was able to classify patients as frail, prefrail, or nonfrail with 80% to 87% accuracy using machine learning algorithms from Bluetooth-based wearable localization, being monitored for 1-7 days continuously in their own home while doing their own typical activities [41].

Studies on Technology Validation

The primary objective of this systematic review was to review the clinical evidence for in-home localization technologies to support in-home monitoring of older adults. We found 36 articles that reported that their technology would be used for localization of clinical populations. Table 4 is a summary of the characteristics of studies focused on developing and evaluating in-home localization technologies for older adults.

Studies on ambient sensors were from North America (3/6 studies, 50%), wireless tags were most studied in Europe (6/6, 100% for Bluetooth or Wi-Fi and 5/7, 71% for other tags), and wireless tags alongside IMUs were solely studied in Asia (8/8, 100%). The majority (25/36, 69%) of studies were from after 2016. The stated purpose of monitoring was for older adults in a general sense in 27 (75%) out of 36 studies, while older adults with chronic diseases or disabilities were specified in 9 (25%) studies. The purpose of monitoring was mostly for health and safety monitoring (21/36, 58%).

The most common localization mode was to measure signal strength (23/36, 64%), followed by time-based localization (8/36, 22%), which calculates the time that it takes for a signal to travel from a tag to a reference point, and the least common was proximity sensing (5/36, 14%). Received signal strength involves estimating the distance between wearables and reference points based on the strength of the wireless signal. Localization accuracy was most reported as a linear distance (23/36, 64%), followed by classification of activities (13/36, 36%), room or area detection accuracy (6/36, 17%), and lastly accuracy in detecting multiple people in a space (5/36, 14%).

Table 5 summarizes the accuracies of different technologies, organized according to the method of localization and the type of accuracy reporting. Ambient sensors included infrared sensors, radiofrequency transceivers, and video feedback. Devices were primarily used for detecting people passing through spaces, with accuracies of 79% to 98% in differentiating people, and 92% accuracy in detecting presence in a room.

Localization technologies	Distance	Activity classification	Room or floor or area detection	Multiple tag and person detection
Accuracy	• Triboelectric tracker [38]: at 1.5 m, 20-30 cm • Unspecified doorway sensors: distance traveled error: 10.5%-24% [40] • Android location-based service: not reported [39] • Ultrasound+RF: 11 cm [37] • Floor vibration sensor: 24-61 cm [42] • BLE+Acoustic+Light Fidelity: 20 cm [43]	• IMU+Mic+Wi-Fi: ADL recognition: 92-99% [44] • Unspecified doorway sensors: activity detection: 92% [40] • Ultrasound+RF: gait speed error: 91% [37], distance walked: 92% • Floor vibration sensor: footstep detection: 95%-99% [42] • Ambient+Scales+IMU: not reported [45]	—	• IR+Pressure Pad+RF transceiver: not reported [46]

[a] IR: infrared.

[b] RF: radio frequency.

[c] Not applicable.

[d] RFID: radio frequency identification.

[e] UWB: ultra-wideband.

[f] BLE: Bluetooth low energy.

[g] IMU: inertial measurement unit.

Bluetooth and Wi-Fi technologies can be used with either smartphones or individual tags, reducing the need for extra equipment for localization when compared to stand-alone tags. Accuracies ranged from 70-250 cm, with room detection accuracies of 70% to 87%.

Localizer tags include radio frequency identification (RFID), UWB, Zigbee, and GPS tags. Linear accuracies were superior to Bluetooth or Wi-Fi, ranging from 5 to 100 cm, with area accuracies of 90%. Tags were also used for fall detection and object detection.

Combining localizers with IMUs allowed for a combination of activity classification and localization. Accuracies ranged from 7.6 to 189 cm across 4 modalities (UWB at 7.6 cm, RFID at 10-40 cm, Zigbee at 83-189 cm, and Bluetooth low energy at 47 cm), while activity classification ranged from 89% to 100%, although reporting was not always clear on what activities were being classified. Area classification accuracies were between 86% and 90%.

Lastly, with unique technologies, including sound-based technology, GPS, vibration sensors, pressure pads, and triboelectric sensors, accuracies ranged from 20 to 30 cm with activity recognition at 92% to 99%.

Summary Statements on Clinical Evidence for Localization

From the 5 moderate- to high-quality clinical studies, 4 studies reported on acceptability of in-home localization systems. Results were mixed, with 2 high-quality studies indicating positive acceptability [38,39], 1 finding below average usability [29], and 1 finding a range of concerns over device obtrusiveness [27].

Two studies reported on clinical outcomes from in-home localization systems. One high-quality study showed no difference in behaviors in older adults with healthy cognition compared with those with mild cognitive impairment [39], and 1 moderate-quality study detected adaptive behaviors at home because of limitations to patient function [37].

Discussion

Principal Findings

This systematic review focused on the usage of localization methods to monitor older adults in their homes for any clinical application. While the primary objective was to evaluate the clinical evidence for localization technologies, a survey of technologies for in-home localization was also undertaken to understand upcoming technologies for localization.

Clinical utility of localization was mixed in this study. In the study by Rawtaer et al [39], cognitively healthy older adults (21 participants) and older adults with mild cognitive impairment (28 participants) were monitored and compared over 2 months using a custom set of motion sensors, proximity tags, a bed sensor, and wearables to capture sleep; activity levels; and forgetfulness regarding medications, keys, or wallets. Among typical activities, there was no difference in behaviors [39]. A second study, examining frailty, used in-home localization to detect frailty by measuring number of transitions, speed of transitions, and statistical features through machine learning algorithms, finding a classification accuracy of 82% to 85% when using random forest plots [41]. The model can be used in the future to detect frailty in the general population. The clinical evidence for using localization technology to support care of older adults is currently limited.

From an acceptability perspective, results were moderately positive [27,29,36,38,39]. Pais et al [38] discovered that ambient sensors garner greater acceptance compared to wearables. Moreover, they noted that older adults and caregivers exhibit higher acceptance levels toward both technologies in contrast to nurses. This trend could be attributed to the necessity for monitoring daily performance issues among older adults and their families. The acceptability of home monitoring has been thoroughly studied previously, finding that the trade-offs are critical to consider when developing these technologies [42-45]. These findings align with the present systematic review, with obtrusiveness being a major detractor for these localization technologies balanced by improved safety and security.

Common technologies for localization include ambient sensors; Bluetooth- or Wi-Fi–received signal strength; localizer tags using RFID, UWB, Zigbee, GPS; or IMUs with localizers. This review also found unique localization devices, including triboelectric trackers, ultrasound, floor vibration sensors, and pressure pads. Highest linear accuracies were found with UWB technologies at 5-20 cm compared with greater than 50 cm for most other technologies. UWB uses time-based localization, which involves measuring the time it takes for a signal to travel from a tag to a reference point and then trilateralizing the signal. Room detection accuracies were comparable across technologies, ranging from 75% to 92% using Bluetooth, Wi-Fi, RFID, radio frequency transceivers, or Zigbee with IMUs.

The current literature is limited as it focuses primarily on technical measures of accuracy. The shift needs to be made toward localization for activity identification that can then be used as evidence to provide an intervention. UWB positioning has the potential to make the shift from where a patient is in the home at a room level to a furniture level that can then allow identification of activities. Further exploration and development of algorithms to automatically detect activities are required before broader clinical usage.

Comparison to the Literature

This systematic review fills an important gap by including clinical results, user acceptability, and technological aspects of evaluating localization devices to support older adults to age in place. There remains little evidence for their usage for older adults, a finding that is supported by other systematic reviews. Lenouvel et al [31] reviewed sensors to measure and support activities of daily living for older adults in 2019. While they did not focus on localization, they found that passive and video sensor networks were used to assess activities of daily living across 13 studies out of their search of 10,782 studies, finding that sensors could detect changes in activity patterns but reported no clinical outcomes and that only 1 study assessed the acceptability of devices.

Another systematic review published in 2018 focused solely on technological aspects of human activity recognition supported with indoor localization. Cerón and López [32] described common localization technologies and data fusion methods, reporting accuracy of activity detection and localization accuracies without consideration for age of participants. Human activity recognition accuracy ranged from 72% to 99% across 27 studies, although the exact types of activities were not reported. Localization accuracies ranged from 0.8 to 7 m, depending on the type of technology, although the type of technology was not reported in the review. These values are comparable to this systematic review.

Strengths of This Study and Recommendations for Future Studies

This systematic review had a strong search strategy, covering the major databases and having 2 reviewers screen, extract, and assess the quality of studies. Agreement between reviewers was high across screeners. The JBI quality assessment tool was used with a lower agreement with a κ of 0.51. Agreement was low due to inadequate training for the 10 clinical articles, a lack of specific definitions of how much clinical information was adequate for the study, and how follow-up was defined in the article. Each study was discussed between reviewers according to a standardized definition for the final results of this study.

While the methodology of this review was strong, the findings were not. There is limited clinical evidence for using localization to support monitoring older adults. It was surprising that there were also few studies that evaluated the acceptability of monitoring technologies. The quality of evidence also needs to be improved, with most studies having fewer than 25 participants with a case study design and the quality of studies being mixed.

Still, existing studies on acceptability of localization technologies form a strong basis for further development. Future studies should be located within the homes of participants, with sample sizes greater than 25 to demonstrate scalability and particular use cases in a broad range of home settings. From a study-design perspective, home monitoring as an intervention is a complex intervention that is challenging to capture in a randomized controlled trial. The recent guidelines by the Medical Research Council and National Institute for Health Research in the United Kingdom provide a new framework for assessment that includes considering the context, stakeholders, economics, and uncertainties in an intervention, grounding it in appropriate theory, and iterating to refine the intervention [46]. Nonrandomized designs, hybrid effectiveness-implementation designs, or n-of-1 trials may be more feasible.

Details around patient populations were scarce. Greater detail in medical histories, functional ability, and practical aspects (social supports, living spaces) need to be provided to generate profiles for how monitoring interventions have helped specific residents. A standard battery of activities of daily living needs to be established to allow accuracy in identifying and assessing activities of daily living to be comparable across studies in the range of indoor spaces being localized and the diversity of impairments common to older adults. There needs to be clearer reporting of the spaces being monitored, accuracy of devices, and types of activities of daily living being monitored to allow comparability. Lastly, study outcomes need to be shaped to demonstrate how monitoring technologies lead to clinically and personally relevant interventions that support aging in place. The 2 studies that looked at clinical outcomes in this systematic review focused on detecting dementia or classifying frailty. Perhaps the more important question is how minimally invasive interventions can be used to either prevent decline or intervene to support residents who are having greater challenges doing self-care activities.

The utility of localization techniques for health care is still untapped. While some initial work on detecting cognitive decline and frailty in the home setting has been documented in this review, further development and clinical evaluation of these technologies to determine potential use cases still needs to be undertaken. Development of these technologies requires a multipronged approach that combines understanding the limits of the technology, including the cost, the clinical applicability of localization for health management, and the acceptability of monitoring to enhance wellness. Technologies such as Bluetooth, Wi-Fi, and IMUs are already well established in the market for various quality of life use cases but not for health care.

Localization could be a powerful supporting tool for managing challenges with cognition, with interventions that take into account a user's living patterns and reminders that are tailored to the home environment. Of upcoming technologies, UWB may be the most exciting, offering much higher accuracies than ambient sensors and wireless technologies such as Wi-Fi and Bluetooth. Cognition, mental health, and frailty could be more accurately measured longitudinally, rather than relying on snapshot clinical assessment tools when combined with collecting information on self-care and in-home activity levels. There is great potential for localization technologies to support wellness in the home.

Conclusions

There is no evidence for the usage of in-home localization technologies for any clinical outcomes and mixed evidence for the acceptability of localization technologies among older adults. However, there is a wide range of technologies available that have promising technical accuracy. The technology is ripe for monitoring devices to be tested clinically, providing data that can detect changes in cognition or frailty and drive interventions. Further study on the acceptability of these devices is also warranted to determine the least obtrusive and easier to use modalities that can bring the most benefit for older adults.

Acknowledgments

The authors would like to give special thanks to Elizabeth Dennett, who helped with the search strategy. This work was supported by Mitacs (IT24450) to AMRR, GG, and ML, as well as NSERC and AGE-WELL (AW-PP2019-PP3) to GG.

Abstract

Background: The population of older adults worldwide continues to increase, placing higher demands on primary health care and long-term care. The costs of housing older people in care facilities have economic and societal impacts that are unsustainable without innovative solutions. Many older people wish to remain independent in their homes and age in place. Assistive technology such as health-assistive smart homes with clinician monitoring could be a widely adopted alternative to aged-care facilities in the future. While studies have found that older persons have demonstrated a readiness to adopt health-assistive smart homes, little is known about clinician readiness to adopt this technology to support older adults to age as independently as possible.

Objective: The purpose of this systematic review was to identify the factors that affect clinician readiness to adopt smart home technology for remote health monitoring.

Methods: This review was conducted in accordance with the Joanna Briggs Institute methodology for systematic Reviews and followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for reporting.

Results: Several factors affected clinicians' perspectives on their readiness to adopt smart home technology for remote health monitoring, including challenges such as patient privacy and dignity, data security, and ethical use of "invasive" technologies. Perceived benefits included enhancing the quality of care and outcomes.

Conclusions: Clinicians, including nurses, reported both challenges and benefits of adopting smart home technology for remote health monitoring. Clear strategies and frameworks to allay fears and overcome professional concerns and misconceptions form key parts of the Readiness for Adoption Pathway proposed. The use of more rigorous scientific methods and reporting is needed to advance the state of the science.

Introduction

Background

The global population is aging, and people are living longer. Adults aged ≥65 years have a high burden of disease, and the current practice of housing and caring for older people in nursing homes is often considered the last resort [1]. With reports of lower-quality care in residential aged-care settings and demands for alternative aging-in-place solutions by a much more technology-savvy baby boomer generation [2,3], health-smart homes (HSHs) are capable of unobtrusive in-home monitoring to support the health and safety of older people. In addition to protecting older adults from unnecessary exposure to communicable diseases such as COVID-19, aging in place has several benefits, including the maintenance of social connectivity and proximity to friends and family [1,4,5]. Furthermore, the ability to age in place supports and maximizes independence, thereby enhancing well-being and quality of life while decreasing the financial burden of residential care costs [1,6,7]. Older adults are a unique population with age-related changes and conditions and yet could remain living in their ancestral homes with the help of HASs, which could also augment public or private home care services. However, while HAS technologies are maturing, to improve wider use of the HAS, gaining an understanding of clinician readiness to use HAS technologies is important because clinicians that make up the multidisciplinary care team constitute important stakeholders [8].

Smart Home Technology for Remote Health Monitoring

The term Internet of Things refers to a collection of “smart” devices that can acquire and connect data or information across environments and act on the information [9], for example, by sending an alert that a person’s overall activity has significantly decreased. Although wearables can be used in an in-home context, there are many different types of wearables for different purposes and that collect different types of data compared with the health-assistive smart home. In addition, wearables usually do not attract some of the privacy concerns associated with remote monitoring using health-assistive smart home technologies. The health-assistive smart home consists of Internet of Things devices such as unobtrusive sensors that are deployed in a home to monitor a person’s routine behaviors and activities of daily living, including movement around the home such as sleeping, eating, steps ambulated, and more without the person having to “wear” a device [10]. The health-assistive smart home can collect and analyze a variety of data with the help of intelligent algorithms. Data can then be used by clinicians to monitor potential changes in health in their older patients [11,12]. Clinicians and the multidisciplinary care team are positioned to be the primary end users of patient data derived from the smart home sensors. Smart devices enable clinicians to unobtrusively monitor their older patients using automated assessment of behaviors that are associated with changes in health, which could support pragmatic, data-driven clinical decision-making [13].

Readiness and Acceptance Models

Readiness and acceptance models have been developed to help integrate computer-based information systems and digital technologies into specific settings, including health care. Researchers have studied the factors that may impact acceptance of and readiness for new technologies for several decades [14,15]. Examples of studies that explore technology readiness and acceptability in clinicians include mobile electronic health records [16], information and communications technologies [17], electronic care plan systems [18], telemedicine readiness [19], and computer-generated nursing care plans [20]. Frameworks and theories have been developed to understand a person’s likelihood of accepting and using health technologies [21]. The technology acceptance model (TAM) is the predominant framework cited in the literature [22-24]. This framework is used to model the behavioral intention that leads people to accept a certain technology [22-24]. In this model, behavioral intention is influenced by the person’s attitude generated from their impression of the perceived usefulness of the technology, which then predicts the actual use of the technology [22-24]. The TAM was expanded to include social influences and cognitive instrumental processes (TAM 2) [22], and later, the TAM 2 was combined with determinants of perceived ease of use to form the TAM 3 [23]. Determinants of perceived ease of use included computer self-efficacy, perception of external control, computer anxiety, computer playfulness, perceived enjoyment, and objective usability [23]. The Unified Theory of Acceptance and Use of Technology was developed from previous work with the aim of explaining end-user intention to and use of IT [24]. Models can help with intentionally integrating computer-based information systems and digital technologies into specific settings, including health care. However, there are larger differences between adopting, for example, an electronic health record and the readiness of clinicians to adopt home health monitoring using smart home technology. Clinician adoption of smart home technology requires clinicians to use and understand a new form of evidence. Accordingly, using the findings of this systematic review, we developed a theoretical model to support clinician readiness for and adoption of HAS technology, which will be discussed at the end of the *Results* section.

Clinician Readiness

The research and development surrounding the health-assistive smart home is maturing, with deployment as part of research studies across a variety of care settings, including private homes, assisted living, residential memory care, and residential care settings such as nursing homes [25-27]. Accordingly, the readiness of clinician end users to adopt smart home technology–generated data for clinical decision-making is important if wider adoption of the health-assistive smart home is desired. Clinicians such as nurses, physicians, and other allied health professionals will play a key role in monitoring older adults living using health-assistive smart home technology. As end users, clinicians will need to use sensor data integrated with other health information and apply clinical judgment to triage information and liaise with the multidisciplinary health care team for early interventions [28,29]. Exploring factors that may impact readiness to adopt, including perceived benefits and challenges, is needed to inform the integration of the HAS into new models of home care and clinical practice. The purpose of this systematic review was to identify and summarize the factors that may impact clinician readiness to adopt smart home technology for remote health monitoring.

Methods

Review Question

What are the factors affecting clinician readiness to adopt smart home technology for remote health monitoring of community-dwelling older adults?

Inclusion Criteria

Participants

A preliminary search showed that, frequently, a variety of clinicians and other stakeholders have been included in studies that examined the phenomenon under review. Accordingly, clinicians aged ≥18 years, such as nurses, registered nurses, clinical nurses, physicians, allied health professionals, and other health care workers, were included. Studies that included nonclinical stakeholders as participants were included if clinicians were also included. Studies were excluded if we were unable to identify clinician participation.

Interventions

Because of the unique data that the health-assistive smart home can generate with the potential to augment clinician decision-making, this review included studies on health-assistive smart home sensor technology embedded or deployed in the home environment (eg, ceilings, walls, furniture, and appliances) to detect motion in persons living in private dwellings in the community, retirement villages, or aged-care homes and residential care homes. Studies focusing on telehealth and remote health monitoring were included if smart home sensors were also embedded in the home. Studies focusing only on wearable sensors or other technologies used for remote monitoring (eg, implanted defibrillators) were beyond the scope of this review and were excluded. Studies that did not provide sufficient information to ascertain whether smart home sensors were embedded or deployed in the home environment were also excluded.

Comparators

This review considered studies that compared the use of smart home technology to usual care. Studies that did not use comparisons such as cohort, case studies or descriptive qualitative studies, were also included. Due to the challenges with the feasibility of implementing the health-assistive smart home in real-world settings, studies that used “mock” or hypothetical health-assistive smart homes to study clinician readiness were included.

Outcomes

The primary outcome of this review was the identification of factors that may impact clinician readiness to adopt smart home technologies. Studies reporting clinician feedback, attitudes, perceptions, and experiences, including barriers, facilitators, and enablers regarding smart home technology, were included. Studies that reported nonclinical stakeholder feedback were included if clinicians were also included in the study.

Types of Studies

This review considered experimental and quasi-experimental studies, randomized controlled trials (RCTs), qualitative studies, case studies, and surveys. Human studies conducted in any geographical area and published in English from database inception to July 2024 were included.

Review Registration

The review protocol was registered with PROSPERO (CRD42020195989) before the commencement of the database searches.

Review Methodology

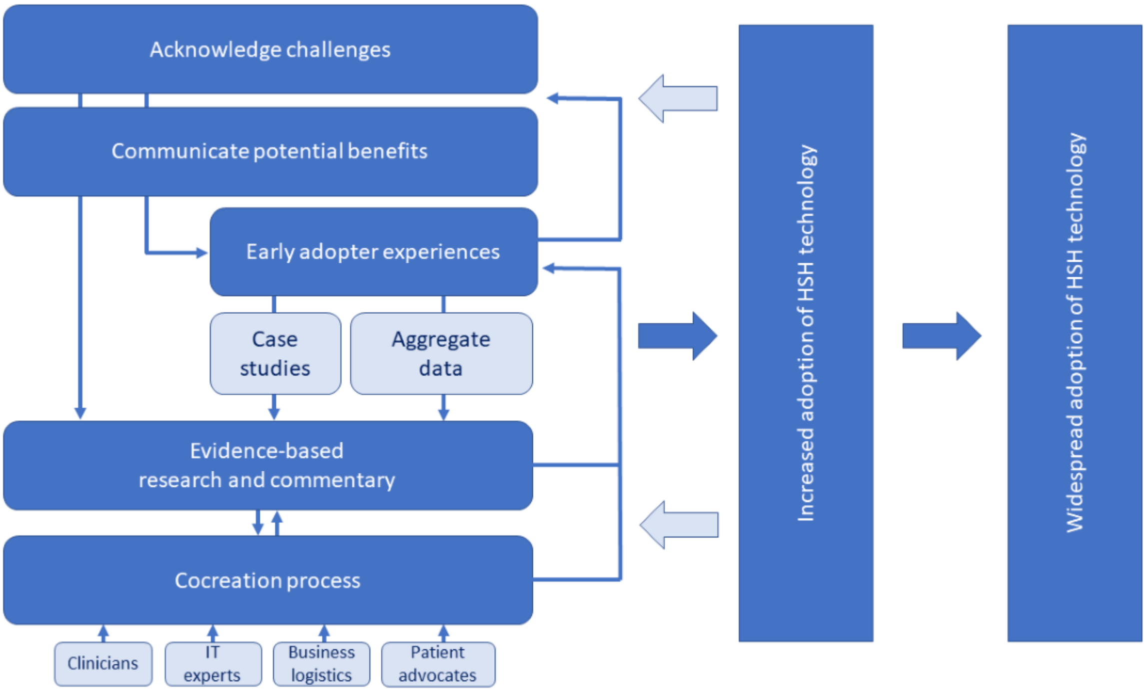
This review was conducted in accordance with the Joanna Briggs Institute (JBI) methodology for systematic reviews and followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for reporting.

Search Strategy and Study Selection

The initial search [30] of 12 databases up to July 2024 resulted in 17,204 references. Additional records were identified (n=24) through manual searching, including searching systematic review reference lists. After duplicates were removed, of the 17,228 study titles, a total of 13,423 (77.91%) were assessed. After the title search was completed, a title screen was performed by MD, and abstract screening was performed independently by 4 reviewers (GD, CG, MD, and DW). Full-text screening was performed independently by GD, CG, MD, and DW. A total of 155 full-text articles were comprehensively assessed for inclusion. Disagreements arising between the reviewers were resolved through discussion until consensus was reached. Of the 155 full-text articles, a total of 128 (82.6%) were excluded for the reasons previously stated. A total of 27 papers addressing clinician readiness, perspectives, and attitudes, among other things, regarding smart home technology were included in this systematic review.

The results will inform researchers and clinicians regarding the challenges and perceived benefits of adopting smart home technology for remote health monitoring. Finally, the findings of this review were used to develop a smart home adoption model for clinicians, which is presented in Figure 1.

Figure 1. Model for clinician adoption of smart home technology. HSH: health-smart home.



Assessment of Methodological Quality and Certainty of Findings

Eligible studies were critically appraised, and methodological quality was assessed by independent reviewers (GD, CG, MD, and DW) using the standardized critical appraisal instruments from the JBI [31]. This allowed the reviewers to achieve a greater insight into the methodological strengths and limitations of the selected studies. Blinding treatment groups was not always conceivable given the nature of the intervention; hence, it was not considered a criterion for inclusion. Any incongruities in appraisal that arose between reviewers were discussed and resolved by all authors. The Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) approach for assessing the certainty of evidence for an effect, summarized in narrative form, was used to assess the overall quality of the findings of each paper [31]. The GRADE assessment evaluates the limitations, indirectness, imprecision, inconsistency, and publication bias of the studies [31]. The overall quality of the evidence was then categorized as high, moderate, low, or very low. In total, 2 reviewers (GD and DW) independently completed the GRADE assessment for each article; there were no disagreements.

Data Extraction

Data were extracted from the studies by 2 independent reviewers (GD and DW) using an adapted version of the JBI standardized data extraction tool. Extracted data included specific details about the populations, study methods, types of smart home technology intervention used, outcomes assessed, and themes relevant to the review objective. Disagreements arising between the reviewers were resolved through team discussions. Both team members' input was equally valued and used when coming to agreements.

Data Synthesis

As the studies included were heterogeneous, the findings of the selected studies were narratively synthesized to examine the barriers, facilitators, enablers, perceptions, and attitudes of clinicians and how these factors may impact the readiness to adopt smart home technology.

Results

Summary of the Search Results

The initial search (Figure 2) of 12 databases resulted in 17,204 references. Additional records were identified (n=24) through manual searching, including searching of systematic review reference lists.

Table 1 presents the comparative characteristics of the studies and the GRADE rating. Table 2 presents the summary of the key factors that may affect clinician readiness to adopt smart home technology, which have been categorized into perceived challenges and perceived benefits. Multimedia Appendix 1 presents descriptive themes and subthemes. The results will inform researchers and clinicians regarding the challenges and perceived benefits of adopting smart home technology for remote health monitoring. Finally, the findings of this review were used to develop a smart home adoption model for clinicians, which is presented in Figure 1.

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.

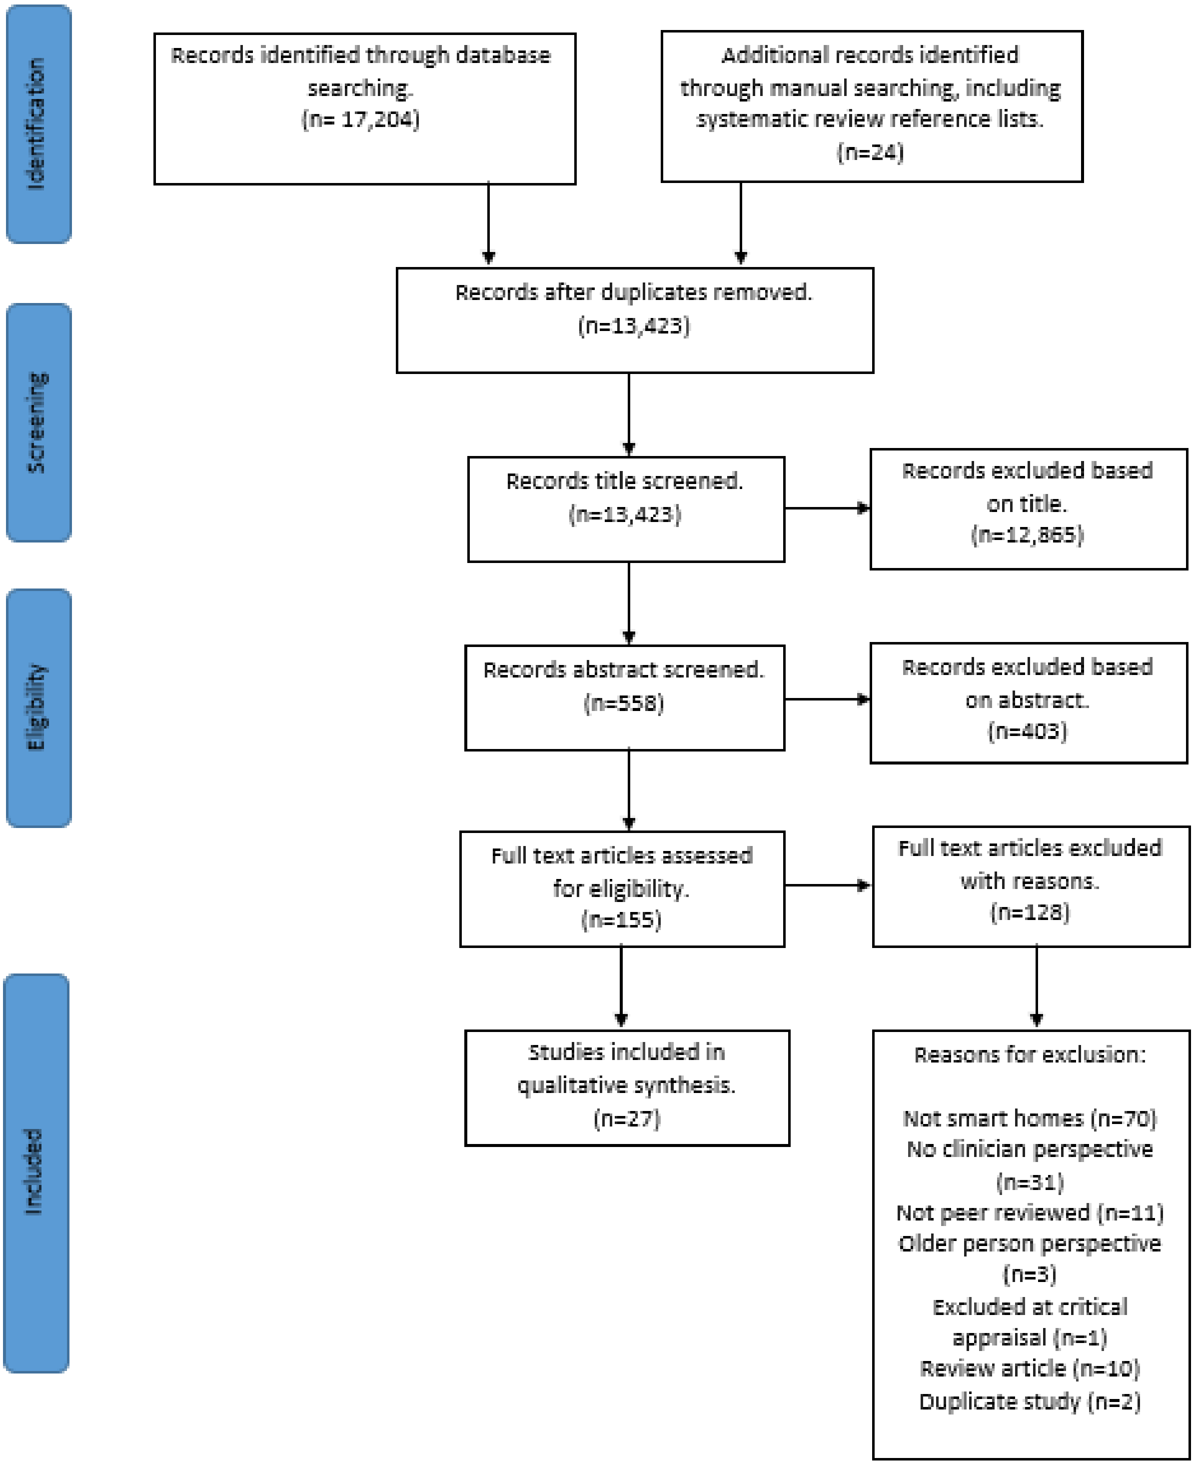


Table 1. Literature review table.

Study and country	Study design and purpose	Sample size and characteristics	Smart home technology	Outcomes assessed	Measures (GRADE[a])
Beaudin et al [32], United States	Qualitative; to elicit specific feedback from health professionals and lay people on how they might use longitudinal health monitoring data for proactive health and well-being	N=34; 8 health professionals; 26 lay people; professionals in aging and cognition, geriatric nurses, home nurses, cognitive psychologists, and OTs[b]	Developed mock sensor visual displays representing a hypothetical patient in a variety of constructs used to elicit feedback on longitudinal tracking ideas	Reactions to longitudinal monitoring in the ho me; types of behaviors, events, and physiological indicators that participants would be interested in tracking; primary question: can monitoring systems be designed that might be adopted by end consumers for personal use?	Interviews (low)
Brand et al [33], United States	Descriptive; to ask multiple stakeholders to rate their level of concern about the privacy of individuals with disabilities when receiving services via smart homes	N=209; 16 volunteers; 44 direct service professionals; 37 administrators or coordinators; 22 managers; 2 licensed practical nurses; 38 licensed practitioners (eg, psychologists, social workers, and behavior analysts); 18 family members or self; 6 teachers, advocates, or attorneys; 3 counselors-job- coach-trainers; 7 participants with multiple roles listed; 16 not clearly identified or specified; 9.6% aged ≥65 years; 27.3% aged 55-64 years; 25.4% aged 45-54 years; 16.3% aged 35-44 years; 19.1% aged25-34 years; 2.4% aged18-24 years	Participants were shown a short explanatory video that described how smart home technology was used to provide services to individuals with disabilities using video cameras, motion sensors, and remote coaches	Information about levels of concern associated with individual smart home technology; privacy concerns across various aspects of smart homes	Survey (low)
Caprani et al [34], Ireland	Qualitative; to explore HCPs'[c] preferences for using and visualizing sensor data	N=14; phase 1: 9 PTs[d]; phase 2: 0; phase 3: 2 OTs, 2 PTs, and 1 nurse; employment settings: community, nursing home, and community	Developed a mock system design based on clinician feedback consisting of smart home sensors to measure activity, gait, health, and sleep	How sensor technology can support the role of HCPs, technicians, and patients	Interviews (low)
Ding et al [35], United States	Qualitative; to explore the service delivery practices of mainstream smart home technology as assistive technology	N=15; 7 OTs, 6 assistive technology professionals, 4 aging-in-place specialists, 2 speech and language pathologists, 2 certified environmental access consultants, 1 PT, and 1 certified living administrator	Home automation devices to support independence in people with disabilities or older adults	Service delivery practice challenges and perspectives on benefits, limitations, and barriers	Interviews (low)

Study and country	Study design and purpose	Sample size and characteristics	Smart home technology	Outcomes assessed	Measures (GRADE[a])
Cohen et al [36], Switzerland	Descriptive and qualitative; to explore the perception of acceptability among CHNs[e] of an IWSS[f] for use in daily practice for the detection of health issues in home-dwelling older adults receiving home care; secondary analysis of qualitative data from a pilot RCT[g] of IWSS acceptability among home-dwelling older adults	N=17; CHNs were 88% (n=15) female; mean age of 26.4 years; practicing in home care for an average of 5.1 years	IWSS placed in living room, bedroom (time in bed), and refrigerator (tracked refrigerator door opening and closing). An algorithm analyzed and detected changes in behavior patterns regarding refrigerator opening and time in bed. CHNs received alerts via SMS text message followed by email and smart home reminders. The CHN had access to a smart application dashboard to discover the nature of the change in movements or activity patterns.	Perceived usefulness and perceived ease of use of IWSS among CHNs; number of alerts transmitted; relevance of IWSS alerts for CHNs in their daily practice	Survey and focus groups (low)
Delbreil and Zvobgo [37], Switzerland and the United Kingdom	Mixed methods; to examine the health professionals' recognition of sensor technology to enhance the QoL[h] of care recipients with dementia	N=60; comprised RNs[i], medical assistants, PTs, OTs, and social workers; physicians were excluded	WSN[j] technology	Effect of wireless sensor technologies on QoL; confidence of caregivers that wireless sensor technologies will lighten caregiver burden while satisfying end-user needs and QoL aspects; barriers to wireless sensor technology use; value derived in the older adult care sector from using sensor technology	Web-based survey (low-moderate)
Dugstad et al [38], Norway (based on the work by Nilsen et al [39])	Longitudinal case study; to identify facilitators and barriers and explore co-creation practices as an innovation strategy during the implementation of digital monitoring technology in LTC[k] for persons with dementia who were night wanderers	Workshops: n=172 (89 municipal health care service staff members, 8 IT staff members, 30 vendors, 14 research institutions, 3 NGOs[l], 5 other public-sector organizations, 20 innovation and funding organizations, and 3 external experts); interviews: n=16 (13 RNs and 3 HCWs[m]); focus groups:9 HCPs and 4 vendors	On the basis of the Digital Night Surveillance Innovation Project; using monitoring technology for a night surveillance intervention for increasing the safety of PLWD[n] who wander; 67 installations of the monitoring technology were implemented; sensors included door sensors, electronic security blankets on mattresses to monitor bed exit, and SMS text message–mediated alarm	Facilitators of and barriers to monitoring technology in long-term residential aged care; co-creation practices as an innovation strategy	Workshops, interviews, and focus groups (low)
Elavsky et al [40], Czech Republic	Mixed methods; to explore the barriers and concerns related to the adoption of smart technologies among different groups of stakeholders	N=390; qualitative data:12 professional caregivers and 9 experts in aging; cross-sectional survey: 369 older adults attending the University of the Third Age	Smart home technologies in care for older adults; ANUME smart bed system	Barriers to the adoption of smart technologies in the care of older adults; solutions to overcome these barriers	Mixed methods (moderate)

Study and country	Study design and purpose	Sample size and characteristics	Smart home technology	Outcomes assessed	Measures (GRADE[a])
Glasby et al [41], United Kingdom	Qualitative; evaluation of decision-making process and implementation of home-based sensor technology “IndependencePlus”	N=23; 3 decision makers and operational leads; 5 care staff members, care providers, and unpaid carers; 2 technology providers; and 1 regulatory organization	Home-based sensor technology “Independence-Plus” in 3 case study sites (1 care provider and 1 local authority); 1 care home with nursing services (23 clients) and 1 community care setting (9 clients); local authority with urban and rural areas (20-30 clients)	Decision-making process and implementation of “IndependencePlus”; barriers to and facilitators of the use of AI[o] in social care	—[p]
Hall et al [42], United Kingdom	Qualitative; to explore the extent of the ethical considerations of implementing monitoring technologies in 3 dementia specialist care homes	N=24; aged 21-64 years, mean age 39.75 years; managers, clinicians, and support workers (specific numbers for each profession not provided)	Bed sensors, pressure mats, sensors in ceiling, door sensors, RFID[q] location-based system, and accelerometer	Ethical considerations when using monitoring technologies in care homes; equality of access to monitoring technologies	Embedded multiple–case study design; interviews (low)
Hunter et al [43] (research brief) and Hunter et al [44]) original paper, New Zealand	Qualitative; to understand the perspectives of HCWs on the use of technology to provide aging in place to inform the development of a prototype system being tested in older persons’ homes	N=44; community-based care:5 nurses, 11 social workers, 3 PTs, 2 OTs, and 1 clinical coordinator; primary care practice:3 GPs[r], 8 nurses, 3 directors, 1 business manager, 2 clerks, 2 geriatricians, and 1 social worker; predominantly female, with a mean age of 46.6 years	Smart home technologies and home monitoring devices, including technologies that involve interaction among societies, complex infrastructures, and human behavior	Health providers’ perspectives on the use of smart home technologies to provide services to older adults; types of information needs; the type of information that should be collected and transferred; the purpose of the information collected; who should receive the information; ethical concerns	Focus groups (low)
Ienca et al [45], Switzerland, Germany, and Italy	Qualitative; to explore the views and attitudes of health professionals and researchers involved in psychogeriatric care and research on IATs[s] for dementia and older adult care	N=17; 41% female; professionals from gerontology, geriatrics, general practice, neurology, neuropsychology, nursing, nursing home management, and psychiatry	IATs discussed in interviews: distributed systems, robots, mobility and rehabilitation aids, handheld or multimedia, software apps, wearables, and human-machine interfaces	Health professional expectations, needs, and perceptions regarding IATs; practical experience with IATs; perceived effectiveness of IATs; health professional recommendations for improving IAT use for end users	Interviews (low)
Islam et al [46], Australia	Qualitative	N=9; clinicians from different settings involved in the clinical care of people with cardiovascular disease or heart failure; 3 cardiologists, 1 pharmacist, 4 nurses, and 1 GP	Smart home system for heart failure, including sensor-enabled medication monitoring; motion sensors; blood pressure, weight, and fat percentage monitoring; voice activation; wearable for activity; sleep and heart rate monitoring; and educational content, alerts, and messaging	Key HCPs’ perspectives on using smart home system to support self-management and home-based care in people with heart failure; types of technologies useful to support the self-management of patients with heart failure; barriers to and facilitators of uptake	Interviews (low)

Study and country	Study design and purpose	Sample size and characteristics	Smart home technology	Outcomes assessed	Measures (GRADE[a])
Klemets et al [47], Finland	Qualitative; to determine how wireless sensor–collected information about an older adult's physical motion can be used by nurses	N=9; nurses (5 from home care team)	Smart home project–developed prototype wireless infrared sensors placed in each room; monitors in-home physical activity, bathroom visits, physical motion, and time spent in different rooms and outside; data are presented as daily physical motion patterns	Challenges to nurses' existing care provision and whether elementary information about older adults' motion patterns could support their work	Interviews (low)
Klemets et al [48], Finland	Qualitative analysis of a case study; to determine how an in-home monitoring system can be used and integrated into home care nurses' workflows and identify the factors that influence system adoption	N=4; 3 RNs and1 head nurse	IOT[t] architecture with PIR[u] motion sensors to monitor activities of daily living, including bathroom visits and time spent in rooms; sensors were placed in 8 residents' apartments, and nurses captured their thoughts and reflections on the in-home monitoring system in a notebook; they were interviewed on the system's use and usefulness; nurses used the in-home monitoring system 2 times weekly for 4 weeks	Nurses' perspectives on a deployed in-home monitoring system	Focus groups and interviews (low)
Lee and Dey [49], United States	Case study (interviews); to determine how reflecting on sensor data about everyday activities will aid patients and their clinicians in making better informed decisions about their care	N=9; 6 primary care physicians and 1 oncology specialist; case studies of 2 older women (aged 81 and 77 years)	Ubiquitous sensor "dwellSense" system deployed in older adults' homes for 10 months to monitor ODLs[v] using smart pill box, phone sensor, and sensor-augmented coffee maker; relies less on machine learning and more on simple task-based sensors and heuristics applied to common tasks	Patients: support self-reflection, self-awareness, and improvement of their ability to live independently in their home; clinicians: how can clinicians make care plans based on information about patients' ODLs based on data captured by the sensing system	Interviews (low)

Study and country	Study design and purpose	Sample size and characteristics	Smart home technology	Outcomes assessed	Measures (GRADE[a])
Mahoney et al [50], United States	Multiphase mixed methods; to gain an understanding of the needs of independently living residents and whether remote residential monitoring using off-the-shelf wireless sensors might address these concerns	Predevelopment focus groups: n=26 (13 residents: mean age 7 9 years, widowed, and 66% female;4 family members [no details given]; 9 staff members: most were middle aged and female); intervention focus groups: n=29—10 residents, 10 family members, and 9 staff members (residents:60% female, White, mean age 83, range 70-91 years, and most were widowed [n=7]; family members: 60% female, White, mean age 56, range 40-76 years, and married [n=8])	AT EASE[w] remote home monitoring system consisting of motion sensors in each room, water sensors in the bathroom, ability to remotely enable or disable the system, a processing unit with internet connection, and a Zigbee computer interface and custom automation software application; additional sensors available but not desired by participants: contact sensors for doors, pressure sensors for beds and chairs, and appliance on and off sensors	Types of concerns for staff, residents, and families for monitoring independently living residents; potential signal interferences due to density; monitoring system adaptability to the concerns of end users without security breaches and invalid alert notices	Focus groups and questionnaire (low)
Martin et al [51], Ireland and the United Kingdom	Qualitative; to investigate care staff perspectives on an ambient-automated home environment in dementia-specific housing to design a user interface	N=7; 5 care staff members and2 senior management stakeholders employed at the housing scheme	Discrete sensor network to support tenant activity and daily living tasks with minimum staff intrusion; sensors included PIR sensors, door contacts, pressure pads, and water and cooker valves	Staff perspectives on tenant activity had the potential to inform the care process; how this information should be presented on a computer user interface from the data monitor in the staff office	Interviews (low)
Newton et al [52], United Kingdom	Qualitative; to explore the views and experiences of people with dementia and their family carers and GPs regarding accessing information about and use of assistive technologies in dementia care	N=56; 17 GPs (mean age 42 years, including 6 trainees and 5 GPs with a commissioning role [mean age 30 years]), 13 people with dementia (mean age 72 years), and 26 family carers (mean age 61 years)	Photographic images including the following assistive technologies: community alarms and telecare, GPS location monitoring devices, signage, reminiscence tools, clocks to aid orientation, simplified telephones with pictures, and dementia-friendly furniture; personal and practical experience with assistive technologies, such as pendant alarms, fall alarms, door exit sensors, pill dispensers, signage, and easy-to-use telephones	Knowledge and experience of accessing information about and use of assistive technologies in dementia care	Interviews (low)
Nilsen et al [39], Norway	Longitudinal single-embedded case study; to identify and describe forms of resistance to the implementation of night surveillance technology in nursing homes and home care services	N=50 participants with 17 HCPs; network of small to medium-sized technology enterprises and3 municipal health and care services; university research group	Digital night surveillance system with digital communication, sensors on doors, and electronic security blankets on mattresses used during the night	Types of resistance among night care staff to the implementation of the monitoring technologies	Co-creation and implementation process using interviews, focus groups, observations in meetings, and workshops (low)

Study and country	Study design and purpose	Sample size and characteristics	Smart home technology	Outcomes assessed	Measures (GRADE[a])
Offermann-van Heek and Ziefle [53], Germany	Mixed methods; to investigate the PC[x] acceptance of assistive technologies in professional care contexts	N=170; 74.7% female (mean age 36.26, SD 11.23 years); 25.3% working in geriatric care, 22.9% working in medical care, and 51.8% working in care of people with disabilities	Scenario of integration of AAL[y] system, including room sensors, microphones, video cameras, and ultrasonic sensors	PC acceptance of assistive technologies in 3 care contexts: geriatric, medical, and care and support of people with disabilities; PCs' perceptions in different care contexts on AAL technologies, willingness to share care-related data, willingness to be assisted by specific AAL technologies in their daily routines, and which are the main predictor variables for AAL acceptance at a data level	Interviews that informed web-based questionnaire (low)
Pais et al [54], Switzerland	12-month observational study; to evaluate a new in-home monitoring system among home-dwelling older adults, their family caregivers, and nurses for the support of home care	N=46; 13 older adults, 13 family caregivers, and 20 nurses (characteristics of nurses not given)	In-home monitoring system DomoCare using ambient sensors to monitor mobility, sleep habits, refrigerator visits, and door opening and closing; wearable sensors: activity tracking and ECG[z]	Opinion on the usefulness of ambient and wearable sensors; satisfaction of the older adults, family caregivers, and nurses with ambient and wearable sensors; impact of sensors on the relationships among the older adults, family caregivers, and nurses; impact on in-home care practice (integration and barriers)	Observational study (low)
Peek et al [55], the Netherlands	Qualitative, longitudinal field study; to gain insights into the positions of stakeholder groups involved in the implementation of technology for aging in place	N=29; 5 groups of stakeholders in the process of implementing technology for aging in place: 6 older adults, 7 care professionals, 5 home care and social work managers, 6 technology designers and suppliers, and 5 policy makers; mean age 32.55 years	Scenarios that describe aging in place and the need for creative solutions to provide good-quality care	Types of technologies that could support aging in place; feedback on when participants would consider that the use of technology for aging in place is a success; what participants need to be able to successfully implement technology for aging in place; what participants can contribute to achieve successful implementations	Focus groups (low)
Rampioni et al [56], Italy and Romania	Qualitative study; to collect and analyze the perspectives of older adults, family caregivers, and stakeholders in the fields of care and technology on a list of devices that promote healthy aging	N=30; 13 older adults; 8 caregivers; 9 clinical stakeholders, including 1 end-user representative; and 8 psychologists; 6 women and 3 men	A 15-minute video about the European project SAVE[aa] was presented; a storyboard was used to show participants how they would interact with the SAVE system; the SAVE system is a multicomponent platform with multiple smart home and wearable sensors streamed directly to a cloud-based platform to detect behavioral and psychological deviation; location services; telemedicine; thermostat; video communications; antiflooding; smart plug (appliances); gas detector; to-do list	Whether the video or storyboards evoked something in their mind and what (features, services, or suggestions to improve the system); why they found it interesting or otherwise, including added value and pains and gains	1:1 interviews with older adults and caregivers; focus group with clinical stakeholders (low)

Study and country	Study design and purpose	Sample size and characteristics	Smart home technology	Outcomes assessed	Measures (GRADE[a])
Verloo et al [57], Switzerland and France	Qualitative; to examine and understand the perceptions of professional caregivers, informal caregivers, and older adults with cognitive impairment by showing photos of different technologies	n=68 CDOAs[ab] (74% women with a mean age of 82, SD 7.2 years; 60 urban, 35% independent, 34% physically impaired, and 31% cognitively impaired); n=21 IC[ac] (mean age 68, SD 13.8 years, with 76% being women and retired [n=13]); n=32 PCs (mean age 46.7, SD 9.4 years, mostly female, 91%; physicians, 10%; nurses, 34%; social workers, 6%; nursing assistants, 10%; care assistants, 31%; and OTs, 3%)	10 photographs of relevant smart technologies, including light path, fall detector, electronic pill box, robot vacuum cleaner, service robot, GPS bracelet, touchscreen tablet, social network, brain training, and activity sensor	Perceptions of these technologies among CDOAs with physical and cognitive impairment, professional caregivers, and informal caregivers	1:1 interviews, focus groups, and photo elicitation interviews (low)

Study and country	Study design and purpose	Sample size and characteristics	Smart home technology	Outcomes assessed	Measures (GRADE[a])
Warner et al [58], Canada	Qualitative; apply an implementation science framework to explore the multilevel barriers and facilitators that could affect the implementation of passive remote monitoring technology in home care settings from the perspectives of key informant stakeholders from Nova Scotia, Canada	N=20; 4 policy makers, 4 home care managers, 6 direct care providers, 3 resource navigators (registered nurses), and 3 technology providers	Passive remote monitoring technology, including motion sensors, cameras, and medication administration monitoring	Key informant stakeholders’ perceptions of the barriers to and facilitators of implementing passive remote monitoring technology among older home care service recipients	Interviews (low)

[a] GRADE: Grading of Recommendations, Assessment, Development, and Evaluation.

[b] OT: occupational therapist.

[c] HCP: health care professional.

[d] PT: physical therapist.

[e] CHN: community health nurses.

[f] IWSS: intelligent wireless sensor system.

[g] RCT: randomized controlled trial.

[h] QoL: quality of life.

[i] RN: registered nurse.

[j] WSN: wireless sensor.

[k] LTC: long-term care.

[l] NGO: nongovernmental organization.

[m] HCW: health care worker.

[n] PLWD: persons living with dementia.

[o] AI: artificial intelligence.

[p] Not applicable.

[q] RFID: radio frequency identification.

[r] GP: general practitioner.

[s] IAT: intelligent assistive technology.

[t] IOT: Internet of Things.

[u] PIR: passive infrared.

[v] ODL: observation of daily living.

[w] AT EASE: Automated Technology for Elder Assessment, Safety, and Environment.

[x] PC: professional caregivers.

[y] AAL: ambient assistive living.

[a] ECG: electrocardiogram.

[aa] SAVE: Safety of Elderly People and Vicinity Ensuring.

[ab] CDOA: community-dwelling older adults.

[ac] IC: informal caregivers.

Table 2. Summary of key factors that may affect clinician readiness.

Theme and subthemes	Exemplary quotes
Perceived benefits	
Improved clinician-patient relationships	• "...Having the ODL data visually available for both the patient and physician can help remove the confrontational aspect of asking the patient about bad habits. Instead, with a shared objective view, the physician can have a conversation about ODL data similar to how she discusses laboratory results with patients." (Physician; Lee and Dey [49]) • "We wouldn't rely completely [on physical motion information], I'd interview, ask, and listen as well of course." (Nurse; Klemets et al [48]) • "We were hoping it would help them with the assessment process and help them to genuinely understand how people use their homes and therefore what their needs were, so if that person wasn't really showing, for example, that they were making or seeming to be making themselves regular drinks, that's something that we would be able to factor in, because sometimes when you speak to someone and they say 'oh yes I eat very regularly and oh yes I've had no trouble at all making a cup of tea,' but they're either telling you what they think you want to hear or forgetting or fibbing or something, so we felt it would be a useful kind of tool to help a professional really understand the holistic needs of someone in not too intrusive a way." (Case study site 2: Participant 04 [41])
Detection and prediction of health events	• "If they found that a client's feet were swollen, this could be explained by sleeping while sitting in a chair rather than sleeping lying down." (Nurse; Klemets et al [47]) • "...for those that we visit less regularly it would be beneficial, those that are still in good shape. If there is a sudden change, we could find out earlier. Parkinson's and Alzheimer's disease have these degradation phases." (Nurse; Klemets et al [48]) • "Reporting on tenant motion within the apartment was therefore deemed to be a useful activity report. Other activity reports requested were, sleep pattern, water usage, front door activity and general activity within the apartment. Staff opinion was that these could be useful on a daily basis to inform the care requirements of individual tenants." (Dementia care staff member; Martin et al [51]) • "...the record provided a 'suggestion of a problem' that he did not detect from his visit in the office and made him suspicious about patient's 'fishy' situation. If he had seen these data during the patient's last office visit, he would have tried to investigate." (Lee and Dey [49]) • "I think it could help patients because it would make them more independent with their care, make them more responsible, and seeing their signs and symptoms will give them the power to manage [them]...and hopefully prevent hospital admissions." (Participant 4; nurse [46]) • "The patient might be thinking, okay, this shortness of breath is [...] probably usual for them, normal for them, but they are not thinking...this shortness of breath may be worse [than usual]. But if it can be picked up with the smart home system, it can be picked up early stage, which can prevent worsening of HF. Preventative measures can be taken before they become really worse when that patient needs the hospitalization." (Participant 8; cardiologist [46]) • "[Remote monitoring technologies]...allows people to respond faster when something goes wrong." (Key informant 11; home care manager [58]) • "Part of the selling point of IndependencePlus was that, you know, the machine learning would pick up when somebody's daily routine had changed and would alert you to that fact. So, you know, the kit would send a text message to a carer saying 'Usually your mum has five cups of tea by this point and today she's only had one,' you know. 'Do you want to check this out?' or, you know, 'Your mum's usually out of bed by this time; she hasn't got up yet, might be worth going round.'" (Case study site 5: Participant 05 [41])
Facilitation of evidence-based practice	• "I think the environment and the type of dementia care...an individualized care closely dependent on the stage of the disease and as adapted as possible to the personal needs (of the user)." (Psychiatrist; Ienca et al [45]) • "I would say it's patient report, when we're recommending a lot of these things it's about independence, safety, and reduced caregiver burden, so those are kind of the things I'm looking for, and also are they still using it in 6 months when they come back for their re-eval or did they abandon it because it's just too complex." (Practitioner [35]) • "I think patients are not aware [...] as to what they need to know and why so it can be hard to drive compliance. Sometimes you have to educate patients multiple times. You know, one individual session just before the patient is being discharged from the hospital is not enough. You have to repeatedly provide the same information to the patient [and] encourage them to ask questions [...] If something like this can be organised, like even if it's telemonitoring [...] or web monitoring, that would be great." (Participant 1; nurse [46]) • "Within advanced HF, people end up having certain devices implanted, like, cardiac resynchronisation therapy pacemakers. These have different sensors as well as implanted in the heart that give us an idea sometimes of whether the patient is holding on to more fluid and helps doctors adjust things before the patient becomes too symptomatic." (Participant 2; nurse [46]) • "...that client...was supported in his home much longer than anticipated...Because the reason why he would get readmitted [to hospital], have frequent admissions to the hospital, was because he was forgetting to take his medication." (Key informant 4; home care manager [58])

Theme and subthemes	Exemplary quotes
Positive impact on patients, clients, and family caregivers	• "If those devices weren't there, I feel that there were some [home care] clients that...would have been normally removed from their home because of the risk..." (Key informant 4; home care manager [58]) • "...that there's...a few long-term care beds that are open, and it's so difficult to get in. And then seniors often land in the hospital and take up the hospital beds...and I know that there's a great deal of stress in terms of the number of...workers that are available...the homecare business or support has been very much challenged...homecare may be only able to provide you with two hours a day when really that senior requires more than those two hours." (Key informant 20; registered nurse [58])
Peace of mind	• "Something like the smart home system, it's a very [...] efficient module or system, because [...] it helps relax the people at home, the patients themselves and the health personnel. Because they know that they are taking care of the patients, [...] even though if he's very far away, they know that he's safe because you can see all the data." (Participant 3; nurse [46]) • "This allows them...to stay at home with that peace of mind, especially their families to know if they've had a fall. That's a big reason why people end up going to long term care sooner, is if they've had frequent falls, if they're not safe at home." (Key informant 13; direct care provider [58])
Perceived barriers	

Theme and subthemes	Exemplary quotes
Impact on clinicians	• "A presently trained and configured family...doctor would think it was junk. They would go, 'Well, that's interesting, I got 9 more minutes...[of the appointment left].'" (Physician; Beaudin et al [32]) • "Nurses claimed that they were too busy in their daily work and that the many other computer systems they already had to use were too time-consuming." (Nurses; Klemets et al [47]) • "Db6 an oncology specialist, expressed that he (and his office staff) would be too busy to review charts of the ODL data before a visit with the patient because they are already overloaded with tasks to perform." (Physician; Lee and Dey [49]) • "People in the clinics have just a general idea of what can be done, but very few ideas, not so much understanding of what that technologically means." (Psychiatrist; Lenca et al [45]) • "I don't have much knowledge about this. It's true and it makes sense that some training on this wouldn't be bad." (Professional caregiver; Verloo et al [57]) • "It's a lot of trial and errors so often times I have to go back to the assessment part of things after trying 1 device that doesn't work, so it's kind of ongoing throughout the course of treatment." (Practitioner 45) • "Yeah, there still isn't a road map. There are no instructions on how to do this. There's no textbook. And oftentimes while manufacturers may make their products compatible, they don't tell you how to combine them..." (Practitioner 45) • "Our lead domiciliary care provider, they're not geared up to looking at health data and making health judgements based on that, so quite rightly they were saying 'we've got this thing that says heart rate spike, what does that mean, do we have to contact a GP, what's going on?' So there was a lot of confusion around that, and we actually stopped using the system through COVID because of that." (Case study site 4: Participant 01 [41]) • "Because so much of it is health metrics or what would indicate medical problems or something that needs medical attention and support, I think that it needs to be the team that knows the most about that information, it needs to be people who can interpret what normal heart rate data needs to look like and what normal sleep patterns might look like...so it needs people who know what they're looking at, know how to interpret it and are skilled and already knowledgeable about how to take that medical data and turn it into actions. This is when we need to call the GP. This is when we need to call an ambulance. This is when we need to change these meds. This is when we need to—you know, it needs to be the people who will make those medical decisions who are interpreting those data." (Case study site 1: Participant 01 [41])
Impact on clinician identity	• "...worried that if he had been given the ODL data, a jury one day may question his 'interpretation of the dots' in the visualization if the patient had an adverse event related (or even worse, unrelated) to the data in question." (Physician; Lee and Dey [49]) • "I think that these instruments should remain assistive tools and shouldn't replace medical examinations, diagnoses or therapies. I find this a risky trend: if doctor-patient contact is abolished and everything runs via apps...I think this is dangerous..." (Psychiatrist; Lenca et al [45]) • "Some night staff felt that the RFID [location-based tracker] system had been used as a 'Big Brother tool for management' to monitor staff activity." (Health care worker 48) • "I think it's hard to keep up with all the technology changes and I find that as soon as I learn something new, my patients have surpassed me or their family members have heard of something..." (Practitioner 45) • "The problem is people probably want all of it and they can't have all of it, so you need to decide what's your highest priority. Is our highest priority to know when somebody's fallen over so we can go and pick them up and maybe get them to hospital, is that our highest priority? I don't know...Or is our highest priority to have lots of data about people so when we come to review them or assess them, we make better decisions?...Or is our priority something as simple and practical as I want a very good automated meds dispenser for people who are able to take their own medication because overnight that saves me about 500 hours of care a week and, what's that, a lot of money?" (Case study site 4: Participant 02 [41]) • "We're changing the way [we provide] care and that needs some different mindsets and skills or additional to what the care staff have. So the care staff generally have very—they want to be supportive and help people—they're that kind of character generally—some more than others are comfortable around technology." (Case study site 1: Participant 02 [41])
Potential adverse impact on the patient	

Theme and subthemes	Exemplary quotes
	• "These are people that no longer use any technology in their daily life, except for a light switch...very few can use a coffee machine, so it's very difficult to approach..." (Gerontologist; Ienca et al [45]) • "What worries me is situations like this, where the children have even put cameras in the bedroom, not to monitor their parents, but rather to reassure themselves." (Professional caregiver; Verloo et al [57]) • "...there is something about, as I am saying, when I enter a patient room then there is something about what I see and smell and find out how things are as a whole, plus he [the patient] might say that today I would like to watch TV a bit longer...for example." (Health care provider; Nilsen et al [39]) • "...it should be person-centred, and technology isn't person-centred...you've got the technology, but you can't use it until he's capable of accepting [it]...you can't treat everybody the same, and that's where technology falls down, because it'd be too [expensive] to personalise it, and then who'd pay for that?" (Nurse 48) • "...these technologies could like bring on a sense of paranoia or bring on some behavioural and psychological symptoms of dementia for someone...oftentimes people talk about being watched, and we brush that off as being a sign of dementia. When in this case...It would be accurate." (Key informant 12; direct care provider [58]) • "I often explain it that we used to, when we were going out for like IndependencePlus and other technology projects in the past, we used to think what technology's out there and let's go and buy it and now let's look at people that we provide care for and fit them to that technology. That is probably the biggest learning, that that's a mistake. We shouldn't be doing that." (Case study site 4: Participant 01 [41])
Concerns about privacy and data security	• "...there are ethical problems if it's used as a means to monitor the person..." (Professional caregiver; Verloo et al [57]) • "I have no problem displaying what I do at work. I rather think of the user, of...Where did the privacy go? I enter and leave the room and do my job, and am supposed to be professional. But the users shall feel that they have a private life when they enter their flat, that they are not going to be under surveillance, 'cause that is unnatural." (Health care provider; Nilsen et al [39]) • "...we get lots of issues or questions from folks around privacy..." (Practitioner 45) • "...going back to the whole privacy thing as well, that's very important to clients. So educating them about how this technology works..." (Practitioner 45) • "The privacy and confidentiality issue will be very important for the patient, especially when we're talking about clouds and everything and how to protect their privacy." (Participant 6; pharmacist [46]) • "The challenge with this, even as a concept, is this idea of it's all a bit Big Brother-like, it's all a bit you know, sort of a bit 'spying'...The challenge would be to break down some of the stigma that might come with that. I'm not necessarily saying that it's true, that it's like a bit Big Brother-like, but I think that is the perception amongst some people who might be resistant to using the technology, you know. If it's just there forever, recording how many times I use the toilet, you know, it's uncomfortable." (Case study site 2: Participant 03 [41])

Outcomes Targeted

Clinician feedback, attitudes, perceptions, and experiences regarding the use of HAS technology is critical because clinicians are an important end-user group [46,58,59]. Clinicians may use the technology to monitor people living with chronic diseases [46] and use the information in care planning [13]. While the smart technology could optimize clinical care delivery and augment clinical decision-making, certain factors may impact clinicians' readiness to adopt smart home technology for health monitoring.

Populations Included in the Review

Among the 27 studies included, most (n=19, 79%) had a mix of clinical and nonclinical participants, including social workers [32-34,43,44], management [33,35,45,50,51,55,58], policy makers [55,58] or decision makers [41], aging-in-place specialists or experts [35,40,41], older adults [40,42,50,55-57], relatives [42,52], informal caregivers [56,57], and technology designers and suppliers [35,41,55,58]. Table 1 shows that the clinician population recruited was highly variable. Health care workers and care staff and support workers were included in several studies [32-34,37,38,40-42,44,51,53,55,57,58]. The represented clinical disciplines included nursing [33,37,38,40,41,43,44,46-48,58], medicine [32,38,39,43,44,46,49,50,52,53], physiotherapy [34,35,37,43,44], ergotherapy [37], cardiology [46], occupational therapy [35,43,44], psychology [33,56], psychiatry [45], pharmacy [46], gerontology and geriatrics [45], speech and language pathology [35], and neurology and neuropsychology [45,50]. Clinicians worked in a variety of settings in various roles, including in community settings such as home care as direct care providers, navigators, or managers.

Smart Home Technology Use

The studies described a variety of smart home–type technology to monitor specific aspects of activities of daily living. The use of mainstream smart home technology such as home automation devices and smart speakers was described [35], and other studies (n=14, 52%) reported on the use of technologies for remotely monitoring several aspects of activities of daily living, including appliance use [41,55]; use of water [51]; medication adherence [47,49,55,57]; phone and coffee maker and kettle use [41,49]; bathroom and toilet visits [41]; time spent in different rooms and time spent outside [48]; cooking [51]; nighttime monitoring of resident location [38,39,42,52]; general in-home physical motion [57]; resident mobility, including steps ambulated, such as location, activity time, and duration [42]; door use and opening [39,41,42,51,52]; health issues [36,55]; fall detection [34,55,57]; wandering detection [55]; and monitoring of getting in and out of bed [39,42,46]. Several studies (n=6, 22%) included the use of cameras or microphones [33,53], wearables to track activity [46,54], and electrocardiograms to monitor heart rate connected to web-based portals and mobile devices

[39]. Pressure mats [42], smart beds [40], security blankets [39], and alarms [52] were used to monitor residents' activities of daily living, such as sleep and other activities, and remind them to engage in health activities (eg, taking their medication and sleep hygiene). Telecare and remote coaching to facilitate communication were also reported [33,39,52]. Authors described monitoring of task-based resident in-home activities [49] to facilitate residents' independence and emotional connectivity while minimizing staff intrusions [37,51]. For example, in the study by Glasby et al [41], the authors report the implementation of home-based sensors with artificial intelligence capabilities in pilot case study sites. The sensors were placed in key locations of individual homes to remotely monitor opening and closing of doors, kettle use, refrigerator door opening and flushing of the toilet [41].

Notably, 30% (8/27) of the studies did not implement the smart home technologies but investigated health care professionals' predeployment preferences for using smart home technologies [34,43,44,46,56,58], privacy concerns [33], and the issues associated with using smart home and telemonitoring systems [43,44,46]. For example, to obtain clinicians' perspectives, Islam et al [46] provided the clinicians involved in the clinical care of patients with cardiovascular disease with a schematic for a prototype smart home system that included sensor-enabled medication monitoring; blood pressure, weight, and fat percentage monitoring; and a wearable for sleep and heart rate, as well as educational content, alerts, and messaging [46].

In another study, Warner et al [58] explored key stakeholders' perceptions of the barriers to and facilitators of implementing passive remote monitoring technology, including motion sensors, cameras, and medication administration sensors among older home care service recipients [58].

Similarly, the studies by Hunter et al [43,44] investigated the issues that are potentially associated with using smart home and telemonitoring technologies to support older adults. The work by Hunter et al [43,44] was first reported as a research brief [43] and later as a traditional research paper [44]. Another study explored whether sensor-generated motion patterns could support the work of nurses [48] and elicited clinician's views on the sensor-generated data visualization displays. The study by Beaudin et al [32] examined the types of physiological indicators that clinicians would like to monitor for the patients in their care [32]. The study by Rampioni et al [56] examined stakeholder perspectives on how information and communications technologies and sensing technologies could address the needs of older adults for active and healthy aging [56].

Discussion

Principal Findings

Perceived Benefits

Many clinicians in the studies included in this systematic review recognized the benefits of integrating smart home technology to monitor and facilitate care of their patients. First, clinicians perceived that overall quality of care can be enhanced with the use of a variety of patient data collected objectively and over time by the sensor technology [32,34,43,45,47-49,54]. For example, previously difficult-to-obtain data such as nighttime behaviors can provide accurate information about a patient's well-being that may otherwise not be included in clinical decision-making [47]. In addition, there is often a mismatch between what patients report and what is actually happening in the home. Understanding the actual holistic needs of patients as unobtrusively as possible was considered helpful for health professionals [41]. Second, clinicians perceived that adopting smart home technology for remote health monitoring could lead to feeling more informed by real-time and just-in-time data [34,46-49]. Provision of just-in-time data can facilitate timely patient transitions [34], allow for appropriate clinical responses [34,47,48], and enable clinicians to act quickly in response to data that could forecast clinical emergencies [46,53,58]. Third, clinicians recognized that the combination of access to real-time, objectively collected data can facilitate clinicians' understanding of patients' needs and risks and tailoring of care approaches accordingly [46,53,58].

Fourth, clinicians perceived that access to data about activities of daily living collected in the context of the patients' environment was beneficial because it could empower clinicians to identify early patterns of decline [32,34,47,48] and changes in cognitive and functional capacity [34,47-49], forecast future health events [46,47], and enable clinicians to tailor appropriate actions to address health concerns [32,49]. In addition, in-context sensor data [32] were considered more reflective of a patient's health, which could empower clinicians to implement and evaluate tailored care approaches and identify and act upon any issues quickly [32,34,48]. Importantly, contextually collected smart home sensor data case studies could be useful to promote adoption of a specific intervention or care approach [49,58].

A final benefit perceived by clinicians was the potential for enhancing clinician-patient relationships and the ensuing positive psychosocial impact on patients. Clinicians recognized the potential of smart home technology to streamline clinical visits, saving clinicians and patients time [43,58] and reducing health care costs [45,50]. Importantly, clinicians could present the collected data to patients in the form of a visual summary [49], which could facilitate meaningful discussions with patients or family members about their care [32,51,58], enabling patient-centered, informed care decisions [48]. Smart home technology–enabled patient-centered care could support clinicians in addressing numerous dimensions of care concerns, such as respect for the values, preferences, and needs of patients; coordination of care and integration of services; communication and accurate, timely, and appropriate information; enhanced physical comfort and emotional support; involvement of family and friends; and transition and continuity of care [58,60]. Addressing these dimensions of care can lead to strong clinician-patient relationships, which can empower patients to feel more involved in their care [61,62] and self-management [46,56]. Consequently, contrary to perceived threats of smart home technology resulting in disconnection between clinicians and patients [39,57], many clinicians reported that the use of smart home technology for remote health monitoring could strengthen clinician-patient relationships and enhance patient motivation [32,50] and social relations [45].

Perceived Challenges

Clinicians perceived several factors that were challenges to the adoption of smart home technology for remote health monitoring. Chief concerns included privacy, data security, and the ethical and moral use of potentially "invasive" technology and the clinicians' capacity to learn how to use the smart home technology and the generated data. First, nearly half (11/27, 41%) of the reviewed studies highlighted clinician concerns about the privacy and dignity of patients and the security of their data [32-35,39,42-44,46,47,51,53,57]. Brand et al [33] provided insight into the privacy concerns of a mix of stakeholders, including nonclinicians. Survey respondents emphasized the importance of both patient privacy and the secure storage of personal data. They were particularly concerned with the use of video cameras with visual fields that included bedroom and bathroom entrances [33]. While such locations within the home are essential for establishing and monitoring important patient norms regarding activities of daily living [63] and well-being [64], in contrast, Nilsen et al [39] acknowledged that monitoring using a digital night surveillance system with digital communication, sensors on doors, and electronic security blankets made it possible to monitor the patient without disturbing them [39]. These findings suggest that clinicians may perceive sensor technology as less intrusive than video cameras. In addition, clinicians who experienced using the smart home technology highlighted that physically entering a patient's room was also an invasion of privacy [39]. Concerns were also raised regarding the privacy and ethical use of sensor-collected data by Peek et al [55] and Islam et al [46]. These authors emphasized the importance of confidentiality and protecting patients' privacy via clear privacy policies when such technology is used. This suggests that both clear policies and a working knowledge of the available smart home sensor technology will be important for its successful adoption by clinicians.

Second, clinicians expressed concerns regarding their capacity to successfully adopt smart home technology, highlighting the demands required to master software and build the requisite competency [35,43,54] and the perceived time required to view and interpret data [47,54]. A lack of familiarity with sensor technology was a clear challenge [39], highlighted by clinicians citing the effort required to "get used to the system deployed" and "understand and interpret graphs" [47]. Notably, Ienca et al [45] reported a lack of clinician technical skills and digital resources as perceived causes of suboptimal care. While clinicians perceived the need to gain competency regarding smart home technology and the interpretation of smart home sensor data as a challenge, clinicians have been described as capable of understanding the depth of information derived from smart home technology over time [47].

In addition, while older adults enjoyed using smart home technology [55], clinicians expressed concerns about patient readiness to adopt complex smart home technology [44]. Similarly, Ding et al [35] explored the service delivery practices of mainstream smart home technology as assistive technology and found that there were concerns about lack of instructions or manufacturer guidelines on the compatibility and interoperability of devices.

Subsequently, the use of mainstream smart technology in combination with other health-related smart home technology may encounter barriers to adoption by clinicians. Clinicians may need to anticipate substantial education and knowledge gaps, especially among patients who may have concerns about Big Brother–type intrusion into their private life [43,58]. The potential deficits (skills and resources) of both clinicians and patients will need to be addressed for broad adoption. Deployment of a user-friendly and easily navigated system [51,55] could facilitate successful adoption and ensure optimal provision of care.

The perceived negative impact of smart home technology on patient well-being is another important factor that could impact clinician readiness to adopt from psychosocial, quality of care, and equity perspectives. Clinicians reported perceptions that smart home technology could be harmful to patients [58,65]. For example, patients may incorrectly interpret their sensor data assuming causation rather than correlation between behaviors and changes in health [32]. This could lead to self-directed lifestyle changes to the potential detriment of their overall health and quality of life [32,39]. In another example, Warner et al [58] found that patients may experience paranoia because of monitoring devices in the home.

Similarly, clinicians recognized that potential evidence of a decline in health could lead to depression or have a negative self-fulfilling effect on a patient's self-perception [32], exacerbating their physical and mental conditions. Clinicians also raised concerns that remote monitoring may create real or imagined distance between themselves and their patients, which could have a negative impact on the health of the patient [39,57]. For example, many patients placed a high value on nurse-patient interactions [60]. Conversely, the question of equity of access was also raised by some clinicians, posing a social justice challenge to adoption wherein some patients may benefit from access to the technology while it remains inaccessible to others [39], thereby making it inequitable for clinicians to adopt smart home technology for certain segments of the population (eg, those who can afford it). All these factors regarding the well-being of patients expressed by clinicians need to be considered because they could impact clinicians' readiness to adopt smart home technology [55].

Finally, some clinicians in the reviewed studies perceived the use of smart home technology as a threat to their professional culture, highlighting both logistic concerns and misconceptions about this technology [39,42,45,57]. In contrast to the perceived benefits of deploying smart home technology, some clinicians raised concerns that it may replace the role of some allied health professionals and create distance with patients [34]. Others expressed concern about the clash of professional cultures [39], emphasizing that technology cannot replace human-delivered person-centered care [39,42,45,57]. Some participants voiced concerns about potential incongruity between health care and IT and business priorities [39,42,45]. Such views highlight an important misconception and knowledge gap regarding smart home technology—that it is deployed to *replace* clinician contact with patients. However, the opposite is true if smart home technology can *enhance* clinician-patient communication [32,51] and enable clinicians to better understand their patients' needs [49] and quickly respond [32,34,47]. Previous negative experiences with technology may exacerbate such misconceptions, highlighting the need for clinician-driven technology showcases and peer-reviewed evidence to establish the credibility, system reliability, and clinical validity of smart home technology [45].

A well-designed co-creation process involving key professional stakeholders can help address negative experiences, the incongruity between health care and IT priorities, and reported logistical concerns regarding time and money cost [35,39,58]. Theoretical models to help advance clinician readiness for smart home adoption could provide strategies that address or mitigate challenges that negatively impact the readiness for adoption. The findings of this systematic review suggest that there are several factors that impact clinician readiness to adopt smart home technology. The factors related to using smart technology and interventions for remotely monitoring patient health and well-being were categorized into perceived challenges and benefits.

If widespread adoption of health smart homes is the goal, a model is needed to facilitate the co-design of technology use, support its implementation, and ensure its ethical use. Figure 1 is a proposed theoretical model that could enable clinicians to weigh the benefits and challenges, including potential ethical issues of smart home implementation.

The first step in the model is to provide clinicians with opportunities to acknowledge both the challenges and potential benefits of smart home technology for remote health monitoring. Discussing potential benefits alone is not nor should be sufficient to convince clinicians to adopt smart home technology. For widespread adoption, potential challenges will need to be practically discussed and addressed. For example, the use of remotely collected sensor data on activities of daily living is a new form of evidence that clinicians will need to learn to use for evidence-based practice. Clinicians will need to have confidence that they will receive training on how to optimize their clinical decision-making using their patients' sensor–collected smart home data [56].

Second, the experiences of early adopters [66] with smart home technology could be useful for clinicians because early adopters can acknowledge challenges, provide education on potential misconceptions, and affirm that clinicians are patient advocates. Early adopters can present the benefits of adopting this technology by showcasing the findings and lessons learned of real-world small- or larger-scale smart home technology implementation. Third, researchers [8] have an important role in facilitating clinician adoption through the co-creation process with clinicians, IT experts, business logistics professionals, patients, and patient advocates that includes the development or refinement of smart home technology, conduct of studies, development of policies, and creation of new smart home technology–enabled care paradigms. The dissemination of small- and large-scale implementation study findings and the presentation of data-driven case studies can collectively provide valuable, pragmatic evidence; critical evaluation; and commentary in peer-reviewed manuscripts. The dissemination of such evidence is useful to enhance clinician readiness and would support eventual widespread adoption of smart home technology for remote health monitoring as a standard of care for older adults who wish to age in place. Finally, reports of experiences of the co-creation process, such as that proposed by Nilsen et al [39] and Islam et al [46] and exemplified by the study by Glasby et al [41], are invaluable as they signpost a practical pathway to adoption and validate the clinical relevance of the purpose of smart home technology to support older adults.

Implications for Clinicians

More studies are showing that both older adults and family caregivers are open to adopting smart homes to facilitate and support aging in place [34,54,67]. It will be important for the members of the multidisciplinary health team to become knowledgeable of smart home technology and how it can be used to augment traditional care models by remotely monitoring health and well-being and supporting efficient and effective care coordination for the older person [51,59]. Although several different health disciplines were part of the studies in this review, it is clear that there are major differences in clinician expectations of the HAS. For example, home health nurses may be interested in smart home data to ensure that the older person is performing their usual daily routines, whereas a primary care physician may be more interested in certain data points that could help with early identification of a change in health. In addition, very little is known about how the different disciplines may envision the integration of the HAS into their clinical practice and the changes needed in the current systems and processes for the translation of the HAS to support the health and wellness of older adults living at home.

To benefit clinical care, clinicians will need to learn some technical and practical aspects of how to use the data collected by the smart home system that may be deployed in the homes of clients whom they are caring for. Accordingly, it is conceivable that the ever-evolving roles of clinicians will include leading change in the digital health space [50]. It is likely that workloads will be impacted; however, more knowledge is needed to understand how to integrate the smart home system into new "smart" models of care and how to use the sensor data to support clinical decision-making. The cost-benefit of this technology as a health care solution, including impacts on staffing shortages and care delivery in rural and remote locations, also needs to be investigated. Finally, for clinicians to embrace the artificial intelligent agent as a new member of the health care team, and to optimize the smart homes' capability, clinicians need to be offered training specifically focused on the use of smart home technology and sensor data interpretation. Tertiary education frameworks need to include these monitoring technologies as a core competency.

Limitations

This review demonstrates that the scientific understanding of clinician readiness to adopt smart home technology is progressing. The studies reviewed were varied and all studies included a range of stakeholders with relatively small sample sizes, making it challenging to synthesize the findings for specific clinical disciplines. The diversity in study populations, which often included multiple types of clinicians and other stakeholders, makes it difficult to extract findings that are directly applicable to any single clinical discipline.

Only English-language papers were included; however, during our search, we did not encounter non–English-language papers. While qualitative studies with relatively small sample sizes are often ranked lower in traditional evidence hierarchies compared with RCTs, which are considered the "gold standard," qualitative research provides essential insights into user experiences that are crucial for designing effective, user-centered technologies and the policies and procedures needed for implementation. Dismissing these contributions in favor of a rigid adherence to RCTs overlooks critical aspects of practical implementation and user acceptance that determine the real-world success of interventions. Moreover, the rapid pace of technological development necessitates timely research to keep up with innovations, suggesting that waiting for large-scale RCTs (or waiting for the funding to execute such studies) might render findings obsolete by the time they are applied or indeed stifle implementation in new models of care. The integration of smart home technology into models of care for older adults has been challenging, requiring researchers to partner with a variety of clinical and nonclinical professionals, such as technologists, designers, clinicians, and business and industry professionals, to study various aspects of co-design, acceptability, and implementation. This could explain why researchers have used a more pragmatic approach for their studies, including nonprobability sampling, purposive and convenience sampling, case studies, and multiple sources of data.

Another major drawback to synthesizing the literature is the incongruence of the definitions used for smart home technology and the fact that most studies included a mix of clinicians and nonclinicians. As clinicians represent a major end-user group, they need to be more involved in smart home co-design and implementation studies. More studies that focus on specific clinician groups (eg, nurses and physicians) are needed to determine the specific factors that could potentially undermine the success of smart home monitoring for patients at home. Finally, the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines should be used to report comprehensive qualitative findings. While the conduct of RCTs may not be sufficiently pragmatic for this field, the use of mixed methods could yield more generalizable findings. The studies by Delbreil and Zvobgo [37], Elavsky et al [40], and Offerman-van Heek and Ziefle [53] are all good examples of providing readers with greater depth of knowledge regarding clinicians' readiness.

Conclusions

This systematic review synthesized the literature on clinician readiness to adopt HAS technology for remote health monitoring—a key determinant for the future successful adoption of such technologies. The review identified several factors that may impact readiness for adoption among clinicians, highlighting both challenges and perceived benefits of smart home technology. The ensuing proposed theoretical model outlines the steps and key roles that early adopting clinicians, researchers, and cocreating stakeholders will have if widespread clinician adoption of smart home technologies for health monitoring occurs. Importantly, an incongruence in the terminology used in the limited body of literature to date reinforces the need for standardized reporting when discussing smart home technology to develop a clear and consistent body of credible evidence. Future research should continue to evolve this body of literature, evidencing the credibility, reliability, and clinical validity of smart home technology through a combination of peer-reviewed case studies, well-designed research trials, and commentaries. Continuing to reflect, act, and report on clinician's experiences of smart home technology will help identify and overcome challenges to adoption and simultaneously affirm and embrace its benefits. Doing so can establish the professional acceptability and clinical validity of this technology, underpinning its widespread adoption in clinical practice.

Abstract

Background: Family and unpaid caregivers play a crucial role in supporting people living with dementia; yet, they are not systematically identified and documented by health systems.

Objective: The aims of the study are to determine the extent to which caregivers are currently identified and documented in the electronic health record (EHR) and to elicit the perspectives of caregivers and clinical staff on how to best identify, engage, and support caregivers of people living with dementia through the EHR.

Methods: People with dementia were identified based on *International Classification of Diseases, Tenth Revision* (*ICD-10*) codes or dementia medications in the EHR. A chart review of people with dementia characterized how caregiver information was documented and whether caregivers had shared access to the patient portal. Caregivers of eligible people with dementia were then recruited through mailed letters and follow-up calls to the homes of people with dementia. We conducted semistructured interviews with caregivers, clinicians, and staff involved in the care of people with dementia within 2 health systems in Maryland and Colorado. Transcripts were analyzed using a mixed inductive and deductive approach.

Results: Caregivers of people with dementia (N=22) were usually identified in the “contact information” or “patient contacts” tab (n=20, 91%) by their name and relation to the people with dementia; this tab did not specify the caregiver’s role. Caregivers were also mentioned, and their roles were described to a varying degree in clinical notes (n=21, 96%). Of the 22 caregivers interviewed, the majority (n=17, 77%) reported that the people with dementia had additional caregivers. The presence of multiple caregivers could be gleaned from most charts (n=16, 73%); however, this information was not captured systematically, and caregivers’ individual contributions were not explicitly recorded. Interviews with 22 caregivers and 16 clinical staff revealed two major themes: (1) caregiving arrangements are complex and not systematically captured or easy to locate in the EHR and (2) health systems should develop standardized processes to obtain and document caregiver information in the EHR.

Conclusions: This exploratory chart review and qualitative interview study found that people with dementia frequently have multiple caregivers, whose roles and needs are captured inconsistently in the EHR. To address this concern, caregivers and clinical staff suggested that health systems should develop and test workflows to identify caregivers, assess their needs at multiple touchpoints, and record their information in extractable EHR fields.

Introduction

The engagement of family and unpaid caregivers is critical for improving care for people living with dementia [1]. More than 11 million family members and other unpaid caregivers provide an estimated 18 billion hours of care to people living with dementia [2]. Caregivers assist with daily activities, cope with behavioral symptoms, schedule and attend medical visits, manage medications, and make medical decisions [3]. Health systems lack systematic and proactive processes to identify and engage with caregivers, meaning that they remain largely invisible [4,5].

The electronic health record (EHR) is a promising tool to enable timely, accurate, bidirectional information exchange and communication between caregivers and health care teams through applications such as the patient portal. Despite the nearly universal adoption of the EHR [6], its application to dementia care remains limited. Developing a feasible approach to identify caregivers of people living with dementia in the EHR would enable health systems to reach them equitably and at scale, include them in decisions, provide support, and recruit them for research that would benefit them [7]. As little is known about how best to achieve this, we conducted an exploratory chart review and qualitative study with caregivers and clinical staff to characterize how caregivers are currently identified and documented in the EHR in 2 health care systems and elicit perspectives on how best to identify, engage, and support caregivers of people living with dementia through the EHR. Qualitative methods are ideal for this purpose, as they can provide a deep understanding of caregivers' lived experiences and of caregiver and staff interactions with the EHR and generate hypotheses about how health systems can better use the EHR as a tool to support caregivers.

Methods

Study Design

This analysis was done as part of a study designed to develop a tool to identify caregivers of people living with dementia through the EHR for pragmatic trials related to medication management. Caregivers of people living with dementia and clinical staff from 2 health systems in Maryland and Colorado were recruited from March to May 2022. Research staff screened the EHR to identify patients aged 65 years or older with dementia (based on *International Classification of Diseases, Tenth Revision* [*ICD-10*] codes or dementia medications; Multimedia Appendix 1) and polypharmacy (defined as taking 5+ medications), who received care at primary care or memory clinics. The dementia diagnosis was confirmed by reviewing clinic notes. Our approach was designed to be pragmatic to characterize the real-world caregiving arrangements of people with dementia. For this reason, we sought to include caregivers regardless of how much time they spent caring for the people living with dementia. To maximize generalizability, we used broad eligibility criteria for caregivers and allowed them to self-identify. Recruitment letters addressed to "family members or friends" were mailed to the homes of eligible people living with dementia. We then called the people living with dementia to identify a caregiver interested in participating. Staff who provided ambulatory care to people living with dementia were identified through lists provided by clinics and recommendations of clinic administrators. They were recruited by email. We stopped recruitment once no new themes were emerging in interviews.

Chart review of people living with dementia whose caregivers participated focused on characterizing whether caregiver identities, contact information, and roles were documented in the EHR (and if so, where) and whether caregivers had registered for proxy access to the patient portal. We developed a chart abstraction form in Microsoft Excel. Two research coordinators (RQR and AED) reviewed charts in the EHR and recorded their findings. These data were discussed with the principal investigator (ARG) during team meetings to identify and adjudicate discrepancies. We conducted semistructured interviews with 22 caregivers and 16 clinical staff (eg, clinicians, nurses, medical assistants, and practice managers). An interview guide was developed based on the research questions. We asked caregivers about their roles and caregiving arrangements and compared this with the information that was documented in the EHR. We also asked whether the patient's health care team ever routinely asked them about caregiving roles and responsibilities and, if so, when. We asked staff how they currently identify caregivers and record their information. Both groups were asked about challenges related to this process and how it could be improved. All participants were also asked for demographic information. Four research team members (RQR, AED, KSG, and TETM) experienced in qualitative research conducted the interviews via phone or videoconference; all interviews were conducted in private locations. Two coders (KSG and TETM) developed an initial codebook based on the Consolidated Framework for Implementation Research and the study aims. Three study team members then refined the codebook by reading transcripts from 5 caregivers and 5 staff. Open coding allowed inductive identification of new themes in addition to deductive coding guided by the Consolidated Framework for Implementation Research. The entire team met to discuss and finalize the codebook. Using this version, a single team member coded approximately 25% (n=8) of the remaining transcripts, which were reviewed by another coder. Discrepancies were discussed at study team meetings until 100% agreement was reached. The remaining transcripts were then coded by a single coder, and the study team met weekly to discuss emerging themes.

Ethical Considerations

The Johns Hopkins University School of Medicine Institutional Review Board (IRB) served as the single IRB and approved this research (IRB protocol 00297952); the Kaiser Permanente Colorado IRB ceded. All participants provided verbal consent. Caregivers at both health systems and clinical staff in Maryland received a US $25 gift card for participating; clinical staff in Colorado volunteered without compensation, as company policy did not allow it. All interviews were audio recorded and transcribed verbatim.

Results

Overview

Participant characteristics are described in Table 1. People with dementia (n=22) had a mean age of 84.1 (SD 6.5) years. Most were male (n=15, 68%) and White (n=15, 68%) and had a mean of 8 (SD 3.5) medications.

Table . Demographic characteristics of participants.

	People with dementia[a] (n=22)	Caregiver[b] (n=22)	Staff[b] (n=16)
Age (years), mean (SD)	84.1 (6.5)	63 (12.6)	48 (9.3)[c]

[a] Data based on chart review.

[b] Data based on interviews.

[c] Three staff members did not provide their ages.

[d] These questions were not asked of both groups.

[e] LPN: licensed practical nurse.

[f] RN: registered nurse.

[g] NP: nurse practitioner.

Caregivers had a mean age of 63 (SD 12.6) years. The majority were female (n=21, 96%) and White (n=16, 73%). Most were the spouse, partner, or adult child of the people with dementia (n=18,82%) and lived with the people with dementia (n=14, 64%). Only 1 caregiver had proxy access to the patient portal. As shown in Table 2, caregiver names and their relation to the people with dementia were usually recorded in the “contact information” or “patient contacts” tab of the chart (n=20, 91%). Caregivers were frequently mentioned in clinical notes (n=21, 96%), where their relations and roles were described with a varying degree of detail (eg, patient lives independently and son helps). One of the health systems had a “lay caregiver” field that was used inconsistently (n=3, 27%). Most people with dementia (n=13, 59%) had an advance directive in the chart that named a medical decision maker. When an advance directive was present, it identified the same caregiver as interviewed only slightly more than half of the time (n=12, 55%). Of the 22 caregivers interviewed, the majority (n=17, 77%) reported that the people with dementia had additional caregivers. Most charts (n=16, 73%) contained documentation implying the presence of multiple caregivers; this information was recorded unsystematically in various locations throughout the chart, and caregivers’ individual contributions were not explicitly described. Two major themes emerged from interviews (described with illustrative quotations in Table 3).

Table . Results of chart review and interviews related to caregiver identification in the EHR[a] (N=22).

Category	Values, n (%)
Interviewed caregiver identified multiple caregivers[b]	17 (77)
Chart review identified multiple caregivers	16 (73)
Locations where caregivers were identified[c] in the EHR	
Contact information[d]	20 (91)
Clinical notes	21 (96)
"Lay caregiver" field	3 (27)[e]
People with dementia had patient portal access	
Yes	18 (82)
No	1 (5)
Inactive	3 (14)
Caregiver had proxy access to the patient portal	
Yes	1 (5)
No	19 (86)
Unknown (patient deceased)	2 (9)
People with dementia had an advance directive (ie, living will or medical durable power of attorney) in the chart that named a medical decision maker	
Yes	13 (59)
No	7 (32)
Unknown (patient reported having advance directive but copy not in chart)	2 (9)
If an advance directive was present, it identified the same caregiver as interviewed	
Yes	12 (55)
No	1 (5)
Unknown (patient reported having advance directive but copy not in chart)	2 (9)

[a] EHR: electronic health record.

[b] Data obtained from the interview; all other data in the table were obtained from chart review.

[c] Fields were not mutually exclusive.

[d] Caregivers were identified in various fields within the "Demographics" or "Snapshot" tabs, depending on the health system, such as "permanent comments," "patient contacts," "additional info," and "alternate contact person."

[e] This field only existed at 1 health system; denominator=11.

Table . Key themes and illustrative quotations.

Participant	Quote
Theme 1: complexity of caregiving arrangements not systematically captured or easy to locate in the EHR[a]	
Caregiver	"We'll spread it out...I am the one that goes to the appointments. If...she needs to be on something new, I work with the doctor and then talk to my sister about it.... I generally will have the current list or whoever has been at the last few doctors' appointments."
Medical assistant	"[The problem list] shows dementia...but there's not any real information in regard to who the caregiver is."
Nurse case manager	"It's a lot of time devoted to...detective work – trying to peel the layers back to figure out who would be an appropriate person to truly get good information from."
Physician	"We don't have a system.... So I do it my way. Another doctor does it their way. A third person does it their way.... In my initial new patient assessment, I put it in my note, but you need to know where to find it."
Theme 2: health systems should develop standardized processes to obtain and document caregiver information in the EHR	
Caregiver	"No one seemed to know what the correct procedure was [to register for shared access in the patient portal].... I was told to fill out this form. Later I found out 'No, that was not the form you were supposed to fill-out.' ...I drove over to the medical clinic 45 minutes each way to get this done."
Caregiver	"I'd like, somehow, when [clinicians] sign into [the EHR] that it's apparent that she has dementia and that her daughter-in-law is the caregiver and that there's a banner there right away so I don't always have to explain myself.... It's necessary [that] I be with her because she is incapable of giving them the information they need.... Somehow, in My Chart, that information would be...a quick blip on the page."
Caregiver	"Every now and then, just ask me how I'm doing.... It's kind of hard to answer with him sitting there."
Nurse case manager	"[The EHR should include] what services they provide, [do] they grocery shop for [the PLWD], prepare meals for them, provide transportation, medication management – all the big things that you're concerned with a memory-impaired person – who can be relied on to help."
Clinic medical director	"I think it would be helpful if [the caregiver information] was a banner that went across [the EHR], so that it's highlighted. So, if a patient has an active health care agent right now, when you open the chart, it's a banner, and it has the name and the number listed. And every time you go within that patient's chart, even every single note that you bring up, has that banner.… But, otherwise, everything else would get lost, the information that was collected."
Physician	"If we can also add [caregiver information] into Epic [so] that we don't need to dig...the problem is you need to know it and you always need to look. There [are] so many scanned papers, but if they can add...the contact information [to a] box...[the] primary caregiver and...the other caregivers, that would be useful."

[a] EHR: electronic health record.

Complexity of Caregiving Arrangements Not Systematically Captured or Easy to Locate

Interviews revealed that most people living with dementia had multiple people who helped them, including family, friends, and community members. Some people who provided instrumental support did not view themselves as caregivers, complicating health system efforts to identify them. Caregivers said that their needs (eg, skills or resources needed for caregiving) were rarely assessed or recorded by the health system. Staff said caregiver information was not collected systematically and that caregiver roles, such as which caregiver helps with medical decision-making and daily activities, including medication administration, were usually described in clinical notes rather than readily accessible fields. This often made it time-consuming and difficult to identify the appropriate caregiver to contact for information exchange. Even when a caregiver was identified by name or relation to the patient, it was often not easy to determine if that caregiver was the relevant person for a particular clinical decision, such as a medication change.

Health Systems Should Develop Standardized Processes to Obtain and Document Caregiver Information

Caregivers expressed a desire to be identified and have their needs routinely assessed and addressed. Clinical staff recommended developing workflows to identify caregivers and assess their needs at multiple touchpoints, including standardized questions in the waiting room, the patient portal, and during scheduling. Staff said that it would be useful to collect information on what tasks caregivers perform and suggested adding a caregiver tab to the EHR to standardize what information is collected and where it is recorded. Caregivers and staff suggested that proxy access to patient portals could facilitate improved identification, engagement, and support of caregivers. However, the complicated proxy enrollment process, which requires downloading and completing forms and providing proof of legal representative status if the patient lacks decision-making capacity, was seen as a barrier.

Discussion

Principal Findings

This exploratory chart review and qualitative study found that people living with dementia frequently have multiple caregivers, whose roles and needs are inconsistently captured in the EHR. Our findings were similar in both health systems. Caregivers emphasized the importance of having their needs routinely evaluated and addressed. Clinical staff suggested creating processes to identify caregivers and assess their needs at various points, such as using standardized questions in the clinic waiting room, through the patient portal, and during appointment scheduling. Participants recommended simplifying the process of obtaining proxy access to patient portals, particularly for caregivers of people living with dementia.

Similar to our findings, a previous study of 211 people living with dementia that did not involve interviews or determine whether people living with dementia had multiple caregivers found that 89% of charts identified caregivers; however, “an extensive search through individual notes” was required to locate caregiver information; few charts documented caregiver needs [8]. These findings have important implications. Caregiver engagement and support are essential components of high-quality dementia care. Patients with poorly supported caregivers face a heightened risk for inappropriate medication use [9], hospitalization, and burdensome treatments [10]. Pragmatic trials may exclude people with dementia when there is no documentation of a caregiver, limiting generalizability [11].

Earlier research has shown that patient portals can be a valuable resource for supporting patients with serious illness and their caregivers [12]. This is illustrated by the fact that patient portal use, such as secure messaging, tends to increase following a dementia diagnosis, reflecting the substantial need for information and communication of people living with dementia and their caregivers [13]. In a pilot study, caregivers of people living with dementia perceived that they received more information about resources from the doctor after completing a caregiver wellness questionnaire in the patient’s EHR [14]. Another study tested an EHR-driven process to identify veterans with unpaid caregivers based on receipt of home- and community-based referrals; however, the process was inefficient [4]. Shared access to the patient portal would facilitate the identification and enable the engagement of multiple caregivers, reflecting the reality of caregiving arrangements for people living with dementia [15]. However, health systems should simplify the complicated proxy enrollment process, which is a barrier [16,17]. To address the concerns identified in our study, health systems should develop and test workflows to identify caregivers, assess their needs at multiple touchpoints, and record their roles and contact information in standardized, clearly defined, and readily extractable fields. These workflows could include fielding caregiver questions as part of the Medicare Annual Wellness Visit, creating a communication plan at the time of dementia diagnosis, and testing different modes of outreach to people living with dementia and caregivers [15,16].

Limitations

This study has some limitations. The small sample from 2 health care systems may not be generalizable to other practice settings. In addition, caregivers who could be identified during recruitment and who agreed to participate may be more likely to be engaged and identified in the EHR. Our broad inclusion criteria may have resulted in people who only spent a few hours caregiving being classified as caregivers. Although both health systems used the Epic EHR, the tabs and fields were different in each system, and the locations where we found caregiver information may not be generalizable. As a qualitative study, this work is designed to be exploratory. However, it is valuable because it provides an in-depth understanding of caregiving arrangements for people living with dementia and of the lived experiences of dementia caregivers in their interactions with the EHR. In so doing, the study generates important hypotheses about how health systems can better support caregivers. Finally, we did not seek to interview paid caregivers, who may be responsible for the day-to-day care of the people living with dementia and accompany them to medical appointments [18].

Conclusions

This qualitative study and exploratory chart review found that caregivers of people living with dementia are identified inconsistently in the EHR. If their roles and needs are documented, this information is not easy to locate. Future studies could develop and test workflows to identify caregivers, assess their needs, and record their information in extractable EHR fields.

Abstract

Background: There are numerous communication barriers between family caregivers and providers of people living with dementia, which can pose challenges to caregiving and clinical decision-making. To address these barriers, a new web and mobile-enabled app, called CareHeroes, was developed, which promotes the collection and secured sharing of clinical information between caregivers and providers. It also provides caregiver support and education.

Objective: The primary study objective was to examine whether dementia caregivers would use CareHeroes as an adjunct to care and gather psychosocial data from those who used the app.

Methods: This paper presents the implementation process used to integrate CareHeroes into clinical care at 2 memory clinics and preliminary outcome evaluation. Family caregivers receiving services at clinics were asked to use the app for a 12-month period to collect, track, and share clinical information with the care recipient's provider. They also used it to assess their own mental health symptoms. Psychosocial outcomes were assessed through telephone interviews and user data were collected by the app.

Results: A total of 21 caregivers enrolled in the pilot study across the 2 memory clinics. Usage data indicated that caregivers used many of the features in the CareHeroes app, though the chatbot was the most frequently used feature. Outcome data indicated that caregivers' depression was lower at 3-month follow-up (t_{11}=2.03, P=.03).

Conclusions: Recruitment and retention of the pilot study were impacted by COVID-19 restrictions, and therefore more testing is needed with a larger sample to determine the potential impact of CareHeroes on caregivers' mental health. Despite this limitation, the pilot study demonstrated that integrating a new supportive app for caregivers as an adjunct to clinical dementia care is feasible. Implications for future technology intervention development, implementation planning, and testing for caregivers of people living with dementia are discussed.

Introduction

Overview

Caregiving and clinical care for the 7 million Americans with Alzheimer disease or a related dementia (ADRD) is complex and expensive, with projected medical costs for this population increasing to just under $1 trillion in 2050 [1]. Further complicating care for people living with dementia are communication barriers among patients, their family caregivers (eg, spouses and adult children), and providers (eg, physicians and nurses), which may negatively impact the collection of information that is needed to make clinical decisions and create additional challenges for caregivers [2,3]. Health IT (HIT) interventions have been identified as having potential for overcoming these communication challenges [4,5]. While there has been an increase in the development and testing of HIT for this purpose, little remains known about how to effectively integrate new HIT into practice to support provider-caregiver communication. In this study, a multidisciplinary team developed a new multifunctional application, called CareHeroes, and conducted a pilot study to evaluate usage and preliminary outcomes for caregivers receiving services at 2 memory clinics. This paper presents findings from the project as well as the extensive implementation process that the team underwent to develop and integrate the app into care. Implications for technology development and testing in dementia care are discussed.

Caregiver-Provider Communication in Dementia Care

Prior research has found that some barriers to caregiver-provider communication stem from caregivers, who have reported that they sometimes have difficulty remembering all of the information they planned to discuss with the care recipient's provider or they become too upset during the medical visit to adequately share information [6]. Other research has reported that caregivers with lower levels of health literacy or who experience anxiety when discussing difficult topics may not effectively communicate with providers [7]. There are also communication barriers stemming from providers and service systems. For example, lack of time to collect sufficient information during the medical visit, insufficient sharing of clinical information across care settings [8], and lack of access to community-based resources for dementia care [9,10].

Poor communication between caregivers and providers may contribute to a number of negative outcomes. For caregivers, the difficulties of health management for people living with dementia place them at increased risk of poor mental and physical health [1]. Communication challenges can also impede clinical decision-making by providers, which can have a negative impact on patient care and outcomes [10]. There are also disparities in experiences with health care providers. For example, African American caregivers are more likely than white caregivers to report that they lacked knowledge about ADRD before their loved one's diagnosis and greater dissatisfaction with the interactions they have with providers regarding dementia care [11], which contribute to disparities in outcomes. For example, while African American and Latino/a populations are at higher risk of ADRD compared to their non-Latino/a White counterparts, they are more likely to go undiagnosed or misdiagnosed [12,13]. Caregivers living in rural communities may face additional barriers to interacting with providers due to the inaccessibility of services [14].

Opportunities and Limitations of IT and AI Apps for Dementia Caregiving and Care

Over the past decade, there has been increased attention on how IT and artificial intelligence (AI) may be used to overcome challenges in dementia care and caregiving [15,16]. An increasing number of studies have examined how tech-based platforms may support caregivers of people living with dementia, though many of the interventions that have been reported in the research literature have not reflected advancements in technology, such as smartphone apps or AI tools [15]. For commercially available smartphone apps targeting caregivers, reviews of existing technologies have shown that they are limited in function, compared to the demands of caregiving; are underresearched, especially with underserved populations; and are not designed to be integrated within clinical care settings [15-17]. Hence, there is a need for increased research that develops an evidence base for advanced technology tools that support this population.

Developing the CareHeroes App

In response, our interdisciplinary team (social work, nursing, physical therapy, geriatric psychiatry, neurology, and computer science) developed CareHeroes, a web-based application that was designed with ongoing input from caregivers and providers, including those from underserved populations [18]. CareHeroes supports caregiver-provider communication through several functions. First, it supports caregiver health literacy through text and video caregiver educational resources about dementia and caregiving. It also supports education through an educational chatbot. CareHeroes also improves the collection and sharing of clinical information about the care recipient between the caregiver and provider. The app includes validated clinical assessment tools, such as the Revised Memory and Behavioral Problem Checklist [19] and ADL/IADL assessments [20], that the caregiver can complete in real time, and the algorithm can create a color-coded table of the responses that can be tracked over time and shared with the provider.

CareHeroes also supports caregivers through self-assessments of depression (Patient Health Questionnaire for Depression and Anxiety (PHQ-2) [21], burden (Zarit Caregiver Burden Inventory) [22], and positive aspects of caregiving [23] and provides the caregiver with feedback based on the results of their responses. A full description of CareHeroes, its design, and features has been reported elsewhere [18,24]. All features on CareHeroes, except for the chatbot, are available in Spanish [25]. There are future plans to translate the chatbot into Spanish.

Preliminary Work to Maximize Potential Adoption in Real-World Settings

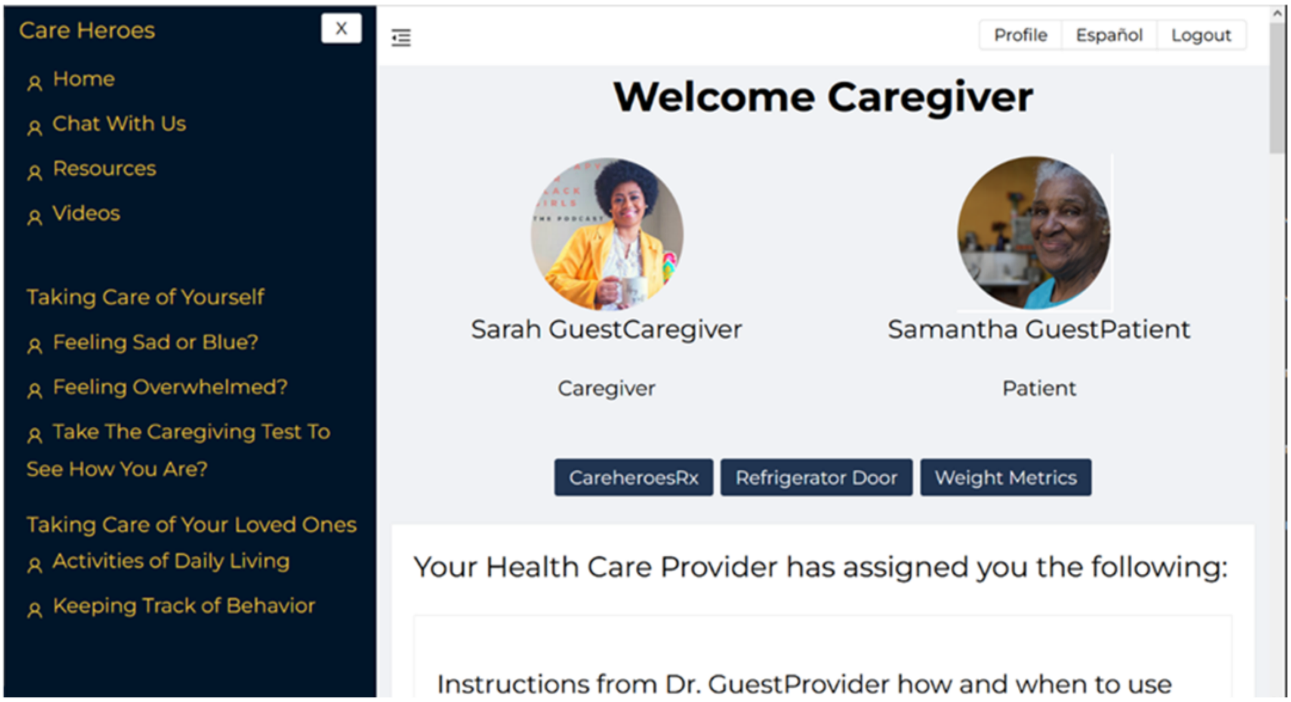
The ultimate goal for CareHeroes was to develop an app that could be integrated into clinical care in real-world settings, and therefore the research team took several initial steps in developing the app to maximize its potential for adoption by providers and caregivers as end users [26]. Early on, the research team conducted needs assessments with stakeholders, which identified potential features of CareHeroes that caregivers and providers though would be beneficial. Surveys were conducted with geriatric home care workers to learn more about communication needs in dementia care [27] and late-life depression care [28]. These studies found that there was little communication between in-home care and primary care providers about older patients' mental health and that home care workers' observations about patients' mental health are not easily shared with other providers. The team also analyzed HIT policy for its potential impact on the app and identified logical ways of fostering interoperability and security for information sharing [29].

After developing an initial prototype of the app, the interdisciplinary team conducted a small beta-testing study in Miami, Florida, where triads of caregivers, geriatric home care managers, and primary care providers used CareHeroes for 11 weeks [18]. The study determined that it was feasible to share information through CareHeroes and that caregivers found it useful and easy to use, though it was found that adoption of the app in real-world settings would be more feasible for dyads of caregivers and primary care providers without the involvement of home health care because it reduced the administrative barriers associated with. These findings informed revisions of the app code. This revised version then underwent alpha testing with 36 caregivers, most of whom were from caregiver populations that have historically been underserved by HIT (eg, African Americans, rural dwelling) [6,30]. The team also conducted focus groups with staff at 2 collaborating memory clinics [31] to gain feedback on the design, capacity, and potential adoption of CareHeroes. This helped the team develop a clinical workflow plan (eg, which clinic staff member collects information caregivers enter in the app, deciding how the information gets to the patient's record). The team also worked with HIT security administrators at both clinics to make sure that information sharing followed HIPAA (Health Insurance Portability and Accountability Act) and organizational policies.

CareHeroes Code Development

The CareHeroes application was developed using a hybrid of agile and unified software development processes [32]. Figure 1 shows the caregiver's home page in the CareHeroes application. CareHeroes was developed based on the requirements of 3 stakeholders. These stakeholders include the health care provider, the caregiver, and the people living with dementia. The requirements included 32 use cases, with 17 caregiver use cases, 5 provider use cases, and 9 use cases focusing on the security of the system. The CareHeroes architectural design is based on a 4-tiered architecture consisting of a client tier (web-based and mobile—to be implemented), a presentation layer, a business logic layer, and the data store layer. The database structure consists of 5 parts. One part each for the user, survey, prescription, and reminder services. The final part of the database is the correlation database, which stores the keys needed to encrypt and decrypt the protected information of people living with dementia.

Figure 1. CareHeroes home page for the caregiver.



Welcome Caregiver

Sarah GuestCaregiver

Caregiver

Samantha GuestPatient

Patient

Your Health Care Provider has assigned you the following:

Instructions from Dr. GuestProvider how and when to use

The implementation of CareHeroes security protocols follows the HIPAA security rule as specified in the Federal Register [33]. CareHeroes uses a role-based authentication system to ensure that only certain users with specific roles can perform certain operations within the system. All electronic communication with the CareHeroes system is encrypted, and all HTTP requests are encrypted using the Secure Sockets Layer protocol [34]. The security protocol is implemented using the database structure previously described.

Chatbot Programming

One of the more novel features of CareHeroes. Compared to existing apps for caregivers of people living with dementia, this is an educational chatbot. For Carehereos, the chatbot was programmed to respond to predetermined topics selected by the user (eg, mood and behavioral disturbances) and to recognized text from user questions (eg, How do I help my father eat?). The topics and content that were programmed into the chatbot and the responses it provided to users were from the book, *The Dementia Caregiver: A Guide to Caring for Someone with Alzheimer's Disease and Other Neurocogntive Disorders* [35] by geriatric psychiatrist, Dr Marc E. Agronin. The book's focus is guiding caregivers through caring for the people living with dementia and themselves. Minor edits were made to simplify language and to shorten responses. See Figure 2 for screenshots of the CareHeroes Chatbot with example text.

Chatbots are programmed to respond to user input (eg, questions, comments) with text or verbal language responses and have become increasingly popular in health care, especially for patient education in other health care settings [36]. For *CareHeroes*, the chatbot was programmed to respond to predetermined topics selected by the user (eg, mood and behavioral disturbances) and to recognize text from user questions (eg, How do I help my father eat?). Specifically, the user could first pick a topic, and then type in free text a question. The chatbot uses text embedding methods to perform semantic matching between the user's question and the list of stored questions.

10:36 AM

What should I do if my loved one is not sleeping?

10:36 AM

Sleep evaluations are best conducted by a neurologist who specializes in sleep disorders. Caregiver observations of general sleep habits and sleep duration, loud snoring, excessive leg movements, and any nocturnal behaviors are crucial to the evaluation. In the past many doctors avoided doing a formal sleep study in individuals with NCDs, because it required an overnight stay in a sleep center, hooked up to multiple sensors on the body. Today these sleep studies can be done much easier at home.

10:36 AM

Which topic do you need information on?

10:38 AM

What is adult day care?

10:38 AM

Most communities have several options for adult day care programs that cater to individuals with moderate stages of NCDs. These are sponsored by a variety of different organizations including city-funded senior centers, religious organizations or community centers, not-for-profits groups like Easter Seals, and for-profit businesses. While many programs are free or low cost, others can have substantial daily rates, especially when meals and transportation are included. Before committing to a program, determine whether the activities are targeted to the level of the impaired person. Have him or her try it out for a day or two to see if it's a good match. Even when there is a cost, it might be less than having an aide during those same hours. Both the socialization and structure of the programs can be extremely beneficial for individuals who might otherwise sit at home isolated and bored.

Methods

Recruitment

CareHeroes was implemented at 2 memory clinics: (1) The Frank C. and Lynn Scaduto MIND Institute at Miami Jewish Health in Miami, Florida, and (2) the Memory Disorder Clinic at the University of Alabama at Birmingham in Birmingham, Alabama. Both clinics provide a variety of services to people living with dementia and their caregivers, many of which are from underserved communities (eg, African American, Latino/a, rural dwelling). IRB approval was obtained from all institutions involved in this project before initiating the study. Recruitment took place between February 2021 and April 2022. In most cases, caregivers were recruited during telehealth visits with providers at either clinic. To be eligible for the study, caregivers had to: have regular access to the internet (via computer or smartphone); be 21 years old or older; provide caregiving activities for at least 2 hours or more per day on average of direct assistance or supervision for a person living with dementia; and have the ability to speak and understand English or Spanish. During the telehealth session, the provider would tell the caregiver about the study and ask if they were interested in more information about the project. In addition, clinic staff reached out to caregivers who were listed on existing caregiver support groups and research participant pools to inform them about the study. Those who reported interest in the study were referred to the research team, which would follow up with the caregiver to determine eligibility and enroll those who were eligible and interested in participating in the study.

Data Collection

Interview Data and Measures

The data collection plan included telephone or Zoom interviews with caregivers at baseline, 3-month, 6-month, and 12-month time points. Each interview lasted between 45 and 60 minutes. The interviewer would record responses using a Qualtrics form. Interview guides included several validated psychosocial measures, and the baseline interview included a demographic questionnaire. To minimize burden, some measures were only scheduled to be included in the baseline and 12-month follow-up interviews.

Communication With Providers

A 3-item scale developed by Lorig et al [37] was used to measure caregiver communication with providers. Each item used a 6-point scale (0=never to 5=always) and measures frequency of which the respondent prepares a list of questions for a physician; asks questions regarding the physician and regarding things the respondent does not know; and discusses personal problems related to the illness with a physician.

Depression

The PHQ-4 is a brief 4-item validated tool to assess overall psychological distress and screen for both anxiety and depressive disorders [21]. The measure includes the 2-item depression screen (PHQ-2) and the 2-item screen for anxiety disorders (Generalized Anxiety Disorder 2 item [GAD-2]). The 4-item response options are scored from 0 to 3, 0=not at all, 1=several days, 2=more than half the day, and 3=nearly every day. The total PHQ-4 score is computed by adding together the 4 items; the overall psychological distress score range is from 0 - 12 (normal: 0 - 2; mild: 3 - 5; moderate: 6 - 8; severe 9 - 12). A total score for the 2 depression items (depressed mood, anhedonia) of 3 or greater indicates depression and a total score of 3 or more for the 2 anxiety items (feeling anxious, uncontrolled worry) indicates anxiety. The PHQ-4 properties have been established for Spanish-speaking Hispanic Americans [38].

Health Literacy About Alzheimer Disease

The Alzheimer's Disease Knowledge Scale (ADKS) is a validated 30-item true or false tool that is used to evaluate the participants knowledge on aspects of Alzheimer disease [39]. This short survey takes approximately 5 - 10 minutes to complete, where each item includes a statement about Alzheimer disease, including risk factors, diagnosis, assessment and symptoms, prognosis, effects on caregiving, and management of the disease.

Caregiver Burden

The Zarit Burden Interview used is a 22-item survey to collect information on caregiver burden, including items relating to dependence in activities of daily living, and assess the frequency of any problem behaviors [40]. The items are answered as never (0), rarely (1), sometimes (2), quite frequently (3), or nearly always (4). A total score ranges 0 - 88, with 0 - 21 identified as no to mild burden, 21 - 40 as mild to moderate burden, 41 - 60 as moderate to severe burden, and scores 61 or above identified as severe burden.

User Data

CareHeroes was also programmed to automatically collect anonymized user data from the app. The program tracked several activities for those using the app, including (1) dates and times for Log-in and log-out; (2) dates and times for clicks on links for educational resources and videos; (3) outcome scores for the care recipient clinical assessments; (4) outcome scores for caregiver self-assessments; and (5) date and time when a caregiver entered a reminder.

Data Analysis

Interview data were entered into an SPSS (IBM SPSS Statistics Developer) database. Data management and analyses were conducted in Stata (version 17) [41]. Because of missing data, the sample was restricted to participants with observations at baseline and the 3-month follow-up, yielding a final sample of 13. Descriptive statistics and bivariate analyses including analysis of variance and paired-sample 1-tailed *t* tests.

Ethical Considerations

The design and procedures for this study received approval from the University of Alabama Institutional Review Board, protocol #19-06-2486, and other involved institutions approved reliance for this protocol approval. Participants were required to electronically sign a consent form using Docusign (DocuSign Inc); they received US $25 for each interview they completed and the data were de-identified.

Results

A total of 21 caregivers initially enrolled in the study (n=13 at the Frank C. and Lynn Scaduto MIND Institute at Miami Jewish Health and n=8 at the University of Alabama at Birmingham). For one caregiver, interviews were conducted in Spanish. Overall, participants were most likely to be a non-Latina white woman caring for a parent or spouse, though the sample was diverse, with 14.3% identifying as African American or Afro Caribbean caregivers and 23.8% identifying Latino/a. Caregivers tended to have moderate to higher incomes and more than two-thirds (68.2%) had a bachelor's or graduate degree. Most participants lived in urban (40.9%) or suburban (50%) communities. Table 1 provides detailed information about the demographics of participating caregivers. A bivariate analysis with outcome variables demonstrated that burden was associated with caregiver income at baseline, but this relationship disappeared at 3-month follow-up (t_{20}=8.42, *P*<.001). No other relationships were found between demographic and outcome variables.

Of the 21 caregiver participants completing the PHQ-4 at baseline, 66.6% (n=7) were classified as having normal psychological distress, 47.5% (n=10) mild, 9.5% (n=2) moderate, and 9.5% (n=2) severe distress. All 21 caregivers reported burden, where 2 (9.6%) scored in the mild range, 5 (23.9%) scored in the moderate range, and the remainder (n=14, 66.5%) reported high levels of burden.

Baseline data also demonstrated that many caregivers who enrolled in the project had high health literacy and were active in care management. The average score for caregivers on the ADKS at baseline was 25.71 (SD 2.31, range 21 - 28), indicating that many caregivers in the sample were knowledgeable (accuracy approaching 90%) about dementia when they enrolled in the study. In terms of communication with providers, on average caregivers reported that they *fairly often* prepare a list of questions for providers (mean 3.67, SD 1.35), *fairly often* discuss any personal problems that may be related to their loved one’s condition (mean 3.43, SD 1.66) and *very often* ask questions about the things they want to know and the things they do not understand about their loved one’s treatment (mean 4.62, SD 0.74).

A missingness analysis was conducted to determine if there were any relationships between participant demographics and attrition at follow up. An independent samples 1-tailed *t* test examining the mean differences between those who completed the Zarit and PHQ-4 at baseline and the 3-month follow-up with those who didn’t complete them at follow-up did not show any significant differences in their scores for either outcome variable. However, a χ^2 test with Fisher exact test was conducted to examine the demographic characteristics of those who completed both baseline and 3-month follow-up assessments on the PHQ-4 total score, anxiety, and depression. It showed that those who identified as Hispanic or Latino/a were more likely to be lost at follow-up than those who did not. This result suggests that the sample might not be entirely representative, as certain demographic groups (in this case, Hispanic participants) might be underrepresented in the group with complete data.

Table . Demographic characteristics of the caregiver participants and bivariate analysis with Zarit at baseline.

Characteristics	Participants, n (%)	Baseline (N=21)		
		Mean (SD)	*t*/*F* test (*df*)	*P* value

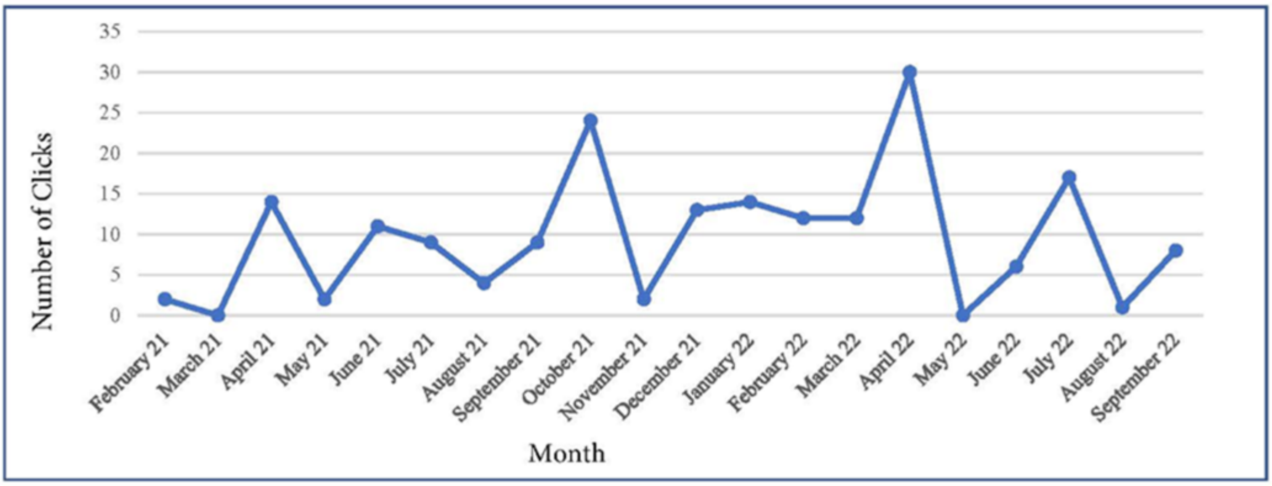
Usage Data Findings

Usage data were collected between February 2021 and September 2022. Figure 3 shows the user activity for *CareHeroes* over time. It should be noted that recruitment took place over a 14-month period, and throughout the project, enrollment ranged from 2 to 12 caregivers at any given time point. However, enrollment peaked between December 2021 and August 2022, which is reflected in the data. Overall, there were 169 actions that caregivers made on *CareHeroes* (eg, link clicks). Participants most often accessed: the chatbot (44 sessions), resource links (30 clicks), the Zarit Caregiver Burden Inventory (22 submissions), and the Revised Memory and Behavior Problem Checklist (19 submissions). Fewer caregivers access the reminder feature (8 entries) and PHQ-2 assessment (13 submissions).

For the chatbot data, caregivers accessed the chatbot 44 times over the course of the study. The most common topics that caregivers explored on the chatbot were how to manage the depression of the care recipient (n=5 total chats), sleep problems experienced by the care recipient (n=4 total chats), and about living wills (n=4 total chats).

Figure 3. CareHeroes usage data over time.



Interview Outcome Data

The outcome measure for knowledge about Alzheimer disease was only scheduled to be assessed at baseline and at the 12-month follow-up. The sample of caregivers who completed 12-month interviews was too small to evaluate this outcome. However, there was enough data to assess outcomes for burden, depression, and anxiety.

Among the 21 caregivers with baseline data, 12 completed the PHQ-4 and 13 completed the Zarit CBI at the 3-month follow-up. At follow-up, it was found that there was a decrease in total scores for the PHQ-4, though this relationship was not statistically significant (t_{11}=1.56, *P*=.15). However, when an 1-tailed *t* test was performed with the separate subscales for the PHQ-4, it was found that caregivers reported significantly lower levels of depression at the 3-month follow-up (mean 1.08, SD 1.08) than they did at baseline (mean 1.67, SD 1.48; t_{11}=2.03; *P*=.03; see Table 2). There was no difference in scores for anxiety during the same time period (t_{11}=1.0667, *P*=.15).

Table . Paired samples 1-tailed *t* test for burden, anxiety, and depression.

	Mean (SD)	*t* test (*df*)	*P* value
Zarit (n=13)		–0.07 (12)	.95
Baseline	21.85 (6.38)		
3-month	21.92 (7.89)		
2 Anxiety items [a] **(n=12)**		1.0667 (12)	.15
Baseline	2.25 (1.48)		
3 Months	1.75 (1.29)		
2 Depression items [a] **(n=12)**		2.03 (12)	.03
Baseline	1.67 (1.32)		
3 Months	1.08 (1.08)		

[a] Patient Health Questionnaire for Depression and Anxiety (PHQ-4) was administered, and from the PHQ-4 items, the 2-item measure of depression (PHQ-2) and the 2-item measure of anxiety (the Generalized Anxiety Disorder-2 scale [GAD-2]) were analyzed.

Discussion

Principal Findings

Over the past decade, the development and research of new technologies to support people living with dementia and their caregivers has increased significantly. However, little remains known about how such technologies can be integrated into clinical care to facilitate caregiver support and secure clinical information sharing. In this pilot study, we were able to demonstrate that caregivers did use *CareHeroes* for education and support. We also demonstrated that new HIT can be integrated into care for secure sharing of patient information in real time. Although outcome data suggests that there was a decrease in caregiver depression at the 3-month follow-up, more research is needed to fully assess the potential impact of using *CareHeroes* on psychosocial outcomes.

Potential of Chatbots for Caregiver Support

Overall, this pilot study recruited a smaller sample than initially planned, and attrition of caregivers in the study was high, which created limits to assessing outcome variables. However, user data indicated that caregivers accessed a variety of features on the app, though the most used feature on the app was the educational chatbot. This was notable because very few chatbots have been developed to support people living with dementia and their caregivers [17]. Chatbots have grown in popularity over the past decade and have become a familiar technology to many through popular chatbots like Apple’s Siri and Amazon’s Alexa [42]. Chatbots offer benefits over other types of information technologies for health education and support in that they may be programmed so they are tailored to the user’s needs. Also, recent advances in chatbots based on large language models, such as ChatGPT, have the potential to significantly improve the responsiveness to caregivers’ support needs.

In a recent study, ChatGPT and Google were evaluated on their ability to respond to common questions that caregivers have [43]. ChatGPT was found to produce results that were more closely aligned with what the question was asking, though it did not provide sources or how old the information was. Both ChatGPT and Google were found to provide responses that were written at a higher reading level than what is recommended for general health education. Similar to other AI chatbot tools, the bot’s responses to the user’s input require regular training. As a result, the quality and availability of information is dependent on how often the chatbot is trained and the content used to train it. As earlier discussed, the chatbot in the *CareHeroes* app is programmed with expert feedback to common questions that caregivers have about dementia and caregiving [35]. Hence, while a Google search of similar questions may result in an overwhelmingly large number of search results that are irrelevant, the *CareHeroes* chatbot is able to provide more direct responses to the questions caregivers often have. In other health settings, it has been found that chatbots can be an effective way of promoting health education, treatment management, and moral support [44,45]. It has also been suggested that chatbots may be an ideal platform for collecting patient-related information [46]. Moving forward, the implementation of *CareHeroes* may be more successful if more features were offered in a chatbot format.

Limitations and Future Research

Like many studies during this time period, the COVID-19 pandemic posed significant challenges to recruiting and retaining caregivers. Initially, the research team thought the increase in telehealth during the pandemic would possibly lead to more caregivers wanting to participate in the study. However, anecdotally, many caregivers reported to the clinic staff that they were overwhelmed by the pandemic and its associated increased need for telecommunication. In such cases, caregivers expressed that learning another new technology was too burdensome. Among the caregivers who enrolled in the study, some reported to interviewers at the 12-month follow-up that they wished they had used the app more because they thought the features would have helped them, but it was difficult to fit using the app within their daily care activities during the pandemic. Similarly, the clinic staff reported that understaffing during the pandemic made it difficult for them to log onto *CareHeroes* regularly. While this pilot study provides direction for future research, more research is needed under more typical circumstances to generate strong evidence about the potential of HIT as an adjunct to clinical care for people living with dementia and their caregivers.

One challenge in the study stemming from the pandemic was that the research team was unable to meet with caregivers in person when they enrolled in the study to orient them with the technology when it was first introduced. This may have impacted their familiarity with using the app, since they were only given instructions over the telephone or Zoom. Future research should identify best practices in training caregivers to use new HIT so that they gain the maximum benefit that the technology has to offer. Similarly, how best to provide ongoing support to caregivers should be identified. For example, examining the effectiveness of embedding instructional videos in the software design on maintaining caregiver engagement with the technology. In this study, caregivers were provided with a helpline that they could call when they encountered a problem with *CareHeroes*. However, it is possible that some caregivers experienced challenges that they did not report to the helpline and stopped using the app when they could not resolve the issue themselves.

Another limitation to this study is that the caregiver participants who enrolled in the study were very experienced and very knowledgeable about ADRD at baseline, which may be associated with their access to specialized memory care, as opposed to primary care. It is suspected that newer caregivers would interact with and learn from the *CareHeroes* app differently. However, the findings from the study's implementation evaluation and outcome assessment provide future researchers with insight on developing tech-focused interventions.

In addition, future studies should also examine how to better integrate new information technologies into clinical care so that they are easily adopted by providers. For example, designing new technologies so that they can be integrated into existing secure systems, like electronic medical records, rather than offering additional programs that require new log-ins can minimize the burden on providers who have to navigate multiple secure software programs on a regular basis. Similarly, more research is needed on technologies that can encourage triadic communication between people living with dementia, their caregivers, and providers. While *CareHeroes* was designed to empower caregivers of patients with dementia, the research team recognizes that more should be done to empower these patients to promote person-centered care.

Conclusion

There has been growing interest in the development of technologies that support people living with dementia and their caregivers. While the features and functions of new technologies will impact their adoption, this paper highlights the importance of implementation planning in order to maximize success in tech adoption, particularly by caregivers. While these findings may provide future direction for researchers involved in developing technologies for dementia care and caregiving, they are also relevant to commercial technology developers who are interested in integrating similar technologies within real-world contexts. Though this research experienced several limitations stemming from the COVID-19 pandemic, the research team credits the early work done to overcoming these challenges and successfully implementing *CareHeroes*.

Acknowledgments

This work was supported by the Agency for Healthcare Research and Quality (grant R21 HS026571); the John A. Hartford Foundation Change AGEnts Grant Program, Professor Ellen L Brown's Nicole Wertheim College of Nursing, Florida International University Wallace Gillroy Endowment and the Erica Wertheim Zohar Chair in Community Mental Health Endowment. The research team used generative artificial intelligence software for proofreading purposes, though the article content is original and created by the authors. IRB approval was obtained for this project from the University of Alabama, and reliance was approved by all other institutions.

Conflicts of Interest

VH is the founder of SmartBot360, which is a health care chatbot company. ELB, PJC, and NR are co-owners of Person First Technology LLC (PFT), which develops and tests technologies for people with dementia and their families. PFT was formed after this research was completed and was not involved with the study.

Abstract

Background: As dementia progresses, patients exhibit various psychological and behavioral symptoms, imposing a significant burden on families and society, including behavioral and psychological symptoms of dementia. However, caregivers lack professional care knowledge and skills, making it difficult for them to effectively cope with the diverse challenges of caregiving. Therefore, it is necessary to provide caregivers with professional knowledge and skills guidance.

Objective: This study aimed to analyze the impact of internet-based training on behavioral and psychological symptoms of dementia in patients, and explore how this training model affects the caregiving abilities and caregiving burden of the family caregivers of patients with dementia.

Methods: Using a consecutive enrollment method, the Department of Geriatrics at Zhejiang Hospital (Zhejiang, China) recruited 72 informal caregivers of patients with dementia. These caregivers were randomly divided into an intervention group and a control group, with 36 participants in each group. The intervention group underwent caregiver skill training via a web-based platform, whereas the control group initially received face-to-face follow-up guidance and was subsequently offered web-based training after 6 months. To assess the effectiveness of the intervention program, we used the Neuropsychiatric Inventory Questionnaire (NPI-Q), the Chinese version of the Zarit Burden Interview (CZBI), and the Sense of Competence in Dementia Care Staff Scale (SCIDS) for evaluations conducted before the intervention, 3 months after the intervention, and 6 months after the intervention.

Results: Between July 2019 and December 2020, a total of 66 patients successfully completed the intervention and follow-up. After 6 months of intervention, the NPI-Q score of the intervention group was 3.18 (SD 3.81), the CZBI score was 10.97 (SD 5.43), and the SCIDS score was 71.88 (SD 4.78). The NPI-Q score of the control group was 8.09 (SD 8.52), the CZBI score was 30.30 (SD 13.05), and the SCIDS score was 50.12 (SD 9.10). There were statistically significant differences in NPI-Q (*P*=.004), CZBI (*P*<.001), and SCIDS scores (*P*<.001) between the intervention group and the control group. Repeated measures analysis of variance showed that compared with before the intervention, there were statistically significant differences in CZBI (*P*<.001) and SCIDS (*P*<.001) scores 3 months after the intervention, while the difference in NPI-Q (*P*=.11) scores was not significant. The total scores of NPI-Q (*P*<.001), CZBI (*P*<.001), and SCIDS (*P*<.001) were significantly improved 6 months after the intervention. In addition, the results of the covariance analysis showed that after excluding the time effect, the web-based training intervention significantly reduced the NPI-Q score (−2.79, 95% CI −4.38 to −1.19; *P*<.001) of patients with dementia and the CZBI score (−13.52, 95% CI −15.87 to −11.16; *P*<.001) of caregivers, while increasing the SCIDS score (12.24, 95% CI 9.02-15.47; *P*<.001).

Conclusions: Internet-based training could significantly reduce the level of behavioral symptoms in older patients with dementia and alleviate the burden on caregivers, enhancing their caregiving abilities. Our results confirmed the effectiveness and feasibility of web-based training, which was of great significance in providing caregiving knowledge training for informal caregivers of persons with dementia.

Introduction

Dementia care remains a major public health challenge for global health systems. According to a recent nationwide cross-sectional study [1], 15.07 million individuals older than 60 years experienced dementia in China. A person with dementia, particularly one with moderate-to-severe dementia, has extensive health and social care needs. The annual total treatment costs of patients with Alzheimer disease in China are predicted to reach US $507.49 billion in 2030 and US $1.89 trillion in 2050 [2]. Dementia severity is an important driver of cost and the proportion of mild, moderate, and severe dementia cases living in a country can influence the cost estimates. In China, 70% of patients with dementia live at home and are cared for by their spouses, children, or other relatives. According to a survey conducted by Alzheimer Disease Chinese [3], there are 3 major difficulties faced by the families of patients with dementia, which mainly are insufficient care capacity, a lack of care resources, and single treatment services. According to the research report [3], 65.43% of caregivers have no hope of treatment and feel intense psychological pressure, 68.69% of caregivers report that their health has been affected, and 78.39% of caregivers said that their social life is often affected.

Behavioral and psychological symptoms of dementia (BPSD) may occur at any stage of the disease progression, with patients exhibiting at least one type of BPSD. BPSD is highly correlated with caregiver burden. Caregiver factors are some of the causes and triggers of BPSD, and insufficient interaction between caregivers and care recipients may lead to the occurrence or exacerbation of BPSD. For family caregivers, caring for people with dementia is perceived as one of the most stressful experiences. During the long-term progression of the disease, the patient's independence will decline, which requires more responsibility and supervision time from informal caregivers. Long-term problems of continuously managing activities of daily living [4,5], behavioral and psychological symptoms [6], and providing emotional, spiritual, and social support place considerable burdens on the family, which can result in mental health problems such as depression. The burden of care can put caregivers at risk of physical and psychological ailments, as well as negatively affect their quality of life, so effective and practical support is essential. Training and supporting family caregivers, especially in the proper management of BPSD, to enhance their ability to cope with BPSD, may help break this vicious cycle [7].

In 2019, informal dementia caregivers spent over 89 billion hours providing support with activities of daily living about 5 hours per day per person with dementia [8]. As the most direct contact and participant, the competence of the caregiver has a direct impact on the outcome of BPSD. However, due to the ongoing COVID-19 pandemic, many support services for dementia caregivers have been reduced, delayed, or even withdrawn, which has substantially increased interest in web-based health services [9]. It is important to create a digital platform that offers invaluable and usable information to caregivers of people living with dementia [10]. In the face of these significant challenges, the WHO developed "iSupport," an evidence-based e-health intervention designed to help dementia caregivers provide good care and take care of themselves [11]. Internet-based supportive interventions can provide convenient and efficient support and education to potentially reduce the physical and psychological burden associated with providing care. Internet-based supportive interventions for family caregivers of people with dementia have been reported in the United Kingdom [11], India [12], the Netherlands [13], Brazil [14], Germany [15], and other countries, but they are rare in China.

This manuscript presents the findings of a randomized controlled trial examining the implementation of internet-based supportive interventions for home care among patients with dementia in China. The trial is an innovative web-based support program that was developed to advance the skills, knowledge, and practice of caregivers, in order to enhance self-care skills in individuals with dementia and simultaneously provide invaluable assistance to their caregivers. The experiment also aims to assess the effectiveness of the web-based support program, and to explore its impact on the caregiving burden and caregiving abilities of dementia caregivers, compared with dementia caregivers who receive routine caregiving interventions after discharge. The primary outcomes of this study consisted of evaluating the severity of neuropsychiatric symptoms in patients with dementia, assessing the burden on caregivers, and gauging the capability of caregivers. We hypothesized that internet-based supportive interventions would lead to greater improvement in primary outcomes than routine caregiving interventions after discharge.

Methods

Study Design

The trial was designed, planned, and executed by the Department of Geriatrics of Zhejiang Hospital (Zhejiang China). A randomized controlled trial design was used to study the feasibility and effectiveness of a nurse-led multidisciplinary team web-based training and support program. A total of 72 caregivers of patients with dementia were recruited from the Geriatric Department of Zhejiang Hospital from July 2019 to December 2020. The recruitment strategy included posting flyers and posters in the geriatric ward. During the patient's hospitalization, the geriatric nurse proposed this protocol to the family caregivers of the patient with dementia. Interested participants were provided with a flyer containing contact information for the research and filled out a contact form. The geriatric nurse confirmed the inclusion criteria and collected the signed informed consent. The control group intervention measures included regular face-to-face follow-up interviews with caregivers to provide education on dementia care knowledge and skills. These measures were conducted every 3 months after the patient's discharge. All participants were assessed at baseline (T0) and postintervention (T1, 3 months after T0; T2, 6 months after T0). Once enrolled, participants had access to the web-based program or follow-up interview for more than 6 months.

Ethical Considerations

All procedures were in accordance with the Helsinki Declaration, and the study was approved by the Ethics Review Committee of Zhejiang Hospital (2019 pretrial case number: 23K). It was registered at the Chinese Clinical Trial Registry (ChiCTR-2200057858). A written informed consent form was sought from each participant.

Inclusion and Exclusion Criteria

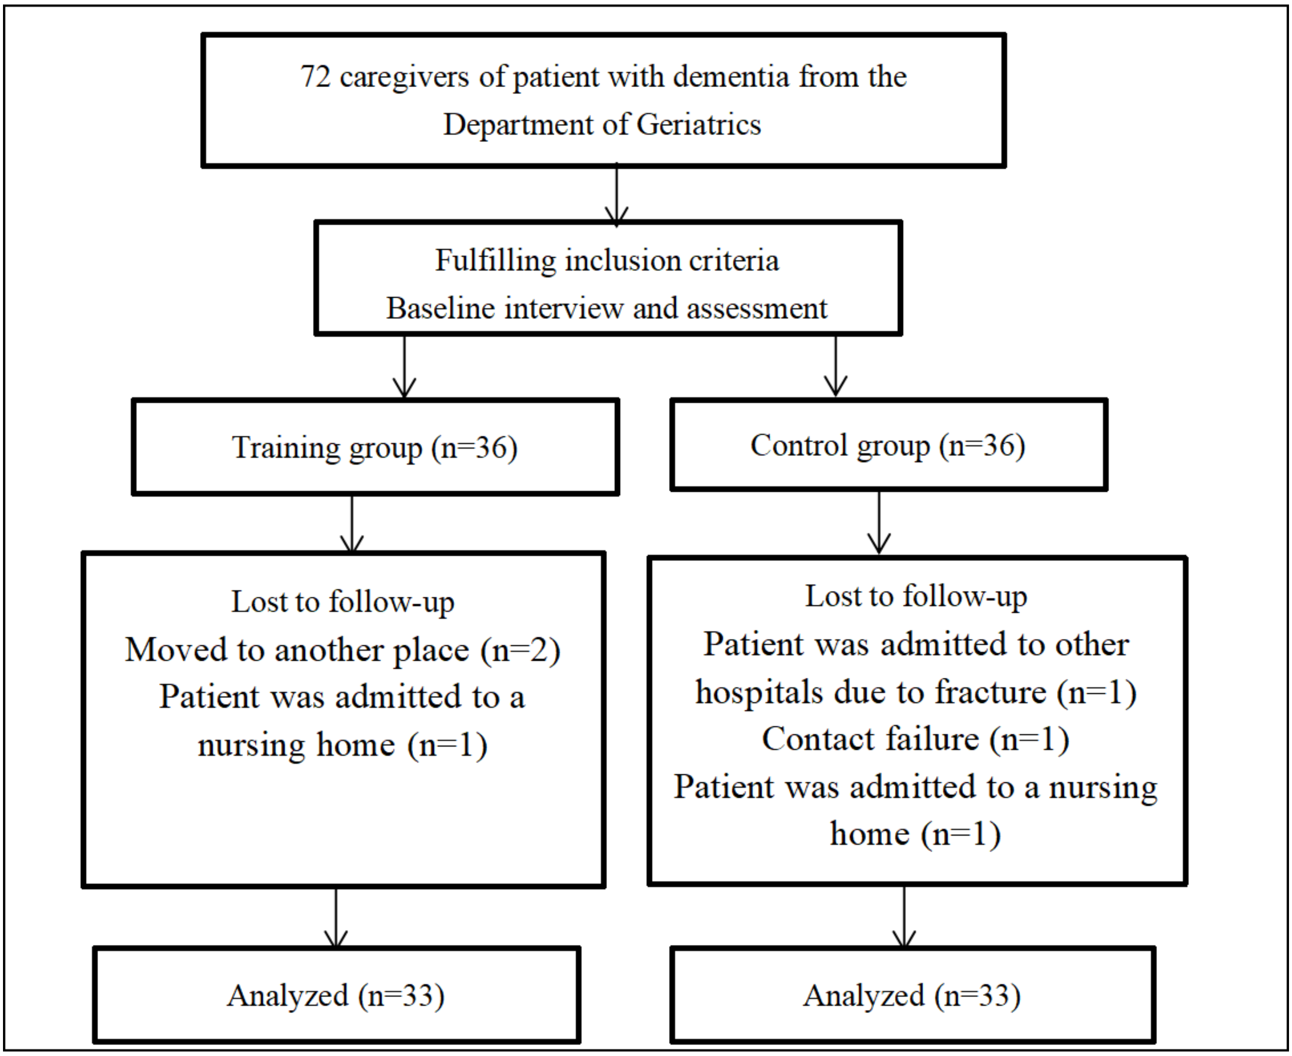
Selection criteria included the following: (1) being a primary, informal caregiver aged at least 18 years; (2) caring for individuals with dementia while living together at home for a minimum of 6 months; (3) having internet access via computers or iPads; and (4) could read, understand Chinese, and following instructions. Participants were excluded if they had severe visual or hearing impairment that was incompatible with participation as assessed by the study staff.

Recruitment, Consent, and Baseline Data Collection

Between July 2019 and December 2020, 72 informal primary caregivers of people with dementia of all subtypes and stages were recruited via the Department of Geriatrics, Zhejiang Hospital. Caregivers meeting the eligibility criteria were informed of initial details about the study and provided with a subject information sheet. Once potential participants decided to participate, they were asked to sign the informed consent form and were informed of their rights. Baseline information was collected by trained interviewers from participants through the completing standardized questionnaires. During the interviews, trained interviewers were blinded to the group allocations. Participants were randomly allocated on a 1:1 ratio assigned to either the intervention or a waiting list control group after baseline assessment. Randomization was carried out using a random number generator.

In the follow-up period, 3 patients in the intervention group and the control group were lost to follow-up, respectively. In the intervention group, 2 caregivers accompanied the patients with dementia when they relocated to a different city, and another caregiver returned to her hometown after the patient with dementia was admitted to a nursing home. In the control group, one caregiver of a patient with dementia accompanied the patient for emergency hospital admission due to a fracture, another caregiver failed to continue contact despite repeated appointments, and one caregiver accompanied the patient to a nursing home (Figure 1).

Figure 1. Flowchart of study participants.



Sample Size Calculation

The experiment was conducted as a parallel-group randomized controlled trial study design, and repeated measures were used. Sample size calculation was based on the primary outcome of the Chinese version of the Zarit Burden Interview (CZBI) at 6 months after baseline. The detection power was set at 90%, and α (2-tailed) was set at .05. Preliminary experiments showed that the CZBI of dementia family caregivers was 21.55, with an SD of 9.89, and an auto-correlation between adjacent measurements on the same individual was 0.70. By providing web-based knowledge and skills training through the internet, the preliminary trial showed that the average CZBI had decreased by 12.5. Using PASS software (version 16.0; National Council on Social Studies), the minimum sample size for each group was identified as 27. Considering a potential 10% loss of samples during the study, the final sample size was determined to be 36 individuals per group.

Intervention

The platform aims to provide opportunities for support, education, and sharing experiences among users across Zhejiang province. In order to provide users with convenient access to the course at any time and place, the platform was designed to operate on any internet-enabled device. In the intervention group, we instructed the informal caregivers of persons with dementia to log in to the platform web page and taught them about the knowledge and skills relevant to home care via the internet. The content on the platform was divided into 5 different themes, which were: computer cognitive training, language training, reality-oriented therapy, daily life rehabilitation, and care skills training. Computer cognitive training includes concentration (picture-text matching), memory (vocabulary memorization), calculation (simulated shopping), and reaction training (fruit picking). Each training time was 20 minutes and was conducted 3 times a week. Language training aims to improve communication by focusing on vocalization, recognition, and the application of words. Reality orientation therapy focuses on presenting patients with facts about the time, date, and current environment. The primary objective for daily life rehabilitation is to increase self-care ability. The 4 themes (cognitive training, language training, reality-oriented therapy, and daily life rehabilitation) have been evaluated in a prior study with pending results and this paper focuses mainly on the fifth theme. The latter theme consisted of 18 lessons (270 min) aimed at improving caregiver care skills (Table 1). In order to encourage participants to complete the web-based course training, the web-based active screen time was calculated. Once participants completed at least 80% of the training sessions (216 min), they would be sent a book (“Long-term Care for Dementia”).

The control-comparison group would receive an educational booklet on caring for patients with dementia provided by the research team. In addition to this education, the control group would also receive face-to-face follow-up guidance and have the option to receive the same intervention after 6 months. The research team’s helpline would also be available 24 hours a day to the control group for caregiver assistance.

Table . Overview of intervention modules.

Theme	Curriculum content
Recognition of dementia	• The concept of dementia • The overview of dementia care • Types and causes of dementia
Physical care for dementia	• Nutritional care for dementia • Excretory care for dementia • Nonpharmacologic interventions for sleep disorders in dementia • BPSD[a] and response strategies
Physical activity maintenance	• Accompany shopping • Accompany outdoor activities • Preventing and delaying the onset of dementia BPSD syndrome
Good memories: cognitive facilitation of care	• Memory training: vocabulary memorization • Computational skill training: calculation (simulated shopping) • Manual activities: reaction training (fruit picking) • Music therapy: this module includes 100 Chinese revolutionary and nostalgic songs, and encourages family caregivers to customize personalized music playlists for the elderly, put them in the proper order, and play them at specific times or activities, such as when they wake up in the morning, at lunchtime, or during evening relaxation time • Spatial orientation training: the platform displays the date, day, weather, season, and holiday. The platform provides prompts to guide the patient in answering questions related to the direction of time • Language training: identifying and describing objects from pictures, finding the correct word, and idiomatic solitaire
Safe harbor: health promotion care	• Safety risks and prevention in home care for older people with dementia: improving the living environment; arranging for special care; setting up reminders such as “Watch out for slipping” and “CAUTION//Hot Water”; avoiding the use of dangerous items such as knives and matches; conducting regular checkups • Emergency response plan for patients with dementia with sudden incidents (stray, fall, and choking) • Sharing family care experience of dementia

[a] BPSD: behavioral and psychological symptoms of dementia.

Measurement Instruments

Due to the in-person meeting restrictions imposed by the COVID-19 pandemic, caregivers participated in two 10-minute web-based self-assessed surveys through Questionnaire Star at 3 and 6 months. The primary outcome measures were the Neuropsychiatric Inventory Questionnaire (NPI-Q), CZBI, and the Sense of Competence in Dementia Care Staff Scale (SCIDS).

The NPI-Q [16] is an observer rating scale that was used to evaluate participants’ neuropsychiatric symptoms across 12 different areas, including delusions, hallucinations, agitation/aggression, depression/dysphoria, anxiety, elation/euphoria, apathy/indifference, disinhibition, irritability/emotional lability, aberrant motor behaviors, nighttime behavioral disturbances, and appetite/eating disturbances. Each symptom was evaluated with a basic screening question (to which participants responded). If a positive answer is given to the screening question, a more detailed exploration of specific areas will be conducted. The neurobehavioral manifestations within a domain are collectively rated by caregivers based on frequency (1 to 4) and severity (1 to 3), resulting in a composite domain score (frequency × severity), with higher scores indicating greater severity of symptoms. The total NPI-Q score is defined as the sum of scores from 12 symptom evaluations, with a maximum score of 144. The Cronbach α coefficient of the NPI-Q was .82, and the test-retest coefficients ranged from .66 to .98 ($P<.001$) [17].

The caregiver burden was measured using the CZBI [18]. CZBI consists of 22 items that require a Likert-type response ranging from 0 (never) to 4 (almost always), with a total score ranging from 0 to 88. A higher score indicates an increased caregiver burden. The internal consistency value, established by Cronbach α coefficient, was .89 and the intraclass correlation coefficient for test-retest reliability of the total score was 0.88.

SCIDS is designed to evaluate the level of competency among caregivers in providing care for individuals with dementia [19]. The scale consists of 17 items across 4 subscales: professionalism, relationship-building, care challenges, and sustaining personhood. SCIDS has acceptable to good internal consistency (Cronbach α=.91) and moderate to substantial test-retest reliability (0.74). The total score on the scale ranges from 17 to 68 points, with higher scores indicating that staff members have a better awareness of dementia care abilities.

Statistical Analysis

Outliers were identified using boxplots, and data distribution was assessed by the Shapiro-Wilk test. Data were tested for normal distribution or variance homogeneity using appropriate tests before statistical analysis with SPSS statistical software (version 20.0; IBM Corp). Continuous variables that followed a normal distribution were expressed as mean and SD and were compared using an independent *t* test between the 2 groups. Categorical variables were expressed as frequencies and proportions and compared using a chi-square test between groups. In repeated measures analysis of variance (ANOVA), when the assumption of sphericity was violated (evaluated using the Mauchly test), the degrees of freedom value for testing the *F*-ratio was adjusted using the Greenhouse-Geisser correction. If there was no interaction effect between time and treatment factors in the repeated measures ANOVA results, the main effects test was used to evaluate the treatment effect. If there was an interaction effect, separate analyses were performed: the within-group effect was evaluated using a one-way repeated measures ANOVA, and the between-group effect was evaluated using a multivariate ANOVA. Bonferroni correction was used for posthoc multiple pairwise comparisons.

Results

Sample Characteristics

The patients in the control and intervention groups were comparable in terms of their baseline data such as sex, education level, marital status, age, BMI, number of children, number of diseases, and number of long-term medications (Table 2). In this study, caregivers averaged 57.74 years old (SD 3.93; range 48-66) and the majority (57/66, 86%) were female. Caregivers were most frequently the patients' distant relatives from the countryside (42/66, 64%) and children (13/66, 20%); the remainder were spouses (11, 16%). Table 2 presents the demographic characteristics of the sample. Among the study groups, demographic and clinical characteristics did not differ significantly.

Table . Sample characteristics.

Category		Intervention group (n=33)	Control group (n=33)
Caregiver age (years), mean (SD); range		58.79 (4.08); 48 - 66	56.70 (3.47); 50 - 64
Sex, n (%)			
	Male	3 (9)	5 (16)
	Female	30 (91)	27 (84)
Caregiver relationship, n (%)			
	Spouse	5 (15)	6 (18)
	Distant relatives from the country-side	22 (67)	20 (61)
	Son or daughter (-in law)	6 (18)	7 (21)
Education level, n (%)			
	Illiterate or primary school	21 (64)	19 (58)
	Junior school	5 (15)	4 (12)
	High school or above	7 (21)	10 (30)
Outcome variables at baseline, mean (SD)			
	NPI-Q[a]	5.97 (6.14)	4.45 (5.43)
	CZBI[b]	24.48 (10.77)	19.85 (11.55)
	SCIDS[c]	59.64 (5.63)	59.76 (7.36)

[a] NPI-Q: Neuropsychiatric Inventory Questionnaire.

[b] CZBI: Chinese version of the Zarit Burden Interview.

[c] SCIDS: Sense of Competence in Dementia Care Staff Scale.

Findings

According to the results of repeated measures ANOVA, as shown in Table 3, it was found that intervention and time had significant statistical effects on the NPI-Q, CZBI, and SCIDS (*P*<.05), and the significant interaction effects of group × time in primary outcome indicators were also found (*P*<.05). Since there were significant differences (group × time effect) in the primary outcome measure, analyses of the individual effects of intervention and time were performed. To verify the significance of intervention effects, multiple comparisons were subjected to the Bonferroni correction for adjustment. The comparison of various data between the intervention group and the control group at different time points is shown in Table 4. After 6 months of intervention, the NPI-Q of caregivers in the intervention group was significantly lower than that of in the control group ($t=-3.020$, $P=.004$); at 3 and 6 months after intervention, the care burden (CZBI) of caregivers in the intervention group was significantly lower than that of in the control group ($t_{3\text{month}}=-2.939$, $P=.005$; $t_{6\text{month}}=-7.858$, $P<.001$). The caregiving ability (SCIDS) of caregivers was significantly higher than that of the control group ($t_{3\text{month}}=6.138$, $P<.001$; $t_{6\text{month}}=12.16$, $P<.001$).

Using the Sidak method to conduct multiple comparisons for the individual effects of time on the primary outcome measure (NPI-Q, CZBI, and SCIDS), the results are shown in Table 5. In the intervention group, the NPI-Q score showed a decrease over time (mean $\text{difference}_{T2\text{-}T1}=-1.39$, mean $\text{difference}_{T3\text{-}T1}=-2.79$), while the comparison group showed a significant increase at the 3- and 6-month follow-up compared with baseline, with statistically significant differences (mean $\text{difference}_{T2\text{-}T1}=1.46$, mean $\text{difference}_{T3\text{-}T1}=3.64$). According to the research results, the severity of NPI-Q in patients with dementia tends to worsen over time. However, this study showed that caregiver knowledge and skills training through an information platform significantly delayed the progression of NPI-Q symptoms in patients with dementia, indicating the effectiveness of this training method.

The intervention group's CZBI scores showed a significant decrease over time (mean $\text{difference}_{T2\text{-}T1}=-7.70$, mean $\text{difference}_{T3\text{-}T1}=-13.52$), while the control group experienced a significant increase (mean $\text{difference}_{T2\text{-}T1}=4.49$, mean $\text{difference}_{T3\text{-}T1}=10.45$). The study revealed that internet-based supportive interventions providing dementia caregivers with knowledge and skills training led to a significant reduction in caregiving burden and were proved to be highly effective.

In terms of caregiving ability (SCIDS), the performance of the intervention group's caregivers significantly improved in the 3- and 6-month follow-ups, with statistically significant differences compared with before intervention (mean $\text{difference}_{T2\text{-}T1}=5.79$, mean $\text{difference}_{T3\text{-}T1}=12.24$). Conversely, the caregiving ability of the control group's caregivers declined during the same period (mean $\text{difference}_{T2\text{-}T1}=-6.70$, mean $\text{difference}_{T3\text{-}T1}=-8.64$). This result indicated that providing knowledge and skills training to informal caregivers of persons with dementia through information technology platforms can effectively enhance their caregiving skills.

Table . Comparison of 3 scores between 2 randomly assigned groups with key outcomes that vary over time.

Measure		NPI-Q[a]	CZBI[b]	SCIDS[c]
Baseline				
	Intervention group	5.97 (6.14)	24.48 (10.77)	59.64 (5.63)
	Control group	4.45 (5.43)	19.85 (11.55)	59.76 (7.36)
3 months after intervention				
	Intervention group	4.58 (4.95)	16.79 (8.05)	65.42 (6.15)

Discussion

Principal Findings

The restrictions of the COVID-19 pandemic have had profound effects on patients with dementia and their caregivers. This study shows that internet-based support and education have a positive impact on family caregivers. The intervention can reduce the NPI-Q scores of patients with dementia, enhance the dementia care skills of informal caregivers, and ease the care burden for caregivers. With the progression of dementia, caregivers not only have to deal with many behavioral, daily living, and safety issues but also lack the professional knowledge and skills to address diverse caregiving challenges. This not only causes them to experience anxiety and depression but also brings care and financial burdens to their families and society. Web-based interventions based on internet technology are highly flexible and suitable for family caregivers, as their schedules are largely consumed by caregiving and they may not have time to attend in-person learning sessions (due to travel and time constraints).

Patients diagnosed with dementia often struggle with a gradual deterioration of emotional regulation and an increased likelihood of displaying behavioral and psychological symptoms. This is closely linked to the decline in cognitive function associated with the condition. Research on caregiver burden indicated that BPSD are strongly correlated with caregiver burden [20]. The prevalence of dementia in Chinese society is expected to increase in the next 40 years. Family members remain the primary caregivers and bear a heavy burden. BPSD not only has a significant impact on the health and quality of life of patients but also brings enormous physical and psychological burdens to caregivers. In this study, the intervention group had significantly lower NPI-Q scores than the control group after 6 months of intervention. The results indicated that internet-based supportive interventions for dementia caregivers can effectively improve BPSD symptoms in patients with dementia. This result is consistent with those of previous studies [21,22]. BPSD symptoms are a prevalent issue among older individuals with dementia. These symptoms often occur repeatedly and can present at varying stages of the disease. Previous research [23] has demonstrated that the emergence of BPSD symptoms is associated with an increased risk of accelerated progression of dementia, reduced cognitive function, and a quicker decline in cognitive abilities in individuals with dementia. Our research has to some extent reduced the incidence and severity of behavioral and emotional symptoms. The meta-analysis results of Leng et al [24] also show that internet-based supportive interventions have potential benefits for the neurological and psychiatric symptoms of patients with dementia.

The research results showed that after 6 months of intervention, the total score of caregiving ability for the intervention group caregivers was significantly higher than that of the control group ($P<.05$), indicating that web-based supportive intervention for dementia informal caregivers can significantly improve their caregiving ability. Providing care for patients with dementia is an incredibly difficult task, and caregivers may struggle with a lack of essential resources, including knowledge, skills, and social support. In this context, the development of knowledge and skills to support family caregivers is essential. The web-based caregiver training intervention plan for dementia caregivers in this project covers the basic knowledge that caregivers should possess. It systematically explains the causes, clinical manifestations, and progression of dementia, promoting caregivers' understanding. Mastering knowledge is a prerequisite for improving skill levels [25]. In caring for patients with dementia, knowing about the disease can help caregivers better care for patients. Only when caregivers have a correct understanding of the illness can they truly empathize with patients and provide them with appropriate care. This study adopted web-based training to enhance caregivers' caregiving skills from 4 aspects: knowledge, skills, self-emotional management, interpersonal relationships, and resource use. In terms of intervention form, web-based knowledge and skills training is more flexible in terms of time, allowing caregivers to choose their free time to increase their participation. The result is similar to the study by Teles et al [26].

After comparing the CZBI scores of the 2 groups of caregivers at different time points, we concluded that within 6 months after the intervention, the CZBI scores of caregivers in the intervention group were significantly lower than those in the control group ($P<.05$). The findings demonstrated that the internet-based supportive intervention had a significant impact on alleviating the burden of care for dementia. This result is consistent with those of 2 studies [26,27]. The meta-analysis carried out by Egan et al [28] and the systematic review conducted by Pleasant et al [29] have also demonstrated web-based training programs' supportive intervention for informal caregivers of persons with dementia were highly effective in reducing their burden. When informal caregivers have mastered basic care knowledge and skills, their confidence in caring for patients is enhanced, uncertainty is reduced, and understanding of patients is improved. This knowledge and skills can reduce the burden on caregivers and enable them to care for patients more effectively. Using home care resources could help maintain health status, minimize symptom relief, and reduce avoidable hospitalizations [30]. This study offers a solution to the challenges faced by informal caregivers by providing them with training through web-based programs. They gain knowledge and skills that allow them to adjust their caregiving schedules flexibly to accommodate the needs of individuals with dementia. This approach not only empowered informal caregivers but also optimized the use of home care resources, making care provision more effective.

Limitations

This study has limitations. First, due to time constraints, the effects of the intervention program in this study were evaluated for only 6 months, and long-term follow-up will be conducted in the future. Second, since manpower, funding, and time constraints prevented long-term research, this study was conducted with a small sample size only. Third, we measured outcomes and exposures using self-reported questionnaires, so reporting errors was possible. Despite these limitations, our plan is still noteworthy because it is one of the few web-based interventions that have a significant impact on fostering positive emotions towards caregiving and reducing the burden on informal caregivers of persons with patients with dementia. Bastoni et al's [31] research has found that monitoring devices are rapidly developing and are seen as promising technologies. This includes monitoring health and safety in homes, as well as providing outdoor location identification for patients with dementia. In the future, we will conduct in-depth research on integrating wearable devices and other mobile information collection terminals into this information platform to achieve real-time monitoring of the health status of patients with dementia.

Conclusions

The long-term care system in China predominantly relies on informal family care. Family caregivers are the mainstay of elderly care at present in China, and their caregiving capacity directly affects the quality of family care. The lack of caregiver competence affects the quality of care because family caregivers lack basic knowledge and relevant skills in caregiving. The Chinese eldercare system relies heavily on informal care provided by family members due to filial piety. China has many patients with dementia due to its huge population base. Family caregivers are the mainstay of elderly care in China currently [32], and their ability to provide care directly affects the quality of home-based care. Caregivers for patients with dementia often face the reality of inadequate caregiving skills and a desire for support. As a family caregiver, one needs to possess a variety of knowledge and skills. This comprises an understanding of the ailment in question, being adept at solving problems creatively, and possessing techniques for maintaining psychological well-being. Informal caregivers play a crucial role in the care of individuals with dementia. Therefore, it is imperative to have interventions in place that not only support them but also alleviate their burden. Major technological advancements should be leveraged to optimize the time and effectiveness of the dementia care workforce [33]. As a cost-effective, convenient, and accessible intervention, web-based solutions have emerged to support informal caregivers. The advantage of web-based support training lies in breaking the limitations of time and space and providing a feasible solution for the popularization of support services. During the COVID-19 pandemic, our research project provided digital resources through web-based support and training to informal caregivers of persons with dementia, which improved the caregivers' skills and alleviated their burden.

Abstract

Background: Informal caregivers of persons living with dementia are increasingly using mobile health (mHealth) apps to obtain care information. mHealth apps are seen as promising tools to better support caregivers' complex and evolving information needs. Yet, little is known about the types and quality of dementia care information that these apps provide. Is this information for caregivers individually tailored; if so, how?

Objective: We aim to address the aforementioned gaps in the literature by systematically examining the types and quality of care-related information provided in publicly available apps for caregivers of persons living with dementia as well as app features used to tailor information to caregivers' information wants and situations.

Methods: In September 2023, we used a multistage process to select mobile apps for caregivers of persons living with dementia. The final sample included 35 apps. We assessed (1) types of dementia care information provided in the apps, using our 3-item Alzheimer disease and related dementias daily care strategy framework, which encompasses educational information, tangible actions, and referral information; (2) quality of apps' care information, using the 11 indicators recommended by the National Library of Medicine; and (3) types of tailoring to provide personalization, feedback, and content matching, which are common tailoring strategies described in the literature.

Results: Educational information was the most prevalent type of information provided (29/35 apps, 83%), followed by information about tangible actions (18/35, 51%) and referrals (14/35, 40%). All apps presented their objectives clearly and avoided unrealistic or emotional claims. However, few provided information to explain whether the app's content was generated or reviewed by experts (7/35, 20%) or how its content was selected (4/35, 11%). Further, 6 of the 35 (17%) apps implemented 1 type of tailoring; of them, 4 (11%) used content matching and the other 2 (6%) used personalization. No app used 2 types of tailoring; only 2 (6%) used all 3 types (the third is feedback).

Conclusions: Existing dementia care apps do not provide sufficient high-quality, tailored information for informal caregivers. Caregivers should exercise caution when they use dementia care apps for informational support. Future research should focus on designing dementia care apps that incorporate quality-assured, transparency-enhanced, evidence-based artificial intelligence–enabled mHealth solutions for caregivers.

Introduction

Background

Alzheimer disease and related dementias (ADRD) present a critical public health concern; in 2023, a total of 55 million individuals were estimated to live with dementia worldwide, with an increase of nearly 10 million expected each year [1]. Often, the care for these persons living with dementia falls on *informal caregivers*—family members, friends, neighbors, or others (hereafter, "caregivers"). In the United States, more than 11 million caregivers were estimated to have provided approximately 18 billion hours of care to people living with dementia in 2022, valued at over US $330 billion [2].

Caregivers of persons living with dementia often lack formal training [2,3] or have little to no knowledge about dementia care [4], representing a substantial information gap [5,6], and they have health information wants (HIWs)—"health information that one would like to have and use to make important health decisions that may or may not be directly related to diagnosis or standard treatment" [7]. Centered around health consumer's perspective, the ADRD HIWs framework suggests seven types of information that caregivers typically want for dementia care: (1) information about treatment or prevention, (2) characteristics of the patient's health condition, (3) daily care strategies for patients at home, (4) practical information about care transition and coordination and end-of-life care, (5) psychosocial aspects of caregiving, (6) resources or scientific updates, and (7) legal, financial, or insurance-related information [8]. Unmet HIWs often lead to a severe care burden and increased stress for caregivers [9,10].

Given the anticipated increase in the number of persons living with dementia and the unlikelihood of a cure in the near future, numerous interventions have been developed to equip caregivers with necessary competencies to fulfill their HIWs (see review by Whitlatch and Orsulic-Jeras [11]). However, the feasibility of most currently available face-to-face interventions is limited due to the demanding nature of caregiving, challenges in finding alternative care for persons living with dementia to attend the programs, and the scarcity of caregiver services, especially in rural or underdeveloped areas [12]. Consequently, internet-based interventions such as web-based courses [13,14], or web-based programs [15,16] have emerged as a potentially efficient alternative, providing information and support to caregivers, as evidenced by the volume of systematic reviews and meta-analyses on this topic [17-19].

According to the review by Boots et al [17], internet-based interventions can be effective in supporting caregivers if they are tailored to the individual needs. For caregivers, timely and personally tailored information is important [20]. It improves their knowledge and enables them to develop coping abilities, so that they can provide competent care throughout the disease trajectory [21,22]. A recent meta-analysis of 17 randomized controlled trials of internet-based interventions has demonstrated improvements in dementia-related knowledge and care skills among caregivers [23]. Not surprisingly, it was discovered that personalized interventions are more beneficial than interventions that are not personalized. Despite these findings, a national caregiver survey in the United States reported that caregivers use health-related internet resources less frequently than the general public [24], which limits the reach and effectiveness of these programs for caregivers at large. Additionally, challenges such as the web layout's inherent limitations and infrequent updates of features further hinder the delivery of tailored information [25,26], thus diminishing the potential effectiveness of internet-based interventions for caregivers. These findings underscore the need to explore more innovative technological solutions to better support caregivers' complex and evolving HIWs.

The Need of This Study

As of 2023, there has been a substantial increase in smartphone uptake among US adults aged 65 years or older, with adoption rates rising from 13% to 76% over the preceding decade [27,28]. Consequently, the use of mobile health (mHealth) apps to support caregivers has attracted much attention recently [29,30]. These internet-based applications, installed on mobile devices (eg, smartphones, wireless tablets), have become important tools for accessing health information and providing real-time feedback, even without computer and network connectivity [31]. They are now the most prevalent technological solutions [32] and have been used to support health education and the care across a wide range of chronic health conditions [33], and have also been tested among different age groups, including older adults [34].

Nevertheless, research on mHealth app–based interventions for caregivers is still at an early stage [29,35]. Recent literature reviews searched available apps, describing most apps as information resources for caregivers [36-38]. While these reviews acknowledged caregiving-related information as one of the most critical components of the apps, none of the studies systematically examined the quality of this information. Moreover, the extent to which these apps provide care-related information tailored to caregivers' HIWs remains unclear. As Brodaty and Donkin [39] have noted, the success of caregiver interventions depends greatly on "the extent to which they are tailored to the needs of the individual and address issues to do with subjective burden." Thus, it is critical to systematically examine mHealth apps for their information provision and tailoring, as a first step in assessing their effectiveness for the support of caregivers.

In the use of mHealth apps to tailor support [40,41], three strategies for tailoring are common: (1) *Personalization*—strategies that convey "explicitly or implicitly, that the communication is designed specifically" for an individual [42]. This is typically carried out by drawing on personally identifiable information, making clear that the messages are designed specifically for the individual, and situating the messages within the individual's specific context. (2) *Feedback*—the provision of "messages to users about their psychological or behavioral states" that reflect user updates [41]. (3) *Content matching*, which entails providing content suitable for individuals' stages of changes [40,42]. Reviews of mHealth apps for caregivers have not considered these strategies as components of tailoring [36,43]. In our study, we therefore systematically examine whether these tailoring strategies have been implemented in existing mHealth apps for caregivers of persons living with dementia, and if so, how they have been implemented.

Context of This Study and Objectives

This study is an essential component of a larger project titled "Tailoring Responses to ADRD Caregivers' InfOrmation wants (TRACO) through Human-machine Collaboration" (R56AG075770). The primary goal of the project is to develop an artificial intelligence (AI)–based system with a mobile app interface that help caregivers in obtaining high-quality, relevant information tailored to their specific HIWs and unique caregiving contexts. While mHealth apps and AI tools can provide tailored information, their full tailoring potential has been underused [44-47]. Hence, this study is designed to systematically examine how mHealth apps provide information and serve as a foundational exploration to better support the development of the TRACO system.

Specifically, this study aims to understand more about the characteristics and the delivery of these apps. Therefore, the following research questions are identified:

1. What types of information do current mHealth apps offer to caregivers of persons living with dementia?
2. What is the quality of information presented in these mHealth apps?
3. How do current mHealth apps tailor their information to support caregivers of persons living with dementia?

Methods

Study Design

Following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [48] and the procedures used in a previous systematic review of mHealth apps [49], we performed 3 rounds of screening to select relevant apps for examination. First, using keywords, we searched Apple's App Store for iOS and Google's Play Store for Android devices. Next, we screened the app store pages, using inclusion and exclusion criteria. Then we downloaded or attempted to download the apps to ensure their accessibility. Finally, using our criteria, we assessed the included apps in order to answer our research questions.

Ethical Considerations

This study did not involve human participants, human data, or any form of intervention with individuals, and therefore did not require approval from an institutional review board or ethics committee. According to the Office for Human Research Protections, research that does not include human participants falls outside the scope of institutional review board review [50]. As no human participants were involved in the research, no ethical concerns related to human subject research were applicable.

App Selection

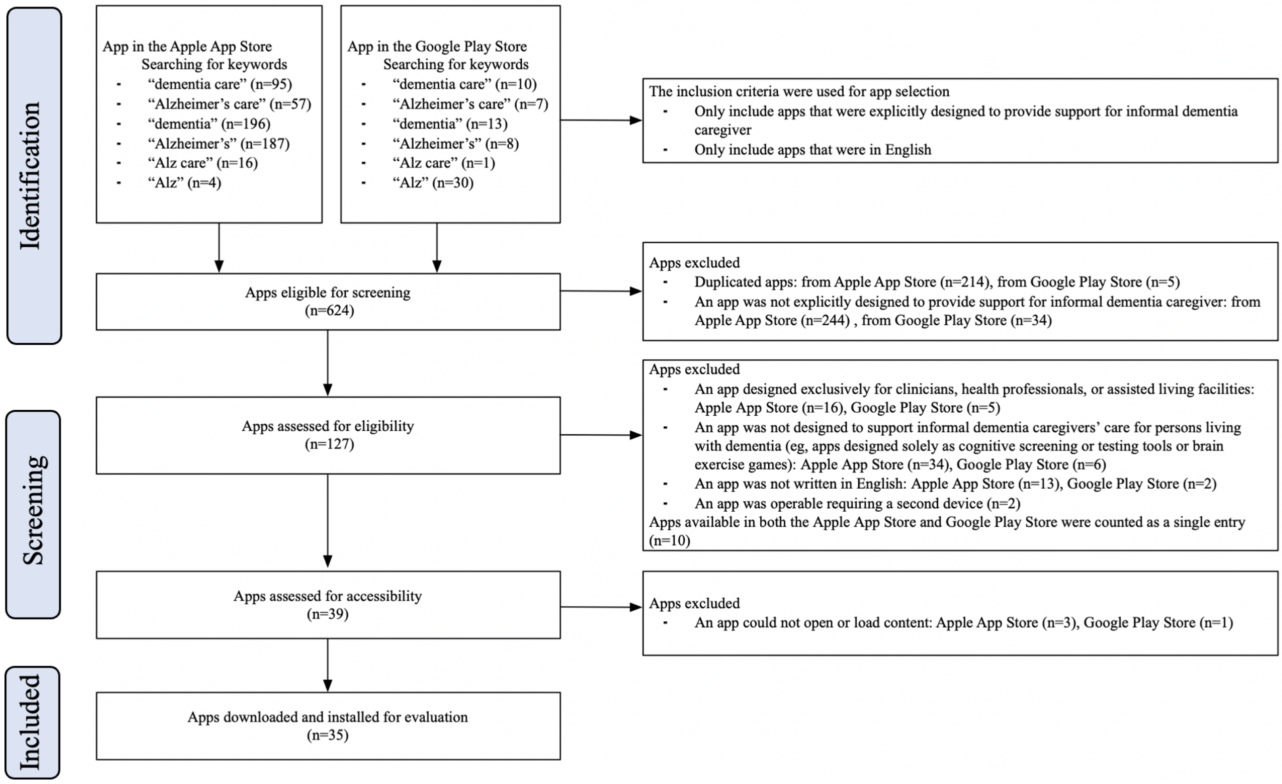
Consistent with prior reviews [36,37,51], our search keywords included the following: "dementia care," "dementia," "Alzheimer's care," and "Alzheimer's." During initial screening, we realized that several apps' titles used the abbreviation "Alz" instead of "dementia" or "Alzheimer's"; we therefore expanded the search to include "Alz." Our initial searches, performed in September 2023, yielded a total of 624 apps from Apple's App Store for iOS and from Google's Play Store for Android devices. We noted from the app store descriptions that many apps cater to various caregiver groups, not solely caregivers of persons living with dementia. These included caregivers of children with cognitive disorders or individuals with Ataxia, among others. Given our study's specific aim to investigate mHealth apps exclusively for caregivers of persons living with dementia, we excluded apps not explicitly designed for dementia care at this stage. After removing duplicates, 127 apps remained.

We then screened the 127 apps for inclusion. Consistent with the scope of this study, we included only apps developed specifically to support caregivers. Apps that did not directly support the care of persons living with dementia were excluded. Specifically, we exclude (1) apps designed to support other dementia care stakeholders, such as health professionals, clinicians, or residential care facilities; (2) apps developed solely as cognitive screening and testing tools or brain exercise games, as they did not focus on caregiving for persons living with dementia. We also excluded (3) apps not in English to maintain consistency with the larger project as stated in the introduction, and (4) those that required the use of second device (eg, smartwatch or wearable gadget). The adoption of such devices typically involves interactions with multiple stakeholders, not just caregivers [52], which is beyond the scope of this study. Both free and paid apps were included.

The research team first discussed a randomly selected subset of 10 out of the 127 apps during weekly team meetings between September and October, 2023, using the established inclusion and exclusion criteria. Any disagreements were resolved through discussions. Subsequently, based on the agreed-upon criteria, 1 researcher (NZ) continued the screening process, ultimately including a total of 39 apps for further assessment. Then, 2 researchers (NZ and BX) independently reviewed a randomly selected sample of these 39 apps (n=13, representing 33% of the total). The agreement rate between the 2 reviewers was high (92.3%), and any differences were resolved through further discussions.

Finally, we downloaded or attempted to download each of the 39 apps to an iPhone and an Android phone for further examination. During this step, we excluded 4 more apps that could not be opened or downloaded, for a final sample of 35 apps: 20 were iOS-only; 5 were Android-only; and 10 were available for both iOS and Android systems. App selection, including the numbers of apps excluded at each step, is illustrated in Figure 1.

Figure 1. App selection process.



Measures

The ADRD Daily Care Strategy Framework to Evaluate Types of Information Provided

To assess the types of dementia care information provided in the apps, we used the ADRD Daily Care Strategy Framework developed in our earlier work [53]. We selected this framework because the types of information it encompasses have been proven in our prior work to be evidence-based care strategies that effectively match the responses to caregivers' HIWs. This framework includes 3 types of information about care strategies: educational information, tangible actions that caregivers can take; and referrals for caregivers to seek help beyond the patient-caregiver dyad (Table 1). Each type of information found in the app was assigned a score of 1, and its absence was scored as 0; scores thus ranged from 0 to 3. Higher scores indicated more types of care information present in the apps.

Table . The Alzheimer disease and related dementias daily care strategy framework.

Types of information provided	Operational definition
Educational information	Provides education about the behavior or situation in question; education about what caregivers could do on their own in response to challenges encountered; focus on caregivers' own knowledge, preparation, and adjustments, not on others'
Tangible actions	Provides information about specific things caregivers can do (on their own) to address situations
Referral information	Provides referral information so that caregivers can seek help beyond the patient-caregiver dyad, for example, peer caregivers, health care professionals, financial advisors, an attorney for elder law, other family members, community organizations, and long-term care facilities

The National Library of Medicine's Criteria for Evaluating the Quality of Web-Based Health Information

The National Library of Medicine (NLM)'s tutorial on evaluating web-based health information offers a comprehensive checklist for assessing the quality of web-based health information [54].

Although the Mobile App Rating Scale [55] is commonly used to evaluate mHealth apps for caregivers [38,51], its criteria for assessing the quality of information—ensuring the app content is correct, well-written, and relevant to the goal or topic of the app—appear too vague for comprehensively evaluating the care-related information provided by the apps. Drawing on the success of previous empirical research that used the NLM's criteria to assess information quality in mHealth apps for cardiovascular disease [49], we adopted the NLM criteria and developed definitions for the context of dementia care to operationalize the NLM’s criteria (Table 2). These included 11 indicators of information quality; the presence of each indicator was recorded as 1, and each absence was recorded as 0 (scoring range: 0 - 11). Higher scores indicated higher information quality.

Table . National Library of Medicine’s criteria for information quality and our operational definitions.

Evaluation criteria	Operational definition
Providing information on who is managing the app	Provides information that could help users understand who oversees the app (eg, information about the app provider’s name). Such information is typically found via the *About Us* button in the app or on the app’s store page.
Providing information about why the app is being provided	Provides information that could help users understand the app’s purpose, intended users, and functionalities. Such information is typically found on the app’s store page or via the *About this app* or *About us* button in the app (eg, indicating that the app is developed for dementia caregivers, or to provide dementia care-related information, or to provide tailored support to dementia caregivers).
Providing the app provider’s contact information	Provides information about the physical address, a contact number or email address for the app developer or administrator, or an option for users to submit questions or comments.
Providing information on the source of the content	Provides information that could help users understand where the dementia care information used by the app comes from (eg, an article or book with authors’ names; or for web-based information, the website from which the information was retrieved).
Providing information on how the content was selected	Provides a logical explanation for how the app’s information was selected (eg, information selected from peer-reviewed journals).
The content that goes on the app is reviewed by an expert	Provides information to make clear that information presented in the app has been reviewed by qualified health care professionals.
Does not use unbelievable or emotional claims	Whether or not the app makes claims that are too good to be true or are based on emotions instead of scientific facts.
Content is up to date	The original National Library of Medicine guidelines do not specify what time frame would be considered up to date; in our study, we operationalized this indicator as app content updated in the past 12 months.
Financial disclosure	Provides information on where the money to support an app comes from (eg, government agencies, nonprofit organizations, or professional service companies). This information can help users understand whether an app’s providers have financial motives that users should be aware of (eg, the sale of courses or consultation services).
Does not have advertisements	Whether or not an app contains advertisements. Note: if a treatment option mentioned in an app was a part of scientific results (eg, reported in a research article), then it was not considered an advertisement.
Personal data privacy disclosure	Whether or not an app asks users to submit personal information (eg, name, phone number, or email address) and personal health indicators (eg, health status or medical history) in order to use certain app features. If asked, whether an app provides information on how users’ personal data will be used.

Types of Tailoring Strategies for Evaluating Apps’ Information Tailoring

We examined whether apps provided the 3 types of tailoring strategies commonly reported in the literature: personalization, feedback, and content matching [40,42]. Our operational definitions for these 3 types of tailoring are provided in Table 3. The presence of each type of tailoring was recorded as 1, and each absence was recorded as 0 (scoring range: 0 - 3). Higher scores indicate more types of tailoring.

Table . Information tailoring strategies and our operational definitions.

Evaluation criteria	Operational definitions
Personalization	App’s output contains personal information (based on the user’s input, for example, the person living with dementia is the user’s grandmother) to make clear that the output was designed specifically for the user and places the messages in the user’s specific context.
Feedback	App’s output contains information acknowledging the user’s specific situation (based on the user’s input) to convey to the user that the system is aware of the user’s situation.
Content matching	App’s output contains relevant responses to the types of health information wants expressed in a user’s input.

Data Analysis

We assessed (1) types of dementia care information provided in the apps, using our 3-item ADRD Daily Care Strategy Framework; (2) quality of dementia care information provided in the apps, using the 11 indicators recommended by the NLM; and (3) types of tailoring provided, using the 3 common tailoring strategies reported in the literature. Further, 2 members of the research team (NZ and BX) initially evaluated 7 randomly selected apps from the final sample according to these measures. For any items with a recorded disagreement, the 2 reviewers met to discuss and reach a consensus. Later, researcher NZ continued and completed the evaluation of the remaining apps. Discussions were consistently held between researchers NZ and BX to address any ambiguities that arose during the evaluation process. The ratings for each measure were entered into a Microsoft Excel spreadsheet, and we used descriptive statistics to analyze each rating.

Results

Overview

Of the 35 apps in our final sample, 10 (29%) were developed between 2012 and 2017. Among them, only 1 (3%) was still having regular updates at the time of our study. Further, 6 (17%) of the apps had actively received updates, for an average duration of 5 (SD 1.55) years before stopping any further updates; 3 had not been updated at all since their initial release. The other 25 (71%) apps were developed between 2018 and 2023. Additionally, 13 (37%) were actively receiving updates by 2023; 7 (20%) had not received any updates since their release; and another 5 (14%) stopped receiving updates after an average of 2.4 (SD 1.95) years.

In total, 15 (43%) apps were created by for-profit companies such as corporations providing health care services or consulting firms; 8 (23%) were developed by nonprofit health care organizations or charities; another 8 (23%) were developed by academic institutions; and the remaining 4 (11%) did not disclose any affiliation of app developers. Most apps were free (28/35; 80%); 5 (14%) were free with in-app purchases; only 2 (6%) were paid apps (requiring US $2.99 and US $3.99, respectively). The largest number of apps (15/35, 43%) were from the United States; 8 (23%) from the United Kingdom; 4 (11%) from Australia, 3 (9%) from Canada, and 1 (3%) from India. The 4 (11%) apps that provided no developer information also provided no information about where they were developed.

Types of Information

In total, 16 (46%) of the apps offered only 1 type of information. Among them, 12 (75%) provided educational information; 2 (13%) offered information about tangible actions, and 2 (13%) offered referral information. Further, 12 (34%) apps offered 2 types of information: 7 (58%) of them offered both educational information and information about tangible actions; 3 (25%) provided both educational information and referral information; and 2 (13%) provided both information about tangible actions and referral information. Only 7 (20%) apps in our final sample offered all 3 types of information. Of the reviewed apps, if an app attempted to offer more than one type of information, its content frequently remained broad and merely basic, in contrast to apps that specialized in providing only a specific type of information. Overall, educational information was the most commonly offered type of information (29/35, 83%), followed by information about tangible actions (18/35, 51%). Information about referrals (14/35, 40%) was the least common type of information provided in the apps.

Information Quality

Of the 35 apps, 17% (6 apps) met 3 - 4 of the NLM’s criteria for web-based health information quality. Another 34% (12 apps) met 5 - 6 criteria, and 40% (14 apps) met 7 - 9 criteria. Only 11% (4 apps) met 10 of the NLM’s criteria, and none met all 11 criteria. Notably, the 4 apps that met 10 criteria were all developed by academic institutions, nonprofit health care organizations, or charities. In contrast, all 6 apps meeting only 3 or 4 criteria were developed by for-profit companies or developers of unknown origin. Apps available on both iOS and Android systems scored higher on average (mean 7.9, SD 2.28, 95% CI 7.14-8.66) than those available exclusively on iOS (mean 6.6, SD 1.73, 95% CI 6.03-7.17) or Android (mean 4, SD 1.41, 95% CI 3.53-4.47). All apps met 2 of the NLM criteria: they clearly stated the purpose of developing the app and avoided making unbelievable or emotional claims. Few explained whether the app’s content was reviewed by experts (7/35, 20%); and even fewer stated how the content was selected (4/35, 11%; Table 4).

Table . National Library of Medicine's information quality indicators covered by the apps.

Information quality indicator	Apps, n (%)
Provided information about why the app is being provided	35 (100)
Does not use unbelievable or emotional claims	35 (100)
Provided information on who is managing the app	30 (86)
Does not have advertisements	29 (83)
Provided the app provider's contact information	25 (71)
Personal information use disclosure	22 (63)
Provided information on the source of the content	18 (51)
Content is up to date	15 (43)
Financial disclosure	13 (37)
The content that goes on the app is reviewed by an expert	7 (20)
Providing information on how the content was selected	4 (11)

Information Tailoring

In total, 6 of the 35 (17%) apps implemented 1 type of tailoring strategy; of them, 4 (11%) used content matching and the remaining 2 (6%) used personalization. The specific content matching strategies varied among the 4 apps. Further, 2 of the apps used web-based discussion forums to deliver responses from platform-verified experts or peer caregivers. The other 2 offered a list of behavioral problems along with possible causes, allowing caregivers to choose, and, on the basis of the caregivers' choice, the app tailored a list of care strategies to address the specific problem expressed by the caregiver.

Of the 2 apps that entailed personalization, each used a unique approach to collect and use personal information. However, neither app successfully delivered tailored support. The first app gathered detailed information on the person living with dementia, such as disease stage and health conditions. The second app surveyed caregivers' stress levels and the person living with dementia's behavioral issues. Despite collecting such personal information, both apps failed to tailor the content depending on user input and provided the same responses regardless of the user data provided. This lack of customization and transparency about how personal information affected content raises concerns about the apps' effectiveness and credibility for offering personalized support.

No app used 2 types of tailoring strategies; 2 (6%) used all 3 tailoring strategies. Both apps used generative AI-enabled intelligent assistants to provide tailored responses. These platforms allowed caregivers to input any queries and provided personalized answers. One of these apps explicitly stated that it used ChatGPT for this purpose; the other did not specify what AI tool it used or how its intelligent assistant was developed.

Discussion

Principal Findings

Previous reviews have found that dementia care apps mainly offer educational content along with generic care tips for coping [36,37]. In our study, we have examined the extent to which care-related information in the apps includes not only educational information but also information about tangible actions and referrals. Tangible action and referral information were underrepresented in the apps. As these 2 types of information can vary greatly depending on caregivers' specific situations [56,57], it may be challenging for apps to provide such information. Current dementia care apps primarily provide extensive static educational information, and so they cannot meet caregivers' specific HIWs [36,38]. Future dementia care apps should consider including elements designed to capture caregivers' specific HIWs, which can evolve as the disease progresses [8].

Recent reviews have primarily used the Mobile App Rating Scale [55] to evaluate apps and have found that the quality of information in dementia care apps falls below minimum acceptable scores [38,51]. Going beyond statistical validation of this known issue regarding poor information quality [36], we have adapted the NLM's information quality evaluation criteria to examine specific attributes that affect information quality. Apps developed by academic institutions or nonprofit health care organizations appeared to align more closely with the NLM's quality indicators. Nevertheless, the lack of indicators for expert-reviewed content and content selection remains a problem. Given the critical role of health care providers in ensuring the accuracy and reliability of information [49,58], further research is needed to explore how to design features that integrate dementia care professionals within information assessment and selection [58,59]. Implementing these improvements will enhance the credibility and reliability of caring-related information and potentially improve caregivers' information-seeking and, ultimately, the apps' adoption rates [60].

Commonly recommended tailoring has yet to be successfully implemented in dementia care apps. By and large, apps' tailoring merely replicates approaches found in web-based discussion forums [61,62]. Yet, there is potential for dementia care apps to provide more tailored, personally relevant learning [36]. The AI-enabled intelligent assistants found in 2 of the reviewed apps may represent a promising approach for delivering tailored information. Recent research suggests ChatGPT's capability to generate high-quality responses to meet dementia caregivers'

HIWs [63]. Nonetheless, recent studies have raised concerns regarding ChatGPT's use in health care, particularly its tendency to conceal its information sources and provide inappropriate references [64]; its outputs may require cautious human oversight to ensure quality [65].

These concerns echo our findings for apps' lack of explanation regarding information selection, including a lack of information about whether their content had been reviewed by health care professionals. If unaddressed, these issues are likely to persist in AI-enabled mHealth apps for caregivers. More rigorous efforts are needed in dementia care research and practice to investigate AI-enabled mHealth tools. There is a need to explore comprehensive frameworks that involve health care professionals in content validation, as well as advancements to streamline these technological processes.

Limitations and Future Directions

Limitations of this study include the following. App evaluation was carried out by researchers with professional expertise in the subject matter; no evaluation was performed by caregivers. Our evaluation relied on guidelines designed from a top-down perspective, reflecting what health care professionals would view as important for evaluating an app's information quality. This approach might not fully align with caregivers' perspectives, and the insights derived might differ from those of caregivers. Given the importance of user-centered design in developing mHealth technology for dementia caregiving [66], future research will benefit from caregivers' evaluation of such technology. User-centered evaluation would ensure that apps meet caregivers' actual needs and preferences. This study only included mHealth apps that were available in English, thus, there could be apps available in other languages that provide high-quality information to caregivers of persons living with dementia. This study did not consider app design or usability when evaluating the type and quality of information provided. Given that academic institutions and nonprofits produced mHealth apps with higher information quality, future developments could include collaborations with for-profit organizations to design tailored apps that meet the needs of caregivers of persons living with dementia.

Conclusion

Tailoring and the quality of care information is limited in current mHealth apps for caregivers. Caregivers should use current dementia care apps with caution when they seek information about caregiving and support. Although mHealth may potentially be effective in meeting caregivers' HIWs, future research is needed in order to develop quality-assured, transparency-enhanced, evidence-based AI-enabled mHealth solutions for caregivers.

Abstract

Background: In the United States, Latino caregivers of individuals with dementia face unique challenges and an elevated risk of adverse health outcomes. Despite the increasing prevalence of Alzheimer disease and related dementias among Latino adults, few evidence-based interventions are tailored to their cultural context. To address this gap, we examined the cultural adaptations required for the STAR caregivers (STAR-C) virtual intervention, an evidence-based intervention that educates family caregivers to manage behavioral and psychological symptoms of dementia. While STAR-C has shown effectiveness, neither the original in-person nor the virtual intervention considered the distinct experiences of Latino caregivers, who often bring culturally significant values into caregiving interactions.

Objective: This study's objective was to test and refine the preliminary cultural adaptations of the STAR-C web-based training modules for Latino caregivers of people living with dementia.

Methods: Through qualitative interviews with 15 Latino caregivers in Washington State, we identified key adaptations to enhance the cultural relevance of the web-based training modules.

Results: The interviews highlighted 4 main themes for adaptation: the delivery of the STAR-C web-based training modules, comprehensive dementia education, simplified problem-solving strategies, and prioritizing caregiver well-being.

Conclusions: This study's findings informed the development of culturally adapted STAR-C web-based training modules that aim to provide tailored support to Latino caregivers. While further research is needed to assess the efficacy of these adaptations, our work contributes to bridging the gap in dementia caregiving for Latino families, potentially reducing health disparities and enhancing health care services for this population.

Introduction

Latino caregivers of people living with dementia are at an increased risk of experiencing adverse health impacts due to caregiving, yet few evidence-based interventions have been developed to support Latino families [1]. In the United States, Latino adults are 1.5 times more likely to develop Alzheimer disease and related dementias (ADRD) compared to non-Latino

White adults [2]. The disparity is due in large part to the health conditions (eg, cardiovascular disease, diabetes, high blood pressure, and obesity) and socioeconomic factors (eg, chronic exposure to economic and social adversity, lower levels and quality of education, and discrimination) that are more prevalent in Latino populations and are associated with cognitive decline [2,3]. The number of Latino people living with dementia is expected to increase to 3.5 million by 2060, leading to a rise in Latino adults caring for family members with ADRD [4]. Although evidence-based caregiver interventions exist, they often fall short in meeting the unique cultural needs of Latino families [1,5,6]. There is an urgent need to develop culturally appropriate evidence-based interventions that address the unique challenges faced by Latino caregivers of people living with dementia and consider the sociocultural context in which they provide care.

STAR caregivers (STAR-C) is an in-home intervention that involves training health professionals to teach family caregivers strategies to manage behavioral and psychological symptoms of dementia (BPSD) [7,8]. Caregivers learn to monitor symptoms, identify possible environmental or interpersonal triggers, and develop effective responses. They also learn strategies for communicating with people living with dementia in a way that supports positive affect and prevents or minimizes problems, increasing pleasant events to improve mood, and improving the support caregivers receive from informal and formal networks. STAR-C is demonstrated to reduce the frequency and severity of BPSD, as well as improve burden, depression, and reactivity to symptoms in caregivers [7]. Recently, STAR-C was reconfigured as a virtual intervention to facilitate large-scale implementation in clinical settings. The virtual intervention, coined STAR-C Virtual Training and Follow-up is being tested in an ongoing trial at Kaiser Permanente Washington [9,10]. For 6-8 weeks, caregivers complete 6 web-based training modules asynchronously and have six 30-minute weekly telephone check-ins with a coach (ie, master's-level social worker or mental health counselor). In addition, support from coaches is provided, as needed, via secure messaging in the Kaiser Permanente Washington patient portal for up to 6 months.

The STAR-C virtual intervention was timely given the COVID-19 pandemic, which shed light on the urgent need for digital health strategies that offer support virtually [11]. Many social and health care services for older adults and their family caregivers shifted from in-person to digital platforms to expand reach during the pandemic [12]. Neither the in-person or virtual STAR-C interventions, however, were developed with explicit consideration of the experience of Latinos providing care to a family member living with ADRD. Caregiver interventions for Latinos need cultural adaptations because cultural values and beliefs, such as *familismo* (dedication and commitment to family) and *respeto* (respect) play a pivotal role in shaping caregiving interactions with people living with dementia, experiences, and perceptions of support [13]. The goal of performing cultural adaptations to evidence-based interventions such as STAR-C is to promote more favorable experiences with the intervention and alleviate the health disparities associated with dementia caregiving among vulnerable populations.

To address the gap in the lack of culturally appropriate evidence-based interventions for Latino caregivers, we sought to culturally adapt the content of the web-based training modules of the STAR-C virtual intervention for Latino caregivers. In our previous study, we identified what cultural adaptations to the STAR-C web-based training modules are needed for Latino caregivers and we designed preliminary adaptations [14]. Preliminary adaptations included expanding the content of the web-based training modules to improve understanding of dementia; revising language that was viewed as stigmatizing, offensive, or culturally inappropriate; and adding cultural examples to reflect the range of family involvement in caring for people living with dementia and multigenerational living [14]. It is unknown, however, whether these modifications sufficiently align with the intended goals of cultural adaptation [15]. In addition, it is unknown whether there are additional opportunities to further enhance the cultural relevance of the STAR-C web-based training modules for Latino families. Therefore, the objective of this study was to test and refine the preliminary cultural adaptations of the STAR-C web-based training modules for Latino caregivers of people living with dementia.

Methods

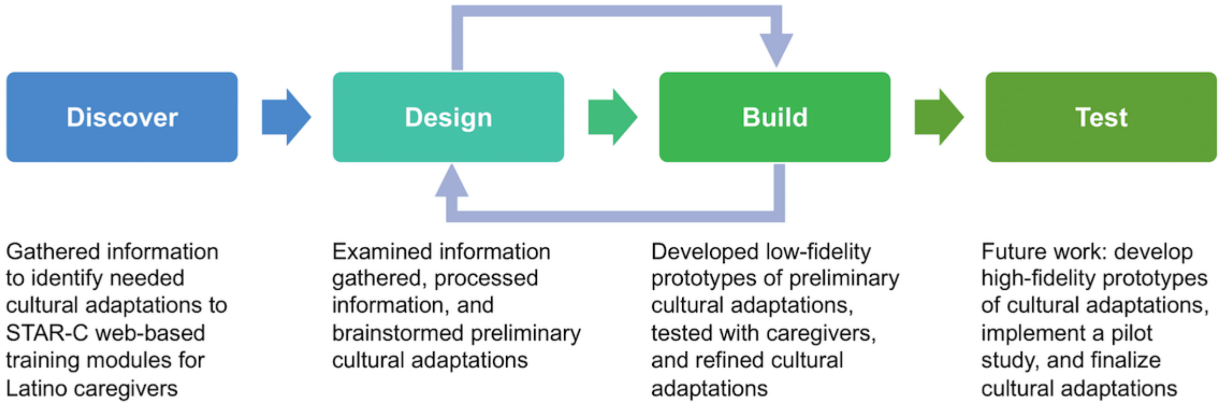
Ethical Considerations

This study was granted approval by the institutional review board at the University of Washington (STUDY00009534). Participants in this study gave their verbal or written consent for their involvement. All the data we collected from participants was labeled with a unique study identification number and not the participants' name or any other information that could identify participants. The contact information of participants was kept in a password-protected file and computer. All data collected from participants were kept confidential and accessible only by our study team. We did not use participants' names in reports of study findings, REDCap (Research Electronic Data Capture; Vanderbilt University) surveys, or audio recordings of interviews. Instead, we labeled everything with this study's identification number. We destroyed data that identified participants when we finished recruitment.

Overview of This Study's Design

Figure 1 [16] illustrates our approach to the cultural adaptation of the STAR-C web-based training modules within the context of the Discover, Design + Build, Test framework. In our previous study, we conducted a qualitative study to gather information about needed cultural adaptations to the web-based training modules for Latino caregivers (the "Discover" phase) [14]. We then used the findings from the qualitative study to brainstorm ideas for preliminary cultural adaptations (the "Design" phase). In this study, we developed low-fidelity prototypes of the culturally adapted STAR-C web-based training modules and tested the prototypes with Latino caregivers (the "Build" phase).

Figure 1. The cultural adaptation of STAR-C web-based training modules within the context of the Discover, Design + Build, and Test Framework. STAR-C: STAR caregiver.



Gathered information to identify needed cultural adaptations to STAR-C web-based training modules for Latino caregivers

Examined information gathered, processed information, and brainstormed preliminary cultural adaptations

Developed low-fidelity prototypes of preliminary cultural adaptations, tested with caregivers, and refined cultural adaptations

Future work: develop high-fidelity prototypes of cultural adaptations, implement a pilot study, and finalize cultural adaptations

Participant Selection

We carried out semistructured qualitative interviews in Washington State with 15 Latino caregivers of people living with dementia who spoke Spanish or English. Caregivers were considered eligible if they self-identified as Hispanic or Latino, were aged 21 years or older, were a child, spouse, or partner, or close friend of someone diagnosed with dementia, lived with the diagnosed individual or within a 5-mile radius, and provided a minimum of 8 hours of weekly care. Our recruitment strategy involved 3 approaches. Initially, we identified potential participants through the electronic health record system at University of Washington Medicine. Additionally, we circulated flyers in both Spanish and English across various locations, including a UW Medicine specialty clinic, a primary care practice-based research network, the Alzheimer Association Washington State Chapter, and local *tiendas* in Latino communities. Lastly, we used media platforms like local Spanish and English radio stations and newspapers to discuss the impact of dementia on the Latino population and publicize this study.

A member of this study's team screened for eligibility the individuals who showed interest in joining this study and arranged interviews for those who met the eligibility requirements. Caregivers received a compensation of US $45 for taking part in this study.

Description of the Low-Fidelity Prototypes

In the STAR-C Virtual Training and Follow-up intervention, caregivers receive 1 web-based training module per week for a period of 6-8 weeks. Textbox 1 describes the topics of the web-based training modules. The core components of the intervention include dementia education, strategies for effective communication, Activators-Behaviors-Consequences (ABC) problem-solving, pleasant events, and caregiver support.

Textbox 1. Topics of STAR caregivers (STAR-C) web-based training module.

Week 1: Understanding dementia, realistic expectations about behavioral treatments for behavioral and psychological symptoms of dementia, and strategies for effective communication.

Week 2: Activator, Behavior, Consequence (ABC) approach to problem-solving, including rationale and development of an ABC plan for target behaviors that caregivers identify.

Week 3: Review of ABC plan (revise if needed).

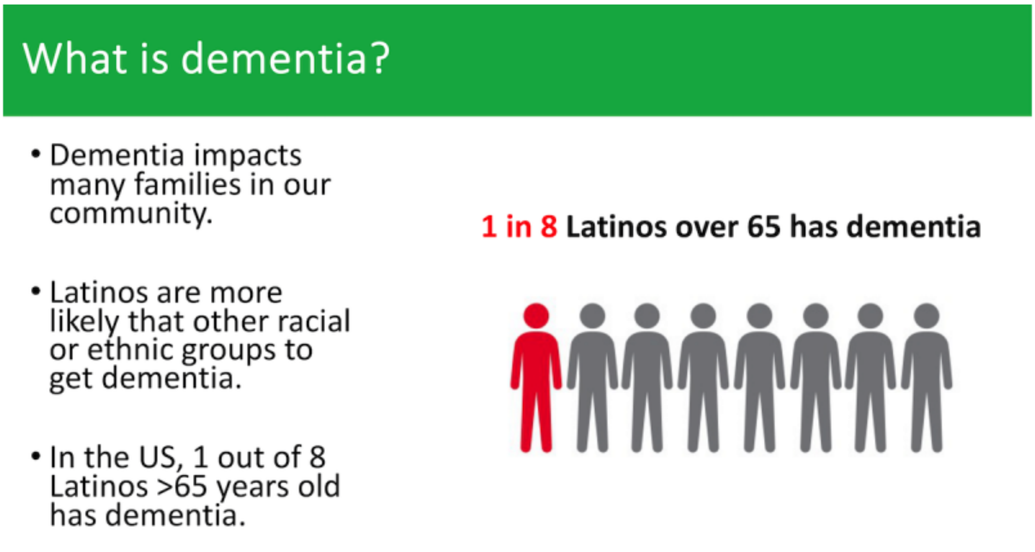
Week 4: Pleasant events and managing negative thinking.

Week 5: Review of ABC plan and pleasant events schedule (revise if needed).

Week 6: Caregiver support strategies for coping with caregiving and maintaining gains.

We created 3 low-fidelity prototypes of the culturally adapted STAR-C web-based training modules in both English and Spanish for testing among study participants. The low-fidelity prototypes were in the form of videos of recorded presentations with images, text, and voice-over. The videos featured short excerpts from various STAR-C web-based training modules. The first video consisted of educating Latino family caregivers on dementia and problem-solving using the ABC approach. This video explained the STAR-C program, dementia, its causes, walked through each step of the ABC approach for problem-solving in dementia, and concluded with a caregiving example of the ABC approach. The second video featured some modifications, including the addition of information about dementia stages, common behaviors exhibited by people living with dementia, and importance of self-care. We also enhanced the visual aesthetics and design of the lessons to make them more visually appealing and added humor. In the third video, we maintained the core content from the previous versions but incorporated interactive images and examples to increase engagement and interactivity. Figures 2 and 3 provide an example of the low-fidelity prototypes.

Figure 2. Culturally adapted STAR-C web-based training module—understanding Alzheimer and related dementias, with a focus on disproportionate impact on Latinos. STAR-C: STAR caregiver.

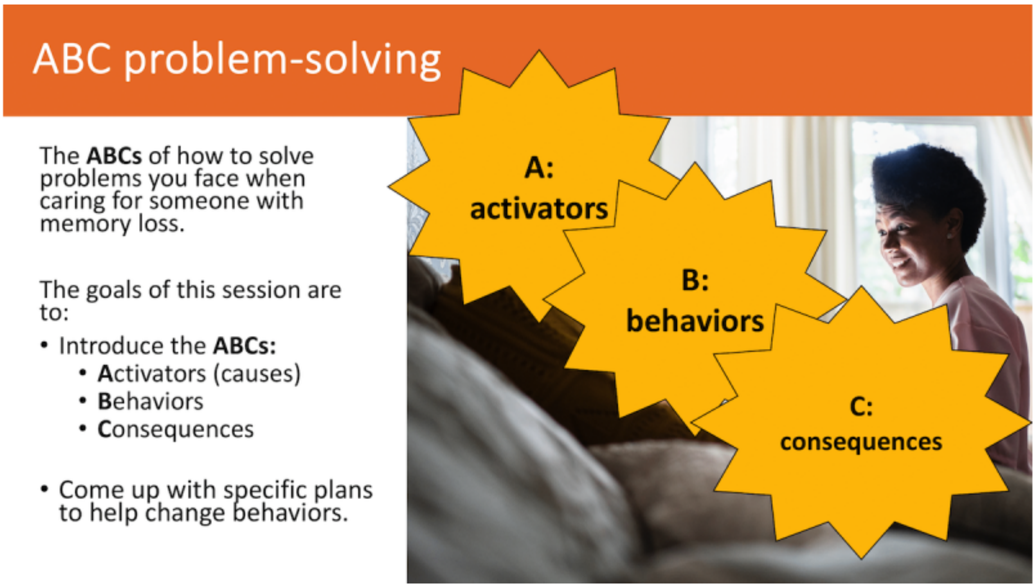


What is dementia?

- Dementia impacts many families in our community.
- Latinos are more likely that other racial or ethnic groups to get dementia.
- In the US, 1 out of 8 Latinos >65 years old has dementia.

1 in 8 Latinos over 65 has dementia

Figure 3. Culturally adapted STAR-C web-based training module—ABC acronym. ABC: Activators-Behaviors-Consequences; STAR-C: STAR caregiver.



ABC problem-solving

The **ABCs** of how to solve problems you face when caring for someone with memory loss.

The goals of this session are to:

- Introduce the **ABCs:**
  - **A**ctivators (causes)
  - **B**ehaviors
  - **C**onsequences
- Come up with specific plans to help change behaviors.

Data Collection

Study participants received the low-fidelity prototypes (ie, videos) via text message, WhatsApp Messenger, or email, depending on their preference, and were asked to watch the video at home on their own time prior to the scheduled qualitative interview. A bilingual or bicultural staff member trained in qualitative research techniques conducted interviews from January to August 2022. These interviews were held virtually, and they took place in either Spanish or English based on the participant's choice. Each interview spanned 30 to 60 minutes in length and was audio recorded and transcribed verbatim by a professional service.

The staff member used semistructured interview guides. For the first 5 interviews, the interview guide asked general questions pertaining to likes and dislikes, queries about the program's dementia content, examination of the ABC problem-solving strategy, assessment of the provided caregiving example, and a series of questions delving into video accessibility, design, and duration. For the subsequent 5 interviews, we revised the interview guide by adding questions focused on participant preferences, such as whether they preferred watching or listening to the video content, their favored method of receiving the videos, and their ideal video length. Finally, after another subsequent 5 interviews, we revised the interview guide again by incorporating additional inquiries centered around evaluating the images within the videos and improving viewer engagement.

Data Analysis

We analyzed the transcripts in their original languages, either Spanish or English, using the qualitative data analysis techniques described by Saldaña [17]. We began by reading through all the transcripts and writing analytic memos to reflect on the content—noting insights, thoughts, and emerging patterns. We then applied deductive codes from a pre-established codebook to the interview transcripts ("protocol coding" [17]). The pre-established codebook was used in a prior qualitative study of STAR-C and was composed of codes representing components of the cultural treatment adaptation framework [14,18]. As an illustration, the codebook contained codes like "Materials and Semantics," "Cultural Examples and Themes," and "Therapeutic Framework" to capture cultural adaptations that were needed in the delivery of the intervention. In the next step, we applied inductive second-order codes to capture the details of participants' feedback ("subcoding" [17]). For example, one of the inductive subcodes under "Materials and Semantics" was "Different BPSD examples" since multiple participants had suggested including in the intervention materials problem-solving examples for different BPSD. Afterward, we grouped the deductive and inductive codes into a smaller number of candidate themes that represented opportunities to improve the cultural adaptations of STAR-C ("pattern coding" [17]). We examined the interrelationship across and within the candidate themes and made refinements to ensure that excerpts within themes cohered and that each final theme was distinct from the others. Finally, we developed a statement to describe each of themes, which are presented in the following section. To manage this coding process, we used Dedoose (version 8.1.8; SocioCultural Research Consultants, LLC).

Results

Overview

Table 1 provides the characteristics of Latino caregivers who participated in this study and a description of their caregiving situation. The average age of caregivers was 48.9 (SD 11.1) years, 13 (87%) identified as women, 7 (47%) were the adult children of the people living with dementia, and 12 (80%) provided 35 hours or more of care per week.

Table 1. Characteristics of family caregivers and description of the caregiving situation.

Characteristics	Family caregivers (N=15), n (%)
Age (years), mean (SD)	48.9 (11.1)
Mexican, Mexican American, or Chicano	15 (100)
Gender	
Woman	13 (87)
Man	2 (13)
Occupational status	
Retired	1 (7)
Employed	5 (33)
Unemployed	1 (7)
Homemaker	5 (33)
Other	3 (20)
Highest level of educational attainment, mean (SD)	
Less than high school	4 (27)
High school	5 (33)
Vocational or technical training	2 (13)
Some college	1 (7)
College graduate	2 (13)
Postgraduate	1 (7)
Devices owned	
Smartphone	14 (93)
Tablet	5 (33)
Laptop	7 (47)
Computer	6 (40)
Owns any device	15 (100)
Caregiver’s relationship to person living with dementia, mean (SD)	
Adult child (eg, daughter)	7 (46.7)
Spouse or partner	5 (33.3)
Other relative	3 (20)
Care provided per week (hours)	
35 or more	12 (80)
5-14	3 (20)
Number of years providing care, mean (SD)	3.7 (2.4)
Caregiver and person living with dementia living together, mean (SD)	10 (66.7)

The qualitative analysis revealed adaptations that were needed in the (1) delivery of the STAR-C virtual intervention, (2) “dementia education” core component, (3) “ABC Problem-Solving” core component, and (4) “caregiver support strategies” core component. The sections below describe the need for these adaptations from the perspective of caregivers, as well as the changes that were made to the STAR-C web-based training modules in response to caregiver feedback.

Theme 1: Adaptations to the Delivery of the STAR-C Virtual Intervention

Design Videos to be Accessible via Audio Only

Latino caregivers reported that they liked that the STAR-C videos combined visuals with narration. They reported that the narration helped to reinforce the visual content and vice versa. They said this combination of visuals and narration was engaging because it helped to hold their attention and made it easier for them to learn the content. For example, 1 Spanish-speaking caregiver said:

> *The thing is that audio and seeing the image are also easier in this type of application. It became more practical and easier for me to learn and understand compared to just reading and seeing it without any—well, at least in my opinion, my brain doesn't work the same way, I believe, but I liked the idea that you can see it, like imagine it, and create that idea.*

However, while the ideal would be to watch the STAR-C videos, some caregivers mentioned that this may not always be practical. They said that they were often occupied with errands, household, and caregiving work, and that it would be nice in these circumstances to be able to listen to the video. For that reason, the caregivers suggested that the videos be designed to be accessible via audio only. Further, 1 Spanish-speaking caregiver stated:

> *Since sometimes one doesn't have much time to sit down and take the time to be looking at the screen. So, I put everything in the background while I do my daily tasks.*

In response to caregivers' feedback, we modified the narration script to ensure that it was independent of visuals and accessible via audio only. The narration focused on providing clear and descriptive explanations of the visual content. Instead of relying on visuals to convey information, the narration script described the key elements, actions, and visuals present in the video. This approach would enable caregivers to form a mental image and grasp the content without needing to see the visuals.

Make Videos Accessible on Multiple Platforms

Latino caregivers expressed a preference for having various methods of accessing the STAR-C videos, including phone applications such as Facebook Messenger, WhatsApp Messenger, YouTube, and other platforms. Caregivers desired video access through platforms they used regularly and were easily accessible on their preferred devices. For example, 1 Spanish-speaking caregiver stated:

> *No, but I hardly use my email. I do check my email, but almost all the information I receive, I receive it through WhatsApp. And then, I can see it right away without any problem.*

A few caregivers encountered technical difficulties when attempting to access the videos such as lack of Wi-Fi access in their homes or limited storage on their phones, requiring troubleshooting. For example, 1 caregiver said she could not view the videos initially because her phone's storage was full. Once the caregiver emptied her phone's storage, she was able to view the videos. In addition, while the caregiver could view the videos on her computer, she did not have Wi-Fi at home and would need to connect the computer to her phone's hotspot.

In response to caregivers' feedback, we considered various options to accommodate preferences and technology access, to ensure optimal accessibility to the STAR-C videos. We would offer caregivers the option to receive the STAR-C videos on phone applications like Facebook Messenger, WhatsApp Messenger, and YouTube, as these are commonly used platforms for communication and information exchange. We would also optimize the video formats to reduce file sizes. Finally, we would offer troubleshooting support to assist caregivers who may face technical challenges while trying to view the videos.

Enable Caregivers to Easily Share Videos With Family Members

According to caregivers, the content in the STAR-C videos had a positive impact on communication and information sharing among caregivers and other family members who assist with caregiving. For that reason, caregivers expressed a strong desire to share the video content with their extended family, including siblings and other relatives involved in caregiving responsibilities. Sharing the videos empowered caregivers to improve their caregiving practices. For example, 1 Spanish-speaking caregiver explained:

> *Moreover, right away, I allowed myself—I don't know if it was allowed, but I sent that information to my sisters-in-law and they were like, "Wow, wait, so I'm going to treat my dad like this, so I can stop this. So, I got irritated by this." My sisters said, "I got it now," because we truly are alone, there really isn't much of a tool at hand that leads you to something like this, and even though it might seem small, a few minutes of video, it was truly very good. So, I can't imagine everything that's going to come [in the future with STAR-C]. Really, I appreciate it, truly.*

Another Spanish-speaking caregiver highlighted the need for education and support at the individual level. They indicated that the program's benefits extended beyond their immediate family, potentially benefiting other caregivers in similar situations. The caregiver explained:

> *I believe what we were missing was educating ourselves more about this… It could be the entire family, because it was in Mexico where my mom, the rest of my siblings, and I were. We were all taking care of dad, and sometimes, even then, we couldn't manage. We were like five adults and my dad.*

In response to caregivers' feedback, we decided that it would be appropriate to encourage Latino caregivers participating in the research study to share the STAR-C videos with other family members if they wished, regardless of whether the other family members were also enrolled in the research study. In addition, we decided to welcome other family members within the same family to enroll as study participants if they were interested and met the eligibility criteria. The program's content could serve as a catalyst for discussion, knowledge exchange, and support among primary caregivers and their extended network of caregivers.

Theme 2: Adaptations to the "Dementia Education" Core Component

Expand Content to Improve Caregiver Understanding of Dementia

Latino family caregivers expressed the need for expanded content in the "Dementia Education" core component to enhance their understanding of dementia. They highlighted the importance of delving deeper into the nature of the disease, its progression, and the various stages it entails.

> *[The video] was very practical, the basics, what [dementia] is, the essentials, but at the beginning, yes, to know a little more about what that type of illness it is, like videos on how it forms in the brain and the stages, that it goes deeper because it progresses in stages and increases day by day. That's what I think.*

Several caregivers identified common misconceptions about Alzheimer disease and memory loss in the Latino community, expressing surprise at the late stages of dementia when physical limitations manifest. They stressed the necessity of detailed information to comprehend the evolving challenges faced by people living with dementia. Caregivers emphasized the significance of incorporating this expanded content to enhance their knowledge and foster a more holistic understanding of dementia.

> *But that part surprised me a lot, which is that the body itself forgets its needs. And it's the final stage. And I would like it if they did include the stages of Alzheimer's or dementia. Because for most people, if you tell them, it's like “oh, they forgot things or put something in the wrong place or they get lost.” But the final stage is the one that very few people know about, it's what happens when your body, even if it gives signals, you don't recognize them. It's like a baby who can't tell you they’re thirsty, they’re hungry, their stomach hurts, and things like that. So, that's when it gets complicated and obviously, the end is near.*

In response to caregivers’ feedback, we further expanded the content of the first video focused on teaching caregivers about ADRD. Our goal was to provide a comprehensive understanding of dementia, untangling its root causes and distinguishing it from the natural aging process. We describe the different stages of dementia to offer Latino caregivers a better understanding about types of cognitive, emotional, and behavioral changes to expect in their family member with dementia as the disease progresses.

Encourage Caregivers to Empathize With Person Living With Dementia

Latino caregivers expressed the importance of fostering empathy toward individuals living with dementia. They highlighted the need to understand and acknowledge the unique challenges faced by both the caregivers and the person with dementia.

A Spanish-speaking caregiver found the examples provided in the program to be highly relatable, acknowledging the frustrations experienced by both themselves and their patients. They said:

> *I loved the examples they provided because they're very real, of diagnosing changes for oneself, the patient or client, or the family. Why? Because it's not the same; it's frustrating for them, as much as for us, because they don't understand us, and we don't understand them. So, we can't say that one is normal, because, to be honest, none of us are normal [laughter]. But yes, we can understand that diagnosis, put ourselves in the shoes of that person, or think about how I would feel if I see that the person taking care of me is frustrated by something I don't even know about, or I'm not comprehending.*

Caregivers also expressed the need to put themselves in the shoes of the person with dementia. Further, 1 Spanish-speaking caregiver said:

> *The only thing is that it would also be good to mention how it's frustrating for them and for us. We should put ourselves in their shoes, how would we like to be treated if we were the ones sick, how would we want to be treated? In terms of frustration or reactions... They won't react the way we would want them to or how we would like them to react, because they have a condition, we don't.*

In response to caregivers’ feedback, we integrated content into the STAR-C videos that would remind caregivers to be empathetic and to consider the perspective of people living with dementia. The added content emphasizes the importance of understanding the frustrations experienced by both caregivers and people living with dementia and the need to approach interactions with empathy and compassion.

Provide Education on how to Reduce Risk of Developing Dementia

Caregivers indicated the need for comprehensive education on reducing their own risk of developing dementia. They highlighted the importance of understanding the impact of dementia while also learning about strategies to combat it. A Spanish-speaking caregiver said:

> *The thing is, for example, I'm looking at my husband's case and I think about myself, and I think, “Well, what can I do to prevent what happened to my husband from happening to me?” Because what will happen if I develop dementia? What will happen to both of us? So, I would like to have more information. What can I do to avoid this? Because I am his caregiver.*

Another Spanish-speaking caregiver, after learning about the prevalence of dementia among Hispanics in the STAR-C video, expressed the need for more information on prevention and early signs. They said:

> *That's really good [the information in the module]. I was genuinely surprised when it said that one in every eight Hispanics has or will develop, right? So, it's a bit alarming, and I think, wow, I don't know, I would like to know more about whether there would be any way to prevent it. It would be great to have more information about prevention or the signs—as it says there, some forgetfulness is normal, certain forgetfulness, right? Like now, being busy with a thousand things, I forgot, and believe me, it happens to me, but I know it's because I have a lot on my plate and I try to do them all. But I would really like if there was information about whether there's any way to prevent this condition.*

Caregivers’ feedback confirmed our previous findings about the need to modify the STAR-C content to include comprehensive education on dementia. In response to caregivers' feedback, we will also be providing caregivers with information on reducing their own risk of developing the condition. By providing caregivers with guidance and knowledge on prevention strategies, STAR-C can empower them to take proactive steps in safeguarding their cognitive health and that of their loved ones.

Theme 3: Adaptations to the "ABC Problem-Solving" Core Component

Simplify the "ABC" Problem-Solving Acronym in Spanish

The "ABC" problem-solving approach in the STAR-C program was regarded as helpful by some Latino caregivers, who found the provided examples to be effective and relatable. However, it was acknowledged that understanding the acronym ("Activators, Behaviors, Consequences") could be a bit challenging for others. Further, 1 Spanish-speaking caregiver explained why she liked the ABC problem-solving approach:

> *So, I found the video to be very original, very realistic. It was done very well because I felt identified. The three ways they presented it, in A, B, and C, personally, it felt very real to me, I loved it, almost perfect, because these are situations that do happen and changes that we do need to make. From the beginning, we don't know how to do it, but with this video or the app that they're going to develop, it seems very practical to me because it will provide a lot of tools and strategies to people who have no idea how to go about it. Like us in the beginning, we were learning as we went through each day.*

Another Spanish-speaking caregiver initially faced challenges in understanding the ABC acronym but gained clarity once the video explained it further.

> *Yes, some of those words were a bit difficult for me to understand, but later on, it was explained what each of them meant.*

Further, 1 Spanish-speaking caregiver reported that while they could understand the content, including the ABC acronym, well due to their extensive Spanish language skills, they acknowledged that a person with limited education might struggle to understand it clearly.

> *I can understand it perfectly, but I think I can understand because I have a very good Spanish. I was a Spanish teacher for many years, so my language and vocabulary are quite extensive. However, I believe that if the same video had to be heard by someone with limited education, they probably wouldn't understand it, at least not clearly.*

These quotes highlight the caregivers' perspective on the need to simplify the "ABC" problem-solving acronym in Spanish. While some caregivers found the explanations of each letter in the acronym helpful, others reported that individuals with limited education may potentially face challenges in understanding the acronym. In response to caregivers' feedback, we simplified the ABC acronym to enhance comprehension and accessibility for a wider range of caregivers. Initially, the ABC acronym was translated as A for "activadores" (activators), B for "comportamiento" (behavior), and C for "consecuencias" (consequences). However, based on the feedback received, we took an additional step to simplify it entirely in Spanish, resulting in the revised form as "las 3 Cs" (the 3 Cs) representing C for "causas" (causes), C for "comportamiento" (behavior), and C for "consecuencias" (consequences).

Add More Problem-Solving Examples With Different BPSDs

Caregivers conveyed a strong desire for the STAR-C program to incorporate a greater variety of problem-solving examples that cover different BPSDs. While some caregivers appreciated the existing examples, they emphasized the importance of including a more extensive range of stories and behaviors to address the diverse challenges encountered in dementia care. For example, 1 Spanish-speaking caregiver stated:

> *I liked everything, the only thing is that I would like them to add a bit more different stories, with different behaviors.*

Another Spanish-speaking caregiver shared their personal experience with their mother's behavior and the importance of addressing such situations.

> *Yes, my mom experiences a lot of panic episodes, and I didn't see that in the video, so in my own way, I handled panic situations in her illness, like waking up at night in a panic: "Where am I? Who am I? Where are we?" So, I didn't see in the video strong things like that, like screaming, situations where you don't know what to do as a family member, so you just hug them. I hugged my mom, I hugged her, I hugged her, and I said, "Calm down, we're okay. I'm your daughter, we're here." I mentioned the house, the surroundings, everything. But she has those night panics out of fear very often.*

These quotes underscore the caregivers' interest in having a more extensive selection of problem-solving examples that address various BPSDs, such as aggression and panic attacks. In response to caregiver's feedback, we will include a broader range of scenarios and behaviors, so that caregivers can gain invaluable insights and strategies to effectively manage the diverse challenges associated with BPSDs.

Demonstrate Problem-Solving With Real People

Latino caregivers reported a desire for more realistic and relatable problem-solving examples in the STAR-C program. They suggested incorporating videos featuring real interactions between caregivers and persons living with dementia to enhance the learning experience. Further, 1 Spanish-speaking caregiver explained:

> *Perhaps, in the example—I mean, I don't know how much of the video or program is left [to be developed], but maybe, I don't know, perhaps the depiction of two people acting out the situation, maybe it would look much more professional or*

> *more—you know, I understand that this requires investment and it requires many things.*

Another Spanish-speaking caregiver reported interest in observing caregiving interactions to better understand effective communication strategies.

> *Perhaps some of this information would be clearer in a video format or as an interaction between two people. Yes, specifically with an Alzheimer's patient. Because if they're [the program] going to be incorporating strategies on how to talk, how to interact, it would be very useful to see the behavior live; how it's happening, how one can communicate with that person.*

Incorporating videos of real people and interactive caregiving scenarios in the STAR-C program can provide caregivers with tangible and relatable examples of problem-solving techniques. Based on caregivers' feedback, future adaptations of STAR-C should demonstrate the app of the problem-solving techniques with real people. These demonstrations may enhance caregivers' experience with the program by presenting solutions in a dynamic and engaging manner.

Theme 4: Adaptations to the "Caregiver Support Strategies" Core Component

Latino caregivers emphasized the importance of seeking assistance and support to alleviate the burdens of caregiving. Many highlighted the value of reaching out to family members or friends when feeling fatigued or overwhelmed, recognizing the need for rest and self-care. A Spanish-speaking caregiver described how the STAR-C program needed to encourage caregivers to take care of their own health and well-being. The caregiver said:

> *[For caregivers] to be well-rested. That's why I mention seeking help in some way, even from family or friends, you can say "I need—" when you feel tired or stressed, very stressed, you need to be able to call someone and say, "Can you take care of my mom for a while? Can you take care of my dad or my wife? I need a break." Because if you're not well-rested or already feeling overwhelmed—I say this because, for example, my sister, when she was taking care of my mom, my sister wasn't emotionally well. She had her own problems, so when it was her turn to care for my mom, there were almost always issues because she didn't have enough patience.*

Participants collectively acknowledged the importance of supporting caregivers themselves, not just the care recipients. They emphasized the need for caregivers to take regular breaks and engage in activities that promote mental well-being. For example, a Spanish-speaking caregiver stated:

> *I just wanted to mention that also the people--sometimes the people who care for others also need to be taken care of, to take a break or do something different in order to continue, to be mentally well enough to keep taking care of our loved ones.*

This comment highlights the importance of recognizing the caregiver's mental and emotional health as it directly impacts their ability to provide effective care. In response to caregivers' feedback, we integrated content throughout the various modules (not just the last module) about the importance of caregiver health and well-being. The content emphasizes the need for caregiver rest, support, and self-care, so that caregivers can be better equipped to provide optimal care to their loved ones.

Discussion

Principal Results

This study's objective was to test and refine the preliminary cultural adaptations to the STAR-C web-based training modules for Latino caregivers. Our qualitative analysis identified key adaptations required in (1) the delivery of STAR-C, (2) the "dementia education" core component, (3) the "ABC problem-solving" core component, and (4) the "caregiver support strategies" core component. Caregivers expressed a desire for STAR-C videos to be accessible through audio-only formats, and they highlighted the importance of making the videos available on various platforms, including those commonly used in their community. They also emphasized the need for the videos to be easily shareable with family members to enhance communication and caregiving practices. In response, we tailored the narration script to facilitate audio-only access and optimized video formats for widespread accessibility. Moreover, caregivers requested comprehensive education on dementia prevention and understanding the disease's stages, advocating for expanded content within the "Dementia Education" core component. This resulted in additional content aimed at enhancing caregivers' understanding of dementia progression and challenges. To further foster empathy, caregivers suggested highlighting the importance of viewing the world from the perspective of individuals living with dementia. Consequently, we incorporated elements emphasizing empathy into the program. Caregivers also sought to incorporate strategies for reducing the risk of developing dementia, leading to the inclusion of content addressing preventive measures. Within the "ABC Problem-Solving" core component, caregivers expressed a need to simplify the "ABC" acronym in Spanish and expand problem-solving examples. We responded by simplifying the acronym and incorporating more problem-solving scenarios to cater to diverse challenges. Additionally, caregivers desired realistic problem-solving examples featuring real interactions between caregivers and persons with dementia. Lastly, caregivers emphasized the importance of caregiver well-being, prompting us to underscore self-care, rest, and seeking support to ensure caregivers' mental and emotional health is prioritized. These adaptations collectively refine the STAR-C web-based training modules for Latino caregivers and provide a culturally tailored, evidence-based intervention to support dementia caregiving in this community.

Comparison With Prior Work

Our study identified several key adaptations needed to enhance the cultural relevance and effectiveness of the STAR-C web-based training modules for Latino caregivers. Notably, caregivers expressed a strong desire for videos to be accessible through audio-only formats, a finding that aligns with a study conducted among Hispanic participants from Spain [19], where a similar preference for audio accessibility was observed. The importance of making videos available on various platforms, as highlighted in our study, is also consistent with research where caregivers expressed openness to learning caregiving information from diverse sources and settings [20].

The cultural adaptations identified in this study to enhance the relevance and effectiveness of the STAR-C web-based training modules for Latino caregivers may have applicability to caregivers from other racial and ethnic minority groups as well. For example, collectivist and familism values tend to be strong in Asian cultures that emphasize family and community interdependence [21,22]. As such, making the STAR-C videos easily shareable with family members to facilitate communication and coordinated caregiving practices may also resonate with Asian caregivers.

Furthermore, our study aligns with prior research by emphasizing the need for comprehensive education on dementia prevention and understanding the disease's stages [20,23]. In a study conducted among various ethnic groups, including Hispanic or Latinos, African Americans, and Asian Americans, it was found that a common lack of knowledge about the early signs of Alzheimer disease existed [23]. This knowledge gap underscores the importance for comprehensive dementia education, a point that resonates with our study's findings. Additionally, another study similarly stressed the importance of greater education regarding the diversity and spectrum of dementia-related symptoms [20].

Caregivers also strongly advocated for simplifying the ABC acronym in Spanish, adding more problem-solving examples, and demonstrating problem-solving with real individuals. These adaptations align with a study assessing Spanish language health information via videos [24], which found that participants preferred videos featuring increased actor participation, as it enhanced their ability to relate the content to real-life situations.

Limitations

Our study has limitations worth noting. First, the low-fidelity prototypes of the STAR-C web-based training modules (ie, videos) we used in this study lacked the realistic appearance and comprehensiveness of the full virtual STAR-C program. This may have limited our ability to obtain accurate perceptions and feedback, as caregivers might not have fully understood or engaged with the low-fidelity prototypes as they would have with a higher-fidelity version of the full STAR-C program. As a next step in this research, we plan to pilot test high-fidelity prototypes of the STAR-C web-based training modules. Second, caregivers' feedback about STAR-C is influenced by their personal preferences and experiences, which may result in us inadvertently prioritizing features or solutions that appeal to the specific subgroup of Latino caregivers participating in this study rather than broader populations of Latino caregivers. We tried to address this limitation by interviewing a diverse group of caregivers including both male and female caregivers (most Latino caregivers tend to be women), caregivers of different ages and family roles (ie, spouse vs child caregiver), and caregivers with different educational backgrounds.

Conclusions

This study addresses a critical gap in the field of dementia caregiving, particularly for Latino caregivers who face unique challenges and disparities in health outcomes. The culturally adapted version of the virtual STAR-C program represents a significant step forward in bridging this gap. Our findings highlight the importance of tailoring interventions to meet the specific needs of Latino caregivers, considering cultural values and beliefs that shape caregiving interactions and experiences. The key adaptations we needed to make to the STAR-C web-based training modules, including accessibility improvements, expanded dementia education, enhanced problem-solving strategies, and a focus on caregiver well-being, underscore the importance of cultural adaptation of evidence-based caregiver interventions for Latino families. While further research is needed to assess the efficacy of these adaptations, we believe that the virtual STAR-C intervention has the potential to improve health care services and health outcomes for Latino people living with dementia and their family caregivers. By addressing the pressing need for culturally adapted evidence-based interventions, we aim to promote more favorable experiences with the intervention and ultimately reduce the health disparities associated with dementia caregiving in this community. This work contributes to the broader mission of advancing health care services for older adults by using technological innovations, serving the interest of health professionals and family caregivers of older adults.

Acknowledgments

This study was funded by the Alzheimer's Association (AARG-20-685260, principal investigator: MR).

Abstract

Background: In recent years, telehomecare has become an increasingly important option for health care providers to deliver continuous care to their patients.

Objective: This study aims to explore the expectations, attitudes, and barriers to telehomecare among caregivers of homebound or bedridden older adults.

Methods: This qualitative study used semistructured interviews to explore caregivers' perspectives on telehomecare for homebound or bedridden older adults. The study adhered to the SRQR (Standards for Reporting Qualitative Research) guidelines. Participants were selected using convenience sampling from caregivers of homebound or bedridden older adults with experience in both in-person home visits and telehomecare services provided by the Department of Family Medicine at Chiang Mai University, in an urban area of Chiang Mai Province in Northern Thailand. Semistructured interviews were conducted. The interviews were audio recorded with participant consent and transcribed verbatim. The framework method was used, involving multiple readings of transcripts to facilitate familiarization and accuracy checking. The study used the technology acceptance model and comprehensive geriatric assessment as the analytical framework.

Results: The study included 20 caregivers of older adult patients. The patients were predominantly female (15/20, 75%), with an average age of 86.2 years. Of these patients, 40% (n=8) of patients were bedridden, and 60% (n=12) of patients were homebound. Caregivers expressed generally positive attitudes toward telehomecare. They considered it valuable for overall health assessment, despite recognizing certain limitations, particularly in physical assessments. Psychological assessments were perceived as equally effective. While in-person visits offered more extensive environmental assessments, caregivers found ways to make telehomecare effective. Telehomecare facilitated multidisciplinary care, enabling communication with specialists. Caregivers play a key role in care planning and adherence. Challenges included communication issues due to low volume, patient inattention, and faulty devices and internet signals. Some caregivers helped overcome these barriers. The loss of information was mitigated by modifying signaling equipment. Technology use was a challenge for some older adult caregivers. Despite these challenges, telehomecare offered advantages in remote communication and resolving scheduling conflicts. Caregivers varied in their preferences. Some preferred in-person visits for a broader view, while others favored telehomecare for its convenience. Some had no strong preference, appreciating both methods, while others considered the situation and patient conditions when choosing between them. Increased experience with telehomecare led to more confidence in its use.

Conclusions: Caregivers have positive attitudes and high expectations for telehomecare services. Although there may be barriers to receiving care through this mode, caregivers have demonstrated the ability to overcome these challenges, which has strengthened their confidence in telehomecare. However, it is important to enhance the skills of caregivers and health care teams to overcome barriers and optimize the use of telehomecare.

KEYWORDS

telehomecare; telemedicine; telehealth; caregivers; older adults; attitudes

Introduction

Thai society has come to recognize the challenge of the aging society and that there is a rapid growth in the number of homebound or bedridden older adult patients with chronic diseases [1]. Homebound refers to a state in which one's life space is limited to their residence, yet they retain the ability to move within their home. On the other hand, being bedridden is a condition in which a person has experienced significant physical weakness and can no longer move about freely, thus being confined to their bed. These 2 statuses are typically caused by the patient's comorbidities and often result in the need for comprehensive care and caregiver [2-4]. As a result, coordinated health care services are essential for these individuals, and home health care services have been found to be effective in improving patient outcomes. A long-term care policy has been implemented to provide home care and social support for this population [1,5]. These services are particularly useful for doctors to assess a patient's living conditions and have been shown to decrease hospitalization, improve physical and psychosocial health, and enhance the overall quality of life for older adults [6,7].

Telemedicine has emerged as a potential solution to bridge the gap between homebound or bedridden patients and health care services [8]. By allowing health care providers to connect with patients remotely, telemedicine can reduce travel costs, provide convenience, and help control the spread of the pandemic [9]. However, there are also disadvantages and challenges associated with this technology, such as the lack of face-to-face communication between doctors and patients and the need for patients to have the technical skills to use these devices [1]. These factors may make the home visit system unsustainable [10].

Over the past 3 years, the COVID-19 pandemic has further highlighted the need for telemedicine, as in-person home visits have been interrupted and transformed into telehomecare for patients requiring continuous health care at home [11-13]. Telehomecare is a form of telemedicine that combines videoconferencing and health monitoring between homebound or bedridden patients and home health care providers [14]. In order to conduct telehomecare for homebound or bedridden older adult care, the caregiver has the main role of helping monitor the patient and to communicate all information to health care team. Therefore, if the caregivers are also older adults and are not proficient with technology, this can pose a barrier, especially for patients living in remote areas [15].

Prior studies on the perception or perspective of the use of telemedicine in caring for older adults have primarily focused on the viewpoints of physicians [16,17] and older adult patients [18,19], rather than caregivers. Physicians have also reported perceiving advantages in the use of telemedicine for older adults, including the reduction of postponed care, the promotion of timely care, enhanced physician efficiency, improved communication with both patients and caregivers, the alleviation of patient travel burdens, and the facilitation of health outreach and educational efforts [17]. The use of technology for health care in older adults could be influenced by their age and the complexity of diseases they face [19], impacting their acceptance of technology [20] and use behavior [21]. It has been noted that the technological acceptance of patients and providers appears to have positive effects on patient outcomes, including self-management and readmissions. The literature also indicates that family caregivers play a vital role in assisting the patient's decision to adopt and engage with technology [22]. Physicians are aware that caregivers have a role in deciding whether to use telehealth services [16]. Overall, it is important to assess caregivers' genuine perspectives and suggestions.

A recent study from the United States has explored family caregivers' perceived benefits and barriers to telemedicine visits for community-dwelling older adults with chronic diseases [23]. Caregivers reported effectiveness in increasing access and continuity of care, but they also expressed concerns about their older relatives' ability to access and use the technology independently and difficulty in establishing patient-provider rapport. However, these results could be different in Thailand and among families of older adults with more limited capacity, such as the homebound or bedridden population. Thus, this study aims to investigate the expectations, attitudes, and barriers concerning telehomecare among caregivers of homebound or bedridden older adults. Specifically, it will explore caregivers' expectations regarding the perceived usefulness of the service in delivering comprehensive care for older adults with limited mobility; the barriers that affect the perceived ease of using the service; and their overall attitudes toward the care provided, including their preferences. The results of this study will provide useful insights for the creation of effective care plans for homebound or bedridden older adult patients and their caregivers.

Methods

Study Design

This study was a qualitative study, using semistructured interviews to investigate the perspectives of using telehomecare for homebound or bedridden older adults, as perceived by their caregivers. The study was reported according to the SRQR (Standards for Reporting Qualitative Research) guidelines [24].

Ethical Considerations

Ethical approval was obtained through the Medical Ethical Committee of Chiang Mai University, Chiang Mai, Thailand

(227/2021). Informed consent was obtained from all participants. The privacy and confidentiality of human participants were rigorously protected throughout this study. Data were either anonymized or deidentified, as applicable, to safeguard the identity of participants. Participants in the study received a monetary compensation of 100 (US $2.7) for their participation.

Recruitment

Participants were selected using convenience sampling from caregivers of homebound or bedridden older adult patients who had experience with both in-person home visits and telehomecare services provided by the Department of Family Medicine at Chiang Mai University. The samples were selected from a list of families of older adults who had received care within the past 2 months. Research assistants reached out to these families via phone calls until the total expected sample size was achieved. The study was conducted in an urban area of Chiang Mai Province in Northern Thailand. Inclusion criteria were that participants must be the primary caregiver and speak Thai, while caregivers with communication difficulties were excluded. The researchers expected to recruit at least 20 participants to achieve data saturation, based on similar qualitative studies [25].

Data Collection

Semistructured in-depth interviews were conducted between November 2021 and March 2022. There were two parts to data collection as follows: (1) participant characteristics and (2) in-depth interviews about the perspectives of using telehomecare for homebound or bedridden older adults. The patient interviews were conducted in Thai by a single researcher (PO) who was trained in the interview method and interview questions by the qualitative researchers (KP and WJ). Each interview was conducted in a private counseling room to help ensure comfort and confidentiality. Each interview was audio recorded with the participant’s consent, followed by verbatim transcription. PO and KP subsequently reviewed the audio record, and any issues that needed further exploration were discussed. Participant characteristics including sex, age, occupation, relationship with the patient, and the duration of care as the caregiver were recorded. Patient diagnoses and homebound or bedridden status were also gathered. Open-ended interview guides were designed and then piloted to make sure that participants were allowed to share their thoughts freely. The interview guide was described in Textbox 1.

Textbox 1. The interview guide.

- How long has your family been receiving home care and telehomecare?
- What was the main reason for switching from in-person care to telehomecare?
- Do you perceive telehomecare as useful for your family?
- As a caregiver for an older adult patient, do you feel confident about receiving care for the patient through telehomecare?
- Can you compare the effectiveness of care between in-person home visits and telehomecare for older adult patients?
- Are you satisfied with these services? Which one do you prefer and why?
- What do you see as potential barriers or concerns regarding the use of telehomecare for caring for older adult patients?

Data Analysis

We followed the framework method for the analysis of qualitative data [26]. Each transcript was read multiple times by the 2 researchers (PO and KP) to aid familiarization and to check the accuracy of each transcript. The key elements of the technology acceptance model and comprehensive geriatric assessment for older adult patient care were used as the analytical framework to help identify key issues, concepts, and themes. The study aimed to address the 2 main research questions, which align with the technology acceptance model in the context of providing care for older adults from the perspective of caregivers. The technology acceptance model is the theory that suggests the predictors toward the acceptance and rejection to use technology. These predictors include (1) perceived usefulness and (2) perceived ease of use which are influenced by, for example, technology anxiety or experience, subjective norms, expectations, trust, cultural diversities, and technology characteristics [27]. These factors, in turn, shape attitudes toward using telehomecare services.

The first question focused on perceived usefulness (expectation), incorporating comprehensive geriatric assessment to determine whether telehomecare is suitable for providing comprehensive home-based care for older adults. Comprehensive geriatric assessment is usually carried out while providing care for older adults at home to increase the understanding of an older person’s care needs and preferences and to help in finding common goals of care [28,29]. Its three key elements include (1) comprehensiveness (physical, psychological, and environmental issues); (2) multidisciplinarity; and (3) person - centered goal setting. The second question concentrated on the perceived ease of use of telehomecare for caregivers caring for older adults. This encompassed concerns and perceived barriers.

To explore our research questions, we adopted the framework method, which used a combined approach, incorporating both deductive and inductive elements for the analysis [26]. The deductive approach was applied to the preexisting theories, specifically the technology acceptance model and comprehensive geriatric assessment. Meanwhile, the inductive approach was used to analyze the expectations, attitudes, and barriers associated with telehomecare among caregivers of homebound or bedridden older adults.

The researchers compared the identified codes and discussed the similarities and differences until they reached a consensus on the emergent themes and subthemes. Then, the preliminary results were interpreted with WJ and CA. All authors read and contributed to the manuscript. NVivo (version 12; QSR International) was used for data analysis. Descriptive analysis was used to describe participant characteristics, including frequency, percentage, mean, and SD. The results were presented to caregivers to receive their feedback.

Results

Sociodemographic Data of Caregivers

A total of 20 caregivers were recruited, of which 25% (n=5) were male and 75% (n=15) were female, with an average age of 59.5 (SD 14.27) years. Fourteen (70%) of the caregivers were identified as the children of the patients, 15 (75%) caregivers had at least a bachelor's degree or equivalent level of education, and the average duration of patient care was 3.3 (SD 2.9) years. Table 1 provides a summary of the general information about the caregivers. The average interview duration was 28.45 minutes, ranging from 20 to 47 minutes.

Table 1. Sociodemographic data of caregivers (N=20).

Item	Value
Sex, n (%)	
Male	5 (25)
Female	15 (75)
Age (years)	
Mean (SD)	59.5 (14.27)
Range	26-87
Relation to patient, n (%)	
Spouse	2 (10)
Siblings	1 (5)
Child	14 (70)
Grandchild	3 (15)
Highest education, n (%)	
Primary school	2 (5)
Secondary school	3 (15)
Bachelor's degree and higher	15 (75)
Duration of receiving home health care (years)	
Mean (SD)	3.3 (2.9)
Range	1.5-15

Health Status of Older Adult Patients

The majority (15/20, 75%) of patients were female, with an average age of 86.2 (range 66-95) years. Among these patients, 8 (40%) patients were bedridden and 12 (60%) patients were homebound. The most common comorbidities included hypertension (15/20, 75%), dyslipidemia (7/20, 35%), dementia (7/20, 35%), and stroke (6/20, 30%). Additionally, 45% (n=9) of patients reported needing assistance for using technology, while 40% (n=8) of patients indicated that they were unable to use technology.

Caregivers' Expectations, Attitudes, and Barriers Toward Telehomecare

Overview

Based on the interviews, it was found that caregivers of older adult patients have specific attitudes and expectations toward taking care of the older adult by using telehomecare. They see it as a valuable service for overall health assessment, although they acknowledge limitations in certain aspects. Communication and device usability challenges were noted, but there is a clear advantage to telehomecare in specific cases compared with in-person visits. Confidence in this service is widespread, yet individual preferences are influenced by family circumstances and situations. Multimedia Appendix 1 shows the framework matrix. The details are provided in the following sections.

It is a Service That Provides an Overall Assessment of a Patient's Health, but Some Aspects May Be Limited

When surveying caregivers' perceived usefulness toward telehomecare for older adult patients within the comprehensive geriatric assessment framework, differing attitudes emerged. Overall, caregivers displayed a favorable attitude toward telehomecare, despite some limitations in specific areas.

Physical Assessment

With regard to the physical assessment of the patients, telehomecare can be more limited than in-person home visits. However, caregivers can mitigate this by providing clearer information through photos and videos.

> *Similar to the case of my mother's mole which turned into a malignant tumor, it was not noticed clearly through VDO call.* [Participant 019]
>
> *It doesn't affect me. If grandma has a pain or where there is any wound, the doctor will ask to take pictures or ask her to walk around to observe the symptom through video call.* [Participant 014]

Psychological Assessment

Caregivers believe that psychological assessments yield similar outcomes through both telehomecare and in-person visits, as doctors can ask questions and provide privacy for patients during an assessment session.

> *It's not different. The doctor asks the same questions, such as "Are you worried about anything?" or "Would you like me to help you with anything?"* [Participant 017]

Environmental Assessment

In-person visits offer a broader environmental assessment experience compared with telehomecare, leading to more precise advice on home environment modification. However, caregivers have found ways to use telehomecare effectively, such as walking around with the device.

> *If the doctor was to visit in person, they would be able to see the home environment and provide advice on how to improve it. If it is stuffy, smelly, unsightly, not suitable for the patient, then the doctor can suggest more than a VDO call. This is because sometimes we don't show the home environment as much.* [Participant 013]

Multidisciplinary Care

Telehomecare facilitates engagement with specialists such as dieticians and physiotherapists, thus enhancing patient care.

> *The telehomecare allows us to have more knowledge from other members of the health care team, especially about how to do physical therapy and how to manage the diet for the patient.* [Participant 015]

Goal of Care and Care Planning

Caregivers play a key role in facilitating communication and treatment plan adherence during telehomecare, ensuring patients follow prescribed plans effectively.

> *We're able to keep up with the treatment plan even during telehomecare because when the doctor has a video call with my grandma, I always listen and take notes, and then I go over what the doctor has told her. I take notes of it all.* [Participant 002]

Communication and Device and Usability Limitations Are Also Challenges

In telehomecare, despite the content, care processes, and follow-ups remaining the same, challenges still arise. The main barriers are related to communication and issues with the equipment, but most caregivers are capable of handling these challenges.

Communication

Challenges include low volume from either the patient or health care worker, low patient inattention, and faulty devices, leading to unclear communication. Caregiver presence during sessions can help overcome these barriers.

> *Grandma's voice is quite soft. She can't speak loud making it difficult for the doctor to hear* [Participant 002]
>
> *During telehomecare, if mother is sitting and trying to listen, it may be necessary for a caregiver to be present to help explain things, as she may have a reduced ability to listen and understand due to her age and weakening internal systems.* [Participant 015]

Technologies and Signaling Systems

Loss of information may occur in telehomecare, but some caregivers have modified or changed the signaling equipment and environment to enhance it, resolving this issue.

> *The sound is a bit lacking, but it's probably my Internet. After changing the Wifi, it's better. My mother's room lacks internet signal.* [Participant 007]
>
> *Barriers? There are some when we use VDO call. Because the phone is old, and we changed the area where we put the phone, so we received a call late. We don't use Wifi.* [Participant 018]

Ability to Use Technology

Older caregivers may encounter difficulties due to their unfamiliarity with technology, affecting their ability to use telehomecare equipment.

> *I am not good at using the smartphone. Sometimes they ask me to take pictures of this and that area and I don't really know how to shoot and am not very proficient in using the device.* [Participant 013]

There is an Obvious Advantage of Telehomecare in Limited Cases Rather Than In-Person Home Visits

Despite some challenges and difficulties, telehomecare offers a clear advantage by providing a means of communication in remote areas.

Scheduling Conflicts

Telehomecare can resolve scheduling conflicts caused by caregiver appointments, enabling remote participation when in-person visits are not possible.

> *There are times when the older adult patient is not at home during the appointment time. Recently, Grandma was at the center. But we communicated through Line in this group. And then we turn on the*

> *camera and talk from 3 different places: the center, the hospital and the office. I can even participate in the call while at work.* [Participant 020]

Inconvenient Home Settings

Telehomecare is convenient when the patient’s home is not suitable for visits, for example, the home space is not suitable for the health care team to visit, or traveling to the home of the patient is inconvenient. It is especially effective when assessments rely on the caregiver alone, as outcomes remain similar without the need for travel.

> *It’s convenient. We don't have to prepare anything. It’s the same. The appointment time doesn’t need to be made, just only when she is unable to sleep.* [Participant 017]

Limited Participation of the Patient

It is also effective when assessments rely solely on the caregiver, for example, when the patient has limited participation in conversation, as outcomes remain similar without the need for travel.

> *...I think it's convenient for both parties. Maybe the patient is taking a nap when the team visit, so eventually the doctor didn't talk to grandma anyway but to me.* [Participant 016]

Everyone is Confident About This Type of Service, but Their Preference Depends on the Family Circumstance and Situation

Overview

When asked about transitioning from in-person home visits to telehomecare, all participants (100%) expressed confidence in receiving telehomecare. Caregivers believed it was similar to in-person visits and met their expectations for health care services. For instance, suggestions about how to reduce health risk behaviors, providing physical therapy advice, managing diet, and offering psychological support for both patients and caregivers.

> *I feel confident because if we have any problems, we can ask just like how we did when the doctor came, but the disadvantage is that the doctor does not see the patient in person but everything else is the same* [Participant 016]

The preference of individual caregivers toward the in-person home visit versus the telehomecare service model is due to personal experiences and all aspects gained during both forms of services. These can be divided into 3 categories.

Preference for In-Person Home Visit

Some caregivers prefer in-person visits because they provide a broader view. These visits allow for a more comprehensive understanding of the patient’s living conditions, environment, evolving symptoms, and overall well-being. In addition, from the direct experience of caregivers, it is easier to identify additional abnormalities during in-person visits that may require treatment. Eight caregivers preferred in-person home visits because they could see more of the overall picture of the patient and the environment.

> *Because the last time the doctor and the nurse came to visit the house, they gave me notice and later, mother had discovered a mole that protruded into a malignant tumor, we didn't know it. We thought it was a normal wart. Here, in-person home visits are very helpful. because sometimes caregiver doesn't know what it is.* [Participant 019]

Preference of Telehomecare

Two caregivers prefer telehomecare over in-person visits because it is more convenient as they require less preparation. Often, during home visits, the patient may be sleeping and most of the communication is with the caregiver.

> *She prefers a VDO call because it is convenient for both doctor and patient. Sometimes the patient will be taking a nap. Most of the patients as old as grandma start napping a lot. If the doctor comes and grandma is not talking to him anymore, she’ll take a nap. This is a waste of the doctor’s time.* [Participant 016]

Preference for Both Methods

Five caregivers had similar preferences for both forms of services. They appreciated that both approaches provided an equivalent level of service and treatment, meeting their expectation and goals of health care services during examinations and treatment processes.

> *I like both. I had no problems with both of them, Through VDO calls, we also get what we need for patient care - medicines and lab results. For me, I don’t have a preference for either method because the specific advantages are different.* [Participant 003]

Additionally, some of the caregivers had no preference between in-person home visits and telehomecare as they found advantages in both methods depending on the situation, such as the current pandemic situation and the patient’s condition.

> *It can be both. But now the doctor says that during the COVID pandemic, he still needs to communicate through VDO call as it is good for both sides. As for the in-person home visit, it provides a visual interaction, but during A VDO call, we still have talking, interviewing, asking questions, providing the health care process which is similar kind of work as well.* [Participant 014]

Discussion

Principal Findings

The study discovered that telehomecare is not the same as in-person visits. It may present certain difficulties and barriers, particularly in the aspects of assessment, interaction, and technology use. Despite these barriers, it has the potential to fulfill requirements and bolster trust among those caregivers who provide care to older adults at home to a similar extent as a face-to-face visit. The majority of patients prefer both forms of care, but it is important to adapt use to fit specific circumstances and conditions.

Comparison With Prior Work

The caregivers of homebound or bedridden older adults expressed positive attitudes toward telehomecare and are prepared to familiarize themselves with this service, comprehending its limitations and the need for its use instead of in-person visits. The previous scope review for patients receiving the telehomecare service at home found that patients desire telehomecare as a supplementary channel, offering easier access to health services from the health care team. This can enhance symptom management and encourage greater self-care [30]. Additionally, 1 study shows that telehomecare patients have greater expectations of telehomecare for the quality and efficiency of patient care, a positive relationship with the team, reduced travel costs [31], and a sense of continuous health monitoring and reassurance from their health care team [32]. If these concerns are addressed in patient care, it will heighten the confidence and satisfaction of both patients and their families.

Moreover, previous studies have found that the majority of participants with a negative attitude toward telehomecare services need more face-to-face health checks than those monitored by telehomecare. This is because they did not have a sense of touch as in in-person visits and were not familiar with using devices. This caused barriers. Conversely, those who are already comfortable with the technology tend to have a more favorable view and see telehomecare as a convenient option, eliminating the need for physically transporting patients to a hospital [8]. These findings align with the results of this study.

Recommendations for Enhancing Telehomecare Services

Based on these results, there are 4 recommendations for enhancing telehomecare services as provided in the following sections.

The Provider Should Enhance the Patients' or Caregivers' Skills to Do Self-Health Assessment

Our study results revealed that it is possible to conduct an overall assessment of a patient's health through telehomecare, but there may be limitations in assessing certain aspects, such as physical assessment. Telehomecare's limitations make it hard to conduct comprehensive videoconferencing or telephone-based health checks, leading to potential medical errors. To ensure effective patient care, family members and caregivers must be involved [33]. Educating them on symptom recognition and initial assessments can help detect abnormalities early, leading to prompt notification for further assessment by the health care team [23]. It is important to provide training and education to caregivers on how to effectively use telemedicine services, as it can improve their skills in self-observing symptoms and mental health management. Telehomecare can also be used to educate and promote self-care, which can lead to better health outcomes for patients. Various channels, such as phone calls, websites, apps, or chats, can be used to provide additional health care skills to caregivers [34,35].

The Health Care Team Should Enhance Their Skills on Telehomecare Services for Patients at Home

A technical problem has been reported as an issue. Therefore, it is crucial for the health care team to possess the necessary skills in telehomecare services to assist patients and their families when they encounter such problems in order to enhance ease of use. It has been suggested that health care teams possess the following skills when delivering telehomecare services [36]: (1) determining when to use telemedicine and assessing the ability of patients and caregivers to use it; (2) proficiency in assessing and caring remotely for patients; (3) effective communication and relationship-building with patients, caregivers, and families; (4) professionalism; (5) basic understanding of information technology; (6) knowledge of laws and privacy protection; (7) ethical considerations; (8) awareness of patient's safety; and (9) awareness of accessibility and service culture. All of these knowledge and skills required by the health care team impact the provision of effective services which are of utmost importance. In some countries, such as the Netherlands, core competencies have been defined for nurses to ensure the effective implementation of telehealth [37].

The key findings from this study suggest that the health care team should know how to assess the situation and select the appropriate service models, whether it could be in-person home visits or telehomecare based on the experience. Although service users have different preferences, circumstances and necessities should be considered. According to the study by Doraiswamy et al [38], it was noted that telehomecare services had previously been used for noncommunicable diseases. However, during the current pandemic, they have become increasingly important for diagnosis, symptom monitoring, rehabilitation physiotherapy, and reducing the spread of pathogens as well [38]. Despite these advantages once the outbreak situation improves, telehomecare services should only be provided in appropriate cases. Patients with positive attitudes toward telehomecare services; who have used technology and have previously received in-person medical treatment; and have difficulties traveling to the hospital due to distance, finances, or health issues are typically considered suitable for telehomecare services. In addition, the content discussed during the telehomecare services should not be of a sensitive nature, particularly in the case of relationships with the caregiver [39]. It is important to ensure that the patient has a suitable place to receive telehomecare services without distractions and can provide the necessary information to the health care team.

The preferences of patients and their families are a crucial factor in choosing the right telehomecare service. It is important for the physician to consider various aspects, including the patient's health, family preferences on service models, and the current social situation. Health care providers should engage in conversations with older adult patients and their caregivers regarding the advantages and disadvantages of telehealth, enabling patients to make informed choices between in-person and telemedicine options [23]. This is to make an informed decision and ensure patient satisfaction with the chosen service in the future.

The Barriers, Especially Those That Are Fundamental to Providing Telehomecare Services, Should Be Removed as Much as Is Feasibly Possible

In our study, we found that barriers to telehomecare can originate from patients themselves, including soft speaking voices or inadequate communication devices. Technology-related barriers, such as poor signal quality or connectivity issues, may also occur. To mitigate these issues, providers and recipients may need to invest in proper equipment, use a microphone that can absorb speech well, and place equipment in the right position to optimize the internet signal [33]. Additionally, the financial aspect of the service should also be considered, it may be useful to have a system to restore certain devices from the service provider but must be weighed against the expenses of the service provider side as well.

Some caregivers struggle to use communication devices, which can cause interruptions in telehomecare services. Patients may also feel incapable of learning to use these devices, according to a study by Huang et al [8]. Thus, telehomecare teams should be knowledgeable about the devices used, inquire about any concerns, and provide assistance to build confidence in using them. To ensure accessibility to all areas, it is recommended to develop strong internet signal towers to support telehomecare for the national benefit.

Interestingly, this study found that the majority of caregivers for older adult patients were highly educated children, with great potential to use technology better than the patient. However, they may still have limitations in using communication devices and technology [40]. Health care providers should not judge their ability based on age or education, and even frail older adults can be trained with help from nurses and caregivers [41]. Each family should be evaluated on a case-by-case basis, and appropriate assistance provided.

Services Should Also Be Provided to Meet Expectations Regarding the Management of Health Problems

Caregivers of older adult patients often have specific expectations from their health care providers, such as recommendations to enhance the patient’s overall health, psychological support, and reducing transportation costs. Our findings support that caregivers perceive telehomecare as useful and prefer it when their expectations are met during the service delivery. Offering services that meet the expectations of patients and their caregivers helps improve the health care aspect and engage in service involvement, which leads to a reduction in hospitalization rates [41,42]. The health care team should strive to meet these expectations to maintain the trust of patients and their families in the telehomecare health care service to the same extent as in an in-person home visit.

Strengths

The strength of this study is that the study involved caregivers with experience in both in-person home visit and telehomecare, allowing for comparison of both services. The study also focused on in-depth aspects related to caring for the bedridden older adults who may have limitations in receiving services.

Limitations

However, there are also limitations to this study. For instance, the information obtained through interviews by health care teams or personnel from the hospital may be biased. To mitigate this, the researchers took measures to ensure that the interviewer was not involved in the treatment of any of the patients and caregivers interviewed. The interview process for participants using convenience sampling may involve selecting individuals who are readily available or easy to reach, potentially leading to a sampling bias. However, the data reach its saturation. Additionally, the sex of participants was 75% (n=15) female, which may yield different insights compared with settings with varying sex ratios among caregivers. However, in Thailand, the majority of caregivers for older adults are female, with a prevalence ranging from 70% to 90% [43-45]. This ratio is similar to that in our study. Given the slight tendency for male individuals to hold slightly more favorable attitudes toward technology use than female individuals, although not substantially [46], it is important to note that this sex imbalance among caregivers should not significantly impact the study’s results. The participants of this study were mainly caregivers of older adults with stable chronic illnesses. Caregivers of patients with more complicated illnesses or the terminally ill may have different attitudes or expectations. We did not include the attitudes of the medical service team with regard to this aspect. These attitudes may affect the outcomes of services and treatment as well, which may be subject to further study. Last, conducting a study comparing telehomecare with no care would underscore the significance of home-delivered care. However, since our initial aims did not include a comparison of these 2 populations, we did not collect data from individuals who have not received the service. It may be worthwhile to consider further research involving families of older adults with health conditions that limit their function but are unable to obtain home care services. Nevertheless, obtaining information about this population could be challenging.

Conclusion

In conclusion, telehomecare is a viable option to supplement in-person home visits. It has the potential to provide quality health care services to patients and allow health care teams to offer treatment and advice remotely. Caregivers have shown a positive attitude toward telehomecare, which is comparable in effectiveness to in-person visits. Despite potential challenges, telehomecare can be a useful alternative in situations where in-person visits are not possible. However, it is important to enhance the skills of caregivers and health care teams to overcome barriers and optimize the use of telehomecare.

Abstract

Background: Acceptance and commitment therapy (ACT), as an empirically based third-wave cognitive behavioral therapy, has shown promise in enhancing well-being and functioning across diverse populations. However, in the context of caregiving, the effect size of available ACT interventions remains at best moderate, sometimes accompanied by high dropout rates, highlighting the need for more effective and feasible intervention designs.

Objective: The objective of our study was to evaluate the feasibility and acceptability of a fully online ACT program designed for family caregivers of people with dementia. This study aimed to boost psychological flexibility and support caregivers, enabling them to realize and prioritize their own life values alongside their caregiving responsibilities.

Methods: A mixed methods feasibility study using an uncontrolled pretest-posttest design was conducted. This intervention included a 9-week web-based self-help program based on ACT incorporating collaborative goal setting and weekly web-based motivational coaching for family caregivers of people with dementia. This study involved 30 informal caregivers recruited through memory clinics and social media platforms in the Netherlands and received approval from the Medical Ethics Committee of the Maastricht University Medical Center+ (NL77389.068.21/metc21-029).

Results: A total of 24 caregivers completed the postintervention assessment, indicating a high adherence rate (24/29, 83%). Caregivers reported positive feedback regarding collaborative goal setting, but some found challenges in implementing new skills due to their own habitual responses or the unpredictable context of dementia caregiving. Personalizing the intervention based on individual value preferences was highlighted as beneficial.

Conclusions: Compared to other web-based self-help ACT interventions for family caregivers, this intervention showed a high adherence and sufficient level of feasibility, which underscores the use of personalization in delivering web-based interventions. Moreover, the potential of this ACT-based intervention for family caregivers of people with dementia was demonstrated, suggesting that further research and a larger-scale controlled trial are warranted to validate its effectiveness.

Introduction

Background

The number of people with dementia is predicted to double every 20 years, which will lead to a corresponding rapid increase in the number of family caregivers [1]. Family care increases the quality of life of people with dementia and reduces formal care costs, thus making a substantial contribution to dementia care management. This is noteworthy as most people with dementia rely on a range of crucial and unpaid support from family caregivers [2]. Although the experience of caregiving might be fulfilling and positive, research also shows that, with advancing dementia, the need for care can become increasingly time-intensive, stressful, and more complex, posing a risk to the overall well-being of caregivers. In the context of dementia, family caregivers may experience inevitable and long-lasting changes due to the progressive nature of the condition and the increasing dependence of the person with dementia on their caregivers.

Importantly, the adverse effects of caregiving can be addressed and improved through a wide range of psychological interventions [3-6]. However, the long-term care situation and associated (inevitable) changes in caregivers' lives underscore the importance of acceptance-based interventions that focus on developing skills to effectively address the management of maladaptive thoughts and emotions and acceptance of ongoing changes [7]. Specifically, the ways through which caregivers perceive and respond to internal (ie, thoughts and feelings) and external (ie, environmental) stressors are significant predictors of negative outcomes in this population [8,9]. Subsequently, acceptance and commitment therapy (ACT), as an empirically based third-wave cognitive behavioral therapy, might be particularly noteworthy due to its scalable focus on promoting psychological flexibility [10]. From the ACT perspective, psychological flexibility refers to efficient functioning in the presence of difficult experiences and is achieved via 6 interrelated core processes. These processes include openness to internal experiences (ie, acceptance), defusing from thoughts (ie, cognitive defusion), being in the present moment and aware of oneself and others (ie, mindfulness), having a distinct perspective on internal experiences (ie, self as context), identifying meaningful action qualities that can be connected with bringing purpose and motivation (ie, values), and active engagement and behavioral action aligned with values (ie, committed action) [11]. Hundreds of randomized controlled trials (RCTs) have demonstrated the effectiveness of ACT in improving overall well-being in the general population and in people with mental or somatic health problems [6,12].

ACT for Family Caregivers of People With Dementia

In the context of dementia caregiving, ACT shows promise in promoting acceptance of change and increasing willingness to take meaningful actions, leading to improved psychological flexibility and better overall functioning in caregivers [13-15]. Several RCTs have demonstrated that face-to-face individual ACT interventions provided by trained therapists result in a significant reduction in depression and anxiety in family caregivers of people with dementia compared to control groups [13,15,16]. Furthermore, non-RCT ACT studies have also shown promise in supporting family caregivers of people with dementia through modalities such as telephones [17], videoconferencing [18], group settings [19], or web-based self-help modules [20,21].

eHealth Adaptations for Family Caregivers

In recent years, technological advancements have facilitated the development and adaptation of a wide range of acceptable and promising psychological programs, from face-to-face to eHealth (ie, the use of internet to promote well-being) [4,22,23]. In particular, web-based self-help interventions are cost-effective and accessible approaches that reduce the significant involvement of health care professionals, allowing caregivers to complete the intervention on their own time using computers, tablets, or mobile devices. Web-based self-help interventions provide materials such as modules, text, and videos, enabling users to navigate the program at their own pace [24].

However, the effect sizes of the available interventions are still at best moderate [3] with a high dropout rate [20], indicating the need for more effective intervention designs [15]. Furthermore, in the context of caregiving, family caregivers of people with dementia are often older adults. The potential lower digital literacy and preference for traditional face-to-face psychological support, coupled with implementation limitations, make them the subgroup of caregivers who most frequently report challenges related to accessing and using eHealth interventions [4]. Thus, in the context of eHealth, guided self-help interventions including "minimal contact" might be a promising approach for this population. In a "minimal contact" approach, health care professionals (eg, coaches) are involved for nontherapeutic purposes and mainly for periodic check-ins, teaching participants how to use the digital tools, and provision of initial rationales [23,25].

Personalizing Self-Help Interventions From the ACT Perspective

Personalizing interventions is an important and effective strategy to increase adherence and prevent dropout rates, making trials, including RCTs, more feasible, acceptable, and effective [26]. One effective and efficient approach to personalization is collaborative goal setting, in which individuals, together with health care professionals, set specific goals based on their own needs and resources before the intervention, leading to increased motivation and, ultimately, behavior change [27]. From the ACT perspective, there is a distinction between goals and value-based choices and their impact on (long-term) behavior change. Goals are typically external and have a clear end point that can be achieved or completed. In contrast, values are meaningful qualities that cannot be obtained or finished but rather help set meaningful goals and guide long-term patterns of behavior. Thus, acknowledging personal values and nesting specific goals underneath them is more likely to drive effective behavior change in the long term [11]. Engaging in value-based activities in the context of caregiving has a positive association with emotional well-being [28] and a negative association with distress [16].

To our knowledge, collaborative goal setting based on caregivers' values has not yet been explored within the context of web-based ACT self-help interventions. Gaining further insights into the feasibility of web-based ACT interventions for family caregivers of people with dementia might contribute to decisions related to the implementation of ACT interventions in clinical practice, facilitating intervention refinements and, ultimately, leading to the design and development of more acceptable, effective, and sustainable interventions for future large-scale controlled trials.

This Study

Despite the growing literature on ACT and the efficacy of eHealth interventions in family caregivers, there is a limited focus on understanding the specific challenges and opportunities of web-based self-help interventions for this population [29]. To date, few studies have used supported or personalized self-help ACT to address the specific needs of family caregivers. The aforementioned studies, although promising [21], showed a high dropout rate [20], or the intervention did not prove highly effective [30]. Therefore, in response to the need for a more efficient intervention design for family caregivers of people with dementia, this pilot trial aimed to use a mixed methods assessment approach (qualitative and quantitative data) to examine the feasibility and acceptability of the ACT for informal caregivers of people with dementia intervention. This web-based guided intervention is designed for community-based family caregivers of people with dementia through web-based ACT modules, collaborative goal setting based on individuals' personal values before the intervention, and minimal-contact motivational coaching during the intervention. Subsequently, this study aimed to address the following research question: what are the practical and conceptual barriers and facilitators influencing the feasibility and acceptability of this guided web-based intervention?

Methods

Overview

This study was a pilot trial with a mixed methods approach, a baseline assessment, a 9-week web-based intervention embedded with web-based weekly motivational coaching, and a postintervention assessment. This study was reported according to the guidelines presented in the CONSORT (Consolidated Standards of Reporting Trials) checklist [31]. The CONSORT checklist is presented in Multimedia Appendix 1 [32]. The complete design is described in the protocol [33], and the methodological details relevant to this feasibility and acceptability study are presented in the following sections.

Participants

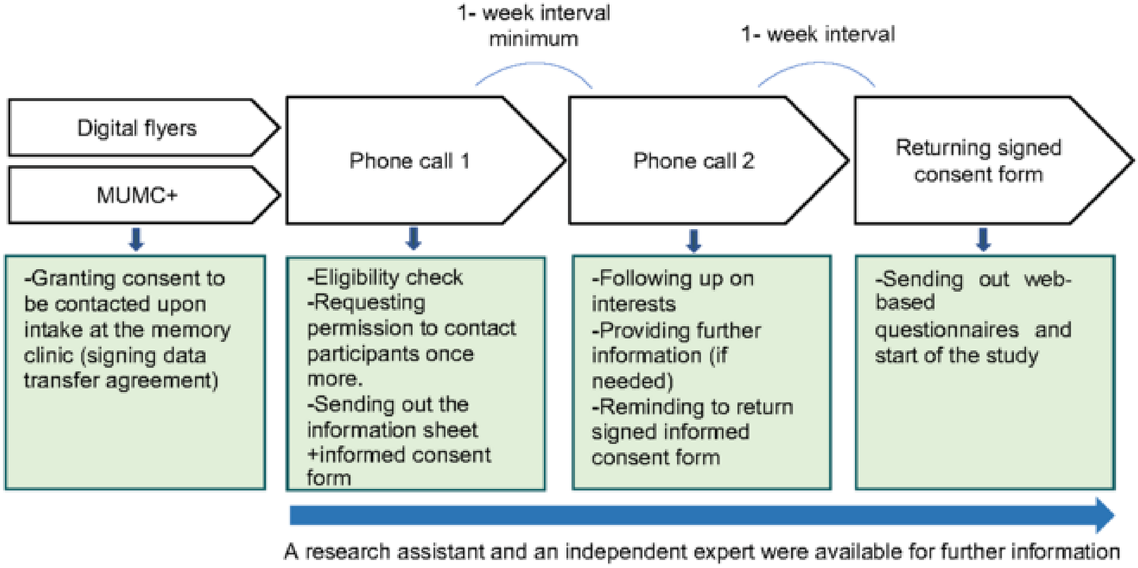
A sample size of 30 participants is considered to be sufficient to enable a reasonable calculation of the key factors relevant to feasibility (eg, attrition rates) and provide useful information required for recommending a larger controlled trial [34,35]. Therefore, 30 family caregivers of people with dementia were recruited for this study.

Eligible family caregivers were recruited sequentially from May 2022 to June 2023. The following inclusion criteria were applied: (1) adult caregivers (aged ≥18 y), (2) self-identified primary family caregivers of a person with a diagnosis of dementia, (3) caring for the care recipient for at least 3 hours per week for at least 3 months, (4) internet and tablet or computer accessibility in the household, and (5) consent to participate. Family caregivers were excluded if (1) they indicated cognitive difficulties or disorders in their medical record (based on self-report) or (2) they had undergone psychotherapy or psychopharmacological treatment during the previous 3 months.

Recruitment Procedure and Screening

Family caregivers were recruited from referrals by clinicians (eg, psychiatrists or psychologists) at the memory clinic of the Maastricht University Medical Center+ in the Netherlands. Furthermore, recruitment took place using printed or web-based flyers and website posts by patient and caregiver support organizations in the Netherlands, the Dutch Alzheimer Association, and local mental health institutions. Information about the study as well as a self-addressed stamped envelope for returning the informed consent form were provided to all the participants via post. When the research team received the signed informed consent form (in paper format), the study officially started. The process of screening and recruitment is shown in Figure 1, and further details on the recruitment procedure can be found in the study protocol [33].

Figure 1. Recruitment procedure. MUMC+: Maastricht University Medical Center+.



Intervention

Overview

The guided web-based intervention followed a written protocol [33]. As a general structure, each week, participants first completed a web-based module and then received a telephone or video call from a motivational coach. Participants were instructed to complete consecutive steps, including (1) a 50-minute web-based video call at baseline with a motivational coach for value-based goal setting, (2) 9 self-help web-based ACT modules (20-30 min each), and (3) an approximately 20-minute weekly web-based video call with a motivational coach for 9 weeks. In addition, participants had the flexibility to extend the duration of the intervention and complete the 9 modules and coaching sessions in 12 weeks. Contact with the coach took place in individual sessions.

Collaborative Goal Setting

Collaborative goal setting [36] was chosen to personalize the guided web-based intervention. During the individual value-based goal-setting session with the motivational coach, each participant set one value-based personalized goal that was specific, measurable, attainable, realistic, and time-orientated (SMART) [37]. Individuals could select from a predefined list of value-based actions or write goals in their own words (Multimedia Appendix 2). The list was prepared based on the ACT model and an adapted version of the valued living questionnaire for dementia caregiving [28,29,38]. Specific value-based actions with clear steps were defined during the collaborative goal-setting session and were embedded into future activities within the intervention. The steps of collaborative goal setting are shown in Multimedia Appendix 3.

Web-Based Self-Help Modules

Details about the intervention can be found elsewhere [33]; in brief, caregivers focused on 1 of the 6 ACT components (ie, acceptance, cognitive defusion, mindful attention, self as context, value, or committed action) in each module, gradually covering all the core principles of psychological flexibility. The 9 self-help web-based modules were released weekly consisting of a standard structure including a brief introductory text, a short video, an ACT-related metaphor, and content-oriented assignments. Module 1 provided a short introduction to ACT and a program overview. In module 2, “Creative Hopelessness” was introduced to reflect on the dysfunctionality of avoidance strategies for difficult thoughts and feelings in life. Modules 3 to 8 reviewed each of the 6 ACT components in detail. Finally, session 9 was a recap of all ACT components incorporating strategies for relapse prevention in everyday life (Multimedia Appendix 4). In addition, ACT metaphors were embedded in the content of the modules. For example, the boomerang metaphor was used for avoiding unpleasant feelings. The concept is that the more one attempts to throw the metaphorical boomerang away, the more forcefully it will eventually return [39].

After completing a module, caregivers received an automated email notification from the website reminding them of the availability of the next module. Access to the modules was sequential, requiring completion in a specific order rather than allowing access to all modules at once. Further details on the content of the website are presented in Table 1.

Table 1. Overview of the 9 modules included in the intervention.

Module	Title	ACT[a] strategy	Example of the exercise
1	Introduction	The introduction of ACT and the content of the program consists of modules with videos explaining ACT components accompanied by metaphorical images and exercises to enhance personal resilience.	“You are now invited to answer these two questions for yourself: Where do you want to go with your life (as a person, privately and in your work)? What stands in your way?”
2	Creative hopelessness	Exploring creative hopelessness strategies among informal caregivers for navigating unpleasant thoughts and feelings.	“Share three personal examples of how you prevent unpleasant feelings, employing strategies like prevention, avoidance, and reduction. This exercise fosters self-awareness about your functioning in challenging situations.”
3	Acceptance	Recognizing caregivers’ potential struggles with negative emotions, this module involves fostering acceptance by making room for unpleasant feelings.	“This exercise encourages reflection on personal pain, strategies for coping, and resulting suffering. Identify specific instances of pain, whether thoughts, feelings, physical sensations, or situations.”
4	Defusion	Addressing the tendency of individuals to take their thoughts seriously, the focus is on defusion—encouraging individuals to distance themselves from difficult thoughts.	“Write a negative self-view, e.g., ‘I’m not good enough,’ then rephrase it as ‘I have the thought that I am not good enough.’ Notice the difference between directly identifying with the thought and acknowledging it as a passing idea.”
5	Self as context	Acknowledging the tendency of individuals to define their self-image based on perceived expectations, the emphasis is on the self as context—creating room for individuals to be themselves and fostering flexibility in their self-image to alleviate stress.	“In ACT, your self-image is like wearing a tailor-made suit that may not fit your current feelings. Reflect on times this felt restrictive and consider less uncomfortable suits you’ve worn. Explore a more flexible approach and think of the benefits of taking them off for a moment.”
6	Mindfulness	Recognizing that excessive focus on the past or future may not always be helpful, the emphasis is on the here and now—encouraging individuals to pay sufficient attention to the present moment, the only time when we can truly live, act, and experience.	“Reflecting on past and future often overshadows the present; embracing the moment enhances life satisfaction. Losing the present in thoughts might result in missing the richness of the present experience. Try to recognize an example of this in your own life.”
7	Value	Recognizing the significance of acknowledging what truly matters in one’s life, the focus is on values—actively encouraging individuals to ask whether their values are sufficiently present in their lives and put them into practice.	Value-sorting task: “Identify core life values using a set of cards, categorizing them as ‘Very Important,’ ‘Important,’ or ‘Not Important,’ and then prioritizing the top 10 values to actively invest in.”
8	Committed action	Emphasizing the facilitation of a more meaningful life, the focus is on committed action—encouraging individuals to define concrete and feasible actions toward their values, actively invest in them, and translate them into value-based actions.	“Take practical steps and reflect on each significant value and ask, ‘What is the smallest, easiest step I can take in the next 24 hours to align my life with that value?’ Ensure specificity and feasibility in these actions for practical implementation.”
9	Psychological flexibility	The concluding module highlights that cultivating psychological flexibility through the practice of the 6 core skills enables individuals to address problems differently and with greater flexibility, enriching their lives in ways that hold personal value.	“You were introduced to all the different ACT components. We invite you to answer the initial questions from Module One again: Where do you want to go with your life (as a person, privately and in your work)? What stands in your way?”

[a] ACT: acceptance and commitment therapy.

Weekly Coaching

A trained research assistant with experience in intervention coaching was appointed from Maastricht University to fulfill the role of the motivational coach. As part of the weekly coaching process, participants were encouraged to complete the weekly module before scheduling a video call. During the weekly coaching, the coach inquired about the participants’ overall experience with the web interface (ie, whether any technical or other issues occurred), how goal attainment was progressing (ie, value-based actions defined during the collaborative goal setting), and whether they experienced a (positive or negative) change in their motivation (Multimedia Appendix 5). Weekly coaching was not intended as a therapeutic function but rather to provide technical support and motivate participants to follow the web-based self-help modules (ie, adherence) and stay engaged with their value-based goals. Thus, goal attainment and module completion were not mandatory before coaching took place.

Sampling and Intervention Quality

Data were collected using the Castor web-based platform provided by Maastricht University. Intervention integrity was monitored independently by experts. Several types of monitoring visits were conducted by the Clinical Trial Center Maastricht for the purpose of quality and control at the beginning of the study (ie, site initiation visit); during the course of the study (ie, interim monitoring visits); and at the end of the study, when participants had completed the study and all data had been collected (close-out visit) [33].

Quantitative and qualitative data were used to inform the feasibility and acceptability of the intervention for the participants and coach. The number of referrals, number of eligible participants willing and not willing to take part, reasons for declined participation or dropout after signing the informed consent form and before starting the intervention (if provided), and amount of time spent on recruiting 30 participants were monitored during recruitment. Quantitative and qualitative data on the intervention procedure were collected to inform use logs and interaction with the web-based modules. Barriers (eg, technical problems or difficulties) to user engagement were qualitatively collected during weekly coaching. To distinguish between intervention rejections and dropouts, we defined dropout as attrition following the start of the intervention (ie, those participants who attended at least one session of the intervention but discontinued it) [26]. Reasons for dropout after starting the intervention (if provided), attrition rate of weekly coaching sessions, and ACT module completion were also recorded.

Assessment

Overview

This study specifically focused on feasibility and acceptability aspects. The preliminary efficacy and changes in psychological outcomes will be reported elsewhere. Further details on the measures of preliminary efficacy are described elsewhere [33].

End-of-Module Questionnaire

Following the previous study, the research team developed the end-of-module questionnaires [40] with the goal of gaining additional insights into the feasibility and acceptability of each module. Subsequently, content comprehension was assessed directly after completion of each module via a feedback questionnaire. This questionnaire included 3 items (ie, “I found today’s module useful,” “I have experienced the content of the modules as stressful,” and “I can apply the content of today’s modules in my daily life”) rated on a Likert scale ranging from 1=*strongly disagree* to 7=*strongly agree* on perceived usefulness, stressfulness, and applicability of each module to one’s daily life.

Goal Attainment

The level of goal achievement, as well as qualitative feedback on the feasibility and acceptability of goal achievement, was collected on a weekly basis during coaching. Goal attainment scaling was mapped on a prespecified ordinal scale, and the number of attainment levels ranged from −3 to +2. Each SMART goal was set at different layers as an “action list” including different levels of goal attainment. Level “0” was set as the “expected” level, and the rest of the levels were defined by a possible change in goal attainment. Any progress from the “expected level” was scored with “+1” as the “better than expected” level or “+2” as the “much better than expected” level. Deterioration in goal attainment was scored with “−1” as the “improvement but less than expected” level. The “−2” score was assigned to the “current” level and addressed “no change” from the goal-setting day, and “−3” referred to the “much less than expected” level in goal attainment. Setting an in-between “−2” score as the “current” level was considered to prevent floor effect and capture deterioration from the “current” individuals’ state [37]. During collaborative goal setting at baseline, each caregiver defined and clarified 5 layers of their SMART goals (from −3 to +2).

The Program Participation Questionnaire

Further insights into the usability, clarity, and acceptability of the intervention for family caregivers was obtained during a postintervention semistructured interview using the Program Participation Questionnaire (PPQ) [40]. The PPQ consisted of 26 items scored on a Likert scale ranging from 1=*strongly disagree* to 7=*strongly agree* focusing on 3 main areas, including the applicability of the intervention in everyday life, feasibility, usability, acceptability, and content quality and quantity (Multimedia Appendix 6). Furthermore, the number of log-ins to the modules and feature use were collected and compared with self-reported data. The feasibility and perceived experience of the coach was evaluated using a brief 6-item coach questionnaire focusing on the intervention’s usability and relevance for the coach, general perceived experience, the program’s positive and negative aspects, and suggestions for improvements (Multimedia Appendix 7).

Demographic Information

During the baseline assessment, family caregivers completed a demographics questionnaire providing information about their age, sex, level of education, living situation (ie, whether the caregiver and the person with dementia lived together or independently), hours of caregiving per week, type of kin relationship with the person with dementia, years since diagnosis, and dementia type.

Data Analysis

The PPQ was analyzed quantitatively and qualitatively. Due to the lack of external criteria to properly define feasibility [41], median scores as a conventional strategy were defined as determinants of the overall feasibility, usability, and acceptability [40,42]. This approach to evaluating feasibility was also previously used in a Delphi study [43]. The overall PPQ scores ranged from 26 to 182. The median score of 130 was deemed as the cutoff and, thus, “acceptable feasibility” [40]. Mean item scores (range 1-7) of <5 (“slightly agree”) were considered as having potential for improvement. Participants further reflected qualitatively on their scores, and their reflections were audio recorded and transcribed verbatim. The deductive content analysis was conducted by authors GLA and RVK using field notes to interpret the quantitative scores on the PPQ [42,44]. In addition, to evaluate whether the intervention components aligned with the specific needs of the target group [45], field notes were classified and deductively coded into four main categories to address the intervention components: (1) overall experience and suggestions, (2) goal setting and value identification, (3) web-based self-help ACT modules, and (4) coaching. Furthermore, the self-report acceptability questionnaires at the end of each module were summarized in SPSS (IBM Corp) using descriptive statistics. Finally, web feature use and the number of log-ins were collected and subsequently compared with self-reported data. Data from the weekly coaching sessions were incorporated to complement the log data and the postintervention semistructured interviews.

Ethical Considerations

The study was approved by the Medical Ethics Committee of the Maastricht University Medical Center+ (NL77389.068.21/metc21-029). All participants provided informed consent, and the rigorous protection of privacy and confidentiality of participants was safeguarded throughout the study. Data were anonymized when applicable to safeguard participant identities. As a token of appreciation, participants received a €25 (US $27.13) gift card for their involvement.

Results

Overview

A total of 33 family caregivers were deemed eligible to participate in the study, of whom 30 (91%) provided informed consent and 24 (73%) completed the postintervention assessment (Figure 2).

In total, 3 eligible caregivers declined to sign the informed consent form citing the extra burden on their caregiving responsibilities (n=2, 67%) and the admission of the person with dementia to a nursing home (n=1, 33%) as reasons for their decision. Of the 29 participants who initiated the intervention, 4 (14%) decided to leave prematurely. Thus, based on the definition of dropout in this study, an adherence rate of 83% (24/29) was recorded, including 1 withdrawal and 4 dropouts.

Of the 30 caregivers who signed the informed consent form, 1 (3%) did not continue the baseline assessment due to difficulties in arranging an electronic device, such as a laptop or tablet, to continue the study. In addition, of the remaining 29 caregivers, 1 (3%) withdrew due to the death of the person with dementia, and 4 (14%) dropped out citing concerns that the study was too time-consuming or emotionally challenging or added an extra burden to their existing caregiving responsibilities. Examples of reasons for dropout included the following:

> *I wasn't that fond of it. It makes you depressed, all that thinking about the past and stuff. It's not what I expected.* [ACT-IC015; aged 63 years; male]
>
> *I don't want to dwell on it, don't want to learn to think differently either, I find that scary.* [ACT-IC018; aged 51 years; female]

No differences were identified between caregivers who dropped out and those who completed the study. Of the 24 participants who completed the study, most were female (18/24, 75%), and the hours of caregiving were often reported to be >15 per week, ranging from 3 to 20. The duration of dementia (ie, time since diagnosis) was, on average, 4.1 (SD 2.7) years, with a higher prevalence of Alzheimer (12/24, 50%) followed by vascular dementia (6/24, 25%). Further sociodemographic characteristics of the caregivers are shown in Table 2.

Figure 2. Participant flow.

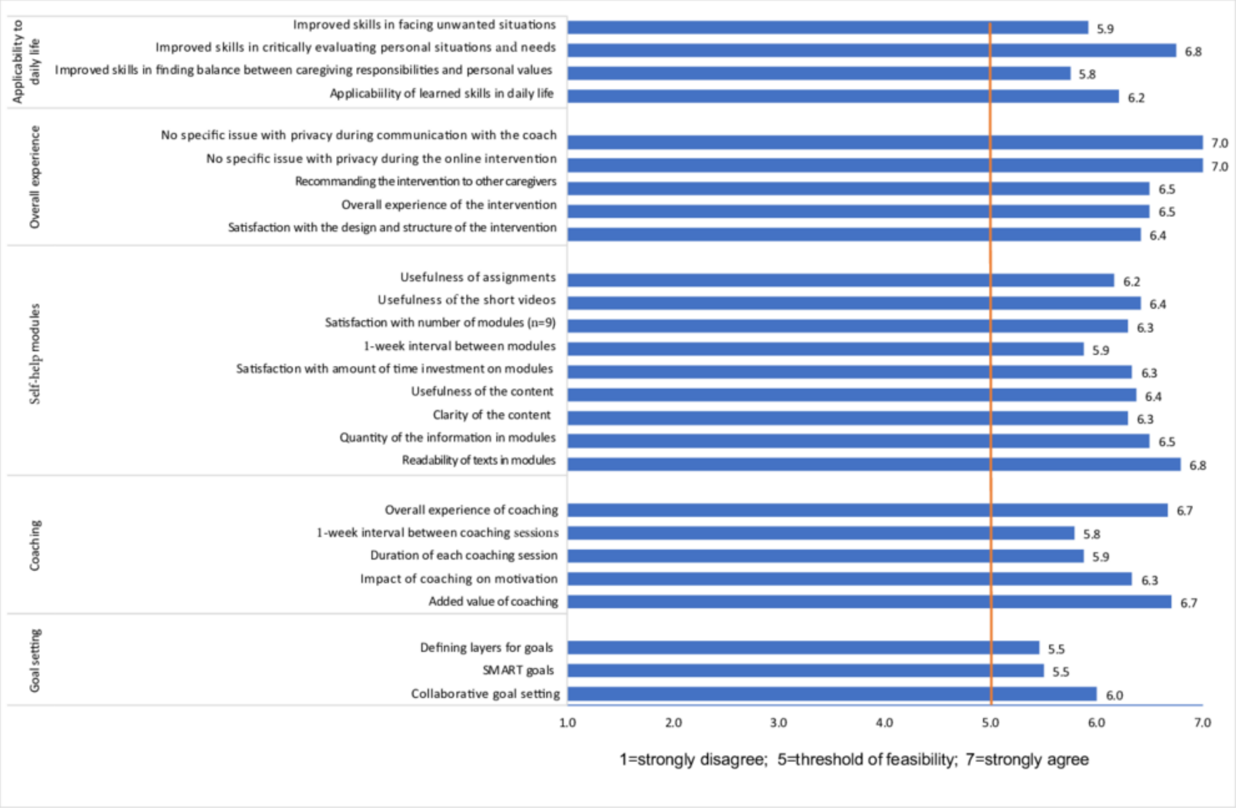
Duration of dementia (y), mean (SD)	4.1 (2.7)

Results of PPQ

Overview

The total score on the PPQ ranged from 90 to 182. The average total score on the PPQ of the 24 caregivers who completed the intervention was 163.4 (SD 22.3). On average, family caregivers gave all items a score of at least 5 (mean 6.29, SD 0.46), with a total median score of 172, indicating high perceived feasibility and acceptability (Figure 3).

Figure 3. Average scores on each item of the Program Participation Questionnaire. SMART: specific, measurable, attainable, realistic, and time-orientated.



The quantitative results of the PPQ on intervention feasibility and acceptability were consistent with postmodule self-report acceptability as well as with deductive qualitative content analysis of the field notes.

Qualitative feedback informed the feasibility and acceptability of the intervention components, specifically (1) overall experience, (2) goal setting and value identification, (3) web-based self-help ACT modules, and (4) coaching. In addition, a semistructured interview was conducted with the motivational coach to gain more insights into study feasibility for the interventionist.

Overall Experience

Overall, participants found the intervention's design comprehensive, logically structured, and strongly interconnected, "like a string of chain," emphasizing that removing a single component would disrupt the functionality of the intervention. Enhanced adaptability to the caregiving role and improved ability to focus on meaningful life values while providing care for people with dementia were noted as valuable components in addressing the balance between caregiving and self-care. Caregivers reported that their enhanced psychological flexibility, achieved through ACT principles, supported their resilience and also positively influenced people with dementia, describing it as a "win-win" situation:

> *It was aligned, enriching, confronting, and educational. Without a coach, it would have been easier to let things slip. Providing care becomes much more sincere and high quality by being mindful. You can only do that if you have space for it, so you have to let go of your need for control. It starts with yourself, and you can apply it everywhere, that is a relaxing feeling. I learned to deal with myself in a different way. I could respond more calmly. I wasn't overwhelmed and overstimulated; it had such a positive effect on the person with dementia.* [ACT-IC 002; aged 47 years; male]

Caregivers suggested the inclusion of a psychoeducational module specifically addressing the application of ACT to the unique challenges caregivers face in dementia care. Such a module may support contextualizing ACT and enhance the understanding of the metaphors used within the intervention, making it more relevant and applicable to the unpredictable and progressive nature of the condition. In addition, some caregivers expressed the desire to have ongoing access to the modules or receive a printed booklet containing all the modules, allowing them to reference the material even after the study. While acknowledging that the intervention was confronting and required more time than initially anticipated, participants still expressed their recommendation of the intervention to other caregivers.

Goal Setting and Value Identification

Family caregivers expressed that setting goals before participating in the intervention was essential for their engagement with the program and establishing a road map toward desired behavior change. Formulating SMART goals made the process more tangible for participants and stimulated a sense of purpose during the intervention, which led individuals to plan and adapt self-management and personal values to their caregiving responsibilities. Most caregivers often emphasized the importance of receiving guidance in value identification, prioritizing goals, breaking value-based actions down into manageable steps, and adjusting goals when necessary:

> *Providing guidance is important because then I receive a kind of confirmation that I should do it as well. Otherwise, it remains so open-ended. The coach allowed me the freedom to set my own goals and provided guidance when needed. Setting goals and timeframes helped me avoid feeling guilty about taking time for myself.* [ACT-IC012; aged 65 years; female]

Goal Attainment

Participants had mixed experiences when it came to engaging with the action list, which included layers of goal attainment, as well as when they were asked to self-report their progress on their goals during meetings with the coach. Some caregivers found the action list to be beneficial for adapting their goals to better align with the changing demands of caregiving, enhancing their ability to navigate through personal values and caregiving responsibilities effectively. Nonetheless, some caregivers encountered challenges in both accomplishing their goals and accurately assessing their level of achievement. Furthermore, a desire to modify their goals was also noted among some participants. Factors that influenced the attainment of goals primarily included caregiving demands such as the inability to leave the care recipient alone, their own health conditions (eg, physical pain), and time limitations. These factors often resulted in adjustments to the goals throughout the intervention. In addition, a shift in focus to a different set of values was another factor that influenced goal adjustment.

Reduced engagement with the action list or failure to attain goals at a desirable level for some caregivers caused feelings of anxiety or increased burden when reporting to the coach:

> *I had the tendency to give socially desirable answers when the coach asked if I had worked on my goals. I would be asked if I had gone cycling, but I can't leave my partner alone. So, I do want to take more time for myself, but the situation doesn't always allow me to engage in outdoor activities.* [ACT-IC 009; aged 74 years; female]

According to the coach, using the SMART framework for goal setting was valuable for structuring collaborative goal-setting sessions. However, adjusting goals to account for comorbidities and caregiving demands presented challenges at times in providing guidance, particularly within limited time frames.

Web-Based Self-Help ACT Modules

Content

The content of the web-based self-help ACT modules was reported mainly as "easy to follow" and helped caregivers in adapting their coping strategies, acquiring new skills to navigate challenges, cultivating mindfulness of the present moment, and reframing their perspective to align with their life values. According to caregivers, following ACT principles in parallel with goals empowered them to gain more insights into psychological flexibility, enabling them to take practical steps toward living in accordance with their values:

> *I went out of my comfort zone...I usually think that if you want something, you'll just do it, but it (i.e., ACT) was truly an eye-opener. I was constantly realising I need to do this, oh yes, I need to pay attention to that as well, of course. Those moments of realisation, I found them very valuable.* [ACT-IC 004; aged 52 years; female]

After completing each module, participants provided self-report feedback and rated the usefulness, stressfulness, and applicability of the content on a Likert scale ranging from 1 (*strongly disagree*) to 7 (*strongly agree*). All participants (24/24, 100%) completed all modules along with the self-report questionnaires. According to their feedback, the web-based self-help modules were generally perceived as useful, with a mean score of 5.6 (SD 0.2; range 5.4-6.1), and applicable to daily life, with a mean score of 5.2 (SD 0.5; range 4.4-5.9). The stressfulness of the content was rated with a mean score of 3.5 (SD 0.8; range 2.4-4.4). Among the various components, the "self as a context" component was identified as the most useful yet one of the most stressful modules after "Acceptance" (Multimedia Appendix 8).

Overall, participants expressed that the ACT modules enabled them to "change attitude," which was necessary for openness and developing skills that are "potentially applicable" in everyday life. However, taking perspective did not always result in actual changes in behavior in everyday life for some (older) caregivers. The most frequently reported barrier to applying new skills "in the situation" was the role of habits. Caregivers often highlighted that implementing new ACT skills took time to "sink in," particularly due to habitized responses to specific cues that developed through years of repetition:

> *You've been doing things your whole life, often unconsciously, and now you're becoming aware of things. Becoming aware and then changing your behavior takes time.* [ACT-IC001; aged 65 years; female]
>
> *In difficult situations, it's not so easy to implement everything you know. You know it now, but it can still be challenging to apply in the situations.* [ACT-IC006; aged 71 years; female]
>
> *With a certain age and lifestyle, it's a significant adjustment, not easy, but the adaptations are necessary.* [ACT-IC011; aged 79 years; male]

According to the coach, extending the completion time frame to 12 weeks allowed caregivers more time and space to learn the materials. However, given the time required to acquire new skills, extending the time frame to >12 weeks could also be beneficial.

Format

Most participants found 1 module per week to be suitable, with some suggesting that 2-week intervals could also work. In total, 29% (7/24) of the caregivers required >9 weeks to complete all 9 modules. Caregivers found the web-based format beneficial as it eliminated the need for additional travel time, making it convenient to integrate the intervention into their daily routines. In addition, the convenience of the self-help modules was appreciated, which allowed caregivers to review the material and take notes at their own pace, offering an opportunity to consider personal preferences:

> *I have difficulty remembering certain things (concerning the intervention material). I have to reread things to apply them properly.* [ACT-IC001; aged 65 years; female]

All participants (24/24, 100%) completed the intervention using computers or laptops with internet access. Regarding the experience of the web-based format, caregivers expressed that the presence of a coach supported them with navigating through the web setup. The combination of video, text, and assignments was expressed as useful to comprehend ACT exercises and metaphors. However, some caregivers chose to review the material either by accessing the web application on their mobile phones or offline by printing the material rather than logging into their accounts via their computers:

> *I printed it out so I could read it and write down my thoughts and notes. I prefer paper over online, which might have to do with my age.* [ACT-IC006; aged 71 years; female]

According to the coach, addressing technical difficulties provided the necessary support for participants with lower digital literacy and prevented dropout due to technical issues.

Coaching

Overall, participants found the coaching sessions aligned, enriching, and constructive. The supportive listening, availability of the coach through multiple channels (video call, phone call, and email) during coaching, technical support for the web-based module, feeling safe with privacy on the web, and flexible rather than fixed coaching appointments were particularly appreciated. Caregivers reported that receiving personal feedback enhanced their active engagement with the entire intervention. This engagement, in turn, increased their motivation to learn new perspectives presented by the ACT modules and strengthened their commitment to achieving their goals. The contact with the coach through digital means was mentioned as added "accountability" and a suitable modality, particularly for those who preferred direct contact with health care professionals.

From the Coach's Perspective

The weekly coaching sessions revealed several prominent barriers faced by caregivers, including technological, intrinsic, and extrinsic challenges. Technological barriers centered on issues related to digital literacy, limited access to digital devices, and a lack of self-efficacy in technology use. The coach addressed these concerns by offering supplementary guidance, providing the option to print materials for offline use, and enabling access to the intervention through a mobile-friendly web application. Intrinsic obstacles included motivational struggles, physical discomfort, and reduced sensory abilities, which influenced the caregivers' willingness to implement new ACT strategies or attain their goals. The coach navigated these barriers through motivational conversations, supportive listening, and adaptable goal setting to accommodate individual preferences and limitations. Extrinsic barriers included time constraints, demanding caregiving responsibilities, and the evolving condition of the care recipient, leading to fluctuations in the caregivers' schedules and diaries.

Regarding the nontherapeutic nature of the coaching, the coach expressed that "caregivers just needed to be heard." However, providing motivation without knowing the context was often not possible, resulting in the duration of sessions exceeding the planned 20 minutes. Although the longer calls were still feasible for the coach, providing flexible availability was not always easy to adjust to daily work responsibilities. Furthermore, the coach noted that conducting data collection fully over the web and providing technical support posed occasional challenges that sometimes required contacting third parties and could result in delays.

Discussion

Principal Findings

This feasibility study was conducted in response to the demand for interventions that are both more scalable and personalized for family caregivers of people with dementia. The findings of this study revealed that caregivers acknowledged the beneficial impact of psychological flexibility. This recognition resulted in perceived positive effects not only in self-management and caregiving quality but also in the applicability of ACT in noncaregiving situations in daily life. This outcome is in line with that of previous research that ACT can be transdiagnostic in addressing psychological flexibility in a heterogeneous sample of caregivers who provided care for individuals at various stages and with various types of conditions, including dementia [46,47]. The findings of this study revealed a high adherence rate of 83% (24/29) at the postintervention measurements, which exceeded the average adherence rate of 57% found in self-guided ACT interventions [48], 73% found in self-help interventions [24], and 69% found in internet-based treatments for the general population [49]. High adherence and overall satisfaction are particularly important findings as family caregivers of people with dementia have the highest dropout rates and reported problems with access and usability of eHealth interventions [4].

The aim of this guided web-based intervention was to broaden the evidence base by exploring practical and conceptual barriers and facilitators influencing feasibility and acceptability. This investigation provides additional insights for refining future interventions and potentially facilitates the implementation of effective controlled trials on a larger scale. This web-based self-help intervention was designed for family caregivers of people with dementia and integrated ACT modules with collaborative goal setting based on personal values and weekly nontherapeutic coaching.

Personalizing ACT Interventions Through Goal Setting

In line with previous research, our findings showed that collaborative goal setting based on caregivers' values holds promise as an approach to address the specific needs of caregivers and personalize interventions [36]. In addition, collaborative reflections and guidance played a crucial role in the process of value, need, and resource identification when setting SMART goals as well as adjusting goals or timings throughout the intervention. This adaptability was perceived as necessary due to the continuously changing care demands and concurrent circumstances for caregivers. Multiple participants who set goals consistent with their originally selected values changed their goals focusing on a different value domain. Consistent with previous research, our findings underscore the significance of maintaining flexibility in future intervention designs, allowing for the selection of personally relevant values and value-focused exercises [50].

From the ACT perspective, values are meaningful qualities that cannot be obtained or finished but rather guide long-term patterns of behavior [11]. Subsequently, acknowledging personal values and nesting specific goals underneath them is more likely to drive effective behavior change in the long term [51]. Thus, the shift in focus to a different value domain may represent a potential intervention effect, enhancing caregivers' motivation to align their lives with their values. Further investigation is also warranted to closely examine the factors that drive caregivers to modify their value-based goals following their involvement in a value-based intervention. Such an exploration will shed light on whether these changes in goals are motivated by a genuine desire of caregivers to align their lives with their core values.

In the context of personalizing ACT interventions, facilitating skill building and modifying behavioral responses in older adults with regard to potential concurrent challenging circumstances (eg, health conditions) might be especially important [52]. Moreover, technology offers opportunities to personalize future interventions by providing real-time feedback or guidance (eg, using experience sampling methodology and "just-in-time" interventions), promoting engagement with and managing multiple goals over time, simplifying complex goals, and facilitating collaborative or interactive reflections [53]. Personalizing eHealth interventions for future studies is particularly noteworthy as person-centered (family) care emerges as a crucial scope of research in the path of global dementia care [54].

Utility of ACT for Behavior Change in Caregivers

Our findings suggest that ACT contributes to an increase in perceived psychological flexibility and perspective taking. For some caregivers, increased psychological flexibility might enable them to prioritize focusing on personal growth and self-care as well as embracing challenges over acquiring high goal attainment scores or external validations and motivation (eg, those provided by the coach) [55]. However, perspective taking for some caregivers did not lead to a reported change in behavior.

For some caregivers, defining an appropriate goal or putting goals into action was challenging due to concurrent circumstances (eg, comorbidities). Family caregivers noted that, despite their change in attitude through practicing ACT, reconfiguring their habitual responses based on the new insights from ACT remained challenging in certain situations. It was difficult to adopt a new mindset and avoid reacting impulsively, especially in response to the unpredictable symptoms of the person with dementia. This suggests that behaviors may be triggered by contextual cues rather than being solely the result of mindful attention or personal willpower [56].

This finding is in line with that of previous research highlighting that habits might impact the relationship between attitudes and behavior, resulting in the regulation of desirable behavior change in the long term. Therefore, a change in attitude in caregivers, although crucial for behavior change, might be influenced by situational factors (eg, behavioral symptoms of the person with dementia), potentially making them less reliable predictors of behavior [56]. Addressing habit formation in the context of dementia caregiving is particularly noteworthy as behavioral symptoms and the deteriorative nature of dementia might lead to an unstable, impulsive, unpredictable, and stressful context for caregivers.

Future design of behavior change interventions can target habit formation and the interplay between attitudes and habits for the consolidation of effective upskilling and long-term behavior change in caregivers. This effort may involve developing ACT interventions with additional modules, such as behavior modification strategies for managing disruptive behaviors [13], tailored mindfulness, or habit reversal training [57]. In this endeavor, specific attention to discovering intervention mechanisms may benefit from the use of experience sampling methodology as a quantitative approach [58].

In addition, several participants in this study suggested the inclusion of an explicit module addressing the specific context of dementia and dementia caregiving. Accordingly, a module designed to incorporate ACT principles and provide guidance on managing dementia-specific challenges, such as effectively managing repetitive questions from people with dementia, could significantly enhance the applicability of ACT to their unique situation. This result is in line with those of previous research highlighting that caregiving itself is a natural value for caregivers [59]. The future development of ACT interventions for caregivers can be centered on values associated with caregiving (ie, maintaining care and improving the relationship with the person with dementia) while allowing for variations among different caregiver profiles based on their individual value preferences [28]. Further empirical research is now needed for further evidence-based understanding of the impact of value commitment on caregiver and care recipient outcomes.

Guided Self-Help Interventions for Caregivers

In the context of caregiving, adhering to web-based self-help interventions and incorporating them into everyday life commitments is thought to be improved by embedding more personal retention approaches (eg, telephone calls), provision of flexibility, personalization, scalability, and guidance [4,14,23]. Our study showed that a web-based self-help ACT intervention with synchronous motivational coaching was highly feasible and acceptable for family caregivers, suggesting that ACT and skill building can be learned through self-help [24].

It is important to recognize the coach's significant role in enhancing adherence, motivation, and confidence in technology use as well as fostering a willingness to adopt eHealth among family caregivers of people with dementia. In line with previous research, our findings suggest that providing training on technological features and access to troubleshooting might be beneficial for caregivers with lower digital literacy as, this way, they might be less likely to perceive eHealth as difficult, incompatible, or ineffective. Furthermore, including dedicated coaches for guidance and offering technical support might more likely generate a positive attitude toward eHealth [29].

Although this study provided insights into the role of coaching in maintaining intervention adherence, providing resource-heavy support does not reflect how ACT-based programs are often used at a broader scale and outside the research context [48]. Future designs of personalized and guided eHealth interventions can explore how technology can provide additional support to health care professionals as providers to reduce personal resources and also facilitate the design of effective and implementable interventions on a large scale. Subsequently, guided self-help interventions for family caregivers can evaluate the effects of varying degrees of contact, allowing for the realization of what is the minimum amount of contact that should accompany self-help to obtain the maximum benefit [60]. To support effective, acceptable, and sustainable interventions, future approaches could involve caregivers in the process of designing interventions to capture both the context and dementia-specific needs of caregivers to be tested in larger samples [9].

Adapting ACT to a Web-Based Format for Older Adults

Although websites are the most common way of delivering web-based ACT interventions and are typically more feasible for researchers to build [61], our results showed the preference of some participants to use the intervention via their mobile phones (web application). Considering that mobile apps are more accessible and are the most commonly accessed method of self-help, future research can consider ACT-based apps for family caregivers to address the discrepancy between the ACT literature and real-world practice [48]. This technological development is noteworthy for bridging the gap to make therapy available, accessible, and affordable for larger populations of family caregivers who do not need heavy support [62]. Implementing interventions in the real world is essential for caregivers as, despite the need for behavior change interventions, most feasible and effective eHealth interventions for family caregivers of people with dementia are not yet ready for implementation and, thus, not implemented in the real world [63].

Strengths and Limitations

This study introduced a blended intervention to address the crucial need for effective interventions in dementia caregiving by exploring the feasibility of a web-based ACT intervention tailored for this population. The strengths of this study lie in its contribution to the need for further evidence-based interventions in the area of ACT and family care, paving the way for future controlled trials and intervention refinement. Additional strengths include high adherence rates, flexibility in delivering the intervention to a diverse population of caregivers of people with dementia, and shedding light on barriers and facilitators that family caregivers experienced over the course of the guided web-based self-help intervention. The mixed methods approach combined quantitative adherence rates and qualitative caregiver feedback for a comprehensive understanding of the intervention.

Nevertheless, this study might be influenced by potential biases, and when interpreting the findings, it is crucial to acknowledge its limitations. Although conducting feasibility studies before an RCT can ensure the design of studies with a higher likelihood of success, the small sample size in this study necessitates caution when generalizing the results to a larger population of caregivers of people with dementia. The study sample size was relatively small (N=30), which may limit the generalizability of the findings. Larger samples are required to draw more robust conclusions and account for potential individual differences among caregivers. In addition, the study duration was 9 weeks, and it lacked a control group, which made it challenging to determine whether the observed positive outcomes were solely due to the intervention or whether other factors may have contributed to the results. Conducting larger studies with long follow-up assessments and including a control group would provide a better basis for assessing this guided web-based intervention.

Participation in the study was voluntary and occurred over the web. Thus, individuals who chose to participate may not constitute a fully representative sample, potentially skewing toward those who are more technologically savvy with higher levels of education and greater familiarity with technology. It is crucial to acknowledge this selection bias and consider generalizability concerns when interpreting the findings. ACT principles underscore that individuals do not always have the autonomy to select the content of any given situation. To convey this concept, ACT uses metaphors that may necessitate intellectual engagement and abstract reasoning [10]. Considering the above-average level of education among the study participants and the availability of a trained coach for questions, our findings may not be broadly generalizable to caregivers with lower digital literacy or a lower educational background.

We used a guided ACT-based intervention blended with other non-ACT complementary techniques (eg, goal setting) and components (eg, weekly coaching), which might have had therapeutic effects. Specifically, some caregivers received more than the anticipated 20 minutes of coaching, leading to an unequal distribution of coaching among participants. This variability, as well as the use of self-report questionnaires, could potentially influence the generalizability of the study findings. In addition, most caregivers were at an early stage of caregiving and cared mainly for people with Alzheimer disease, limiting the understanding of how the intervention works across different contexts and stages of dementia caregiving.

Conclusions

This study was conducted to evaluate the feasibility and acceptability of a guided web-based self-help ACT intervention for family caregivers of people with dementia. The high adherence rate and positive feedback from caregivers indicate the intervention's feasibility and acceptability. The findings suggest that family caregivers can learn ACT principles and use them to enhance their psychological flexibility through self-help. Moreover, personalizing the intervention through collaborative goal setting based on individuals' values was found to be promising for addressing the specific needs of caregivers. The findings also suggest that ACT can be adapted to a web-based format, increasing accessibility and scalability for a diverse and large sample of caregivers. However, the absence of a control group and small sample size limit the drawing of definitive conclusions. Some caregivers faced challenges in translating new skills into behavior change due to habitual responses. Larger controlled trials are needed to validate the feasibility in a more diverse caregiver sample and determine the effectiveness of ACT-based interventions in this population. This study highlights the need for future interventions to address habit formation and the interplay between attitudes and habits in unpredictable and continuously changing caregiving contexts. In addition, exploration of the impact of value-based behavior on caregiver and care recipient outcomes should be considered in further research. It is hoped that the results of this feasibility study will pave the way for future effective controlled trials and the implementation of evidence-based research in real-world settings.

Acknowledgments

The authors express their sincere gratitude to all family caregivers who participated in this research, acknowledging their enthusiasm and willingness to share their experiences. We also appreciate the presence of Roos Roberts for their dedication during screening and coaching sessions, which has made valuable contributions to this study. The research presented in this paper received funding from the European Union's Horizon 2020 research and innovation program under the Marie Sklodowska-Curie grant agreement 813196 and was carried out within the framework of the Dementia: Intersectorial Strategy for Training and Innovation Network for Current Technology (DISTINCT) Innovative Training Network.

Abstract

Background: The increasing prevalence of Alzheimer disease and Alzheimer disease–related dementia in the United States has amplified the health care burden and caregiving challenges, especially for caregivers of people living with dementia. A web-based care planning tool, Olera.care, was developed to aid caregivers in managing common challenges associated with dementia care.

Objective: This study aims to preliminarily evaluate the quality and usability of the Olera.care platform and assess the preferences of using the technology and interests in learning about different older adult care services among caregivers.

Methods: For interview 1, we aim to understand caregiving needs and let the participants start engaging with the platform. After they engage with the platform, we schedule the second interview and let the participants complete the Mobile Application Rating Scale. The survey also included sociodemographic characteristics, caregiving experiences, communication preferences in technology adoption, and older adult care service use and interests. Descriptive statistics were used to describe the quality and usability of the platform and characteristics of the participants. We conducted 2-sample 2-tailed *t* tests to examine the differences in the Mobile Application Rating Scale evaluation scores by caregiver characteristics.

Results: Overall, 30 adult caregivers in Texas completed the evaluation. The majority were aged ≥50 years (25/30, 83%), women (23/30, 77%), White (25/30, 83%), and financially stable (20/30, 67%). The Olera.care platform evaluation showed high satisfaction, with an overall mean rating of 4.57 (SD 0.57) of 5, and scored well in engagement (mean 4.10, SD 0.61), functionality (mean 4.46, SD 0.44), aesthetics (mean 4.58, SD 0.53), and information quality (mean 4.76, SD 0.44) consistently across all participants. A statistically significant difference (P=.02) was observed in functionality evaluation scores by duration of caregiving, with caregivers dedicating more hours to care rating it higher than those providing less care (mean 4.6, SD 0.4 vs mean 4.2, SD 0.5). In addition, caregivers with less caregiving experience reported significantly higher evaluation scores for aesthetics (P=.04) and information quality (P=.03) compared to those with longer years of caregiving. All participants expressed a willingness to recommend the app to others, and 90% (27/30) rated the app overall positively. Most of the participants (21/30, 70%) favored anonymous interactions before receiving personalized feedback and preferred computer browsers over mobile apps. Medical home health services were the most used, with a diverse range of services being used. Caregiver support groups, medical providers, memory care, meal services, and adult day care were among the most desired services for future exploration.

Conclusions: The Olera.care web-based platform is a practical, engaging, easy-to-use, visually appealing, and informative tool for dementia caregivers. Future development and research are essential to enhance the platform and comprehensively evaluate it among a broader population.

Introduction

Background

With the population of Americans living with Alzheimer disease (AD) and AD-related dementia projected to grow from 6.7 million to 13.8 million by 2060, there is a need for effective and innovative solutions to address the increasing health care burden, particularly with caregivers of people living with dementia [1,2]. Oftentimes, these caregivers are unpaid or informal family members or friends who provide care mostly related to activities of daily living [3,4]. Due to the variability in disease progression and the caregiver's personal needs, family caregivers encounter diverse unmet needs, including challenges related to the physical and emotional deterioration of the people living with dementia [5-7]. Particularly, caregivers of people living with dementia report difficulties related to assisting the care recipient with activities of daily living, identifying the right older adult living services, navigating the financial and legal aspects of caregiving for people living with dementia, and finding relevant and concise information on dementia and dementia caregiving [5-7]. Due to the multifaceted and individualized burdens that caregivers of people living with dementia face, they are particularly susceptible to experiencing emotional, physical, and financial challenges that increase with disease progression [3,6,7].

To aid informal caregivers with challenges related to dementia care, many digital technologies have been developed that focus on either the needs of the caregiver or of the people living with dementia [8]. These solutions range from web-based training to web-based forums and caregiving groups, psychological and educational forums, and videoconferencing technologies [9,10]. Despite the many digital interventions to aid caregivers and their care recipients, these solutions do not adequately address the individual needs of caregivers of people living with dementia, leading to limited adoption of technologies outside of pilot studies [5,11]. Previous studies have shown that, despite the availability of digital interventions, the unique and individual needs of caregivers of people living with dementia are not always adequately addressed, leading to limited technology adoption and potentially contributing to sustained or increased emotional, physical, and financial burdens associated with caregiving [6,9]. To increase the use of technology that aids caregivers of people living with dementia, technology development should involve caregivers' feedback on usability and align with caregivers' expectations and needs [7,12,13]. However, not many studies have investigated the usability and usefulness of technology interventions for dementia care or involved caregivers of people living with dementia in the development process to accurately address caregivers' needs [10,12,14-16].

With the plethora of digital technologies available today to aid in dementia caregiving, there is a need for an evidence-based, engaging, adaptable, and preference-based platform for informal caregivers of people living with dementia to aid them in identifying resources and education on dementia relevant to their and their care recipient's needs [5,7,11,17]. Previously, our qualitative study reported that caregivers are looking for several features in such a web-based navigation and resource platform: "(1) a comprehensive database of commonly needed professional services, (2) mental health and caregiver support groups, (3) educational resources on dementia and caregiving, [and] (4) a platform that is easy to use, aesthetic, reliable, and interactive" [5]. Some current solutions that function as resource finders or navigators include the Community Resource Finder by AARP and the Alzheimer's Association, the Alzheimer's Navigator by the Alzheimer's Association, and CareNav by the Family Caregiver Alliance. While these web-based tools provide databases and tips for locating resources and education on dementia and caregiving, they do not provide categorized recommendations or resources tailored to the stage of dementia of the people living with dementia and based on caregiver characteristics and preferences.

The overall performance rating of a digital app by users is greatly affected by several behavioral factors according to the theory of planned behavior, which states that an individual's intention to use or adopt technologies is greatly influenced by their attitude toward the technologies [18,19]. Thus, the more favorably a caregiver views a technological intervention, the more likely they will be to adopt and use the product. In addition, an individual's adoption of a technological intervention is greatly influenced by their perception of technology self-efficacy, which is defined as an individual's confidence in applying a technology to perform a task [20-23]. The more positive an individual's attitude and initial experience, the more likely they are to use the technology as their perceived self-efficacy increases [24]. The Mobile Application Rating Scale (MARS) is a widely used tool to test the performance of health mobile apps and digital platforms based on the functionality, design, information quality, engagement, and subjective quality of the digital apps [25].

Objectives

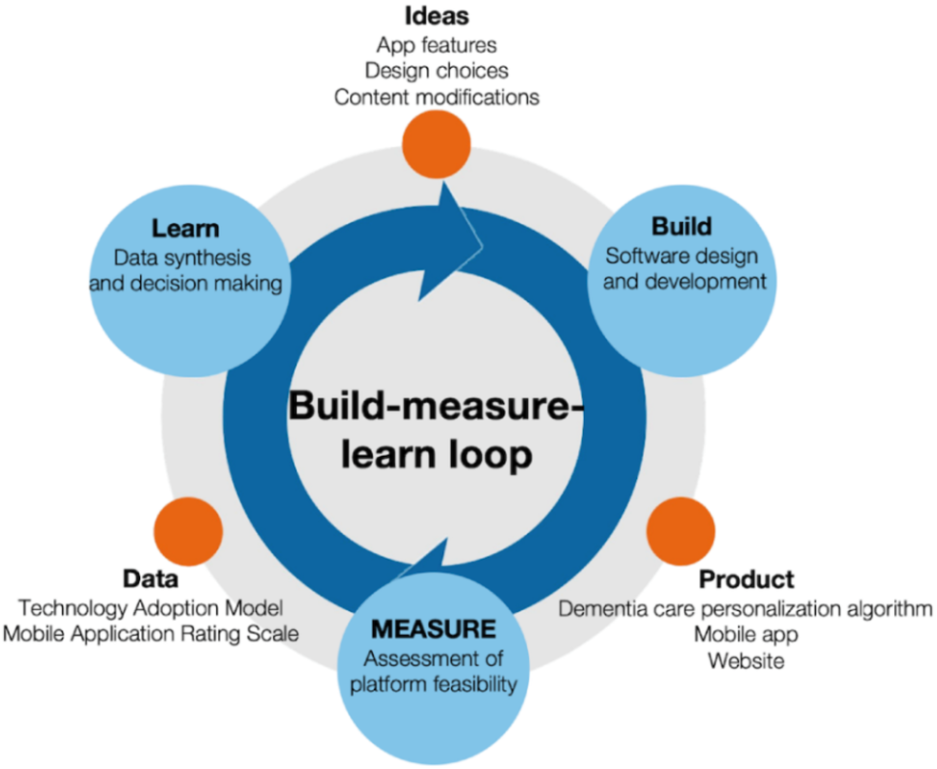
To address caregivers' needs and expectations of a web-based platform to assist them in the care of their care recipient, we developed a web-based care planning tool, Olera.care, that assists caregivers in navigating common challenges by supplying personalized recommendations and curated sets of resources (eg, care services, products, and professionals) as well as education on dementia and caregiving for people living with dementia. This pilot study aims to evaluate the functionality and usability of the initial Olera.care platform for caregivers of people living with dementia in addressing their needs with personalized education and resource matching.

Methods

Overview

This pilot study was conducted to support the development and evaluation of the usability of the Olera.care digital platform. The development and testing of the platform adopt an iterative “build-measure-learn” approach (Figure 1) that places caregivers at the forefront of design and development, ensuring that our platform continually evolves to meet their evolving needs and expectations [26]. This framework ensures that our platform iteratively evolves through an ongoing process of design and development, incorporating frequent touch points with family caregivers to assess the usability and functionality of a given prototype and align subsequent development with caregiver wishes and expectations for digital assistance technology. Participants in the study were engaged in 2 rounds of Zoom (Zoom Video Communications, Inc) or telephone interviews from January 2022 to May 2022 to (1) understand their caregiver needs, (2) engage with the platform, and (3) complete a technology survey assessment, including the modified MARS, via a Qualtrics (Qualtrics International Inc) web-based form. Each MARS item used a 5-point scale to assess the engagement, functionality, aesthetics, and information quality of the Olera.care digital platform among unpaid caregivers of people living with dementia in Texas.

Figure 1. The build-measure-learn approach used to research and develop Olera.care.

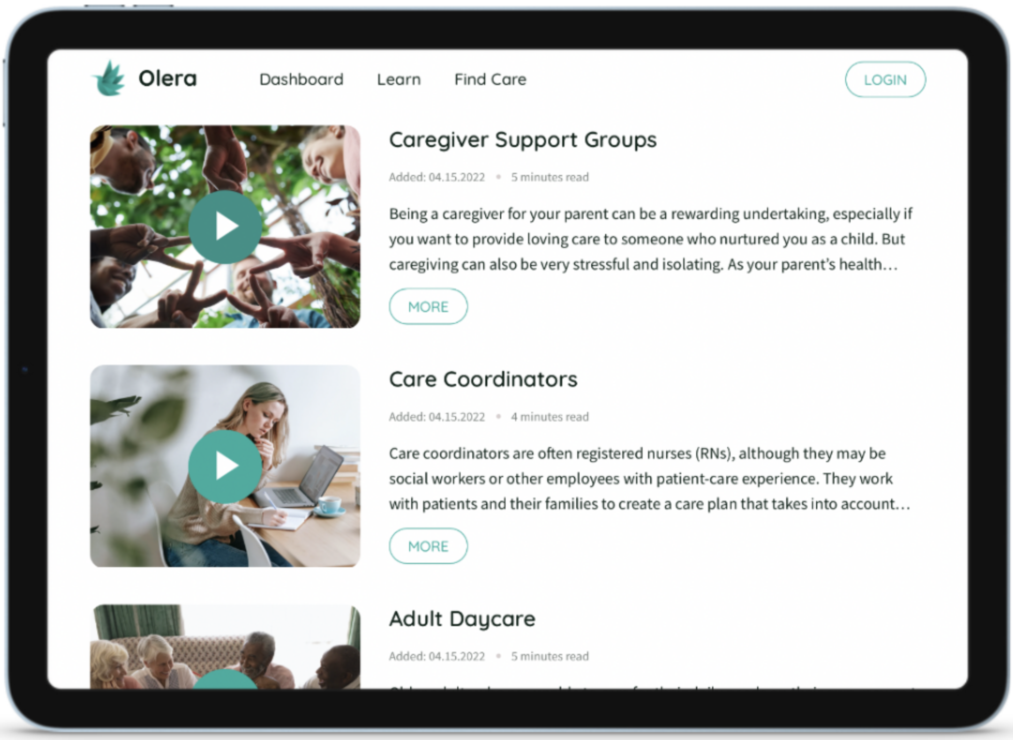


Platform Development and Testing

Development of a Digital Platform Capable of Providing Personalized Information on the Legal, Financial, and Estate Planning Aspects of Caregiving for Dementia, Including Information on Local Resources Most Relevant to Caregivers

We developed a robust web application that provides tailored educational videos and articles on topics associated with the most prominent challenges and struggles that caregivers of people living with dementia face as evidenced by our previous work identifying common pain points in the caregiving journey [5]. Personalized information is curated based on answers to a caregiving questionnaire and an algorithm developed to sift through a data repository and present the most relevant information pertaining to a user’s circumstances. Our growing content repository currently hosts 66 original articles and video postings that cover various topics, including legal, financial, and estate planning. In addition to personalized education, the developed web application can present tailored listings of relevant professionals in the legal, financial, home care, older adult living, and older adult care coordination industry (Figure 2). Credentialed professionals are presented in a personalized directory that is curated based on our algorithm’s assessment of caregivers’ current professional needs, preferences, and geographic location.

Figure 2. Content repository example of the Olera.care platform.



Caregiver Support Groups

Added: 04.15.2022 • 5 minutes read

Being a caregiver for your parent can be a rewarding undertaking, especially if you want to provide loving care to someone who nurtured you as a child. But caregiving can also be very stressful and isolating. As your parent's health…

Care Coordinators

Added: 04.15.2022 • 4 minutes read

Care coordinators are often registered nurses (RNs), although they may be social workers or other employees with patient-care experience. They work with patients and their families to create a care plan that takes into account…

Adult Daycare

Compilation and Management of Relevant Financial, Legal, and Estate Planning Resources Available in Our Target Area

We have created a repository database that includes information on >22,000 professional service providers and 66 original educational articles or videos. This database is integrated with our web application's user interface to allow users to sort through it quickly and effortlessly for information most relevant to their current needs (Figure 3). Of note, relevant service providers included in our database are certified financial planners, Medicare insurance agents, older adult law attorneys, older adult care planners, older adult housing facilities (memory care and assisted or independent living), rehabilitation centers, hospice or palliative care agencies, and in-home professional caregivers as well as home health services. These services have been included because of direct commentary noted on interviewing current dementia caregivers about their service needs when providing AD and AD-related dementia family caregiving for a loved one [5].

Recommended providers: Elder Law Attorney

Preliminary Assessments of the Usability and Functionality of the Technology Using Techniques Such as End-User Surveys and Real-Time Monitoring

We evaluated the usability and functionality of our caregiver support platform with a pilot panel of 30 current family caregivers of persons living with dementia who met our eligibility criteria. Participants interacted with the web application in a test environment. They were asked to use the main functions and rate the usability and functionality on a modified MARS, which is a well-established instrument used as a benchmark for digital health apps. In addition, real-time monitoring during participation helped researchers identify areas for improvement in the user experience.

Participant Eligibility and Recruitment

Participants were recruited through academic and community networks, such as the Texas A&M University Center for Community Health and Aging and the Brazos Valley Area Agency on Aging. We used both traditional and digital channels to reach out to potential participants. These included printed materials such as physical or electronic flyers, outreach emails, and social media platforms (eg, Facebook, Instagram, and Twitter) as well as engagement with web-based forums such as local caregiver support group meetings.

Individuals expressing interest in participating in the study were provided 2 options to complete the eligibility screening: participants could access a web-based form by following the recruitment materials' QR code or web link; alternatively, they could contact the Olera.care team via telephone to obtain information about the study and take the eligibility screening survey over the telephone.

The eligibility screening survey collected relevant information to examine whether interested individuals met the following inclusion criteria: (1) be aged ≥18 years; (2) be a nonpaid caregiver of a person living with dementia; (3) be the adult child, spouse or partner, other family member, or legal guardian of a person living with dementia; (4) be engaged in making legal or financial, older adult living, or medical decisions for a person living with dementia; (5) be seeking older adult care services in Texas; and (6) have access to a smartphone or computer with internet access.

After the eligibility screening process, participants who met the inclusion criteria were asked to provide their full name, contact information, preferred mode of contact (ie, telephone or email), and preferred day and time for subsequent outreach by the research team.

Ethical Considerations

Ethics approval was obtained from the Texas A&M University Institutional Review Board (2021-0943D). The study personnel asked all participants to provide electronic informed consent in the screening survey. Upon the completion of the eligibility screening survey, participants were presented with an informed consent document. This document provided instructions on how to convey their consent to participate in the study and their willingness to be recorded and followed up via the Qualtrics platform. The consent form covered important information, including the rationale for inclusion; the research objectives; the voluntariness of participation with the option to withdraw at any point; the anticipated participation duration and procedures; the potential risks, benefits, and costs of participation; and how participant confidentiality would be protected.

Assessments and Measurements

Evaluating the Quality of the Olera.care Platform Using the MARS

We used the MARS as a robust assessment tool to evaluate the quality of the Olera.care platform among the caregiver participants. The MARS provides a multidimensional assessment of the engagement, functionality, aesthetics, information quality, and overall subjective quality of the Olera.care platform. To tailor the assessment to our study's specific context, we selected 13 items from the MARS questionnaire that were directly relevant to the Olera.care platform. Our methodology for adapting the MARS questionnaire was 2-pronged: first, we evaluated and retained items based on their relevance to our platform's functions, omitting nonapplicable elements such as gestural design; and second, we modified the wording of the retained items to better reflect our platform's unique features. These items were adapted and modified for our assessment objectives while retaining the original item classification across the 5 dimensions. The modified items and responses, while maintaining the integrity of the MARS, ensure an effective evaluation of our digital platform. Participants provided ratings for each MARS item using a 5-point scale (1=inadequate, 2=poor, 3=acceptable, 4=good, and 5=excellent), with each response tailored to the content of the respective item. An overall subjective quality rating of ≥3.6 was set as the threshold to indicate good usability and quality of the Olera.care platform according to past literature [27], allowing us to effectively report the platform's overall quality from assessment among the caregiver users.

Assessing Willingness, Self-Efficacy, and Communication Preferences in Technology Adoption

To understand the willingness and preference for technology use, we further assessed participants' intention to use the Olera.care platform, self-efficacy for using the technology, and preferences for web-based communication and platform format. The participants were asked whether they would like to use the technology in the future, with the response options being "yes," "maybe," and "no." They were also asked about their confidence level in using the technology, with the response options being "uncertain," "neither certain nor uncertain," "somewhat confident," and "very confident." In addition, participants were asked about their preference for anonymity when seeking information on the internet and whether they would consider sharing personal information for receiving individualized answers. The net promoter score, which was created in 2003 and has been used in a variety of industries such as insurance, technology services, communications, and health care [28], was used to evaluate the willingness of participants and provide insights for user experience management. Responses on a scale ranging from 0=strongly disagree to 10=strongly agree were used. Scores from 0 to 6 were classified as *detractor*, scores of

7 and 8 were categorized as *passive*, and scores of 9 and 10 were designated as *promoter*. Participants were also asked whether they preferred a website-based format or a mobile app format.

Assessing the Use of, and Interests in, Older Adults Care Services Among Caregivers

To gain a deeper understanding of our targeted population's preferences and needs for planning older adult care and to continually enhance and optimize our platform, we assessed the level of interests in older adult care services among caregivers. Caregivers were presented with 21 types of older adult care services (eg, home health, hospice care, memory care, caregiver support group, and assisted living), and they were asked to select ≥1 of the following responses: "currently using," "have used before," "would like to learn more," and "would never use." This assessment allowed us to gather valuable insights into caregivers' engagement and interests in various older adult care options, informing our efforts to better serve their needs.

Sociodemographic and Caregiving Characteristics of Caregivers

We collected the sociodemographic and caregiving characteristics of participants to understand how representative our study population was for the Texas caregiver profile and whether the major platform evaluation outcomes differ by the background characteristics of participants. The caregiver characteristics collected included age, sex, race, ethnicity, the highest level of education completed, employment status, general financial status, caregiving role, and length of providing care.

Analysis

Descriptive statistics were used to describe the engagement, functionality, aesthetics, information quality, and subjective quality of the platform and caregiver characteristics and responses. Mean scores and SDs were calculated for each MARS item. We conducted 2-sample 2-tailed *t* tests to compare the differences in the major MARS evaluation scores by caregiver characteristics. All analyses were conducted using Stata (version 17.0; StataCorp LLC).

Results

Participants' Characteristics

Of the initial 822 respondents who completed the prescreening surveys, 150 (18.2%) met the eligibility criteria, of whom, after excluding 115 (76.7%) individuals for not being available to attend interviews, 35 (23.3%) were enrolled into the study. Of these 35 enrolled individuals, 30 (86%) interacted with the platform and completed the study survey of technology evaluation and caregiving needs (Figure 4). The sociodemographic and caregiving characteristics of participants are summarized in Table 1.

Of the 30 participants, the majority were aged ≥50 years (n=25, 83%), women (n=23, 77%) , White (n=25, 83%), non-Hispanic (n=27, 90%), had bachelor's or graduate degrees (n=22, 73%), and were employed for wages (n=12, 40%) or retired (n=12, 40%). Financially, 67% (20/30) had surplus funds at the end of each month, while 30% (9/30) just about managed to meet their expenses or faced deficits. Most of the participants were recruited via email invitations (13/30, 43%) or web-based advertisements (11/30, 37%), with some also recruited through in-person presentations and personal connections (5/30, 17%). In terms of caregiving characteristics, the majority of the participants identified themselves as primary caregivers (20/30, 67%), reported to have provided care for at least 1 year (28/30, 93%), and dedicated at least 20 hours weekly to caregiving in the past 3 months (21/30, 70%).

Quality Assessment of the Olera.care Platform

Overview

The descriptive statistics of the Olera.care platform evaluation by the MARS dimensions and items are presented in Table 2.

The mean overall satisfaction rating of the Olera.care platform among the participants was 4.57 (SD 0.57) of 5. Mean scores for engagement, functionality, aesthetics, and information quality were 4.10 (SD 0.61), 4.46 (SD 0.44), 4.58 (SD 0.53), and 4.76 (SD 0.44), respectively.

Table 2. Modified Mobile Application Rating Scale items and responses of participants.

Dimensions, items, questions, and response items	Participants, n (%)	Score, mean (SD)
Engagement		4.10 (0.61)
Entertainment: compared to other older adult care finders, websites, or alternative resources for older adult care information you may have used, do you think this app is fun to use?		3.67 (0.80)
Highly entertaining	5 (17)	
Fun	11 (37)	
OK, fun enough	13 (43)	
Mostly dull	1 (3)	
Dull	0 (0)	
Interestingness: compared to other older adult care finders, websites, or alternative resources for older adult care information you may have used, does this app present its content in an interesting way?		4.53 (0.57)
Very interesting	17 (57)	
Interesting	12 (40)	
Slightly interesting	1 (3)	
Mostly uninteresting	0 (0)	
Not interesting	0 (0)	
Functionality		4.46 (0.44)
Performance: how well do the app's features, components, and buttons work?		4.57 (0.57)
Works perfectly	18 (60)	
Very functional	11 (37)	
App works overall	1 (3)	
Some functions work	0 (0)	
App is broken	0 (0)	
Ease of use: how easy is it to learn how to use the app?		4.57 (0.50)
Very simple	17 (57)	
Easy to learn	13 (43)	
Usable	0 (0)	
Somewhat confusing	0 (0)	
Very confusing	0 (0)	
Navigation: does moving between pages make sense?		4.28 (0.59)
Moving between pages is perfectly logical, easy, clear and intuitive	10 (33)	
Moving between pages is easy to understand and navigate	17 (57)	
Moving between pages is understandable after some time and effort	2 (7)	
Moving between pages is understandable after a lot of time and effort	0 (0)	
Moving between pages is difficult	0 (0)	
Missing	1 (3)	
Aesthetics		4.58 (0.53)
Visual appeal: how good does the app look?		4.53 (0.63)
Very visually appealing	18 (60)	
High-level visual appeal	10 (33)	
Some visual appeal	2 (7)	
Little visual appeal	0 (0)	
No visual appeal	0 (0)	
Graphics: how high is the quality of graphics, buttons, and content?		4.53 (0.63)

Dimensions, items, questions, and response items	Participants, n (%)	Score, mean (SD)
Very high quality	18 (60)	
High quality	10 (33)	
Moderate quality	2 (7)	
Low quality	0 (0)	
Very poor quality	0 (0)	
Layout: how would you rate the design? Are the arrangement and size of buttons and content on the screen appropriate?		4.67 (0.61)
Very professional	22 (73)	
Mostly professional	6 (20)	
Satisfactory	2 (7)	
Bad design	0 (0)	
Very bad design	0 (0)	
Information		4.76 (0.44)
Accuracy of app description: after reviewing the home page, does the app contain what is advertised and described?		4.79 (0.41)
Highly accurate	23 (77)	
Mostly accurate	6 (20)	
Somewhat accurate	0 (0)	
Slightly misleading	0 (0)	
Very misleading	0 (0)	
Missing	1 (3)	
Quality of information: is the content in the app relevant to helping with older adult care planning?		4.76 (0.44)
Highly relevant	22 (73)	
Relevant	7 (23)	
Moderately relevant	0 (0)	
Barley relevant	0 (0)	
Irrelevant content	0 (0)	
Missing	1 (3)	
Quality of visual information: are images, videos, and graphics clear and easily understandable?		4.73 (0.45)
Perfectly clear	22 (73)	
Mostly clear	8 (27)	
Somewhat clear	0 (0)	
Mostly unclear	0 (0)	
Completely unclear	0 (0)	
Subjective quality		4.15 (0.51)
Stimulates repeat use: how many times do you think you would use this app in the next 12 months if it was relevant to you?		3.77 (0.86)
>50	6 (20)	
10-50	13 (43)	
3-10	9 (30)	
1-2	2 (7)	
None	0 (0)	
Worth recommending: would you recommend this app to people who might benefit from it?		4.27 (0.14)
I would recommend this app to everyone	13 (43)	

Dimensions, items, questions, and response items	Participants, n (%)	Score, mean (SD)
There are many people I would recommend this app to	12 (40)	
There are several people I would recommend it to	5 (17)	
There are a few people I would recommend this app to	0 (0)	
I would not recommend this app to anyone	0 (0)	
Overall satisfaction rating: what is your overall star rating of the app? (1 star=poor; 5 stars=excellent)		4.57 (0.57)
5	17 (57)	
4	10 (33)	
3	1 (3)	
2	0 (0)	
1	0 (0)	
Missing	2 (7)	

Engagement

Participants reported high levels of engagement with the Olera.care platform, with 97% (29/30) describing it highly entertaining or fun or fun enough, and 97% (29/30) expressing that it was interesting to interact with.

Functionality

In terms of functionality, the majority of the participants assessed the Olera.care platform positively, with 60% (18/30) perceiving it as working perfectly and 37% (11/30) rating it as very functional. Moreover, 57% (17/30) found it very simple to learn to use, and 43% (13/30) considered it easy to learn. An impressive 90% (27/30) of the participants reported that it was easy to navigate between pages.

Aesthetics

The aesthetics of the platform received favorable feedback from participants, with 93% (28/30) expressing that it was visually appealing, highlighting the high quality of graphics, buttons, and content. The design and layout of the content were described as professional.

Information

In terms of information quality, nearly all participants (29/30, 97%) noted that the app contained relevant and clear information. A substantial 73% (22/30) found the information highly relevant for older adult care planning, while 23% (7/30) considered it relevant. Visual information was deemed perfectly clear by 73% (22/30) of the participants and mostly clear by 27% (8/30).

Subjective Quality

Participants expressed a strong inclination to use the app in in the next 12 months, with 20% (6/30) planning to use it >50 times and 43% (13/30) aiming to use it between 10 and 50 times. Importantly, all participants indicated their willingness to recommend the app to those who may benefit from it. In terms of overall satisfaction, most of the participants rated the Olera.care platform positively, with 57% (17/30) rating it as excellent and 33% (10/30) as very good.

Intention to Use the Olera.care Platform, Self-Efficacy of Technology Use, and Platform Preference

In this study, a substantial proportion of the participants expressed a positive intention to use the Olera.care platform (Table 3), with 90% (27/30) indicating a definite willingness ("yes"), while the remaining 10% (3/30) expressed a more tentative interest ("maybe"). In terms of self-efficacy in using technology, 40% (12/30) of the participants reported feeling "very confident," 57% (17/30) indicated a moderate level of confidence ("somewhat confident"), and 3% (1/30) expressed uncertainty. In the context of online communication with a representative, 70% (21/30) of the participants favored remaining anonymous before sharing contact information. Furthermore, 43% (13/30) of the participants expressed willingness to share personal information to receive personalized assistance. In terms of platform preference, most of the participants (22/30, 73%) preferred the computer browser format, 10% (3/30) preferred to use a mobile app, and 17% (5/30) did not have a preference. This preference for computer browser format directly ties into overall user satisfaction, which is a critical determinant in the net promoter score categorization. Focusing on optimizing this platform could lead to higher user satisfaction and thus more promoters.

Table 3. Intention to use, self-efficacy of use, and preferences for communication and platform.

Questions and response items	Participants, n (%)
Intention to use the app	
Would you use this app?	
Yes	27 (90)
Maybe	3 (10)
No	0 (0)
Self-efficacy to use technology	
When it comes to your confidence in the use of technology, which of the following best describes you?	
Uncertain	1 (3)
Neither certain nor uncertain	0 (0)
Somewhat confident	17 (57)
Very confident	12 (40)
Preferences when asking a representative	
When researching older adult services on the web, I'd appreciate the ability to ask a representative a question anonymously before sharing my contact information (0=strongly disagree; 10=strongly agree).	
9-10 (promoter)	21 (70)
7-8 (passive)	3 (10)
0-6 (detractor)	6 (20)
When researching older adult services online, I would consider sharing personal information (contact information, etc) with a representative to better determine my loved one's fit for the service (0=strongly disagree; 10=strongly agree).	
9-10 (promoter)	13 (43)
7-8 (passive)	6 (20)
0-6 (detractor)	11 (36)
Preference for platform	
When searching online for information on older adult care planning, would you prefer to use a computer browser or download a mobile app?	
Computer browser	22 (73)
Mobile app I can download to my phone	3 (10)
No preference	5 (17)

Caregivers' Use of, and Interests in, Older Adult Care Services

We also examined the current and past use of, as well as interests in, different types of older adult care services among the caregiver participants (Table 4). Among the participants, 63% (19/30) were currently using medical home health services, 33% (10/30) used hospice care, and 30% (9/30) employed certified financial planners. In addition, 27% (8/30) relied on house maintenance service, and 23% (7/30) engaged insurance agents and older adult law attorneys and participated in public and free older adult programs. Memory care, nonmedical home aid, and adult day care each had a 20% (6/30) use rate, while services such as assisted living, independent living, transportation, skilled nursing, medical providers, and rehabilitation facilities were used by 7% (2/30) to 13% (4/30) of the participants. Older adult living referral agents, caregiver support groups, and yard services were used by 3% (1/30) of the participants. The results suggest the diverse range of older adult care services currently being used, with medical home health being the most used service.

Table 4. Caregivers' use of, and interests in, older adult care services (n=30).

Older adult care services	Participants, n (%)
Using currently	
Home health	19 (63)
Hospice care	10 (33)
Certified financial planner	9 (30)
House maintenance	8 (27)
Insurance agent	7 (23)
Older adult law attorney	7 (23)
Public and free older adult programs	7 (23)
Adult day care	6 (20)
Memory care	6 (20)
Professional home caregivers	6 (20)
Have used before	
Professional home caregivers	13 (43)
Older adult law attorney	10 (33)
Rehabilitation facility	10 (33)
Insurance agent	9 (30)
Certified financial planner	7 (23)
Older adult living referral agent	7 (23)
Hospice care	7 (23)
Transportation services	7 (23)
Skilled nursing	6 (20)
Home health	6 (20)
Public and free older adult programs	6 (20)
Would never use	
Yard services	8 (27)
Certified financial planner	7 (23)
House maintenance service	7 (23)
Care manager	7 (23)
Insurance agent	5 (17)
Independent living	5 (17)
Assisted living	4 (13)
Meal service	4 (13)
Memory care	3 (10)
Rehabilitation facility	3 (10)
Older adult living referral agent	3 (10)
Would like to learn more	
Caregiver support group	24 (80)
Medical providers	23 (77)
Memory care	19 (63)
Meal service	19 (63)
Adult day care	19 (63)
Older adult living referral agent	18 (60)

Older adult care services	Participants, n (%)
Transportation services	18 (60)
Care manager	18 (60)
Skilled nursing	17 (57)
Assisted living	17 (57)
Public and free older adult programs	17 (57)

Regarding past use, 43% (13/30) had previously used nonmedical home aid, and 33% (10/30) had engaged older adult law attorneys and used rehabilitation facilities. Insurance agents were consulted by 30% (9/30) of the participants, and 23% (7/30) had used certified financial planners and older adult living referral agents, as well as hospice care and transportation services. Skilled nursing, medical home health, and public and free older adult programs were previously used by 20% (6/30) of the participants, while independent living and adult day care had a use rate of 17% (5/30). Memory care, assisted living, meal services, and yard services were used by 13% (4/30), while house maintenance, care managers, and medical providers were used by 7% (2/30). Caregiver support groups were attended by 3% (1/30) of the participants.

In terms of preferences for further exploration, 80% (24/30) expressed interest in learning more about care support groups, while 77% (23/30) were interested in understanding medical providers better. In addition, 63% (19/30) showed interest in memory care, meal services, and adult day care. Furthermore, 60% (18/30) were interested in older adult living referral agents, transportation services, and care managers. An additional 57% (17/30) desired to learn more about skilled nursing, assisted living, and public and free older adult programs. Interestingly, all older adult care services were mentioned as areas of interest by participants.

For services that would never be considered, some of the participants (18/30, 60%) indicated reluctance toward specific services, with yard services (8/30, 27%), certified financial planners (7/30, 23%), and house maintenance (7/30, 23%) being among those mentioned, while none expressed a definitive refusal to consider nonmedical home aid or hospice care.

Platform Feature Evaluation Results by Participants' Characteristics

We conducted 2-sample *t* tests to assess variances in platform feature evaluation results based on caregivers' characteristics, providing mean scores and SDs for reporting (Multimedia Appendix 1). The evaluation results for the Olera.care platform, spanning engagement, functionality, aesthetics, information quality, and overall satisfaction, were notably consistent across all caregiver groups. However, a statistically significant difference (*P*=.02) was observed in the functionality evaluation scores, with caregivers dedicating at least 20 hours to care (mean 4.6, SD 0.4) rating it higher than those providing less care (mean 4.2, SD 0.5). In addition, caregivers with <5 years of caregiving experience reported significantly higher evaluation scores for aesthetics (mean 4.7, SD 0.4 vs mean 4.3, SD 0.7; *P*=.04) and information quality (mean 4.8, SD 0.2 vs mean 4.6, SD 0.3; *P*=.03) compared to those with a minimum of 5 years of caregiving experience.

Discussion

Principal Findings

This research lays the foundation for the development of digital tools tailored to the needs of caregivers. The principal findings involve the quality and usability of the Olera.care platform, a web-based care planning tool designed to assist caregivers of people living with dementia in addressing their legal and financial needs and enable them to access functional care services. The results suggest that the Olera.care web tool is a practical, engaging, easy-to-use, visually appealing, and informative digital platform designed to provide resources that address common challenges faced by family caregivers of people living with dementia [5]. The study assessed caregivers' intentions to use the Olera.care platform, their expectations for caregiving educational content, and their preferences for web-based information delivery. These aspects are crucial in our iterative build-measure-learn framework of research and development, which underpins our commitment to caregiver-centric product design.

The results indicate that the tested Olera.care web tool can distinguish itself not only in terms of practicality and user-friendliness but also in the quality of its content and its degree of personalization. We acknowledge existing solutions such as the Community Resource Finder by AARP and the Alzheimer's Association, the Alzheimer's Navigator by the Alzheimer's Association, and CareNav by the Family Caregiver Alliance. These platforms offer valuable databases and guidance for dementia caregiving. However, our Olera.care platform differentiates itself by providing recommendations and resources that are not only categorized but also personalized and tailored to the caregiver's specific characteristics and preferences. This unique aspect of Olera.care addresses a gap in current offerings and stands in contrast to many currently available web-based information tools such as static web pages, resource directories, or learning modules, which can be inadequate in addressing certain needs due to their lack of user engagement, personalization, relevance, and adoptability [29,30]. By contrast, the Olera.care platform attempts to involve users in the design of the platform and address these issues effectively, and the platform stands out for its interactivity, visual appeal, personalization capabilities, and informative content, making it a valuable resource for family caregivers of people living with dementia.

One noteworthy finding is that participants who devoted more weekly hours to caregiving and had limited cumulative caregiving experience tended to rate the Olera.care platform more favorably. This suggests that the platform offers specific support and benefits to caregivers with heavier caregiving workloads and those with limited prior caregiving experience. This insight underscores the importance of tailoring digital tools to the specific needs of caregivers in different situations, considering their experience and time commitment [29,30]. Such findings are integral to the build-measure-learn framework, guiding the iterative development of the platform to better align with the specific needs of caregivers. Furthermore, the relevance of the Olera.care platform is heightened in the context of the COVID-19 pandemic, which significantly disrupted family caregiving arrangements, as evidenced by more than half of these arrangements being affected [31]. This disruption led to heightened psychological burdens on caregivers, including increased depression, anxiety, and loneliness [31,32]. The pandemic also exacerbated the shortage of professional caregivers, further challenging the support systems for older adult care. Studies highlight the increased stress levels among caregivers, particularly those caring for individuals with severe dementia [33], and the overall strain on mental health resources for both caregivers and patients [34]. With the increasing social and support needs of caregivers, internet-based tools are crucial to help caregivers to access information and gain support [35].

Another significant finding pertains to the use of, and demand for, older adult care services. Many caregivers reported using or intending to use services such as home health, hospice care, insurance agents, older adult law attorneys, and financial planners. However, there is notable interest in exploring other services, such as caregiver support groups, medical providers, skilled nursing, memory care, public and free older adult programs, meal services, adult day care, and various older adult living alternatives. The data indicate that these services are often underused, potentially leading to unmet needs among older adults and their caregivers [36]. This underuse may stem from a lack of awareness about the availability of older adult care services among caregivers [37]. This insight has prompted a shift in our database curation strategy, and we are focusing now on underused yet high-demand care services and programs to make them more readily available to caregivers through our platform.

The high engagement, functionality, aesthetics, and information quality of the Olera.care digital platform can be attributed to several underlying principles and strategies. First, the platform's unique approach of involving caregivers in the design process has proven highly effective. We demonstrated that technology interventions developed with input from the target population will increase overall satisfaction with, and preference for, the product. Second, the curated content and resources of the Olera.care platform, informed by leading experts, have been rated highly relevant by the participants, with 73% (22/30) reporting the content as highly relevant with a mean MARS score of 4.76 (SD 0.44) of 5. This demonstrates the significance of expert guidance in creating a resource that resonates with the target audience [26]. The curated content and resources on the Olera.care platform can be further improved through the incorporation of artificial intelligence and large language models, allowing for improved and personalized recommendations based on an existing recommendation system [38]. Large language models can process large data sets across numerous relevant variables (eg, specific needs, geographic location, and financial constraints) to provide the most appropriate care solutions. To increase the accuracy of the large language model, the data would have to undergo rigorous quality control and standardization. Industry experts that we are currently working with to inform our curated content could also validate the model through feedback on its accuracy and quality. The model's recommendations can also be consistently improved through the input of new data, further increasing the accuracy of its recommendations.

Limitations and Future Research and Practice

It is important to acknowledge the limitations of this pilot study, which we view as opportunities for further learning and refinement within our build-measure-learn framework. First, the small sample size and lack of racial and ethnic diversity among the participants may limit the generalizability of the findings, pushing us to expand our research scope. The participants in this study were also mostly technology savvy and well educated. However, the demographic characteristics of the caregiver participants in this study aligned well with the caregiver profile in the United States (ie, the majority were women: 23/30, 77%; aged ≥50 years: 25/30, 83%; and non-Hispanic White: 25/30, 83%) [39]. The study populations also represented some diversity in financial levels and caregiving experiences. Future research should aim to include a more racially and ethnically diverse study population to ensure a broader representation of caregiver experiences and preferences. Second, all acceptability and usability metrics in this study were self-reported, which could introduce self-report bias. However, we used a validated tool, the MARS [25], which was adapted according to platform features. Third, given the limited sample size and insufficient statistical power in the subgroup analyses, both significant and nonsignificant *t* test results should be interpreted cautiously. Furthermore, the study's short duration of interaction with the digital platform also limits our understanding of the platform's long-term usability and usefulness for caregivers of people living with dementia.

A future study should be conducted with a larger and more diverse group of caregivers, allowing for a more comprehensive assessment of the platform's long-term perceived usability and ease of use, thus enabling us to continually learn and refine the platform. For future practice, we are focused on enhancing the accessibility and visibility of our web application for family caregivers by integrating it into the existing care delivery framework through strategic digital marketing, primarily using organic search engine optimization. This strategy ensures that our platform aligns with user search behaviors, making it easily discoverable by those in need of caregiving resources. Simultaneously, we are committed to maintaining universal accessibility, opting for a broader reach via effective search engine optimization strategies over direct integration into health plans. Our platform, designed more as a comprehensive digital health tool than a conventional medical device, provides holistic care planning support for family caregivers. Financially, we have chosen a sustainable business-to-business revenue model, focusing on advertising and commission-based referral fees from businesses serving our caregiver community, which allows us to offer our services free of charge to families. This approach is underpinned by the older adult care industry's potential for low-cost client acquisition, enabling us to provide much-needed support to families without financial burden and ensuring that our platform remains accessible to all caregivers in need.

Conclusions

The Olera.care platform, characterized by its practicality, interactivity, ease of use, visual appeal, and informativeness, shows promise as a valuable tool for dementia caregivers. With the pilot group of caregivers' engagement and feedback, the platform provides tailored support to meet the specific challenges of dementia caregiving. Future development and research are essential to enhance the platform and comprehensively evaluate its efficacy in supporting caregivers and alleviating caregiving burdens across broader and more diverse populations.

Acknowledgments

The authors acknowledge the support provided by the Center for Community Health and Aging at Texas A&M University and their community partners. The authors extend their sincere appreciation to the family caregiver participants' engagement and contributions to evaluating the Olera.care platform. This study was supported by the National Institute on Aging Small Business Innovation Research program (1R44AG074116-01).

Authors' Contributions

TF, LD, SL, and MGO contributed to study design. LD, TF, MNH, JV, and QF contributed to study implementation and data collection. QF contributed to data analysis. QF, MNH, MGO, and LD contributed to data interpretation. SL and MGO contributed to supervision. QF, MNH, and LD contributed to the original draft writing. All authors contributed to critical revision of the manuscript.

Conflicts of Interest

LD is an executive and owner of Olera, Inc.

Abstract

Background: Informal caregivers (IC) play an important role in the community as health care providers for people who are dependent on self-care. Health literacy contributes to empowerment, better care, and self-management of one’s own health and can be developed using digital technologies.

Objective: This study aims to map scientific evidence about the use of digital technologies to promote health literacy and the empowerment of ICs.

Methods: We conducted a scoping review following the Joanna Briggs Institute methodology. The CINAHL, MEDLINE, Scopus, and PubMed databases were searched to find primary studies on the theme. Inclusion criteria were based on the Population, Concept, and Context logic. To be selected for analysis, studies must have involved informal or family caregivers aged ≥18 years who provide care to dependent persons and who have access to the internet and digital devices (computer, smartphone, and tablet). A total of 2 independent researchers (SS and LVH) performed the screening process. This study is part of a main project that was approved by the Ethics Committee for Health of the Regional Health Administration of Lisbon and Tagus Valley (reference 058/CES/INV/2022).

Results: A total of 9 studies were included in the review. The analysis of the studies showed that ICs use digital tools, such as computers and smartphones, with smartphones being the preferred tool. ICs use the internet to access information; manage home tasks; communicate with relatives, their peers, and health care professionals; and take part in forums. Due to difficulties in leaving their houses, forums are highly valued to preserve human connections.

Conclusions: The use of digital technologies to convey clear, objective, reliable, and accessible information is a strategic action for promoting health literacy and for contemplating the variable care needs of ICs. By working with ICs in the development of new technologies, researchers are building a new tool that meets ICs’ needs.

KEYWORDS

health literacy; empowerment; digital technology; informal caregiver; family caregiver

Introduction

Background

Population aging is a social challenge worldwide. As life expectancy increases, the incidence of chronic and incapacitating diseases also increases [1]. The high levels of dependence and the complex management of health status raise awareness of the increasingly relevant role of informal caregivers (ICs) in terms of care and health promotion of their relatives [2]. The ICs, defined as *someone who provides nonremunerated care to a person with a long-term illness, disability or other health need, or long-term care, outside a professional or formal framework*, are considered essential both to the care of people in the community and to the economy of European Union countries [3]. ICs are more and more important to patients as well as to health care professionals [4]. They play a central role in the planning, training, and provision of services to people with care needs [2,3]. In practical terms, ICs collaborate in providing health care at home to people who show an impairment in self-care, activities of daily living, and instrumental activities of daily living. The needs change over time, as does the level of dependency of the person cared for [5].

In most situations, ICs are not prepared to play this role. This transition in caregivers' lives brings out feelings of insecurity due to the unknown and the lack of knowledge and skills to ensure that the person cared for is given proper care [5]. This way, ICs' existing and acquired knowledge is extremely important and becomes necessary for the implementation of interventions destined to promote the development of skills and the involvement of relatives in patient trajectories to improve patient outcomes [2-4].

A vital point in health policies is the investment in the health literacy (HL) of ICs. HL is central to empowering people, their families, and communities, promoting greater control over decisions and actions affecting their health [6]. HL is defined as the ability to access, understand, evaluate, and apply information about health care, disease prevention, and health promotion to maintain and promote quality of life during the life course [7].

Through HL development, conditions are created for individuals to gain knowledge and skills, make informed decisions, and feel motivated to adopt a behavior that improves their health status and well-being [8].

Considering that HL is a health determinant, mediator, and moderator, it is important to ensure that citizens access reliable, useful, and updated health information to help them make the best decisions about their personal health, their family's health, and the community's health [9-11]. Proper access to information allows to promote and increase citizen empowerment so that they participate in their health care, leading to shared responsibility and informed decision-making [12].

As an agent, the health care professional plays a central role in effective communication and in conveying reliable information to the population. User-relative–health care professional communication significantly affects health outcomes and user satisfaction concerning health services [13]. Digital technologies have created an opportunity for health professionals and health organizations to directly communicate with many people in real time. This digital revolution in communication allows to customize information, help people set health targets, and interact in real time [1].

Information and Communication Technologies (ICTs) is the set of technologies and equipment that, in an integrated manner, allow working and communicating information, including computers and the respective applications, the internet, and telecommunications [14]. They are part of the citizens' routine, with an increasing use of educational platforms. The internet is considered a privileged means of interaction with the population that needs health care [1].

ICTs improve the quality of life of older adults and their caregivers and their access to quality care, contributing to improving the social lives of caregivers and decreasing their isolation via social activities and intergenerational relationships [15]. These aspects contribute to balanced physical, mental, and emotional health and to a decrease in depressive symptoms and sadness. Digital technologies are considered *a key component and facilitator of sustainable health systems and universal health coverage* [16]. Digital technology is a strategy that can promote accessibility to health care for all citizens. Digital means can be used to increase access to reliable, useful information and to strategies that meet the needs of the highest possible number of ICs, whether in real time or not [1]. However, accessing and handling these technologies requires digital literacy, which is one of the barriers identified by studies in certain groups considered vulnerable, such as older adults. Digital HL is the ability of citizens to use digital platforms to manage their health, validate web-accessible health information, and communicate with health professionals [17].

Objectives

In Portuguese literature, there are only a few scientific studies conducted by nurses that refer to the use of digital technologies as a resource to empower dependent people and family caregivers [1]. The need to know if dependent people and their ICs have access to digital technologies and use them when they have health needs gave rise to the following research question: "Which digital technologies are used for promoting Health Literacy and empowering the Informal Caregiver?" For the mapping, we used the following guiding questions: "Do the Informal Caregivers have access to digital technology?" and "Do the Informal Caregivers use digital technologies to improve their health literacy and empowerment concerning the care of the person cared for?" To answer these questions, this review aims to map the scientific evidence regarding the use of digital technologies to promote HL and empower ICs.

Methods

Overview

This is a scoping review conducted according to the methodology recommended by the Joanna Briggs Institute (JBI) [18]. Scoping reviews are used to identify knowledge gaps, enhance knowledge described in the literature, clarify concepts, or investigate research conduct [19].

The theme was searched in the JBI Database of Systematic Reviews, CINAHL, MEDLINE, Scopus, and PubMed, and no systematic review was found for this same theme. The inclusion criteria were based on the Population, Concept, and Context logic: the Population included all informal or family caregivers aged ≥18 years who provide care to dependent persons and who have access to the internet and digital devices (computer, smartphone, and tablet).

The search was conducted from April 4 to 18, 2022, and included primary qualitative and quantitative studies and mixed method studies in English, Portuguese, French, and Spanish, during 5-year period between January 2017 and December 2021, to obtain the most recent studies published on this theme. Key terms and inclusion criteria were used as a strategy to identify papers that were relevant to the search.

Study Selection, Data Extraction, and Analysis

According to the JBI's recommendations, the search strategy was performed in 2 steps [18]. There was an initial search of the electronic platform EBSCO, in particular, MEDLINE and CINAHL, with the natural keywords informal caregiver; family caregiver; health literacy; empower; digital technology; and community, following the search for the indexing term MH "Empowerment." Subsequently, we carried out an analysis of the words used in the title, the abstract, and the terms indexed as well as the keywords presented in the description of each searched article. We then carried out a second survey in which the indexing terms and keywords were searched in MEDLINE (PubMed), CINAHL (via EBSCO), MEDLINE (via EBSCO), and Scopus (Textbox 1).

A total of 2 independent reviewers (SS and LVH) analyzed the relevance of papers using the information included in the title and abstract, considering that the study population must be defined and the goal must be associated with digital tools.

It was necessary to retrieve the papers after reading the abstract. Full papers were obtained for all studies with the inclusion criteria. A table was filled with the defined criteria, considering the goals and the results of the study that would answer the research question. After reading the full text, 2 papers showed a divergent opinion. This situation was discussed and resolved without the need to speak to a third reviewer.

The screening process identified 442 studies. Of the 442 studies, 77 (17.4%) were duplicated and so were excluded. Of the remaining 365 studies, 320 (87.7%) were excluded for their titles and 25 (6.8%) for their abstracts, based on the inclusion criteria that had determined their eligibility. In the second step, there were 20 papers for full-text review. Of the 20 papers, 11 (55%) were eliminated because of the following reasons: 4 (20%) because their goals did not relate to the technological needs of ICs but to the person cared for; 4 (20%) because they were about another type of nontechnological experience; and 3 (15%) because they were about behavioral therapies and coping strategies. Figure 1 [20] shows the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart for the identification and selection of the studies.

A data collection instrument was made to extract information from the selected studies, including the following items: author, country, year of publication, study goal, study type and methodology used, population, sample, types of interventions, main results, and conclusions. The results were analyzed based on their content and organized according to the research question and goals.

Ethical Considerations

This study is part of a main project that was approved by the Ethics Committee for Health of the Regional Health Administration of Lisbon and Tagus Valley (reference 058/CES/INV/2022).

Results

Studies Characteristics

In total, 9 studies were included in this review after the search. According to the JBI’s guidelines, after the selection, the studies were organized based on their research question and goals (Tables 1 and 2).

Table 1. Summary of study characteristics.

Paper title	Authors, country, and year	Goal	Type of study and methodology	Population and sample
What is “care quality” and can it be improved by information and communication technology? A typology of family caregivers’ perspective	Leslie et al [21], Canada, 2020	• To determine how ICTs[a] can support family caregivers who play the caregiver role	• Qualitative study • Method • Focus group	• FC[b] of older people • Sample: 25
Effect of an innovative model of complexity care on family caregiver experience: qualitative study in family practice	Nickell et al [22], Canada, 2020	• To learn about the experiences of FC of older people with complex needs, using the Interprofessional Model of Practice for Aging and Complex Treatments	• Qualitative study • Method • Individual interviews	• FC of older people with complex needs • Sample: 20
Building a Research Roadmap for Caregivers Innovation: Finding from a Multi-Stakeholder Consultation and Evaluation	Egan et al [23], Scotland, 2021	• To explore a future roadmap for innovation from IC[c] participation	• Mixed study • Method • Interview • Questionnaire	• ICs • Sample: 112 • Professionals and researchers • Sample: 62
The care capacity goals of family carers and the role of technology in achieving them	Leslie et al [24], Canada, 2020	• To identify the goals of FC when caring for older adults and how technology can help achieve those goals	• Mixed study • Method • Focus group • Questionnaire	• FCs • Sample: 25
Mobile Support for Older Adults and Their Caregivers: Dyad Usability Study	Quinn et al [25], United States, 2019	• To determine the usability of a mobile app within the older population and in their relationship with ICs	• Observational study • Method • Questionnaires	• Older people and ICs • Sample: 24 (dyad 12)
Preferences for using a Mobile App in Sickle cell Disease Self-management: descriptive Qualitative study	Mayo-Gamble et al [26], Canada, 2020	• To explore health preferences for using an app in the process of facilitating the self-management of adults with sickle cell disease and their caregivers who live in urban and rural communities	• Qualitative study • Method • Focus group	• Adults with sickle cell disease and caregivers • Sample: 43
A Digital Mobile Community App for Caregivers in Singapore: predevelopment and Usability Study	Lwin et al [27], Singapore, 2021	• To provide a clear understanding of the implementation along with a usability study to gauge user opinion of the “Caregiver’s circle” app within Singapore	• Qualitative study • Method • In-person interviews • Questionnaire	• ICs • Sample: 103
Improving the Quality of Life of Family Caregivers of People with Alzheimer’s Disease through Virtual Communities of Practice: A Quasiexperimental Study	Romero-Mas et al [28], Spain, 2021	• To describe the relation between the quality of life of ICs of people with Alzheimer disease and their participation in a VCoP[d] (virtual community with the exchange of knowledge and an emotional support and collaboration culture) • To determine the impact of ICs’ HL[e] in the quality of life and involvement in the VCoP	• Quasiexperimental study • Method • Phone calls and in-person contact • Focus group • Evaluation scales • Control group with and without VCoP intervention • Questionnaire	• ICs of people with Alzheimer disease • Sample: 38 before the test and 37 after the test
Patient Portals as a Tool for health Care Engagement: A Mixed-Method Study of older Adults with Varying Levels of Health Literacy and Prior Patient Portal Use	Irizarry et al [29], United States, 2017	• To explore attitudes in relation to choosing the portal and its utility as a tool to involve health care with different levels of HL	• Mixed-methods study • Method • Phone interview • Focus group	• Older people • Sample: 100

[d] VCoP: virtual community of practice.

[e] HL: health literacy.

Table 2. Summary of study results.

Types of interventions	Main findings	Conclusion
Intervention made with 10 focus groups from May 2017 to August 2018. Each session took 2 hours. Bottom-up approach with thematic content analysis.	Technologies that are only focused on the task can lose their value as they lose the capacity to provide information that is relevant to caregivers' needs. ICTs[a], as the intermediary for an improvement in quality of life and as providers of relevant information that are enabled with knowledge and caregiver needs' change. Smartphones can be an extension of access to software.	ITC product development supported by ICs[b] should focus on human relationships and expand a facilitating communication, allowing their participation in decision-making and allowing them to express their concerns and goals. Technology appears as a support to receive information that is relevant to caregivers' needs and to establish human connections.
Individual interviews with 13 family caregivers about the caregiver role and their (physical and emotional) well-being. The patient and the caregiver are encouraged to play a more active role in the process of their disease by raising questions and discussing actions.	Caregivers reported that they no longer felt lonely in this role because they were given basic information about the disease as well as existing resources and equipment. They felt recognized and heard; they were able to express their uncertainties, stories, and suggestions, increasing their commitment to caregiving. They searched the internet.	Involving ICs as part of the multiprofessional team increases their perception and understanding of the caregiver role and their trust in their ability to perform this role and facilitates their empowerment.
A mixed approach was used: A 10-minute multisector consultation from June 15, 2020, to September 30, 2020. Web-based questionnaire on social media.	In total, 108 of the 112 (96%) ICs use digital technology. The hybrid approach (both in person and web based) can work for caregivers. The experience of ICs in collaborating with universities to work via multiple communication channels should be valued. Deep knowledge of needs and existing gaps allows one to contribute to technological innovation to overcome existing technological barriers and learn what the facilitating mechanisms are. The ICs mentioned the need for improved financial, emotional, psychological, training, and educational support.	A technological approach in the following areas is required for the health and well-being of ICs: information, monitoring technology, and communication with other ICs and professionals. The experience of ICs in collaborating with universities to identify priorities and actions that speed up searches and future political decisions about significant and innovative solutions should be valued.
Sequential method, focus group, and web-based questionnaire. In total, 10 focus groups with 25 family caregivers. The intervention took place from May 2017 to August 2018. First part: discussion of targets and technological solutions. In what they think technology can help them. Second part: web-based questionnaire about 7 fields: physical health, mental health, well-being, social connection, education, employment, and finances.	Technology maintains the ability to care and allows ICs to develop coping strategies, guide themselves, and socialize. Technology is an intermediary that connects ICs to information support and other caregivers. Key targets for ICs are to reinforce and preserve their ability to provide care.	Technology is well positioned to find the best self-care to facilitate the connections needed for a social life. Technological targets and suggestions should imply that the understanding of care as a source of overload was transformed into a more resilient, sustainable caregiving model. Technology can help promote such resilience but can be limited to the role of an intermediary that connects family caregivers to information supports and peers.

Types of interventions	Main findings	Conclusion
• Participants completed a skill evaluation questionnaire and downloaded an app to their smartphones or computers that was used for a month. • Then, participants completed 2 questionnaires that evaluated app features and esthetics and their relationship with the app. • App features: user profile, family health history, health information, receiving studies based on their health profile, and establishing a relationship with their caregivers.	• Study results showed normal levels of digital competence for the older adults and high levels for the ICs. Older adults use their smartphones to make calls (9/12, 75%) and read emails (7/12, 58%). They access the internet (4/12 33%) but on their computers. ICs use their smartphones for calls, SMS text messages, emails, and the internet equally (11/12, 92%). They access the internet via their phones. • This study concluded that 50% (6/12) of ICs want to use the app to manage the appointments and clinical information of the person cared for and to access specific information that allows them to share and discuss to commit to the caregiving; they believe that the app’s esthetic dimension is important.	• Technologically experienced caregivers play an essential role in showing the benefits of technology for supporting care provision for older adults. • There were high levels of use of technology among the older adults and caregivers, but there was only an average use of the mobile app. Additional training is recommended for the older adults and caregivers, including behaviors directed toward keeping digital health records.
• In total, 5 community listening sessions were made with 1 urban and 1 rural community. Each session took 2 hours. A questionnaire about demographics and access to technology was applied. • Where they searched for information about self-care in relation to the SCD[c] and what was their satisfaction level with the search for and support about management and resources. A total of 7 aspects were evaluated: self-management information, such as receiving information, which information they wish to receive, changes in disease management, support types, barriers to and facilitators for the use of apps, and mobile app preferences.	• Participants are receptive to using the app to self-manage the disease. A mobile app reduces the information access barrier. In rural communities, the app increases ICs’ access to resources. • The internet is the reported source to learn about self-management techniques and receive information, reinforcing the importance of reliable websites. ICs want emotional support, information support from the family, and follow-up from health care professionals. Positive feedback about the app included easy configuration and a good interface. • Barriers: participants were not comfortable using the internet because they struggled to identify relevant, reliable information. The notification system, information trackers, and the fact that they can communicate with their health care professionals and caregivers were aspects valued by patients.	• The results can be used to develop a patient-centered health app that is easy to use to facilitate disease self-management, thereby increasing access to resources by relatives that live in rural communities.
• A predevelopment survey was made about the following issues: care, support provided, and what they would like in a caregiving mobile app. Identifying the needs of ICs and the gaps in web community networks. • Demographics about the health of the person cared for and about the ICs’ physical and mental health. • What is the level of use of digital means when searching for information and support. • A total of 32 caregivers completed a web-based questionnaire and in-person interviews, followed by a usability test.		• Caregivers enjoyed the “Caregivers’ Circle” and were confident that this app could help them improve their quality of life. • Including many resources that caregivers need daily in 1 app can help save time and help them live without problems.

Types of interventions	Main findings	Conclusion
	- ICs said they liked using the app. They said it was useful, easy to use, and helpful to improve the quality of life because they included multiple resources: a public forum for discussions with the community and other ICs in the same region without ever leaving home and a market to purchase and sell material and equipment required for caregiving. Including many resources that caregivers need daily in an easy-to-use app allowed them to save time and helped browse without any issues. - The use of smartphones created an opportunity for the caregiving community to use technology in a useful way. - The app included caregivers' ideas, which created an app that facilitated caregiving. - As to concerns about safety and security, trust would increase if the app were supported by a renowned organization. - ICs have suggested that the app should include a resource that would help with mental health, namely, relaxation techniques, motivational quotes, and guides that would remind them to take care of themselves.	
- The study took place between July 2017 and April 2018. - Previous contact was made with the AFMADO[d] association, and explanatory sessions were held (individual and group). In total, 2 groups were created, 1 with and 1 without health care professionals. Intervention: developing an app based on the CoP[e] theory, with space for chatting and a member file with information about each member. - The following aspects were evaluated before and after the VCoP[f] intervention: quality of life, HL, and the Barthel scale associated with the Spanish population.	- QoL[g] was 66.6 and increased to 69.5. - There was no discrepancy between sexes for the QoL. Age was the only sociodemographic criterion that affected the quality of life; older adults increased their QoL to 74.6. Young people went from 66.7 to 67.85. Spouses said that the app had a positive impact on their QoL. - Regarding HL[h], the average rate of 26.10 (in 40) increased to 30.68. Internet interventions can help caregivers meet their needs, which is a positive experience. - Allowed to get to know their peers and to feel less lonely.	- Caregivers can benefit from the VCoP because it enables interaction and knowledge sharing between caregivers and helps them meet their needs. - VCoP's impact is governed by age and relationship with the person cared for. It was positive for the caregivers' quality of life, at a physical level, when the functional condition of the person with Alzheimer disease worsened. - The VCoP was considered a useful tool. - HL had a positive impact on the physical area of the QoL of caregivers.
- First contact made by phone (data collection: demographics, health, "Deficit of quality-of-life technology" questionnaire, and CREATE[i]). - Classified participants according to their HL level and portal use. This classification resulted in 4 groups (group 1: high HL, yes portal; group 2: high HL, no portal; group 3: low HL, yes portal; and group 4: low HL, no portal). - Second contact made with 4 focus groups (N=75) aimed at analyzing participants' attitudes. Sessions took 1 hour, were recorded, and used NVS[j].		- The study concluded that there should be more research focused on the attitudes and experiences of ICs of older adults as substitute users for the older adults. - Health organizations should connect people to technology by adopting the following strategies: campaign to disclose the benefits of technology and how they meet people's needs; offer specific training so that they can use technological tools in a secure, trustful way; include ICs in the campaign and training; and create workflows where people can communicate to update data, exchange information, and clarify any doubts that validate their knowledge. This would create a tool designed for support and commitment.

Types of interventions	Main findings	Conclusion
	- Participants with the higher HL who use the portal struggle to solve issues without the digital support and feel more pressured to use these methods. - Those who do not use the portal say they do not feel safe using it due to the risk of sharing personal data and prefer to use the phone. People with low HL who do not use the portal do not have experience using computers, are not trained, and do not have internet access at their homes, but those who use the portal say they are more interested in learning and training with new technologies. - People who are more familiar with accessing health information using the internet might be more willing to participate in research related to digital technology. The study revealed that HL was a factor that contributed to trust when accessing digital health information. However, it was not directly related to the motivation to get involved in health care. If portal users understand the benefits, this would be a motivation for portal use. Specific technology training is required to gain trust. ICs play a potential role in improving access to portal use for older adults who cannot access portals.

Main Findings

Table 2 shows the main findings and conclusions of the studies described in the papers.

Regarding the year of publication, the studies were published in year 2017 (1/9, 11%); year 2019 (1/9, 11%); year 2020 (4/9, 44%); and year 2021 (3/9, 33%). They were conducted in the following countries: Canada (4/9, 44%), the United States (2/9, 22%), Scotland (1/9, 11%), Singapore (1/9, 11%), and Spain (1/9, 11%). Of the 9 studies, 3 (33%) followed a qualitative approach, 4 (44%) followed a mixed approach, 1 (11%) was observational, and 1 (11%) was a quasi-experiment.

The results of the studies enabled us to address the guiding questions. On the question "Does the Informal Caregiver have access to digital technology?" the studies show that ICs have access to and use digital technology [23,25]. They describe which types of technological resources are used more frequently by them: smartphones with mobile apps or internet access. The internet is the source of choice for accessing health information and learning about self-management techniques, with the importance of reliable websites being emphasized [22,25,26]. Smartphones are used to make calls, send SMS text messages and emails, and access the internet [25]. Apps are used to manage the appointments and medical information of the person cared for and to access specific information that allows ICs to share and discuss to commit to the caregiving relationship [25]. The esthetic dimension, ease of configuration, and nice interface are app features that are valued by ICs [25,26].

Privacy and security issues seem to be a factor that limits the use of technologies because users feel insecure due to the risk of sharing personal information [19,27]. Struggling to identify relevant and reliable information is also a factor that causes apprehension when it comes to internet use [26]. The degree of trust when accessing digital information seems to be related to the HL level of users [29]. Users with low HL levels who did not use the technology that was being analyzed had little experience using computers, no training, and no internet access at home. Those who used the portal showed increased interest in learning and practicing with the new technologies [29]. This fact reinforces the need for specific training on the use of digital technologies to gain trust [29].

Regarding the question “Does the Informal Caregiver use digital technology to improve their HL and their training in caring for the person cared for?” the studies show that the use of digital technology can benefit the population as well as caregivers [21,25-27,29].

ICTs lower information access barriers and provide relevant information that is enabled when there is a need to gain new knowledge [21,26]. ICTs are perceived as giving ICs the opportunity to guide themselves and interact with other caregivers, which allows them to get to know their peers and feel less lonely [24,28].

Caregivers say that by using digital technologies, they can obtain basic information about the disease, such as symptoms and treatment options, and about existing resources and equipment, which makes them feel less lonely in this role [21-23]. With the support of digital tools, caregivers felt recognized and heard and could express their uncertainties, stories, and suggestions, which increased their commitment to care provision [22]. Technology also maintains their caring ability and allows them to develop coping strategies [24].

The use of technology is also referred to as an intermediary for an improved quality of life [21,28]. This perception of the improvement of the quality of life is boosted when the technology that is used includes multiple resources, such as the fact that there is a public forum for community discussion with other ICs in the same region without having to leave home, a market to purchase and sell materials and equipment that is needed for providing care, and an alert system or information trackers [26,27]. The integration of the multiple resources that are needed by caregivers daily in an app that is easy to use allows them to save time and provide help to browse without problems [27].

Another aspect referred to by the studies concerns suggestions or factors that can improve the experience of ICs when using digital technologies. One study described that new technologies that are only focused on the task can lose their value as they lose the capacity to provide information that is relevant to caregivers’ needs [21]. It is important that ICs collaborate in the development of technologies because their deep knowledge of the needs and existing gaps contribute to technological innovation, which allows them to overcome the existing technological barriers and learn facilitator mechanisms [23].

The expectations of ICs as to digital technologies also seemed to be an important aspect to consider because they can increase the technology used. ICs hope that technologies can provide emotional and psychological support, informative support from the family, training and education, and health care follow-up [23,26]. In a more practical way, ICs suggested that there should be resources that help them with their mental health, namely, relaxation techniques and motivational quotes and guides that would help them remember to take care of themselves [27].

Discussion

Informal Caregivers’ Role in the Health Care System

According to the studies that were analyzed, demographic changes are leading to an increasing need for long-term care, which results in people informally caring for their relatives. Being an informal or family caregiver brings uncertainties, isolation, and overload [21,27]. Studies have shown that the involvement of the caregiver in the care plan is essential. The active involvement of ICs as a member of the interprofessional care team results in an improved experience, increased caregiver capacity, and the appreciation of the caregiver role [22,24].

These results are in accordance with the literature where ICs are considered “one of the elements of the sustainability of social and health systems” [30]. This emphasizes how important it is for health care professionals to work with ICs to find the strategies that are most adequate for effective empowerment [30]. The empowerment of ICs should be “a priority in health care organizations and the nurse assumes a major, dynamic, empowering role when it comes to the most adequate response to meet those needs” [31].

The World Health Organization (WHO) has defined a long-term strategy for the expansion and use of digital health, emphasizing the positive impact that it can have on health care access and provision as well as on the health and well-being of the population and caregivers [23]. According to the literature, health technology is “one of the strategies used by the health care professional to empower citizens to use it in a secure way” [32].

The Use of Digital Technologies Supporting Caregivers

The studies revealed that low HL was a barrier to accessing digital information and the correct use of technological tools. Lack of training makes browsing difficult and results in user insecurity [26,29]. The initial findings of a European survey on population HL carried out by the WHO Action Network on Measuring Population and Organizational Health Literacy indicate that 22% to 58% of the population find it challenging to access and interpret digital health information [33]. By contrast, the European data report shows that, in 2019, in European countries such as Finland, the Netherlands, the United Kingdom, and Germany, 75% of the active population had basic digital skills [34].

Promoting HL improves safety in caregiving and decreases the risk associated with this activity [32].

Using digital technology in the health field can benefit the caregivers and the general population [21,25-27,29].

Questions about privacy and security when using these digital tools are an important factor for users. Although there is an increasing concern about what is the best way to develop emerging web-based technologies (eg, ethical data use), the results show that a hybrid model with a web-based and in-person approach can work well for caregivers in rural areas [23]. The model that includes digital technology and an in-person approach is pointed out as a more reliable model for the ICs.

These results are in line with the American study that described that ICs use the internet (77.5%) to access health information for themselves (73%), for others (67.5%), and to communicate with the physician [35].

The results highlight that ICs intend to use digital tools to establish communication relationships with people cared for, their family members, the peers, and health care professionals [21,23,24,27,28].

Principal Findings

The text highlights privacy concerns limiting technology use, underscoring the impact of low HL on users' digital engagement. ICs benefit from digital tools by experiencing empowerment, recognition, and an improved quality of life. The integration of multiple resources in one technological tool supports caregiving, saving time and facilitating daily tasks. The collaboration of ICs in technology development is crucial for innovation and overcoming barriers, emphasizing the need for user-driven solutions.

Limitations

As for the analysis of the included studies, it was not possible to use a tool to evaluate study quality. In the papers that were analyzed, it was not possible to identify references about improvement opportunities arising from the research process. The fact that the samples in the presented studies are small does not allow us to extrapolate data to the population.

The included papers were published in English, French, Spanish, and Portuguese, and the inclusion of articles in other languages could have brought more relevant information to this review. However, searching in 4 databases allowed us to expand the search comprehensiveness.

Comparison With Previous Work

In Portugal, there are few scientific studies carried out by nurses that refer to the use of digital technologies as a resource to train people with dependence and ICs.

Conclusions

Evidence found in studies revealed that ICTs such as digital platforms, portals, and web-based community groups were preferentially used by informal caregivers via mobile apps and that computers were used more by the people cared for. Studies showed that ICs had access to and used digital technology not only to meet the needs of the person cared for but also to meet their own needs. Studies have shown that digital technology is an accessible tool for empowering ICs. However, there were concerns regarding privacy, security, and the use of these tools, which should be considered by health care professionals and researchers. It is also important to highlight the necessity of providing digital training for both ICs and the individuals under their care.

ICs play a key role in the provision of quality care to the dependent people to whom they commit. It is crucial to understand how digital tools can be effectively and beneficially used to empower ICs.

The participation of ICs is essential when it comes to developing digital tools (platforms, mobile apps, and portals) because they can contribute to developing tools that meet users' needs (ICs and the people cared for). The use of digital technologies can guarantee access to knowledge, thereby empowering caregivers when it comes to making a decision and sharing care provision with health care professionals. It is important to emphasize the significance of digital empowerment in enhancing the digital health literacy of both ICs and those they care for. Digital technology allows accessible, targeted, and effective communication. Health care professionals and researchers should guarantee information reliability, security, and clarity and optimize existing resources.

Authors' Contributions

SS contributed to the design of the paper; contributed to the collection, analysis, and interpretation of the data; and drafted the paper. LVH contributed to the interpretation of the data, drafted the paper, and substantively revised it. MFF contributed to the design of the paper and the collection, analysis, and interpretation of the data. AH contributed to the design of the paper and the interpretation of the data. GC contributed to the interpretation of the data and substantively revised it. ASC contributed to the design of the paper and the interpretation of the data and drafted and substantively revised the manuscript.

Abstract

Background: The COVID-19 pandemic has catalyzed a move from face-to-face to digital delivery of services by hospitals and primary care. However, little is known about the impact of digital transformation on organizations supporting unpaid caregivers. Since the start of the COVID-19 pandemic, the value of care provided by such informal caregivers is estimated to be £111 billion (US$ 152.7 billion) in England.

Objective: This study aims to analyze service uptake patterns (including digital service options) over the pandemic period in an English caregivers' support organization covering a population of 0.98 million; measure changes in organizational performance, service efficiency, and quality; and identify the views of caregivers on service provision and future digital delivery.

Methods: This was a retrospective analysis of the use of digital versus nondigital support services (January 2019 to June 2021) by caregivers in city and rural geographic areas. We compared organizational performance and service quality indicators for 2 financial years (2019-2020 and 2020-2021). A survey was conducted to identify barriers and facilitators to digital service uptake, the computer proficiency of caregivers (the Computer Proficiency Questionnaire, 12-item version), and preferences for future digital service provision. Quantitative data were analyzed using Stata 13 (StataCorp LLC). Thematic analysis was used for open-text survey responses.

Results: The number of caregivers registered with the organization rose from 14,817 in 2019 to 20,237 in 2021. Monthly contacts rose from 1929 to 6741, with remote contacts increasing from 48.89% (943/1929) to 86.68% (5843/6741); distinctive patterns were observed for city versus rural caregivers. There was an increase in one-to-one contacts (88.8%) and caregiver assessments (20.9%), with no expansion in staffing. Service quality indicators showed an improvement in 5 of 8 variables (all $P<.05$). The 152 carers completing the survey had similar demographics to all registered caregivers. The Computer Proficiency Questionnaire, 12-item version, mean score of 25.61 (SD 4.40) indicated relatively high computer proficiency. The analysis of open-text responses identified a preference for the organization to continue to offer face-to-face services as well as web-based options. The digital services that were the most highly rated were carers’ well-being assessments, support needs checks, and peer support groups.

Conclusions: Our findings show that staff in the caregiver support organization were agile in adapting their services to digital delivery while dealing with increased numbers of registered clients and higher monthly contacts, all without obvious detriment to service quality. Caregivers indicated a preference for blended services, even while recording high computer proficiency. Considering the economic importance of unpaid caregivers, more attention should be given to organizations funded to provide support for them and to the potential for technology to enhance caregivers’ access to, and engagement with, such services.

Introduction

Background

During the COVID-19 pandemic, social distancing policies limiting physical contact transformed how people were able to access health and care services and sped up digital transformation in many sectors. In the United Kingdom, traditional hospital services rapidly moved from face-to-face to digital services, from simple websites to web-based platforms, to reduce the chance of infection transmission [1]. In primary care, general practitioners (GPs) also adopted a *digital first* approach for consultations [2]. However, how those organizations that are contracted to support unpaid caregivers adapted their services is not known [3]. Such organizations are not part of the National Health Service (NHS) but are instead contracted by local government [4]. Before the pandemic, expenditure on the services these organizations provided was reduced by 11% over the 6-year period from 2015 to 2021 [5], while 36,000 more carers were directed to their services [5]. It is recognized that unpaid carers play a crucial role in providing essential care worldwide [6]. Bearing these facts in mind, the absence of research on how these organizations moved to web-based delivery, what impact this had on service delivery, their ability to do this without affecting service quality, and the response of client caregivers are noteworthy.

Before the pandemic, an NHS report on the *Widening Digital Participation Programme* identified that organizations supporting the well-being of carers had largely been forgotten [7]. Currently, many countries are introducing policies of *active aging*, supporting older people to live independently in the community rather than entering expensive long-term residential care [8,9]. As a result, while the number of staff employed by care homes has remained unchanged from 2012 to 2022 in England, there has been a 27% increase in domiciliary care workers who support people in their own homes [10]. The pressures on unpaid carers have inevitably increased. Currently, the care provided by unpaid carers in England is estimated to be equivalent to that provided by 3.2 million full-time paid care workers [11,12], nearly 6 times the size of the paid workforce of 510,000 domiciliary care workers [13]. In addition, the continuity of care provided by family carers is becoming increasingly important in the context of a high annual turnover of domiciliary care staff (31.5% in England) [13].

Across the world, countries are developing integrated long-term care strategies to support their aging populations as recommended by the World Health Organization [14]. England has established 42 new integrated care systems (ICSs) to underpin integration between health and care services in these geographic areas [15]. Proposals for joining up care include the idea of *wrap-around services* for care recipients plus their caregivers, but there is no mention of organizations that provide support for unpaid caregivers. Although the national ICS strategy incorporated a digital plan, this currently excludes mention of organizations that support informal carers [16]. Such services are typically provided by charities or not-for-profit organizations that themselves may have limited expertise in digital transformation [17]. In this context, it is important to better understand the experiences of such carer support organizations during the pandemic and the response of the caregivers they support.

Objectives

This study aims to provide evidence to address this important research gap. The research has 3 main objectives: to analyze changes in service use patterns (including services accessed and the uptake of digital options); to assess any impact on organizational performance, service efficiency, and key quality indicators; and to identify user clients’ preference for future digital services.

Methods

Overview

We analyzed data collected by an organization providing support for 20,237 caregivers, covering city and rural geographic areas. Data were downloaded and fully anonymized. The uptake of digital and traditional services was examined over a 30-month period from January 2019 (before the pandemic) to June 2021 (after COVID-19–related restrictions were lifted). Service-level performance and proxy quality indicators were constructed and compared for the prepandemic financial year (2019-2020) and through the following initial lockdowns (2020-2021). The analysis of a user feedback survey undertaken at the end of this period (September 2021) explored barriers and facilitators to digital service uptake, the computer proficiency of caregivers, and views on future digital service provision. The organization’s digital preparedness before the pandemic was assessed.

Ethical Considerations

This retrospective study using fully anonymized existing data received ethics approval from the Coventry University Ethics service (P163079).

Organizational Setting

The study was undertaken at the Carers Trust Heart of England (CTHE). The organization operates in the complex UK sector that provides support for unpaid carers [4]. The CTHE is contracted to provide carer assessments and caregiver well-being services in 2 separate geographic areas: city area (Coventry) and rural area (Warwickshire, including towns and villages). The 2 areas have a total population of 0.98 million, and they are covered by a single ICS. Services provided include an assessment of a caregiver's needs, information on health and care services, benefit entitlement, assistive technologies, and peer support. Before the pandemic, the CTHE had made a number of changes to its IT systems, moving everything to a single cloud platform so that databases could be accessed from anywhere. Laptop computers and mobile phones had been provided to all frontline staff, all of which greatly facilitated home working. Job descriptions were also adapted to mention hybrid working. Throughout the observation period, the number of CTHE staff providing direct support to adult carers remained relatively constant at 14 well-being advisers, 3 administrators, 3 specialist roles (ethnic minority support worker, mental health worker, and carer trainer), and a manager for each area. A separate team provided support for young carers; this activity was excluded from our study. The CTHE is a member of a network of 124 Carers Trust partners across England, Scotland, and Wales. Members work within a national framework of policies, procedures, and internal quality assurance programs.

Longitudinal Data and Analysis

Overview

CTHE staff downloaded select activity data routinely collected for adult carers registered with the service (Multimedia Appendix 1). Young carers (aged <18 y) were excluded. Data were fully anonymized before being provided to the research team for analysis. Data cleaning and analysis were conducted on the imported raw data using reproducible coding files. Statistical analysis used Stata 13 (StataCorp LLC). The hypothesis was that there would be an increase in the use of web-based methods, although it was unclear whether digital levels would be sustained, what the impact on service delivery levels and quality would be, or what views client carers might have on a future digital service.

Service Use Patterns

Descriptive statistics were used to examine service use patterns and changes in the means of accessing services (ie, in person vs digital) [18]. Monthly contacts handled by the service were the primary variable used to explore use patterns over the 30-month period (January 2019 to June 2021). This covered two 15-month pre- and postpandemic periods, with the first national lockdown occurring midway in March 2020. The levels of service use by city versus rural carers were examined, together with the primary reasons for contacting the CTHE.

Service Performance Levels and Quality Indicators

Four key activity measures reported to commissioners each financial year were extracted from the data downloads. These included the number of carers supported, the number of one-to-one contacts, the number of carers' assessments completed, and numbers of carers attending group activities. The CTHE also collected structured feedback from the client after every contact (Multimedia Appendix 1). Five proxy quality indicators routinely reported to the funder were also extracted. A further 3 proxy quality indicators were constructed from the raw data to identify whether a contact had *reduced stress*, *increased control of personal life*, or *increased confidence*. Changes in all 8 quality indicators were compared for the 2 financial years 2019-2020 and 2020-2021, with P values for percentage changes estimated using the Pearson chi-square test of association between the characteristic variables and the corresponding totals [19].

Survey of Client Caregivers

Registered adult carers were invited by the CTHE to complete a feedback questionnaire in September 2021 to review provision and help plan future services (Multimedia Appendix 2). Responses were fully anonymized before being provided to the research team, with a minimum target of 60 responses set for analysis. Closed questions requested information on the use of digital services, barriers and facilitators to access, and satisfaction with the services accessed, while open-text comment boxes enabled people to expand on their responses. Respondents were also invited to complete the Computer Proficiency Questionnaire, 12-item version (CPQ-12) to assess their computer proficiency [20]. As well as being made available on the web, feedback questionnaires were also mailed by the CTHE to carers. The characteristics of respondents were compared to those of adult carers on the register where possible. Open-text responses were analyzed for content using thematic analysis and cross-referenced to gain an understanding of the underlying reasoning behind the views expressed [21].

Results

Longitudinal Data Analysis

Registered Carer Characteristics

Data on registered carers (Multimedia Appendix 1) were analyzed over the 30-month period from January 2019 to July 2021. During this time, the total number of carers registered with the organization increased from 14,817 to 20,237 (Table 1). Those living in the rural area rose from 1685 to 4778 (183.6% increase), while those in the city showed a more modest rise from 13,132 to 15,459 (17.7% increase). Overall, the proportion of rural caregivers increased from 1 in 10 (1685/14,817, 11.37%) to 1 in 4 (4778/20,237, 23.61%).

Table 1. Demographics of registered caregivers and survey respondents.

Characteristics	Caregivers, n (%)
Rural caregivers	
January 2019[a]	1685 (11.37)
January 2020[b]	3035 (17.63)
July 2021[c]	4778 (23.61)
Registered caregivers (n=17,641; March 2020)[d]	
Race and ethnicity	
Black (Caribbean or African)	406 (2.3)
South Asian	2382 (13.5)
White	13,972 (79.2)
Sex (female)	11,467 (65)
Aged ≥65 years	9067 (51.4)
Employment status	
Retired or gave up work to care	7868 (44.59)
Working or in training	3369 (19.1)
Unemployed	1270 (7.2)
Survey respondents (n=152; September 2021)	
Rural caregivers[e]	80 (56.3)
Sex (female)	97 (63.8)
Employment status	
Retired or gave up work to care[f]	33 (59)
Working or in training[f]	18 (32)
Unemployed[f]	2 (3)

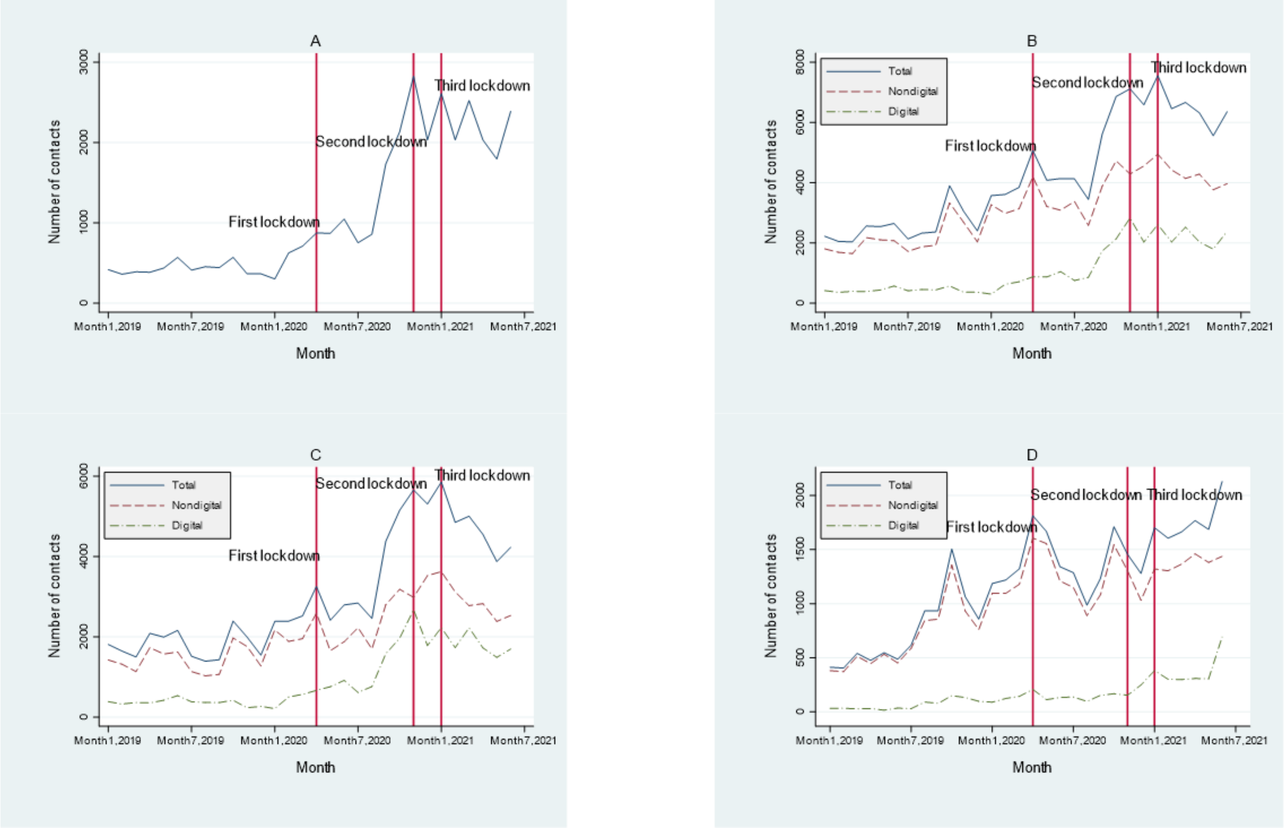
[a] Total registered carers: 14,817.
[b] Total registered carers: 17,246.
[c] Total registered carers: 20,237.
[d] Midway through the study period.
[e] 142 respondents provided information on their location.
[f] 56 respondents provided information on their employment status.

The demographic characteristics of registered carers were analyzed based on data recorded midway through the observation period from January 2019 to March 2020 (Table 1). The age and sex breakdown is comparable to national figures for carers [12]. Two-thirds (11,467/17,641, 65%) of the respondents were female carers; approximately half (9067/17,641, 51.4%) were aged ≥65 years; and over three-quarters (13,972/17,641, 79.2%) were White. In terms of their employment status, nearly half (7868/17,641, 44.59%), the largest group, were retired or had given up work to care, with only 1 in every 5 (3369/17,641, 19.1%) working or in training.

Service Use Patterns

Over the 30-month period (January 2019 to July 2021), digital services were provided alongside face-to-face services. The former included the use of email, SMS text messaging, Zoom, WhatsApp, and Microsoft Teams, as well as web-based group sessions. Use patterns were analyzed over time (Figure 1). The 3 vertical lines indicate the time points at which major national COVID-19–related restrictions were applied (ie, lockdown periods). From 2019 to 2021, monthly carer contacts with the well-being support service rose from 1929 to 6741, with telephone contacts rising from 818 to 3071 per month, and digital contacts from 125 to 2772 per month. A separate analysis of digital contacts during this period (Figure 1A) shows that, alongside a near–5-fold overall increase in the monthly rate, there were peaks coinciding with the national lockdowns. A separate analysis of digital versus nondigital contacts (Figure 1B) uncovers a clear change in the balance between the two, with digital contacts rising from 6.48% (125/1929) to 41.12% (2772/6741) of all contacts by the end of the period.

Figure 1. Number and types of contacts. (A) Digital contacts (all carers). (B) Breakdown of digital and nondigital contacts (all carers). (C) City carers (breakdown of digital and nondigital contacts). (D) Rural carers (breakdown of digital and nondigital contacts).

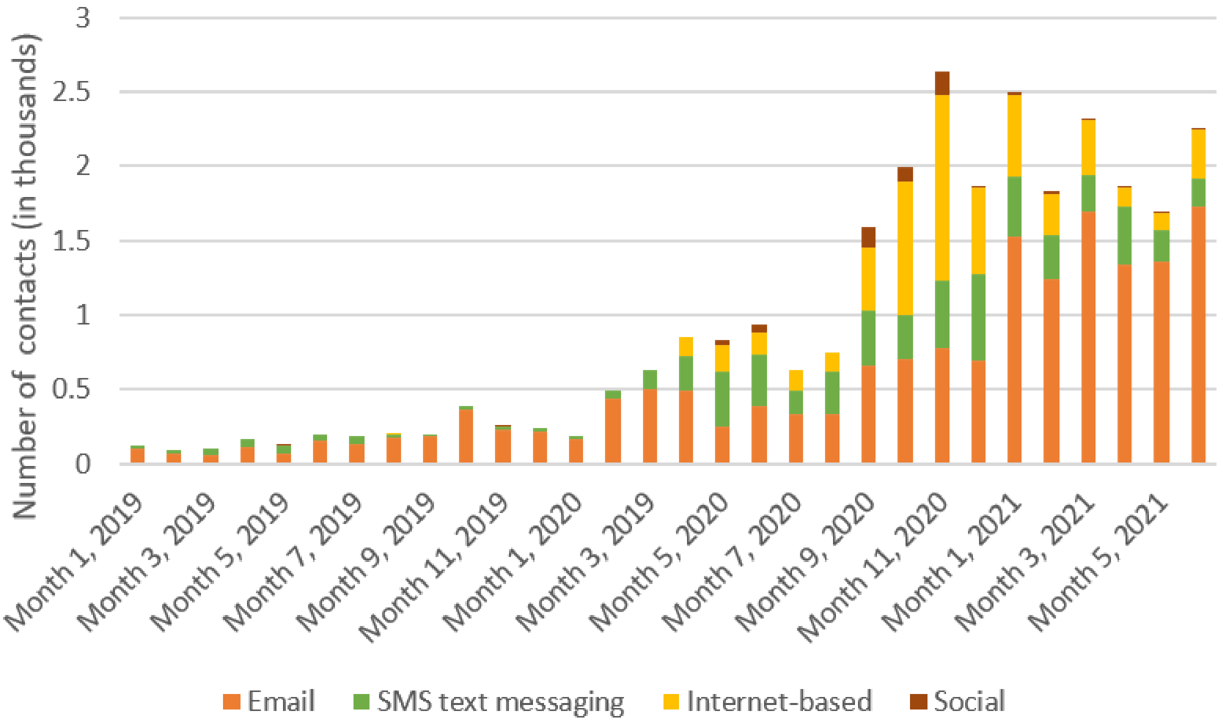


A separate examination of rural and city caregivers uncovers distinctly different patterns. For city carers (Figure 1C), digital contacts started to climb steadily from the start of the pandemic, almost reaching parity with face-to-face contacts around the time of the second lockdown. They then started to tail off toward the end of the 30-month observation period. Rural carers (Figure 1D) demonstrated a much slower initial uptake, with the rate of digital adoption only really starting to pick up after the second and third lockdowns. However, unlike in the case of city carers, rates were continuing to rise at the end of the observation period.

Types of Digital Contacts Used

Digital contacts were categorized into 4 broad groups. Two represented more flexible asynchronous methods (ie, email and SMS text messaging), whereas 2 represented fixed-time synchronous methods (ie, internet-based communication using Zoom, WhatsApp, and Microsoft Teams) and social digital group activities. Before the pandemic, only asynchronous methods were used, and rates were very low (Figure 2). With the first national lockdown (month 15), the use of other digital methods started to be added. Over time, the use of internet-based communication increased, overtaking SMS text messaging, although email remained the principal form of contact. “Social” groups were the least used form of digital contact used, possibly due to greater difficulties in arranging and delivering these. Their use peaked between September 2020 and January 2021 (ie, between the second and third lockdowns).

Figure 2. Number of digital contacts per month versus type of remote access.

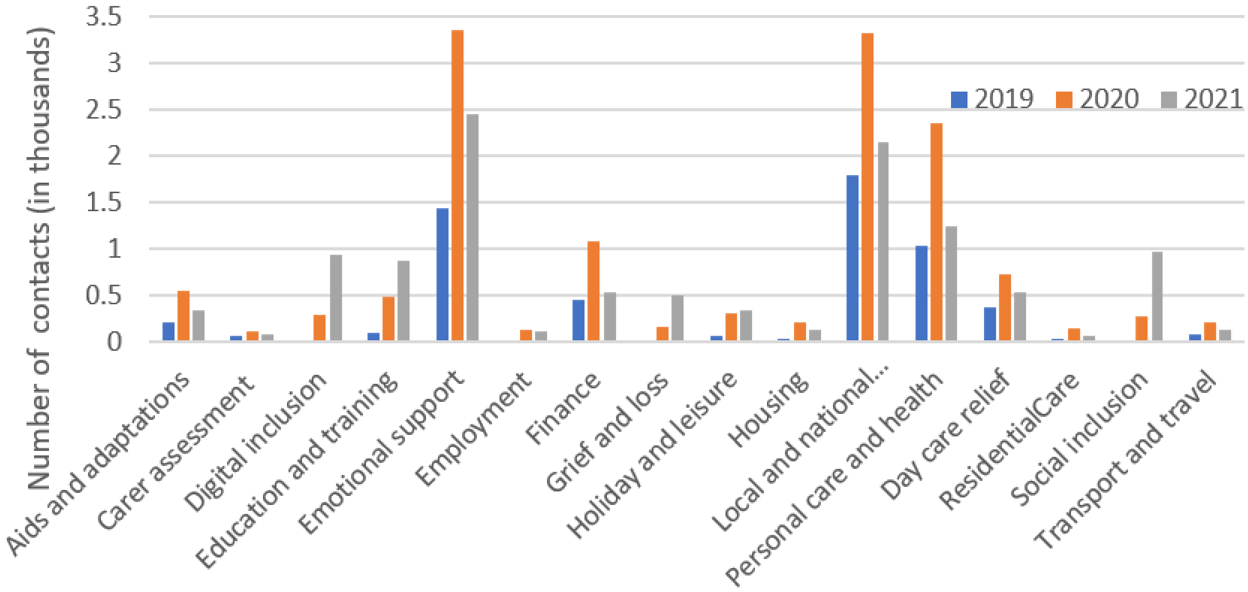


Types of Services Accessed

Well-being services available to carers at the start of the pandemic were mostly delivered via carers center appointments, home visits, and various outreach activities. During the pandemic, carers center appointments ceased after the first lockdown, with home visits and outreach activities significantly reduced. The well-being services provided were information and advice on aids and adaptations, carers' assessment, education and training (including digital), emotional support, local and national health and social care services, personal care and health, residential care and day care (for cared-for persons), and social inclusion and interests (including links to local and national groups). Other services included peer support and emergency planning. During the pandemic, additional services were introduced to address specific needs: a *grief and loss* service, *employment support* working collaboratively with employers, and *finance support* to reduce carer hardship.

Analysis of the reasons for contacting the well-being service over the 3-year period from 2019 to 2021 indicated that, irrespective of the year, the 3 most common reasons were *emotional support*, *local and national information*, and *personal care and health* (Figure 3). All 3 reasons peaked in 2020 (early pandemic period), as did information on *day care relief* and *aids and adaptations*. Advice related to *digital inclusion* and *social inclusion* were unusual in showing a steep rise in the final 6 months, from a base where both were 0 in 2019. *Education and training* showed a similar pattern, possibly partly related to digital training needs. The most frequently new service accessed was *finance*, with the *grief and loss* service reaching a similar level in the final 6 months.

Figure 3. Pattern of carer support services contacted over time.



Service Performance and Quality

Activity levels demonstrated an increase of 88.8% over 2 years in the numbers of one-to-one contacts and an increase of 20.9% in individual carer assessments (Table 2). At the same time, there was a decrease of 70.6% in numbers attending group activities. Among the 5 proxy quality indicators routinely reported to the funder, those critical to well-being all showed an improvement (ie, *feeling less alone*, *making it easier to cope with caring role*, and *helping improve physical health*), as did the extra 3 indicators constructed (ie, *reduced stress*, *increased control of personal life*, and *increased confidence*). Improvements ranged from 13% for reduced stress (*P*=.001) to 1% for others (*P*>.05). The only measure to show a significant decrease was *help dealing with health and social care professionals* (*P*=.001). This may, in part, be due to pressures experienced by health and social care staff during the pandemic.

Table 2. Change in carer contact type and quality indicators (from 2019-2020 to 2020-2021).

Survey of Client Caregivers

Respondents

A total of 152 caregivers completed the survey. Personal characteristics (age and sex) were largely comparable to those of all caregivers registered with the CTHE (Table 1). Ethnicity was not recorded in the survey. In terms of employment, the 2 largest groups were those who had retired or people who had given up work to care and those in work or training. The survey respondents included a higher percentage of rural caregivers than the carer register (85/142, 59.9% vs 4778/20,237, 23.61%); of the 152 respondents, 10 (6.6%) did not provide information on their location. Information provided in the survey showed that nearly half of these respondents (70/152, 46.1%) were caring for a husband, wife, or partner and 27.6% (42/152) for a parent, whereas the remaining 26.3% (40/152) had *another relationship*. Nearly one-third (41/148, 27.7%) of people providing more detailed information were caring for someone who was living on their own, and in 78.9% (112/142) of responses, care was provided solely by the unpaid caregiver. Where there was access to support from domiciliary carers, this averaged 19.5 (SD 30.7; range 2-40) hours per week. The CPQ-12 Questionnaire was completed by 94 (61.8%) of the 152 respondents. Respondents achieved a mean score of 25.61 (SD 4.40), with city and rural carers exhibiting similar proficiencies (Multimedia Appendix 3 [20,22]).

Prepandemic Use of Services and Main Barriers

Historically, respondents reported using a broad range of services (Table 3). Reasons for not accessing a particular service were provided by 82.2% (125/152) of the respondents; the remainder (27/152, 17.8%) reported only registering with the CTHE after the first lockdown. Two barriers to use were timing and travel distances, but far more respondents, from 28.6% (30/105) to 39.6% (40/101), perceived lack of awareness of a service as a barrier to its use. A further 33% (30/90) to 44.6% (45/101) stated that, before the pandemic, they had no need for a particular service. During the pandemic, some respondents had stopped using community outreach sites (14/114, 12.3%) and carers centers (19/114, 16.7%); a very small percentage (from 2/114, 1.8% to 4/114, 3.5%) had started to use these services. With cessation of home visits, 21.9% (25/114) reported that they had started to use telephone support during the pandemic.

Table 3. Carers' use of services before the pandemic and perceived barriers to use.

Service	Used 1-12 times (2019), n/N (%)	Barriers to use of a service, n/N (%)			
		Timing not suitable	Too far to travel	Not aware of service	Not needed
Carers center (drop-in visit)	23/116 (19.8)	12/105 (11.4)	5/105 (4.8)	30/105 (28.6)	37/105 (35.2)
Carers center (appointment visit)	16/117 (13.7)	8/101 (7.9)	5/101 (5)	32/101 (31.7)	42/101 (41.6)
Home visits	16/112 (14.3)	9/101 (8.9)	2/101 (2)	30/101 (29.7)	45/101 (44.6)
Outreach (eg, community site)	14/114 (12.3)	4/101 (4)	5/101 (5)	40/101 (39.6)	36/101 (35.6)
Telephone support	48/122 (39.3)	4/88 (4.5)	0/88 (0)	28/88 (31.8)	34/88 (38.6)
Group activities	34/121 (28.1)	11/90 (12.2)	7/90 (7.8)	26/90 (28.9)	30/90 (33.3)

Which Digital Services Were Used During the Pandemic?

Three-quarters (114/152, 75%) of the respondents identified (from a predefined list) which digital support services they used during the pandemic. Email (58/114, 50.9%), Zoom or Microsoft Teams (32/114, 28.1%), and WhatsApp, SMS text messaging, or video (10/114, 8.8%) were most commonly used, mirroring data presented in Figure 2. No respondent had used Skype or FaceTime. The most valued digital support services were carers' well-being assessments, support needs checks, and peer support groups. When asked to indicate which web-based group activities they had experienced (respondents could tick as many as appropriate), 28.8% (34/118) replied. Those carers who provided a response most frequently accessed web-based training and resilience courses (14/24, 58%), virtual yoga sessions or quizzes (10/23, 43%), virtual cafes (9/22, 40%), and "carers evening chat" (4/16, 25%).

A total of 102 comments were entered by participants. These were analyzed for thematic content and commonalities. Three superordinate themes were identified (Textbox 1). These included 8 subthemes (2-3 subthemes emerged for each superordinate theme). A selection of comments relating to each subtheme were extracted. The first theme, how to help carers use digital services in the future, highlighted aspects such as a need for more publicity, activities provided at different times and in different formats, and technical help for persons who are digitally excluded. The second theme, offering a selection of well-being services, contained 2 strong subthemes. One was the view that digital services are invaluable and the second was that face-to-face services are essential for certain functions and for those who are digitally excluded because of their age or for financial reasons. The third and final theme emerging from users was the need to tailor future digital services to meet individual caregivers' needs. This might include, for example, not only addressing the practical elements of caring or issues of isolation and confidentiality but also acknowledging that "people need more than their problems fixing" and not losing the personal service previously provided, which is highly valued.

Textbox 1. Themes from qualitative analysis of responses.

Theme 1: things to help me use digital services in future

- The need for more publicity and better communications
- “I was not aware of the online services, more information/publicity would be helpful.”
- “Better information of services you can use.”
- “Old fashioned ‘come join us’ flyer through the post. My elderly parents need constant encouragement and they don’t read emails and my repeating them...or reading them out does not have the same impact.”
- Technical help and digital inclusion
- “[C]an’t use a computer, [need] help to set up Zoom.”
- “I am not comfortable using online services.”
- “Not everyone is online so cannot avail themselves to online forums...also the cost of broadband needed to use Zoom etc. which requires higher speed etc. is quite prohibitive if you are living on a fixed income.”
- Activities at different times and in different formats
- “They just don’t fit in as they are at times when I’m caring for my mother.”
- “Due to work pattern [I am] not always available.”
- “A wider range of subjects for the online service. Perhaps short podcasts of interesting places in the world e.g. videos of museums around the world or tourist destinations or cultures and traditions or other countries.”
- “A blend of online and face-to-face better. Also, a brief catch-up call if you can’t make a session as guilt can set in for me if I’m overloaded and I feel unable to continue.”

Theme 2: offering a selection of well-being services, including on the web

- Web-based services are invaluable
- “Online saves time travelling and you can access it whilst still caring for the patient in your own home.”
- “Living through COVID has been like being relocated to the moon, no contact with anyone. At a time when in person is still beset with logistical problems the online equivalent is a lifeline.”
- Face-to-face services still necessary
- “It (digital) was a necessary substitute during lockdown but nothing replaces face-to-face interaction.”
- “Nothing is as helpful as face-to-face help, especially where counselling and support services are concerned. Many carers, especially those caring for someone with dementia are elderly and not used to computers.”

Theme 3: tailoring future services

- Practical elements of caring
- “A list of possible areas to look at and their contact details e.g. home cleaners, meals on wheels etc.”
- “I have as a parent, many worries about what will happen when I can’t ‘go on’...Legal advice for preparations for the outcome.”
- “Recommended places approved by members experiences. Where to get...Equipment, grants assistance etc. positive recommendations for work carried out for adaptations by local companies.”
- Addressing isolation and confidentiality
- “I feel very isolated as a carer and being able to go to meetings/events/social gathering and see and speak to people normally I feel is very important, both for me as a carer, and my husband who has mixed dementia.”
- “I feel it is of great importance that you can discuss on a one-to-one level in person or telephone on the day. Not every carer can talk freely about what is going on for themselves and especially if the cared for is listening.”
- Addressing changing times and loss of personal service
- “Go back 15 years and the carers center was a place where you could turn up to have a chat with whoever was on the desk. With the move to the library the feel changed— interactions more like ‘please state the nature of your problem’ than ‘how are you, how are things going?’ People need more than their problems fixing...it is more the emotional and community support. That’s it—emotional support as well as practical support.”

Discussion

Principal Findings

To our knowledge, this is the first large-scale study to analyze the impact of the COVID-19 pandemic on the provision of well-being services for unpaid caregivers. The longitudinal analysis of >20,000 rural and city carers identified, as expected, a move away from face-to-face to web-based service access. The shift observed mirrors those reported by researchers for other services during the pandemic, such as GP practices [2]. However, over the period from January 2019 to June 2021, the number of monthly contacts handled by the carer support organization more than tripled, with no significant changes in staffing levels. Before the pandemic, digital contacts were exclusively by email or SMS text messaging. During the pandemic, additional options were introduced, including Zoom, WhatsApp, and Microsoft Teams, with new web-based group sessions also offered to carers.

Within the context of a 37% increase in the number of carers registered, the organization managed to increase the number of one-to-one contacts by 88.8%. This increase was particularly evident in rural areas, with the ratio of such carers on the register rising from 1 in 10 carers to 1 in 4 carers by the end of the observation period. Rural carers demonstrated slightly different behaviors, showing much slower initial digital adoption rates. In terms of carers' rating of the service received, 6 of the 8 quality indicators showed an improvement, and the other two showed only a minor, nonsignificant decrease. The largest improvement was observed in reduced stress, consistent with the findings of a systematic review of caregiver web-based interventions [23]. Our survey identified a high level of computer proficiency among carers, at or above that reported for other older populations [20,22]. Even so, respondents expressed a preference for the organization to continue to offer face-to-face services as well as web-based options to meet a carer's preferences and the type of well-being support required.

Comparison With Prior Work

Before the pandemic, researchers reported that the uptake of web-based services by older adults in the United Kingdom remained relatively low, despite their potential benefits [24]. A European examination of web-based services available to support informal carers also found a lack of reliability and usability [25]. A qualitative study of the views of caregivers on suitable technologies to assist their caregiving identified similar themes to this larger study, in particular that digital technology needs to be tailored to users' needs in order to ensure adoption [26]. Although it is acknowledged that there may be a huge potential to use such tools to support unpaid carers, it is recognized that wholesale adoption may risk inadvertently exacerbating existing support through digital exclusion [27]; for example, the testing of digital tools in a real-world setting has identified a *digital inverse care law*, with those most in need of support least likely to engage with digital health platforms [28]. In addition, a review of eHealth interventions to support caregivers of older adults also highlights the importance of using appropriate language and text, as well as helping caregivers learn how to use the intervention [29].

Our research shows that, during a crisis such as the COVID-19 pandemic, an organization providing support for the well-being of caregivers was able to successfully implement remote service provision using a mix of traditional and digital tools without a detrimental impact on the reported quality of individual contacts and in the context of an increased workload. Systematic reviews of internet-based interventions to support caregivers have to date reported mixed results and called for more high-quality studies [30,31]. A recent review of factors influencing the implementation of eHealth to support informal care found a gap in knowledge regarding success factors and limited focus on the well-being of the unpaid carer, with the focus being principally on the person receiving care [32]. Similarly, studies of telecare that focus on conditions such as dementia usually do not differentiate the caregivers' needs, instead usually considering the caregiver and the older person or care recipient as a dyad [33-35]. Early in the pandemic, there were some calls to move "carers from the back of the queue" when considering digital services [36]. However, a recent research study of digital interventions for carers of people with dementia still considers need in terms of the dyad, with caregivers in a secondary role [37]. In the United Kingdom, the 2019 report for government on preparing the health care workforce for the digital future recommended that the NHS should work with carer organizations to prioritize the education of patients and caregivers alongside the health care workforce [38].

It is important to consider the indicator that showed a significant deterioration in our study. This was associated with support in accessing health care and social care services, both presumably disrupted by the COVID-19 pandemic. A review of carer support has identified that the ability to coordinate access to such services is particularly valuable, with the integration of home care and community care able to improve outcomes for older people [39,40]. This seems to be particularly important for carers of people with a mental health condition [41]. In Australia, the integration of digital care and clinical care is being assessed to coordinate mental health teams, caregivers, and service users as active partners [42]. The potential for appropriate digital technology to provide support and reassurance is recognized as a benefit for both the caregiver and the person for whom they care [43]. In some parts of the world, volunteers are also being integrated into care to help caregivers use custom-built apps [44].

Investment in innovation to provide optimum support services for informal caregivers could be highly cost-effective. The workforce of unpaid carers represents approximately 6% of the UK population and, together with the 1.3 million registered carers who receive a small carer's allowance, informal caregivers are widely acknowledged as a crucial component in care delivery [12,45]. Furthermore, since the start of the pandemic, the value of unpaid care provided in England is estimated to be £111 billion (US$ 152.7 billion) [46] and in the United States >US $450 billion annually [47]. The UK government has recently set out a range of policies aimed at empowering unpaid carers, with a dedicated, although small, £25 million (US $26.72 million) budget for this purpose [46]. The danger is that the initiatives will once again focus on caregivers rather the sector that supports them. Thus, the opportunity to integrate organizations such as the one in this study into the wider community-based care system will be missed. This study also questions the stereotype of low digital capability among older carers, with CPQ-12 scores demonstrating high computer proficiency. Even so, survey responses indicate that large-scale naïve digital transformation is unlikely to be effective. Instead of a “one-size-fits-all” approach, there is a need for person-centered support (face-to-face as well as web-based options) as part of the service, together with training for those who need it. Meanwhile, there are emerging indications of a move toward providing solely web-based support, with some suppliers looking ahead to younger and more digitally engaged carers who are assumed not to require face-to-face services [48]. The lower cost of web-based support services may make this seem an attractive option for commissioners in the United Kingdom. A similar situation has occurred in primary care with disruptive innovators entering the NHS market to provide web-based GP services, with the evaluation reporting mixed findings and providers withdrawing from some NHS contracts [49]. For any caregiver support service evaluation, as well as delivery costs, there will need to be a careful consideration of utility (ie, quality and effectiveness from the user perspective) [50]. Although this study was set in England, the findings will be relevant for other countries where digital services to support the well-being of informal caregivers are in use or are being developed.

Limitations

There are a number of limitations to this study that need to be acknowledged. First, it is unclear how representative, in terms of its digital readiness, the organization studied is of the whole sector. There are no national audits of such carer support organizations, although it is known that >60% of care homes still use internet connections that will not support full digital transformation [16]. Second, the cohort excluded young carers, which inevitably limits generalizability to the wider population of carers [51]. In addition, an important subgroup (working caregivers) could not be identified due to limitations in the data. A quarter of older workers in England currently have caring responsibilities, and this percentage is expected to increase as the population ages [52]. Third and last, although we identified a high level of computer proficiency in survey respondents, this may not be fully representative because most of the respondents (136/152, 89.5%) completed the survey on the web. Further research is needed to provide evidence on these subgroups before drawing any final conclusions about web-based support services.

Conclusions

Looking to the future, the integration of health care and care services to meet the complex care needs of a country’s aging population is recognized as a global challenge [53]. Considering the importance of unpaid carers, more attention needs to be given in all national strategies to organizations that support this important *free* workforce. Our study highlights a number of issues worthy of further consideration and study that have implications for the design of future cost-effective digital initiatives. These include the lack of any audits of the digital readiness of organizations that provide support for caregivers; the need for a better understanding of rural carers; evidence of the cost-effectiveness as well as the use of different forms of support for caregivers; and the potential for collaboration among different partners within ICSs to better support unpaid caregivers, enhancing their access to, and engagement with, support services after the COVID-19 pandemic.

Acknowledgments

The authors would like to thank a number of staff at Carers Trust Heart of England: Anna-Marie Shanley (quality and performance officer) for data downloads; Steve Thomson (head of business development), Yvonne Moore (business support service manager), and Jacqueline Lucid and Michelle Sawyer (well-being service managers) for valuable advice; and to Claire Dale, chief executive officer, and Melanie Boag, deputy chief executive officer, for their support. Thanks are due to Carers Trust Heart of England for funding the time of AK, SN, and MC to undertake the analyses. The funder had no role in study analysis, the interpretation of data and the writing of the manuscript, or in the decision to submit the paper for publication. Thanks are also due to Dr Michael Loizou (Wallscourt Associate Professor in Health Technology and Life Sciences, University of the West of England, Bristol, United Kingdom) who acted as adviser to the project.

Authors' Contributions

MC and SW developed the original concept. MC, DW, and AS jointly developed the analysis plan for the study. AJK and SN undertook data analyses. AS wrote the first draft of the article, and all authors critically revised the paper for important aspects. All authors read and approved the final manuscript.

Abstract

Background: Alzheimer disease and related dementias (ADRD) are a growing global health challenge. ADRD place significant physical, emotional, and financial burdens on informal caregivers and negatively affects their well-being. Web-based social media platforms have emerged as valuable sources of peer support for these caregivers. However, there has been limited investigation into how web-based peer support might influence their mental well-being.

Objective: This study aims to examine the dynamics of sentiment scores, a major indicator of mental well-being, among informal ADRD caregivers, specifically how their sentiment changes as they participate in caregiving experience discussions within 2 ADRD web-based communities.

Methods: We collected data from 2 large web-based ADRD caregiving communities, ALZConnected (from November 2011 to August 2022) and TalkingPoint (from March 2003 to November 2022). Using the Valence Aware Dictionary for Sentiment Reasoning and Linguistic Inquiry and Word Count, we calculated sentiment scores for each post and evaluated how the initial sentiment score of a topic initiator evolves within a discussion thread. Structured topic modeling and regression analysis were used to identify the primary topics consistently associated with sentiment changes within these threads. We investigated longitudinal sentiment trends to identify patterns of sentimental stability or enhancement due to prolonged engagement in web-based communities by plotting linear interpolation lines of the sentiment values of each individual user.

Results: The ALZConnected dataset comprised 532,992 posts, consisting of 57,641 topic threads and 475,351 comments. The TalkingPoint dataset was composed of 846,344 posts, consisting of 81,068 topic threads and 765,276 comments. Our research revealed that topic initiators experienced a notable increase in sentiment as they engaged in subsequent discussions within their threads, with a significant uptick in positivity in the short term. This phenomenon is part of a broader trend of steadily rising positive sentiment among ADRD caregivers. Using structured topic modeling, we cataloged a diverse range of topics that included both emotional aspects, such as family emotions, and practical concerns, such as diagnosis and treatment and everyday care practices. We observed that sentiment scores were positively aligned with discussions about family and daily routines life (coefficient=3.53; *P*<.001), while topics related to illness (coefficient=–1.37; *P*<.001) and caregiving facilities (coefficient=–1.98; *P*<.001) tended to correlate with lower sentiment scores. This evidence highlights the significant impact that both the time of participation and the posting content have on the sentiment changes of caregivers.

Conclusions: This study identifies sentiment changes among informal ADRD caregivers through their interactions in 2 extensive web-based communities. These findings emphasize the importance of early emotional support within a topic thread and demonstrate a predominantly positive sentiment in these communities over time. These further highlight the value of web-based peer support and its potential to enhance the emotional well-being of informal ADRD caregivers.

Introduction

Alzheimer disease (AD) is the most common cause of dementia, a clinical syndrome that severely impairs a person's memory, language, and judgment and planning abilities [1]. AD and related dementias (ADRD) are increasingly prevalent health issues all over the world [2]. The responsibility of caring for people living with ADRD falls primarily on the unpaid informal caregivers, typically the family members and friends of the people living with ADRD [3,4]. These informal caregivers face a wide range of physical, emotional, and financial challenges that can cause significant stress and negatively affect their health and well-being [5]. Notably, many informal ADRD caregivers claim to have emotional exhaustion that manifests in caregivers as a result of prolonged emotional stress and the constant demands of caregiving. [6].

Understanding the emotional challenges informal ADRD caregivers face and offering appropriate support to enhance their well-being is of vital importance. Prior investigations into these issues have primarily relied upon traditional offline strategies, such as surveys [7,8] and interventions [9]. Additionally, the primary support for ADRD caregivers mainly comes from local, offline resources like charities and community support groups, with efforts like those of Meyers et al [10], who are committed to advancing ADRD research through collaborating with funded researchers and communities. The study by Robinson et al [11] uses existing cross-sectional survey data from the National Institute of Nursing Research–funded National Caregiver Training Project to examine differences between users and nonusers of community services among caregivers of persons with dementia. While these methodologies play an important role in studying and assisting informal ADRD caregivers' needs, they come with inherent challenges. Caregivers may face hurdles in accessing offline support due to geographic constraints [12], resource limitations [13], and individual preferences. As for researchers, offline studies demand financial and human resources and can introduce potential geographical and demographic biases in the collected data.

Recognizing the limitations of offline support, social media platforms have emerged as a valuable, convenient resource for caregivers to gain informational and emotional support that may not be easily obtained in traditional offline face-to-face interactions [14,15]. A recent survey indicated that web-based communities could provide informal caregivers with a sense of understanding, empowerment, support, and belongingness, thus reducing social isolation and improving the emotional well-being of these caregivers [16]. Despite the potential benefits of web-based support, there is a lack of research examining whether informal ADRD caregivers receive positive emotional feedback when discussing their caregiving experience or challenges in web-based communities. This is important because an improved sentiment change observed from posts on web-based platforms may indicate a positive impact of web-based peer support on a caregiver's emotional well-being [17].

In this study, we investigate the changes in the sentiment exhibited by informal ADRD caregivers through their published posts on web-based platforms in 2 large web-based communities, ALZConnected and TalkingPoint. ALZConnected is a web-based community powered by the Alzheimer's Association for any person affected by ADRD in North America, while TalkingPoint is a web-based ADRD community organized by the UK Alzheimer's Society. The selection of these platforms was based on their substantial user base, which provides a rich dataset for analysis, and their focus on ADRD, ensuring that the study's insights are directly applicable to this group. Web-based peer support has been shown to offer a wide range of benefits, including informational and emotional support [18,19], which should also be valuable for caregivers facing the complex challenges of ADRD. Therefore, we hypothesize that the sentiment of informal ADRD caregivers revealed in their published posts will be improved after interacting with other caregivers in web-based communities. Specifically, we investigated the following 3 research questions (RQs) to test this hypothesis.

- RQ1: How did the sentiment of the topic initiator change within a topic thread?
- RQ2: What topics in initial posts were associated with sentiment change?
- RQ3: How did the sentiment of a web-based caregiver change over time within the community?

To investigate these questions, we apply sentiment analysis and statistical methods to determine whether engaging in web-based communities can provide emotional benefits to informal ADRD caregivers.

Methods

For context, there are several key terms that we rely upon in this paper. Web-based communities generally structure discussions into disparate topic threads. Each thread is defined as an initial post followed by several subsequent comments, where these comments contribute to the ongoing discussion initiated by the original post. We refer to the user who initiates a topic thread as the "topic initiator" of the topic thread. The comments published by topic initiators within their own topic threads are called "self-comments."

Data Collection and Preprocessing

We collected data from two large, representative web-based communities that create a unique environment for ADRD caregiving discussions: (1) ALZConnected and (2) TalkingPoint. ALZConnected was established by the Alzheimer's Association [20] as the first and the largest web-based community for any person affected by ADRD in North America. TalkingPoint, on the other hand, is a web-based community organized by the Alzheimer's Society [21] in the United Kingdom for people living with ADRD or their caregivers to share information, advice, and support with one another.

We focused our analysis on a specific subset of forums that are dedicated to ADRD caregivers who share caregiving experiences, seek assistance, and engage in caregiving discussions. To ensure relevance and coherence, we conducted a preliminary selection process, manually reviewing the top 20 most viewed or commented posts within each relevant forum to assess their alignment with caregiving topics. This selection process was designed to retain the vast majority of relevant posts while excluding those that were not relevant to our study, such as posts from individuals with ADRD themselves or from forum administrators. In TalkingPoint, we focused on users with a label of a registered user or new member. In ALZConnected, we focused on users who self-identified as ADRD caregivers. The selection criteria varied between forums due to differences in their search functionalities and user engagement metrics.

We gathered all publicly accessible data from these 2 communities using a web crawler built with the *BeautifulSoup* package of Python (version 4.11; Python Software Foundation). We removed punctuation, special characters, and emojis, and converted the text to lowercase.

Ethical Considerations

Our study received an exemption from human participants research by the institutional review board at Vanderbilt University Medical Center (IRB 221732). Informed consent was waived due to the study's exempt status. To ensure participant privacy and confidentiality, all quoted texts have been paraphrased to prevent user identification. No compensation was provided to participants, as the research involved minimal risk and did not require direct interaction.

Sentiment Evaluation

To mitigate measurement bias that can result from applying off-the-shelf models to our dataset, we applied 2 popular sentiment analysis tools, specifically, Valence Aware Dictionary for Sentiment Reasoning (VADER) [22] and Linguistic Inquiry and Word Count (LIWC) [23], to calculate the sentiment scores of web-based communications to quantify the overall sentiment expressed. These tools were chosen for their ability to consistently analyze large volumes of text data, making them suitable for our study. While they do not have traditional performance metrics like accuracy or F_1-score, they have been validated in numerous studies for their reliability in sentiment analysis.

VADER is a module of The Natural Language Toolkit [24] that provides sentiment ratings based on the words used. It operates as a rule-based sentiment analyzer, where terms are categorized as positive or negative based on their semantic orientation. In this study, we selected the VADER compound score, calculated by summing the valence scores of each word in the lexicon and then normalizing it to a range between –1=most extreme negative and +1=most extreme positive as the sentiment evaluation score.

LIWC calculates the percentage of words in each linguistic category by mapping the words of a given text into a predefined word list of that category [25]. This tool has been widely adopted in social media content–based research [26]. In this study, we focused on the tone category in LIWC, which summarizes the 2 dimensions of positive and negative emotions into a single variable. The LIWC tone score ranged from 0% to 100%, with higher scores indicating a more positive emotional tone. The delineation occurred at 50%, where scores above (below) indicated a positive (negative) tone. In this study, we standardized the LIWC tone score to a range of –1 to 1 to align it with the VADER score range.

The sentiment score, as calculated by VADER and LIWC, reflects the emotional tone inferred from the text and serves as a proxy for emotional support in our study. For example, the post "Hi kids! I want to take a moment to thank all the veterans and their families on this forum..." received a predominantly positive sentiment (VADER 0.94, LIWC tone 0.98), while the post "My mother has lived with my husband and me for a year and I have always felt frustrated and resentful towards her..." was evaluated as predominantly negative (VADER –0.96, LIWC tone –0.84). "Emotional support" is defined here as the presence of supportive feedback inferred from positive shifts in sentiment scores following responses to a user's posts, which will guide our analysis of the changes in sentiment throughout the subsequent research questions.

RQ1: Sentiment Changes of Topic Initiators

To measure a topic initiator's sentiment score changes within a topic thread, we focused on the topic initiators who published at least M (M>0) self-comments with a topic thread. This threshold ensures that the topic initiator contributes sufficient conversational involvement. In this study, M was set to a value that ensured at least 95% of the users posted at most M self-comments.

For each topic thread with at least M self-comments, we define an array, , to represent the sentiment scores of the initial post and the following M self-comments in chronological order. As such, S_0 is the sentiment score of the initial post, while the S_i where i ∊ {1,...,M} is the sentiment score of the ith self-comment. We defined sentiment change, S_Δ, as the difference between the average sentiment score of m self-comments and the initial post's sentiment score: , where , and $m \leq M$. We analyzed the sentiment score changes and generated distributions of these changes with a 95% CI.

To address potential bias from highly active users who contributed a large number of topic threads, we repeated the comparison by randomly selecting a group of P ∊ {5%,10%,25%,50%} of the total number of topic threads in each community. We conducted a pairwise 2-tailed t test to evaluate the difference between and , where N represents the number of selected topic threads in each comparison. We examined the difference at the significance level of α=.05/4 with Bonferroni correction. This adjustment ensures that the error rate remains at the conventional 5% level across all 4 testing groups.

RQ2: Association Between Sentiment Changes and Initial Post Topics

We used the structural topic model (STM) [27] to infer the topics that were communicated in the initial posts, with the subsequent goal of exploring their correlation with sentiment changes. STM is an advanced modeling technique that allows for the incorporation of document-level metadata to inform the discovery of topics within textual data. This unsupervised machine learning approach is particularly adept at handling large, unstructured datasets by identifying latent thematic structures without the need for preassigned labels. This capability makes it an excellent tool for exploring the vast and varied content found in web-based caregiver discussions, where topics may not be clearly defined in advance. Next, we applied ordinary least squares regression, as implemented in the Python package *statmodels* (version 0.14.0), to investigate what kinds of topics in the initial posts are associated with sentiment change.

Before applying topic modeling on the initial posts, we removed stop words and special symbols and discarded words that occurred less than 10 times in the dataset. Since STM is an unsupervised machine learning strategy, we rely on 2 metrics—exclusivity and semantic coherence—to determine the appropriate number of generated topics. Exclusivity refers to the uniqueness of the most frequent words in a topic, while semantic coherence [28] quantifies the co-occurrence of words in a topic in a general context or all the posts. We assess STM for topic numbers ranging from 5 to 30 and select the optimal number K of topics for further analysis [14].

Subsequently, we rank the topics by their prevalence across all documents, a process that involves examining the expected proportion of words in each document attributed to each topic. We calculate the expected topic proportions (ETP) using the *estimateEffect* function in the *STM* package. With this distribution, we conducted a regression analysis where the topic proportions served as independent variables, and the changes in sentiment scores, which were calculated by VADER compound scores or LIWC tone changes, served as the dependent variable. In this regression, we only considered the topics that held an ETP greater than the mean ETP of K topics. For instance, in a model with 20 topics, we would expect an ETP of 5% per topic (1%/20 or 100%/20) on average and only include topics that exceeded 5% in the regression analysis for each initial post.

RQ3: Temporal Changes of Caregiver Sentiment

We defined the active time of a web-based caregiver in the community, up to the point of writing a specific post, as the duration from their account registration to the posting date of that particular post. We analyzed sentiment changes over various fixed time intervals, as 1 week, 2 weeks, 1 month, 3 months, 6 months, 1 year, 3 years, 5 years, and 10 years. For each time interval, we selected posts from active users who had contributed within the designated time frame (0 to the specific interval) and continued to post at least once after that period. For example, to assess sentiment changes for active users within 1 year, we only consider users who have published at least 2 posts (either initial posts or comments) within a year and still have at least 1 post beyond the 1-year period. As such, we ensure that every user included in a time-period analysis is still active in contributing posts. We focused on time intervals where at least half of the users remained active.

To quantify the change in sentiment for active users over time, we plotted linear interpolation lines with 95% CIs to analyze trends in the sentiment values of each individual user. We calculated the Spearman coefficient of correlation [29] to analyze similarities in trends across communities, as well as to validate results across different sentiment analysis tools.

Results

Basic Statistics

We collected data from ALZConnected from November 14, 2011, to August 6, 2022, and TalkingPoint from March 31, 2003, to November 3, 2022. Table 1 provides basic statistics for both datasets. The different time periods for each dataset reflect the respective forum's establishment dates and the availability of their archival data, with no intercommunity comparison being made.

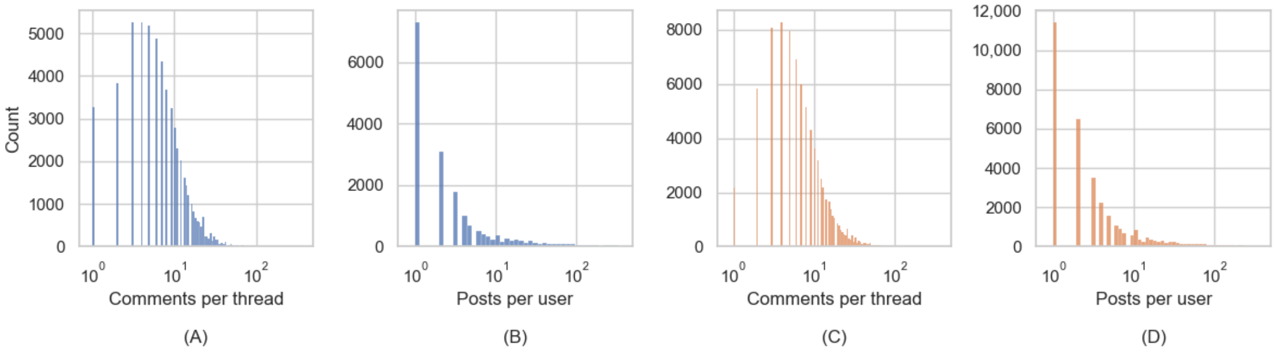
Table 1. Summary statistics for the datasets in this study.

Community	Total posts, n	Topic threads, n	Comments, n	Authors, n	Topic initiators, n	Commentors, n	Time period
ALZConnected	532,992	57,641	475,351	18,569	12,590	14,964	From November 14, 2011, to August 6, 2022
TalkingPoint	846,344	81,068	765,276	34,551	27,907	26,651	From March 31, 2003, to November 3, 2022

The ALZConnected dataset covers 532,992 posts, consisting of 57,641 topic threads and 475,351 comments. It involves 18,569 unique users, 12,590 (68%) of which are topic initiators and 14,964 (80.1%) are commenters, indicating that a nontrivial proportion of users engage in both creating and discussing content. The TalkingPoint dataset covers 846,344 posts, consisting of 81,068 topic threads and 765,276 comments. It involves 34,551 unique users, 27,907 (81%) of which are topic initiators and 26,651 (77.1%) are commenters.

Both datasets exhibit a long-tailed distribution with respect to the number of comments per topic thread (Figures 1A and 1C). For example, most topic threads contain around 10 comments while a few inspire extensive dialogue. Similarly, the distribution of posts per user (Figures 1B and 1D) indicates that, although many users occasionally participate, a small subset of highly active users contribute the majority of the content. These phenomena hold true in both ALZConnected and TalkingPoint. The consistency in posting and user activity patterns across both communities highlights common behaviors in user engagement within social media caregiving forums.

Figure 1. (A,C) The distribution of the number of comments per topic thread and (B,D) the number of posts per user in the ALZConnected and TalkingPoint web-based communities. The plots show the log-scaled x-axis for ease of viewing.

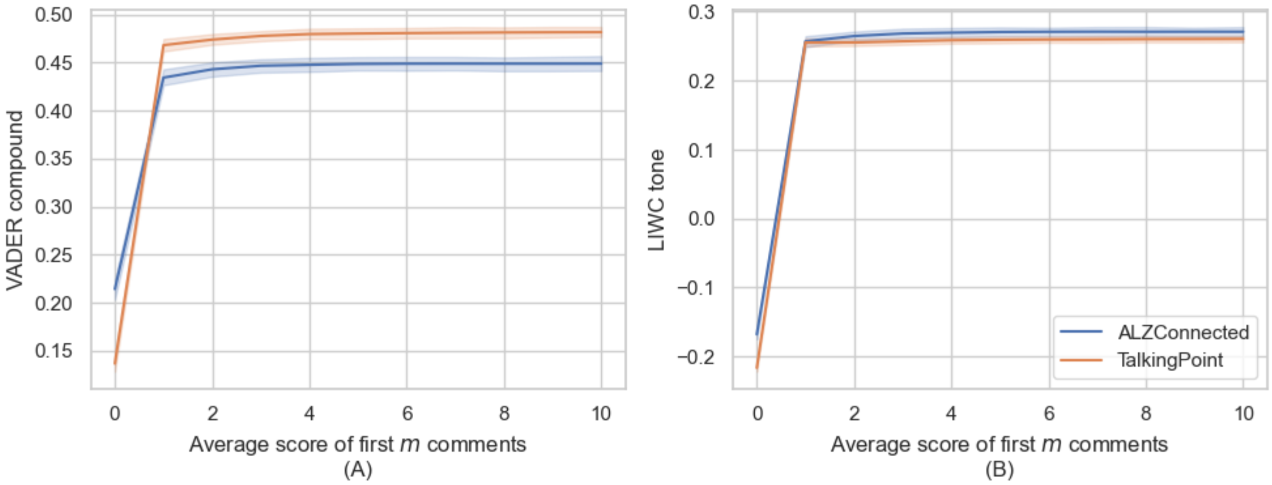


RQ1: Sentiment Change of Topic Initiator

After removing threads lacking self-comments, 30,739 (53.3%) out of 57,641 topic threads from ALZConnected and 53,995 (67%) out of 81,068 topic threads from TalkingPoint remained, comprising 79,869 and 181,049 self-comments, respectively. In ALZConnected, 95% of the topic initiators have fewer than 6 self-comments, while in TalkingPoint, 95% of the topic initiators have fewer than 8 self-comments. To minimize the influence of highly active users, we focused on measuring sentiment changes for the first M=10 self-comments, encompassing 30,209 (98.3%) out of 30,739 and 52,370 (97%) out of 53,995 topic threads, respectively, in ALZConnected and TalkingPoint.

Figure 2 shows how the sentiment score changes within a 95% CI, in terms of VADER compound (Figure 2A) and LIWC tone (Figure 2B), throughout the count of self-comments m. The m=0 on the x-axis corresponds to the initial sentiment score S_0 while m>0 corresponds to the average score of the first m self-comments. For example, a post in ALZConnected stated, "I am overwhelmed with sadness. This entire week, my husband's condition has worsened, leaving him fixated on repetitive thoughts that I cannot divert…[rephrased]" with initial sentiment scores (VADER –0.85, LIWC –0.88). After receiving comments from 3 users, the caregiver's follow-up post showed, "Thank you for your response...My husband, diagnosed with early onset Alzheimer's 5 years ago, isn't physically ill, yet we face immense challenges. [rephrased]" with sentiment scores improving to (VADER 0.54, LIWC –0.48). Thus, it is evident that initial engagement in web-based community discussions is associated with a notable increase in sentiment scores, suggesting prompt emotional support for topic initiators (RQ1). Both VADER and LIWC indicate a substantial increase in the sentiment score as the number of self-comments m grows from 0 to 1. This is followed by a slow, gradual increase as the number of self-comments further increases. This suggests that web-based community interactions effectively provide prompt emotional support to topic initiators. However, these positive changes in sentiment do not escalate rapidly with the frequency of topic initiators' activities within the web-based communities.

Figure 2. Sentiment changes as a function of the number of self-comments. The x-axis indicates the count of self-comments. For example, m=2 represents the average sentiment of the first 2 self-comments under each author's thread. LIWC: Linguistic Inquiry and Word Count; VADER: Valence Aware Dictionary for Sentiment Reasoning.



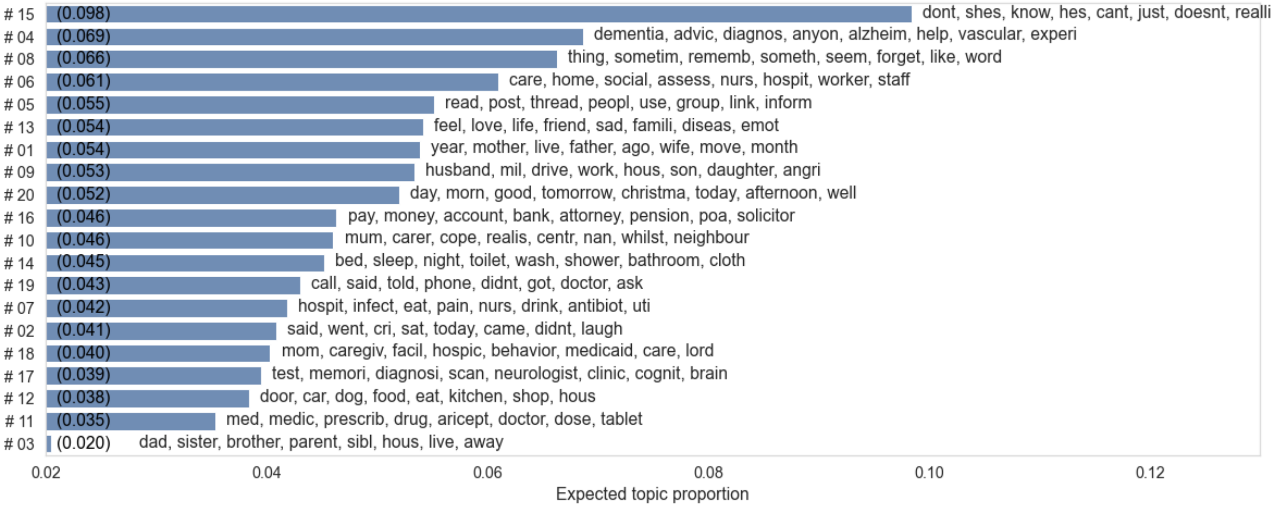
VADER and LIWC show different patterns of changes in sentiment scores. Notably, the VADER compound score indicates a higher initial sentiment in ALZConnected compared to TalkingPoint. However, when the number of self-comments exceeds 1, the sentiment value in TalkingPoint surpasses that of ALZConnected. Conversely, the LIWC tone score shows an opposite trend, though the differences between the 2 communities are less distinct. This dissimilarity might arise from variations in the training corpora used by VADER and LIWC.

We investigated whether the initial sentiment significantly differed from the average sentiment across the first 10 self-comments. The results indicated statistically significant differences between the 2 sentiment values in both web-based communities for all test groups, with *P* values approaching 0, significantly lower than the significance level of α=.0125 (Bonferroni-corrected from α=.05/4). These findings emphasize that web-based interactions have a prompt and noticeable impact on the sentiment of caregivers in web-based communities.

RQ2: Sentiment Changes Correlates with Initial Post Topics

In determining the ideal number of topics for our STM, we evaluated metrics of exclusivity and semantic coherence across a spectrum ranging from 5 to 30 topics. The analysis indicated that a set of 20 topics achieved an optimal balance between word distinctiveness and thematic relevance. Thus, we retrained STM on this number of topics. Figure 3 visualizes this topic modeling, showing the most representative words for each topic and indicating the relative topic proportions, which quantitatively reflect the prevalence of each topic across all analyzed documents.

Figure 3. Topics generated by structural topic modeling, sorted in decreasing order of expected topic proportions. The proportion of each topic is shown to the right of each bar, while the top 8 most representative words in the topic are shown to the right.



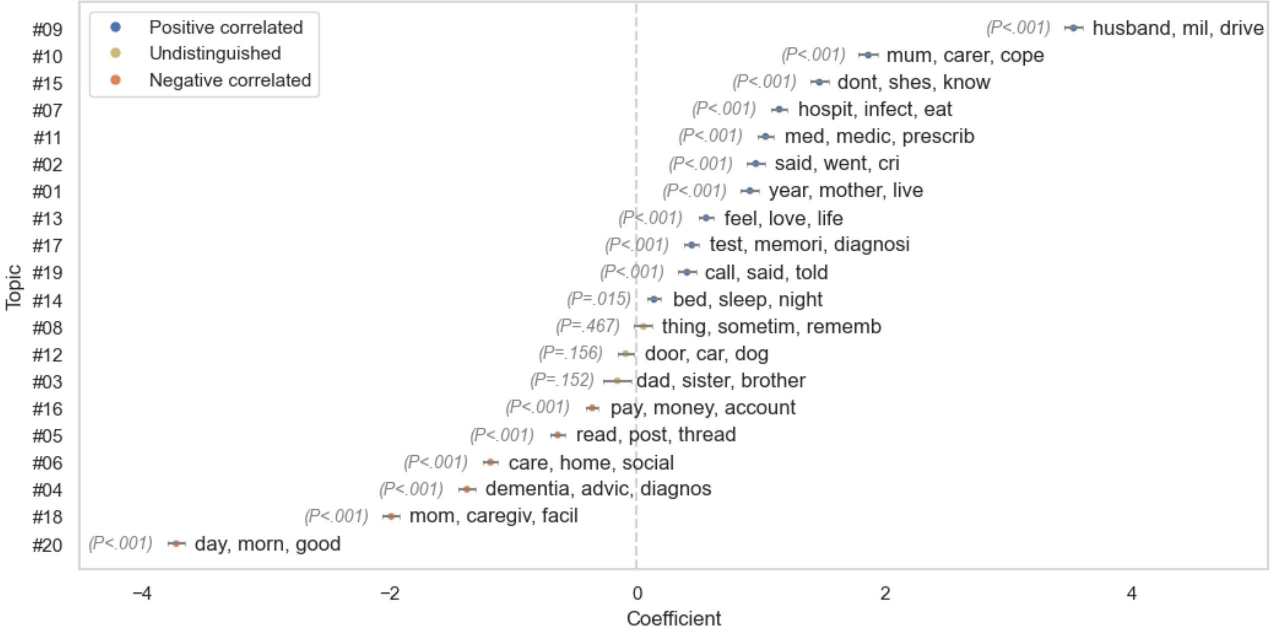
From Figure 3, it was evident that several topics were related to sentiment. For instance, topic #13, which is about "family members feelings," is characterized by frequent words like "feel," "love," and "sad." The ETP of this topic is 5.4%, which stands out as notably high when considering an even distribution across 20 topics would average 5% per topic. This suggests that discussions related to family members' feelings are more prevalent in the dataset than what would be expected by chance.

The following posts are representative examples of this topic: "Sadly, I am letting you all know that my poor mother has left this earth; she passed away peacefully surrounded by her family [rephrased]" and "I miss my husband every day, he is getting further away from us...This disease has taken away his mind, I feel exhausted, and life is not fun at all [rephrased]." These topics are related to sentimental changes and offer insights into the deeply personal and heartfelt experiences of community members. Additionally, we identified topics that convey specific emotional actions. For example, topic #2 contains the keywords "cries" and "laughter," reflecting the diverse sentimental landscape caregivers are facing. A typical initial post from this topic is "When I was a little boy, I often dropped my spoon, and now my old man does the same thing, which makes me laugh and cry at the same time [rephrased]."

In addition to sentiment-related topics, we identified other commonly discussed topics. For example, topic #4 (dementia, advic, diagnos) delved into information related to diagnosis and treatment, providing a relatively objective description. Topic #14 (bed, sleep, shower) centered around caring for people living with ADRD's daily life, while topic #16 (pay, money, account) was about financial matters. Notably, topic #1 (mother, father, wife) and topic #09 (husband, son, daughter) specifically addressed personal relationships such as those with spouses or adult children. Those topics align with previous studies, which have shown that spousal caregivers and adult-child caregivers make up a significant portion of informal ADRD caregivers [30].

To clarify the relationship between the content of initial posts and subsequent changes in sentiment scores, as outlined in RQ2, we present in Figure 4 the influence of each topic on the VADER compound sentiment scores. Blue (positive) and orange (negative) dots represent correlation, each topic's *P* value is displayed beside its associated keywords. This analysis indicates that most topics are statistically significant (*P*<.001), indicating that various topics are significantly linked to sentiment changes within the topic threads.

Figure 4. The coefficients of each topic with VADER compound sentiment changes: blue (positive) and orange (negative) dots indicate correlation, while yellow dots indicate undistinguished features where *P*>.05. VADER: Valence Aware Dictionary for Sentiment Reasoning.



When considering specific topics, topic #9 (husband, mil, drive), exhibits the highest positive correlation with changes in the VADER compound score. This topic talks about family relationships and daily life. This suggests that many users of web-based platforms find comfort in sharing their daily experiences and connecting with others. As a result, emotions tend to become more positive as individuals engage in such sharing and communication. By contrast, the most negatively related topic is topic #20 (day, morn, good), which is primarily related to time. This topic illustrates how, as time progresses, the sentiments expressed by caregivers tend to become more negative, possibly due to the progressive nature of dementia. For example, a representative initial post on this topic starts optimistically, "Good morning, we are already halfway through March...enjoy the day, it's looking good [rephrased; VADER compound of 0.97]." However, as the thread continues, the same author later expresses increasing despair: "Hi [name], not a very good afternoon... Every year I try to finish it by February, but time flies so fast... Things are getting worse for [name]. I hope there is no reincarnation because things are going to be terrible here in a hundred years [rephrased; VADER compound –0.96]."

This transition from a positive to a negative tone, marked by the significant shift in VADER scores, reflects the worsening symptoms over time and the understandable decline in caregivers' moods.

Furthermore, topics directly tied to sentiment, such as topic #2 (said, went, cri) and topic #13 (feel, love, life), exhibit strong positive associations with sentiment changes. In topic #2, discussions often begin with sentiments of sorrow, as seen in posts like, "My mom has not gotten better...I understand why they call it a long goodbye [rephrased]" and typically conclude with acknowledgments of support, "Thank you so much for your support...I know I am not alone. [rephrased]."

Similarly, topic #13 features initial expressions of emotional turmoil, "This is hard to explain but I've been having a weird feeling of loss today...[rephrased]" which transitions into expressions of gratitude, "This is great advice [name]...thank you for staying with me [rephrased]." This indicates that the forum effectively caters to individuals seeking to express their emotional experiences.

Topic initiators may receive positive emotional support, likely due to the compassionate and empathetic nature of users in web-based communities; while topics closely related to illness and caregiving facility, such as topic #4 (dementia, advic, diagnostics) and topic #18 (mom, caregiv, facil), display a negative emotional correlation, underscoring the stress and difficulties that caregivers encounter.

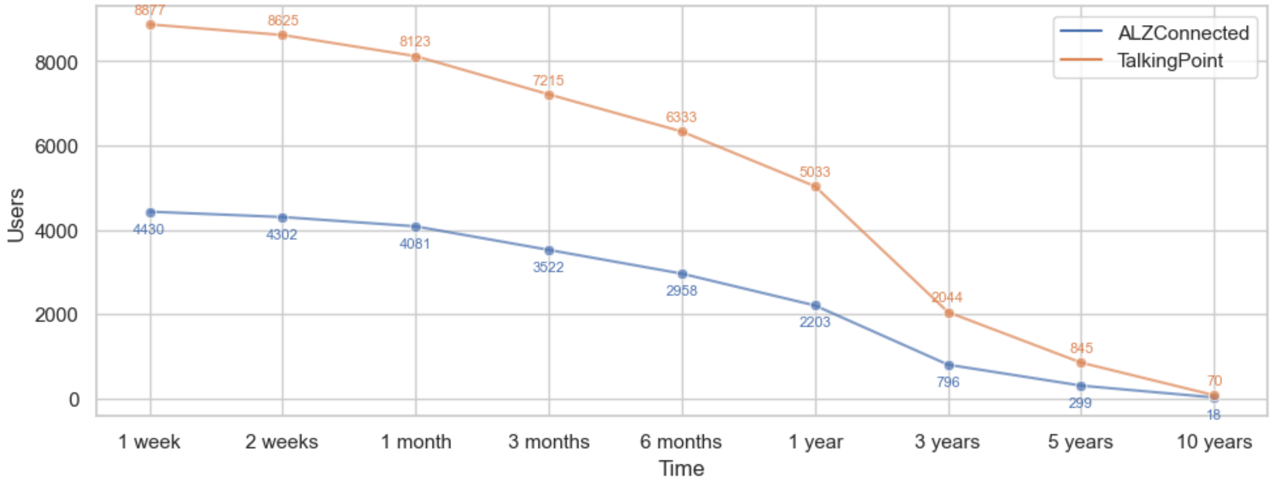
It is worth noting that the performance of LIWC tone scores closely mirrors that of the VADER compound hence we did not present the figure here.

RQ3: Temporal Changes in Caregiver Sentiment

Next, we computed the changes in sentiment according to the VADER compound score and LIWC tone over time. We partitioned users into different timespan groups (from 1 week to 10 years) based on their active time and displayed the sentiment trends in each phase.

Figure 5 shows the number of users active in each timespan, revealing a notable drop in the number of users active for more than a year. For instance, in the ALZConnected community, out of 4430 users who were active for over a week, only 796 (18%) were active for over 3 years, while only 299 (7%) were active for over 5 years. Interestingly, there is a small fraction of users, 18 (0.4%) out of 4430 users in ALZConnected and 70 (0.8%) out of 8877 in TalkingPoint, who remain active for over 10 years. Due to the substantial reduction in active users after the 1-year mark, our subsequent sentiment trend analysis concentrates on the 1-week to 1-year timespan, capturing a more representative (50%) sample of the community's active users.

Figure 5. The number of users that are active in each timespan in the 2 web-based communities.



This analysis examines the trajectory of sentiment scores among caregivers over time to understand the effect of sustained participation in web-based communities. To improve the readability of the figure, we used linear regression lines, along with linear interpolation and its 95% CI, for the data points in each subplot. Figures 6 and 7 provide a comprehensive view of the VADER compound and LIWC tone sentiment changes, respectively, in the web-based communities. Each subplot demonstrates the trend of sentiment change for eligible users in various timespans.

Figure 6. VADER compound sentiment score temporal trend via active time separated into certain time spans. VADER: Valence Aware Dictionary for Sentiment Reasoning.

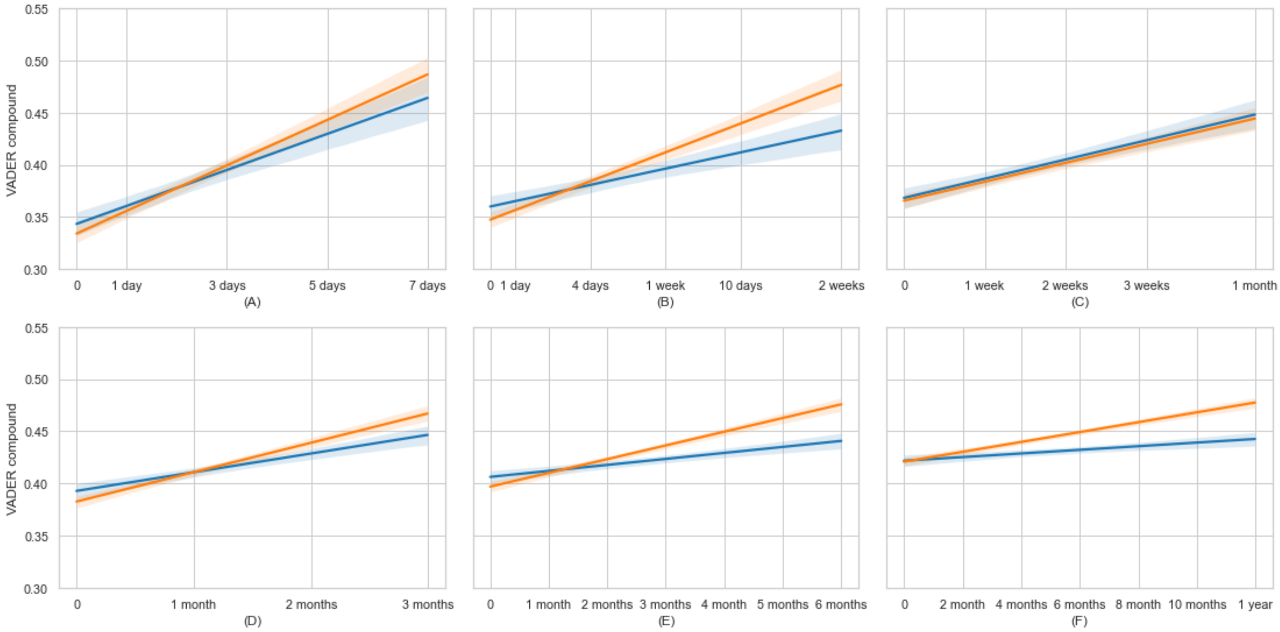


Figure 7. LIWC tone sentiment score temporal trend via active time separated into certain time spans. LIWC: Linguistic Inquiry and Word Count.

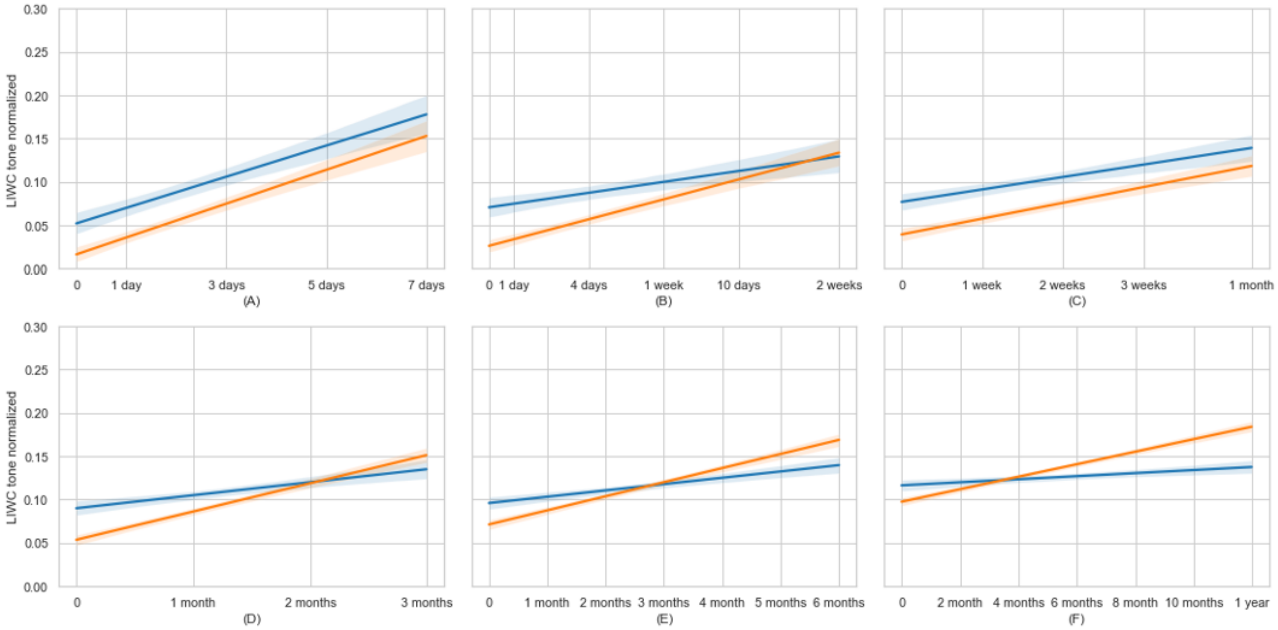

The analysis reveals an overall positive sentiment trend in both web-based communities, suggesting that engagement in these forums is generally associated with positive emotional expression. Notably, as the active time interval grows, the increase in sentiment weakens. The Spearman rank-order correlation between the VADER compound score and active time within 1 week, 1 month, and 1 year are 0.062, 0.038, and 0.021 (all statistically significant at *P*<.001), respectively. This finding suggests that participation in the web-based community increases a user's sentiment. However, the effect becomes less pronounced as users spend more time in the web-based community. Third, in both sentiment score measures, there is no substantial difference between ALZConnected and TalkingPoint, showing that both communities provide an environment for ADRD caregivers to express their feelings, supporting the validity of analyzing sentiment changes in ADRD caregivers in either community.

Discussion

Principal Findings

This study illustrates patterns related to the sentiment score changes of informal ADRD caregivers within 2 large web-based communities, shedding light on the role of web-based peer support in enhancing their emotional well-being.

Our investigation into the sentiment changes of topic initiators revealed a prompt elevation in sentiment scores compared with their first self-comment. For example, within a TalkingPoint thread spanning 2 years with 8264 comments, the topic initiator initially expressed frustration, stating, “Fed up to the back teeth today. Had a bad night and all day, Mum talking to the clock and asking her Mum to come and get her [VADER –0.36, LIWC –0.22].”

However, after receiving responses from 3 other commenters, one of which is “wish I could draw I had a great image in my head...OK I’ll stop. I just wanted to make you laugh—that’s the best I can come up with [VADER 0.75, LIWC 0.80],” the tone of the conversation shifted positively, as indicated by the first self-comment, “Haha, I feel better now, coming here is like taking a tonic. Thanks, my TP friends. Gotta go, mom has to go to the bathroom so I got the cat out [VADER 0.93, LIWC 0.98].”

This initial boost was followed by a gradual yet continuous improvement as the number of self-comments increased, emphasizing the efficacy of web-based communities in delivering prompt and ongoing peer support to caregivers. Jenkins et al [31] found that web-based support can significantly contribute to well-being, suggesting a similar benefit for ADRD caregivers who actively participate in web-based communities.

Moreover, the continuously increasing trend in sentiment score suggests that web-based peer support is effective in increasing social inclusion [32], which helps to maintain an emotional balance. A plausible explanation is that long-term caregivers in web-based communities who have years of caring experiences, when becoming more capable of caring for people living with ADRD through learning from web-based peers, may sustain stable sentiments. This assumption can be proved by the same example thread as mentioned above, which includes the topic initiator’s 1064 self-comments. As the self-comments progressed from learning new caregiving skills (“Learned a new way to talk to my mom”) to sharing resources (“Same thing happened to me, [name], I recommend you read this book [title], it really helped me”), a strong sense of community and mutual support was ultimately fostered. The last self-comment we collected from a topic initiator was “Hi ladies, hope you all had a great Christmas break, and everyone had a blast. I miss you all and hope the new year is just as great. Big hugs [VADER 0.97, LIWC 0.98].”

As long-term caregivers in web-based communities progressively enhance their caregiving skills through continued engagement with the community [33], their increased proficiency makes their caregiving responsibilities more manageable [34], thus improving their overall quality of life.

However, the sentiment trends of long-term users exhibited a slower sentiment improvement rate compared to short-term users. One possible reason could be that the trajectory of caregiver burdens is highly dynamic and complex due to increased behavioral impairment and decline in functional status in people living with ADRD [35]. This complexity makes it unrealistic to remove all the stressors in this long-term caregiving journal. In other words, informal caregivers will be in stressful situations, and an upper limit of their emotional well-being may exist even when receiving support from other peers in web-based communities. Cultural complexity in caregiving, which includes diverse cultural norms, values, and caregiver expectations, further influences these experiences. It is reflected in the findings of Ajrouch et al [36] that, although often overlooked in research and service delivery, the role of cultural complexity in ADRD care has been recognized.

Furthermore, our topic modeling analysis identified various ADRD caring topics, including those discussing diagnosis, treatment, daily care, and financial matters. We found that topics discussing personal and heartfelt caregiving experiences exhibited a significant positive correlation with sentiment improvement. For example, an initial post in topic #9 aligned with this trend: “My husband has been taking [drug] for anger for about [specific] days now, but it’s not working. Nothing he’s tried seems to work. It drives me crazy [rephrased].” In response, subsequent commentators provided valuable support, sharing experiences with this drug or offering emotional support through sympathy and comfort. These interactions contributed to a more positive sentiment score in the self-comments.

However, our topic analysis also revealed that posts associated with ADRD, and caregiving facilities were correlated with lower sentiment scores, which might be due to the inherent challenges of ADRD caregiving related to these topics. The complexity of ADRD poses significant emotional and psychological challenges for caregivers [37]. For instance, an indicative initial post from topic #4 reads, “Hi, I am a full-time carer for my [age]-year-old husband who has vascular dementia and is profoundly deaf. Is there anyone on the forum who is in a similar situation? Thank you [rephrased].” The responses to this post included, “Hi [topic initiator name], my [age]-year-old husband has vascular dementia but without the added complication of being deaf. He lives so much in his own world most of the time that he often seems to be deaf, though. It doesn’t feel nice [rephrased].” These interactions led to the topic initiator’s self-comment, “Thank you all for your responses. It seems to be totally deaf, and dementia is quite uncommon. You are right—I do often feel lonely and isolated, as he must as well. I feel very sad [rephrased].” This is a typical example of negative sentiment change resulting from communication with other users of web-based platforms in the community. ADRD caregivers often witness their loved ones struggling with a loss of identity and independence. As caregivers provide care and support for individuals with ADRD, they often experience feelings of sadness, frustration, and helplessness [38]. In this situation, the decrease in sentiment may be caused by the continued narrative of their negative caregiving experience. However, sharing these challenging experiences with other web-based peers may foster a sense of belongingness among caregivers [39,40], which may lead to a long-term sentiment improvement, as shown in our sentiment temporal trends analysis.

Limitations and Future Works

While sentiment analysis tools provide valuable insights, they may not fully capture the intricate nuances and complexity of human emotions within the ADRD caregiving context. Future analyses may consider combining supervised machine learning for more precise sentiment classification. Although our study identified a correlation between topic initiators and positive sentiment change within threads, it is important to delve deeper into understanding whether web-based interactions directly cause sentiment changes. Our future research will expand the analysis to include all comments within a thread, thus offering a more comprehensive view of the community's support structure. This approach will allow us to better understand the overall sentiment dynamics and support mechanisms across the platform, addressing the skewed perspective that may arise from focusing solely on self-comments.

The use of STM in our analysis, while powerful for identifying dominant themes from large text corpora, can also present challenges. These models may generate overlapping themes that do not distinctly separate different but related caregiving aspects, due to the unsupervised nature of the topic generation process. This overlap can sometimes obscure the clarity of how specific topics impact caregiver sentiment. Future studies might explore refined modeling techniques that can more effectively differentiate closely related topics or apply hierarchical models to capture nested thematic structures.

Also, our study only examined the registered users who actively write posts on web-based platforms. Since both web-based communities are open to anyone, the data primarily reflect the experiences of active contributors, potentially overlooking the perspectives of passive users or those who may face barriers to participation. This selective participation may concentrate the content creation among a small subset of highly active users, which might narrow the findings to this more vocal group. Additionally, the lack of demographic data on participants limits the generalizability of our findings across diverse caregiver populations, which could result in an unrepresentative sample. It will be interesting to investigate how discussions on web-based platforms, as collective knowledge, can influence the emotional well-being of all caregivers, including those who only observe interactions without contributing directly. Such findings will help to expand the impact of web-based peer support, which is unique to open web-based communities.

Conclusions

To the best of our knowledge, this is the first study to investigate how sentiment changes among informal ADRD caregivers within 2 open, large, existing web-based communities using computational methods. We observed improved sentiment score trends at both the topic thread and community levels, highlighting the positive impact of web-based peer support for both short-term and long-term caregivers on web-based communities. However, we did find some topics that are negatively associated with sentiment improvement, which reflects the complexity of some caregiving burdens that might not be easily solved at the emotional level. Overall, our findings indicate that peer support in web-based communities can be powerful in assisting informal ADRD caregivers.

Abstract

Background: In 2022, the US Department of Health and Human Services released the first National Strategy to Support Family Caregivers, identifying actions for both government and the private sector. One of the major goals is to expand data, research, and evidence-based practices to support family caregivers. While IT tools are widely deployed in health care settings, they are rarely available at scale in community agencies. In 2019, the state of California recognized the importance of a statewide database and a platform to serve caregivers remotely by enhancing existing service supports and investing in a web-based platform, CareNav. Implementation commenced in early 2020 across all 11 California Caregiver Resource Centers.

Objective: This paper describes the implementation strategies and outcomes of the statewide implementation of CareNav, a web-based platform to support family caregivers.

Methods: The Consolidated Framework for Implementation Research (CFIR), including a recent addendum, guided this mixed methods evaluation. Two major approaches were used to evaluate the implementation process: in-depth qualitative interviews with key informants (n=82) and surveys of staff members (n=112) and caregivers (n=2229). We analyzed the interview transcripts using qualitative descriptive methods; subsequently, we identified subthemes and relationships among the ideas, mapping the findings to the CFIR addendum. For the surveys, we used descriptive statistics.

Results: We present our findings about implementation strategies, implementation outcomes (ie, adoption, fidelity, and sustainment), and the impact on population health (organizational effectiveness and equity, as well as caregiver satisfaction, health, and well-being). The platform was fully adopted within 18 months, and the system is advancing toward sustainment through statewide collaboration. The deployment has augmented organizational effectiveness and quality, enhanced equity, and improved caregiver health and well-being.

Conclusions: This study provides a use case for technological implementation across a multisite system with diverse community-based agencies. Future research can expand the understanding of the barriers and facilitators to achieving relevant outcomes and population impact.

Introduction

Background

Family caregiving is gaining visibility as an important public health issue, with 1 in 5 families engaged in long-term care for older adults and persons with disabilities often lacking adequate resources and supports [1]. The complexity and intensity of caregiving for older adults and persons with disabilities is increasing as the population ages, and more individuals live longer with physical, cognitive, and mental health challenges. Family caregivers enable family members and friends to live with chronic conditions in their environments of choice, assist with navigating acute health crises and hospitalizations, and provide comfort and support at the end of life. More than half of all family caregivers provide complex care, including medical or nursing tasks previously performed in inpatient settings, delivering most of the care after discharge from hospitals [2]. State-level data reveal that in California, at least 4.4 million family caregivers assist individuals aged >18 years; of these caregivers, more than half (56%) are employed while providing care. These individuals provide an estimated US $81 billion worth of unpaid care each year [3].

Caregivers remain relatively invisible in the health care system, to their employers, and in their communities; yet, they bear the brunt of delivering most of the long-term care for the aging population. Caregivers report a lack of knowledge regarding the best caregiving practices, often learn how to deliver care on their own, and are worried about making mistakes [2]. Most caregivers are employed, but their income is often compromised by the caregiving role [3]. While family caregivers report positive aspects of caregiving, they also experience strain, depression, and loneliness; moreover, they neglect their own health-related conditions because of the caregiving role [2]. There is evidence of health disparities in caregiving demands, supports, and resources among diverse populations by race or ethnicity and socioeconomic status [4]. Recent systematic reviews have concluded that caregivers require information and skills training, tools to improve coping with the physical and emotional burden of caregiving, paid and unpaid help, effective communication with the person in their care, and support to address barriers as they navigate the health care system [5,6].

In 2022, the US Department of Health and Human Services released the first National Strategy to Support Family Caregivers, identifying actions for both government and the private sector [7]. One of the major goals is to expand data, research, and evidence-based practices to support family caregivers. While IT tools are widely deployed in health care settings, they are rarely available at scale in community-based agencies. Clinical settings use consumer-facing features such as secure internet portals that enable individual access to the electronic health record and facilitate secure email messaging between the person and the health care provider, as well as internet-based resources for education, information, advice, and peer support [8]. IT tools could be highly beneficial for community-based caregiver assessment, service delivery, and the evaluation of a broad range of interventions, increasing access and convenience. To date, most projects examining innovative IT tools focus on feasibility and acceptance with studies of limited sample sizes [9-11].

The California Caregiver Resource Center System

Established in 1984 by the Comprehensive Act for Families and Caregivers of Brain-Impaired Adults to support caregivers and care recipients, the California Caregiver Resource Center (CRC) system includes 11 sites with catchment areas covering the entire state. Staffed with administrators, family consultants, and educators, the CRCs respond to caregiver inquiries or referrals by conducting a short intake followed by a structured standardized assessment should the caregiver want to proceed. Before 2020, these assessments were completed on paper, either in person or by telephone. In 2020, the CRCs conducted 6126 intakes, with 4299 proceeding to full assessment. In some cases, caregivers have a simple query that is satisfied with the initial contact; others seek longer-term support. After the assessment, family consultants develop recommendations for community-based services and supports based on caregiver priorities and needs, including appropriate referrals for respite, counseling, financial or legal consultation, education, and support services. The CRCs do not address the health care needs of the care recipient; instead, they recommend follow-up with health care providers.

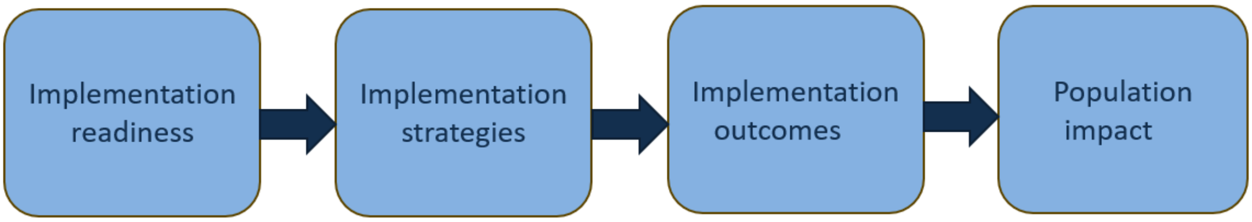
The Implementation of a Statewide Caregiver Database

Recognizing the importance of a statewide database and a platform to serve caregivers virtually, in 2019, the California Department of Health and Community Services invested in a web-based platform, CareNav, across the existing support network, the California CRC system. The Department of Health and Community Services committed to funding expanded caregiver services and the deployment of CareNav over 3 years (2019-2022). In essence, the deployment of CareNav converted a manual record system to an electronic system with expanded functionality to manage client services and supports. The proprietary software platform CareNav was developed by the San Francisco Bay Area CRC, Family Caregiver Alliance, in collaboration with software developer Quality Process [12]. CareNav enables standardized caregiver self-assessment, a web-based record of client information and encounters, secure communications, and the ability to create a care plan as well as tailored information and resource content. Clients may complete the assessment either on the web or by contacting staff members who administer and document the assessment in the electronic record. The system includes administrative functionality for tracking service authorizations and contracts, generating aggregate profiles, and producing management reports on staff activities.

Led by the Family Caregiver Alliance, statewide CareNav implementation included related training for all CRC sites on platform use, data quality improvement, and change management. The University of California Davis Family Caregiving Institute was engaged to evaluate the implementation process. A previous publication described the implementation process and early outcomes [13]. The Consolidated Framework for Implementation Research (CFIR) guided our evaluation [14]. Early findings indicated that leadership, communication, the harmonization of processes across sites, and motivation to serve clients using technology were critical elements of success.

The aim of this paper is to describe further progress, including implementation readiness, implementation strategies, and subsequent implementation outcomes and population impact of the web-based resource IT tool or platform (CareNav) at the 11 California CRCs. A recent addendum to the CFIR went beyond evaluating the outer setting, the inner setting, the intervention characteristics, staff characteristics, and the process of implementation by augmenting the original model with implementation outcomes and population impact [15]. The dynamic sustainability framework [16] informed the interpretation of the sustainability of implementation outcomes. The conceptual model for this study incorporated both the CFIR addendum and the dynamic sustainability framework, adapted from the work of Damschroder et al [15] and Chambers et al [16], and is depicted in Figure 1.

Figure 1. Consolidated Framework for Implementation Research addendum.



Methods

We used a mixed methods sequential triangulation design to examine the implementation process and outcomes, including focused interviews with CRC staff members and leaders and surveys of both staff members and caregiver clients.

Ethical Considerations

The study was determined as exempt research and approved by the University of California Davis Institutional Review Board (IRB ID: 1561379-2). No identifying information was collected from participants in the focused interviews and surveys. Participants were informed of the study's purpose and the voluntary nature of participation. In the focus interviews, participants provided oral consent to participate and to be recorded. In the surveys, participants provided assent by completing the survey.

Recruitment

We recruited participants from the 11 California CRC sites. For focused interviews, we sent an email invitation to all leaders and clinical staff members as well as the implementation team. All current leaders and staff members of the 11 CRCs were eligible to participate in the focus group interviews. For the staff survey, we sent email invitations to all CRC staff members to complete. The survey was administered electronically between July and September 2023. For caregiver surveys, the sites distributed surveys quarterly to all caregivers served in the past quarter (4 quarters during the year between July 2022 and June 2023). Caregivers were given the option to complete the survey electronically or on paper, mailing the response to the sites, whose staff members entered the data in an electronic database.

Focused Interviews

We conducted within-site focus group interviews with leaders and staff members of each site (22 focus groups in total) and interviewed 2 key informants from the implementation team. After obtaining consent to participate and be recorded, we used a semistructured interview guide to explore the CareNav implementation process, challenges and facilitators, anticipated system and client outcomes, satisfaction with the process, and training activities. The interviews were conducted over Zoom (Zoom Video Communications, Inc) in March and April 2022 and audio recorded. The duration of the interviews ranged from 45 to 60 minutes.

Surveys

The Readiness Survey

The readiness survey is a tool assessing staff preparation and confidence regarding the implementation process and self-efficacy using a 5-point scale (1 represents the most negative response and 5 the most positive response) [13]. The readiness survey also assessed knowledge about CareNav, caregiver support to use CareNav, and implementation outcomes encompassing CareNav adoption and developmental phases (fidelity). Six items addressing developmental phases rated current CareNav use and willingness to expand CareNav use according to functionalities previously identified in the focused interviews. These items were tailored to either clinical or administrative staff, depending on role. Clinical staff responded to 15 items focused on using CareNav to guide assessment and encouraging clients to access CareNav. Administrative support staff responded to 14 items focused on using CareNav data to make decisions. Open-ended questions identified benefits and concerns about CareNav, as well as suggestions for improvement.

The Caregiver Satisfaction Survey

The caregiver satisfaction survey assessed satisfaction with services, confidence in caregiving, knowledge, caregiver stress, and experiences with the web-based platform and technology. The surveys included items rated on a 5-point scale. Scores range from 1 (*strongly disagree*) to 5 (*strongly agree*), with 5 indicating the most positive impact. The survey also invited comments from caregivers in an open-ended format. Surveys were translated into Spanish and back translated into English and clients could select either English or Spanish versions.

To encourage caregivers to participate in the satisfaction survey in a safe environment and minimize social desirability bias, the surveys were anonymous, and associated demographic data were not collected.

Data Analysis

The recordings of the focus group interviews were transcribed, audited, and then imported into Dedoose qualitative data analysis software (SocioCultural Research Consultants, LLC). We used qualitative descriptive methods to analyze the transcripts and open-ended responses to the surveys [17,18] and established a 3-phase protocol for analysis. In the first phase, 3 members of the research team reviewed the transcripts and developed initial codes and definitions. In the second phase, 2 team members coded the transcripts, meeting weekly with the third member to discuss coding decisions; refine code definitions; reach consensus about the coding; and identify themes, subthemes, and relationships among the ideas. In the third phase, we mapped the themes to the CFIR addendum and the dynamic sustainability framework. We documented analysis notes, codes, and refinements in an audit trail.

Quantitative data from both surveys were analyzed using SPSS software (version 27.0; IBM Corp) to generate descriptive statistics. Mixed methods data analysis was performed after the completion of separate analyses of the survey and focused interview data. During this phase, we integrated quantitative and qualitative results and interpreted the findings in relation to the CFIR addendum and the dynamic sustainability framework.

Results

Participants

Across 11 CRC sites, 80 members of the staff (clinical staff members [family consultants or social workers]: n=43, 54%; administrative support staff members: n=10, 13%; and leaders [directors, clinical directors, and managers]: n=27, 34%) participated in 22 site-specific focus group interviews, with between 2 (2%) and 15 (19%) participants per site. In addition, we conducted 2 individual interviews with key informants from the implementation team.

For the readiness survey, there were responses from 118 staff members, of whom 112 (94.9%) completed at least 80% (12/15 for clinical staff and 13/14) of the readiness survey responses, and 105 (89%) submitted a demographic survey. Most of the participating staff members served in clinical roles (70/112, 62.5%), and the remaining (42/112, 37.5%) were in administrative roles.

All samples were diverse across age and racial identity, with most of the participants being female (60/82, 73% in the focused interviews and 85/105, 80.9% in the readiness survey). Demographic characteristics of the samples are presented in Table 1.

For the caregiver satisfaction survey, of the 5782 caregivers served during fiscal year 2022-2023, a total of 2229 (38.55%) responded. In addition to responding to the survey items, caregivers were invited to make comments about the services. Caregivers provided 1210 comments about the services, of which 40 (3.31%) were in Spanish. While we did not collect demographic data in these anonymous surveys, we present the characteristics of the population of caregivers who completed assessments between July 2022 and June 2023 with the CRC sites (n=5782) in Multimedia Appendix 1.

We present survey results and major themes from the qualitative data that reflect major components of our conceptual model: implementation readiness, implementation strategies, implementation outcomes, and population impact.

Table 1. Demographic characteristics of staff members participating in the focused interviews and readiness survey.

Participant characteristics	Interviews (n=82), n (%)	Readiness survey (n=105)[a], n (%)
Age (y)		
≤25	8 (9.8)	1 (1)
26-35	30 (36.6)	39 (37.1)
36-45	11 (13.4)	27 (25.7)
46-55	12 (14.6)	11 (10.5)
56-65	11 (13.4)	13 (12.4)
>65	4 (4.9)	6 (5.7)
Declined to answer	6 (7.3)	8 (7.6)
Sex		
Female	60 (73.2)	85 (81)
Male	16 (19.5)	13 (12.4)
Other	1 (1.2)	3 (2.9)
Declined to answer	5 (6.1)	4 (3.8)
Racial and ethnicity[b]		
African American or Black	4 (4.9)	5 (4.8)
Asian or Pacific Islander	12 (14.6)	17 (16.2)
Hispanic or Latinx	34 (41.5)	39 (37.1)
Native American	2 (2.4)	2 (1.9)
White	30 (36.6)	37 (35.2)
Other	1 (1.2)	2 (1.9)
Declined to answer	5 (6.1)	10 (9.6)

[a] Of the 118 survey respondents, 105 (89%) submitted demographic surveys.

[b] Percentages may not total 100 because respondents could select multiple racial identities.

Implementation Readiness

We assessed the implementation readiness of staff members with the readiness survey. Overall, participants had very positive attitudes toward the implementation of CareNav, with a mean total readiness score of 4.3 (SD 0.5) on a scale of 1 to 5, where 5 represents the most positive response. Average responses to all items were in the positive range (Table 2).

Table 2. Readiness survey responses 3 years after implementation launch (n=112).

Item	Score, mean (SD)
Knowledge and beliefs about CareNav	
CareNav improves the ability to record services	4.4 (0.8)
CareNav provides tailored and accessible information for caregivers	3.8 (1.0)[a]
Clients should be given a range of service delivery options to ensure they select one that works best for them	4.8 (0.5)
Self-efficacy	
Prepared to use CareNav	4.3 (0.7)[a]
Confident to use CareNav	4.4 (0.7)
Capable to use CareNav	4.5 (0.7)[b]
Readiness for change	
Positive regarding the expansion of CRC[c] services	4.4 (0.8)[b]
Positive regarding using CareNav	4.1 (0.9)[a]
Willing to do new things	4.4 (0.7)
Know where to obtain help	3.5 (1.3)
Total readiness score	4.3 (0.5)
Developmental phases of CareNav implementation	
Use CareNav data to understand the needs of diverse clients	3.7 (1.3)
Clinical support	
Use CareNav to guide assessments and enter data in real time	4.3 (1.0)
Encourage clients to access CareNav through the portal	3.1 (1.2)
Would like to expand use of CareNav to coordinate client support	3.8 (1.0)
Administration	
Use CareNav data to make decisions regarding the CRC site and its programs	3.6 (1.0)
Would like to expand use of CareNav	4.3 (1.0)

[a] n=111.

[b] n=109.

[c] CRC: Caregiver Resource Center.

Implementation Strategies

Overview

The implementation process entailed iterative, continuous, and long-term activities using real-time analysis of client data with adaptation and refinement. Focus group participants and key informants described 3 main strategies used: data harmonization and quality, training and technical support, and group learning. Figure 2 summarizes the implementation strategies.

Figure 2. Implementation strategies.

Data Harmonization and Quality

The goal of creating a statewide database and service management system carried several important assumptions, including standardizing the assessment, adopting common workflows around services and referrals, and agreeing to shared metrics for success. CRC site staff members and the Quality Process technology team engaged in data harmonization and quality, facilitated by the evaluation team. During the early part of the project, the design team engaged in deep learning at each site to understand the local conditions and to map the technology implementation path. The overall approach to initial deployment was to optimize the common elements and to minimize customization. The philosophy of designing and scaling CareNav necessitated balancing the unique data collection and integration needs of each site, with the goal of creating a state-level decision support and resource provision system to expand services for California caregivers. Thoughtful decisions were made regarding the extent of the site-level flexibility that the system could support for each CareNav feature without compromising uniformity.

The evaluation team conducted extensive analysis of CareNav data, including variables collected at intake, assessment, and reassessment, providing rapid-cycle feedback to the CRC sites when data discrepancies were identified. The evaluation team also raised issues around data quality and integrity to the CRC directors and clinical directors for discussion and consensus building. Implementation involved data harmonization—the integration of data sources and structures from the 11 sites—requiring processes to ensure data quality and consistency. There were 2 major issues in the implementation of a standardized assessment: mapping previous data to the appropriate fields in CareNav and coming to consensus on variable definitions to reconcile diverse interpretations of specific data points.

Several threats to data quality had to be resolved through consensus building. First, staff members held diverse beliefs about data accuracy and quality, which led to different practices in collection and entry; for example, staff members varied in how they conducted and recorded assessments, ranging from the majority of consultants administering the standardized assessment and completing data fields in a systematic way into the electronic record to consultants at 1 site using the standardized assessment as a general guide for conversation and later entering their interpretation of the client's narrative as data. At this site, consultants conducted guided interviews, after which another staff member entered the data. Data integrity was further threatened because staff members interpreted the meaning of data fields differently and subsequently recorded with this bias. These issues were compounded when staff members conducted the interviews in languages other than English (the only language currently supported by CareNav), then translated and entered data. Complex concepts, such as spirituality or loneliness, carry different cultural meanings and are subject to linguistic inaccuracy across translation. Finally, site leaders varied in their commitment to ensuring data quality and in their ability to provide guidance to their teams to achieve consensus and accuracy.

Training and Technical Support

Technology deployment requires extensive training and technical support. Users begin with different levels of technical and data understanding; therefore, leaders must customize training to establish shared foundational knowledge and skills and to address site- and person-specific learning needs. Furthermore, CareNav features a client portal, necessitating the preparation of caregivers—both in general digital access and specific coaching—to use the program. The implementation team advanced training and support in several ways, with site-specific education sessions, statewide web-based training, and site and individual technical support, as well as assisting staff members to support caregivers [13].

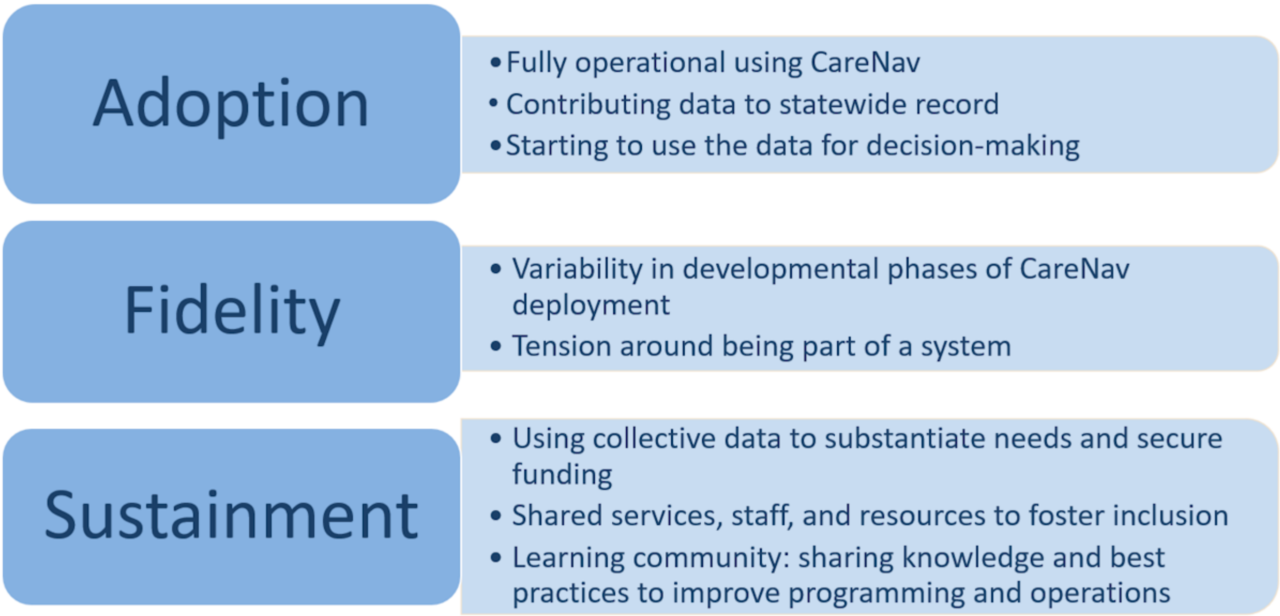
Group Learning

The statewide deployment of CareNav offered the CRC sites new opportunities for collaboration and group learning. Several subgroups were formed, including those focused on clinical, leadership, and data management issues. Within these subgroups, members across the state engaged with one another in lessons learned and shared educational materials and best practices among the sites. A statewide education committee was formed to identify and develop collective resources for both staff members and clients. The collective also focused on cross-site marketing efforts, including a central website with links to all sites, enhancing the general visibility of caregiver resources and improving the ability of clients to find the appropriate support.

Implementation Outcomes

Implementation outcomes (adoption, fidelity, and sustainment) were assessed using qualitative and survey data gathered from staff members and clients. Figure 3 summarizes the main themes encompassing implementation outcomes.

Figure 3. Implementation outcomes.



Adoption

By fiscal year 2021-2022 (approximately 2 years after launching CareNav at all California CRC sites), all CRCs had adopted the new platform and were fully operational, using CareNav and contributing data to the statewide record. A year later, in 2023, most of the staff survey participants (101/112, 90.1%) agreed (somewhat or strongly) that everyone on staff regularly used CareNav.

CareNav Functionality

Participants described the most significant features of CareNav: the standardized assessment, reports, and the client portal. The CRC sites use these CareNav features for 2 primary purposes: as client records to facilitate serving individual clients and for consultant- or site-level management of the client population. Table 3 summarizes CareNav features and their use, along with more detailed description.

Table 3. Standardized assessment, report generation and a client portal are CareNav features.

Functionality	Standardized assessment	Report generation	Client portal
Client level			
Client records	Data collection and service history	Client use and web-based resource use	Self-administration of intake and assessment
Case management and decision support	Access to client records for all staff members on the team	Aggregate client data and units of service	Messaging clients and assigning resources
Staff-client interaction and service provision	Generating tailored resources	Client engagement and units of service	Asynchronous access and communication
Consultant, site, and system levels			
Caseload management to support efficiency	Navigation features (search, sort, and filter)	Clinical staff caseload	—[a]
Outreach and diversity, equity, and inclusion	Ease of access for diverse clients	Outreach and service for target populations	Convenient access to services
State-level planning	Aggregate summary of client needs	Populations served and service provision	—

[a] Not applicable.

The most common and universal use of CareNav is for client data collection. The sites described the advantages of having streamlined longitudinal records that are accessible in real time. CareNav provides ready access across staff, facilitating the continuity of client service and support, as well as case management along the service trajectory. CareNav improves team capability, facilitating care coordination among staff members, streamlining client communication, and building trust. Clinical directors and administrators use aggregate client data to manage and assign caseloads for staff members and guide outreach and program planning priorities. At the system level, standardized data collection has enabled the first-ever comprehensive view of caregiver needs in California, populations served, a comparison of clients to other caregivers in state or national databases, and service provision. CRC directors identified the power of this information to guide strategy, resource allocation, and policy:

> *One of the things I love as a director, is how we can look at the data and what we can do with the data...I'm able to look at our numbers and look at sort of our demographics, look at the profile of who we're serving, and I've been able to take that information and talk to county funders about...who are the caregivers in...County that your funding has to serve?...We were able...to look at the difference between what's going on with our folks in rural areas and what's going on in nonrural areas. And it was a surprise to people that, it's the same... And that was really awesome, because we were expecting our rural folks to be faring probably, I think worse because they were more isolated...So we can use that internally as well...And we looked at...our need to be more accessible to our diverse populations...I was able to...look at...some of our rural areas, and...we haven't really served our Indian population, our tribal communities, as well as I think that we should.* [Director]

The client portal is a major innovation for CRC service delivery, providing clients with continuous access to the CRCs to post queries, complete assessments, review tailored resources, receive service vouchers, and communicate with CRC clinical staff members asynchronously. The adoption of this feature is a multifaceted process that requires the involvement of clinical staff members and clients. The clinical staff members reported that some clients prefer self-administration of the intake and assessment because it is faster and more convenient than an interview, while others prefer engaging with staff members for the assessment. CRC clients reported that they appreciate the convenience of choosing a time to complete the assessment, the privacy compared to speaking on the telephone, and the ability to complete part of the assessment and return to it later:

> *We appreciate having the access to be able to do the assessment and the reassessment online and to be able to compare especially...an old reassessment to what we're doing now, so you can see side by side...so I can see the changes and that helps generate a little bit more conversation...if we see a bigger change...we can have that conversation of what happened, how has that impacted you as a caregiver? And...being able to offer a little bit different resources, then maybe...I wouldn't have been able to do before, just because I wasn't able to see the change.* [Staff]

The client satisfaction survey collected information about caregiver experiences with the web-based platform. Of the 2125 respondents, most were offered web-based services (n=1734, 82%), and a quarter of the respondents (n=533, 25%) indicated having used the CareNav system. Most of the caregivers who used CareNav were satisfied with the experience (extremely satisfied: 255/533, 47.8%; somewhat satisfied: 170/533, 31.9%). Those who did not use CareNav were asked about the reasons for not engaging with the web-based program. The largest barrier to use was awareness about the program (439/1390, 31.58%), followed by the impression that the caregiver did not need CareNav (265/1390, 19.06%) and a lack of technology experience (192/1390, 13.81%). Access to the internet (55/1390, 3.96%) and finding the platform too confusing (21/1390, 1.51%) were minimal barriers.

Staff members at sites offer varied levels of expertise and motivation in supporting clients, with some unable or unwilling to provide the necessary technological support and education to enable client self-administration. Some sites took a proactive approach, having a dedicated staff member to monitor clients who start a record and to reach out to offer support, as well as to send invitations to sign up and complete the web-based intake form before an appointment with a family consultant. A third of the clinical support staff members (23/70, 33%) in the survey reported encouraging clients to access CareNav through the portal.

Fidelity

Site-level analysis of CareNav use revealed that while all CRC sites now use CareNav for daily operations, individual sites represent different dynamic stages of the operational integration of CareNav, outreach approaches, and expansion of services, as well as diversity, equity, and inclusion efforts. The sites were categorized as *early phase* or *advanced phase* for each of the 6 dimensions. We categorized sites as *early phase* if they focused on more technical, basic, and passive actions and as *advanced phase* when they presented a more strategic approach and more use of data- and outcome-oriented operations. Table 4 depicts the developmental phases of the implementation of the platform across the 11 sites.

Table 4. Fidelity: the developmental phases of implementation by site.

Dimension	Developmental phase description		Site-level developmental phase (sites: N=11)											
	EP[a]	AP[b]	1	2	3	4	5	6	7	8	9	10	11	AP sites, n (%)
CareNav functionality	Client level: data collection and documentation	Client level: case management and decision support; consultant, site, and system levels: caseload management	EP	AP	AP	AP	AP	AP	AP	AP	AP	AP	AP	10 (91)
CareNav feature: standardized assessment	Asynchronous and selected fields; dedicated technical staff members entering paper data	Synchronous, comprehensive data collection; staff members or clients enter electronic data in real time	EP	AP	EP	EP	AP	AP	AP	EP	AP	EP	AP	6 (55)
CareNav feature: report generation	Predefined templates for reports	Flexible reports run by sites as needed; use reports for decision support	EP	AP	EP	AP	AP	AP	AP	EP	EP	AP	EP	6 (55)
CareNav feature: client portal	Passive approach	Active approach: staff members encourage and support clients to use client portal	EP	AP	AP	AP	EP	EP	EP	AP	AP	EP	AP	6 (55)
Outreach approach	Historical relationships and referral sources	Using data to guide and evaluate selective outreach	EP	AP	EP	EP	EP	EP	EP	EP	AP	EP	AP	3 (27)
Diversity, equity, and inclusion	Translation of materials and focusing on specific local ethnic groups	Broad definition of diversity (race and ethnicity, geography, LGBTQ[c] identities, and income) and using data to identify opportunities for inclusion	EP	AP	EP	EP	AP	EP	EP	AP	AP	AP	EP	5 (45)

[a] EP: early phase.

[b] AP: advanced phase.

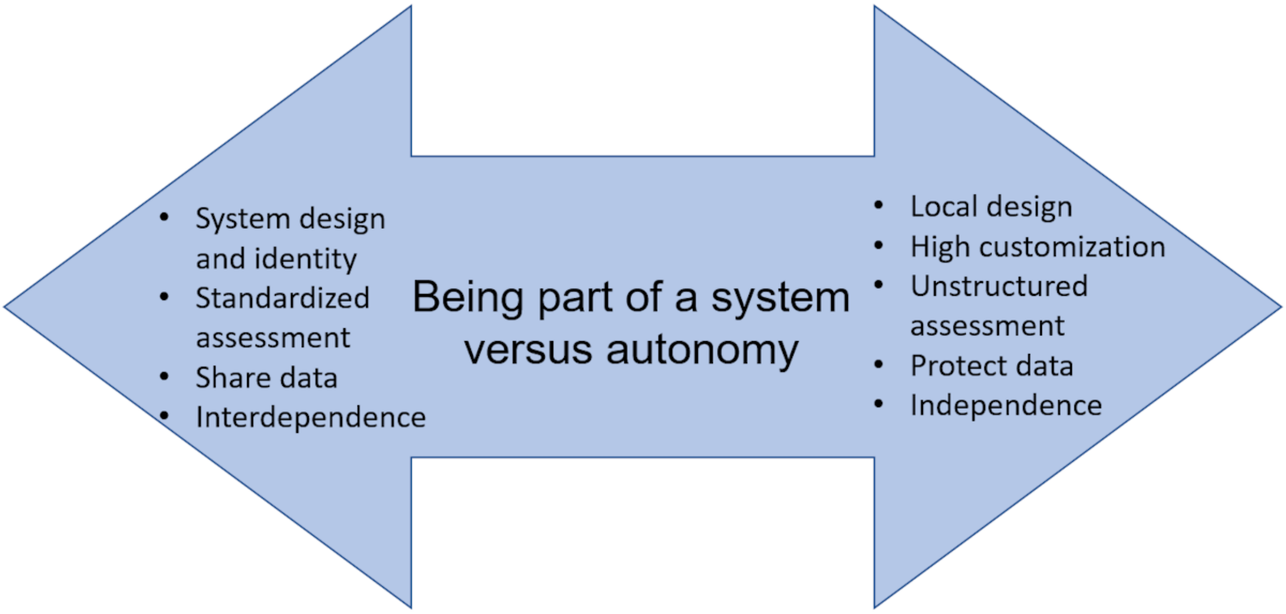
[c] LGBTQ: lesbian, gay, bisexual, transgender, and queer.

As can be seen in Table 4, the sites are in different phases of implementation depending on the dimension: of the 11 sites, 1 (9%) is operating at an advanced level across all dimensions, and 1 (9%) is at an early level across all dimensions. The most advanced dimension across sites is data collection and documentation, while the dimension with the lowest advancement, with only 3 (27%) of the 11 sites at advanced level, involves using data to create strategies for outreach:

> *Learning a new system. It just requires...time and patience and flexibility. And one thing came up...about CareNav in particular...there's a lot of functionality built into it. We can do a lot of things with CareNav. And so right now we're doing, maybe we're only using a certain percentage of all of the tools that are built into it, and really learning how.* [Staff]

The developmental phases were shaped by the baseline systems in place at each site and their unique local conditions and relationships. A major interview theme related to the developmental phase was how each site weighed the benefits of incorporation into the CRC system alongside the benefits of autonomy as an individual CRC (Figure 4). For some sites, CareNav implementation involved a shift in service philosophy, in addition to implementing new technology; for example, this shift triggered a tension between a professional philosophy valuing open-ended interviewing and the standardization of the intake and assessment processes, an important feature of incorporation into a larger system with a uniform database. Most of the tension around being part of a system centered on standardized assessment, coupled with the ability to customize reports to meet local needs. This tension was most acute when a site had a previous data management system in place, requiring adaptation and harmonization. Another area of tension related to the extent to which sites are proactive in reaching the population of the region versus being more reactive and relying on established referral sources. As a statewide system with a commitment to expand services, advanced sites are using data to identify unmet needs in the region and designing strategies to connect with underresourced communities and to tailor programs to meet cultural and linguistic requirements. Furthermore, they are collaborating with one another to leverage resources across regions.

Figure 4. The tension between being part of a system and being autonomous.



The readiness survey results (Table 2) illustrate the overall extent to which CRC staff members and leaders integrated CareNav and service expansion dimensions into their operations and future plans. The highest-rated items (mean 4.3, SD 1.0) were using CareNav to guide assessments and enter data in real time and a desire to expand the use of the platform. The lowest-rated item was encouraging clients to use the portal (mean 3.1, SD 1.2). Most of the participants with clinical support roles (56/70, 80%) used CareNav to guide assessments and enter data in real time, and two-thirds (43/70, 61%) would like to expand the use of CareNav to coordinate client support. Only a third of the clinical staff members (23/70, 33%) agreed that they encourage clients to access CareNav through the portal.

A little more than half of the participants with administrative roles (23/42, 55%) used CareNav for decision-making regarding the CRC site and its programs (eg, targeted outreach and program offerings), and more than two-thirds (30/42, 71%) were willing to expand the use of CareNav (eg, generating new reports, using data for program improvement, and making decisions). Two-thirds of the participants (69/112, 61.6%) used CareNav data to understand the needs of diverse clients (eg, in terms of race, ethnicity, geography, sexual orientation, gender identity, and income). They reported using these data to implement various strategies, including collecting demographic data, targeting grant funding and outreach based on a comparison between intake data and census demographics, improving linguistic access, training staff, and expanding the resources available in CareNav.

Sustainment

The focused interview participants highlighted having a shared identity and mission, sharing data and collaborating as critical elements to actualize the potential of a system of delivery for California's caregivers and to promote sustainability. The most commonly discussed system outcome was the statewide identity across the sites that has created various opportunities for current and future partnerships. Several expressed pride in being part of a system that is a model for the nation and has a goal to support all caregivers in California. Both staff members and leaders identified the creation of new structures supporting long-term collaboration between the sites and the use of the CareNav statewide comprehensive database as a path to sustainability. They recognized the power of working together and using their collective data to better serve clients and to substantiate client care needs toward the goal of securing funding for sustainability.

CRC leaders also identified system-level outcomes that benefit clients directly. They recognized the potential of shared services, staff, and resources to foster greater inclusion across race or ethnicity and language groups. This has particular impact for service to smaller or more geographically dispersed populations. The statewide shared calendar of virtual events is a prime example of the wide and efficient dissemination of useful culturally and linguistically appropriate resources across the entire state.

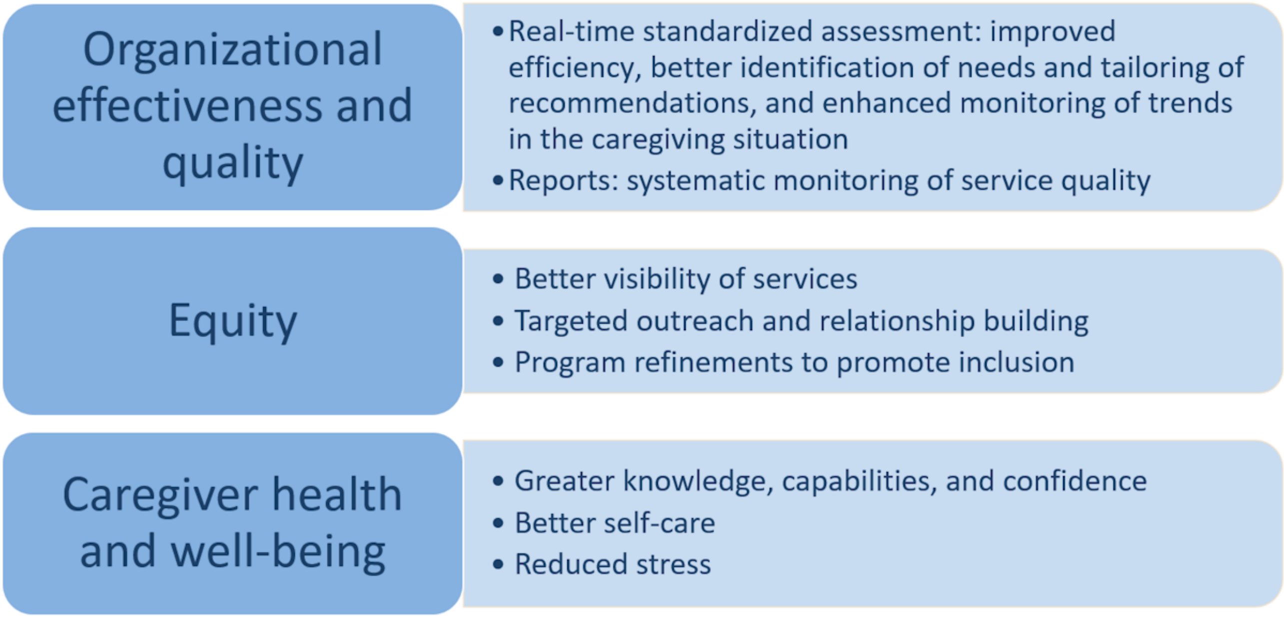
The CRC leaders have formed a learning community with one another, sharing best practices and knowledge to improve the quality of their programming and operations. Directors and clinical directors have developed system-wide clinical policies and engaged in cross-site marketing efforts. Several statewide meetings involving directors, clinical directors, supervisors, and education coordinators are building collective momentum. The statewide education committee enriches site-level effectiveness and creates shared resources, as a director explains:

> *Since we've gone forward with CareNav, our entire Caregiver Resource Center system has really gone through a massive enhancement. And I think a lot of it is the work that the directors and the staff have done. So we're getting together on a regular basis. We're meeting. We are developing, you know, policies with the clinical side, the staff, they're getting together and they're coming up with policies. We've created a marketing campaign. Through Zoom, we're now sharing education events statewide and collecting data statewide. So again, CareNav is critical tool. But I think the driving force behind everything has been this kind of movement of the Caregiver Resource Centers coming back together, working with lobbyists, legislators, leveraging money to come in and support our efforts.* [Director]

Population Impact

The impact on the population manifested in 3 major ways: achieving organizational effectiveness and quality, promoting equity, and enhancing caregiver health and well-being. Figure 5 depicts the population impact.

Figure 5. The population impact.



Organizational Effectiveness and Quality

Leaders described greater operational effectiveness and responsiveness as well as improved quality of services. The real-time standardized assessment assured better identification of needs and tailoring of recommendations for clients. With the documentation of repeat encounters, staff members were able to monitor the caregiving trajectory and augment resources as needed. The web-based platform enabled better communication among staff members and greater efficiency in serving clients as a team. Site leaders valued the ability to monitor the quality of service and to use data to guide decision-making around staff assignments and program priorities. The client portal facilitated timely and consistent communication with clients at convenient times for them as well as a central repository of individualized resources and services.

The most reported impact of CareNav on serving clients was the ability to provide more resources for more people in a faster and more convenient way. Many staff members noted improved client-provider relationships because CareNav allows a transparent means to provide services, accessible to both staff members and clients, fostering a more collaborative relationship. The virtual messaging tools enable timely and consistent communication. Web-based statewide resources provide more options to clients than a small regional program can offer, providing more opportunities for caregivers to access educational and support group resources from any site.

Equity

CareNav promotes equity by targeted subgroup analysis to better understand the experiences and priorities of diverse caregivers, enabling more thoughtful tailoring of both outreach and programs. The aggregate profiles of clients served by each CRC provided information about the reach of the programs and the gaps in service for subpopulations in the region. Synthesis of the data identified opportunities for developing new partnerships in the community to promote visibility to, and acceptability for, underserved caregivers. The data also provide guidance for strategic planning around program enhancement to achieve cultural congruence and to promote inclusion. Leaders have forged new shared services, staff, and resources to foster inclusion. A statewide shared calendar of virtual events, such as educational resources in various languages, has increased access for all regions. Several sites have collaborated to match staff members to their regional linguistic diversity, enabling the provision of consultation in the preferred language of the caregiver. Some staff members expressed concern about the digital divide disproportionately affecting certain client populations because of cost, internet access, or technological literacy. To accomplish digital equity, staff members recognize that full client engagement will require further tools and education to prepare clients to use the CareNav platform.

Caregiver Health and Well-Being

All parties identified benefits for caregivers, including improved health and well-being. Specifically, clients appreciated having a centralized resource that records precise identification of both care recipient and caregiver needs, coupled with tailored resources. Overall, staff members reported that CareNav has improved their ability to identify and respond to client needs and has changed the way they engage with clients:

> *[T]hat [the results of the assessment] gives you room to have a conversation...No wonder you're feeling so overwhelmed. Look at, this is what you just told us. We're not guessing you're overwhelmed. You just told us you were overwhelmed, right, by answering these questions in that way. So, having the questions you ask in CareNav, sort of be the structure for that, the clinical interview...but taking that information and using it for developing the care plan...You said you don't have your financial...documents in order, so...perhaps that should be on your care plan, right? Is that something that you can commit to do?...you're feeling overwhelmed and isolated, perhaps one of our support groups might work, right?...what we ask in the assessment tells you, sort of, informs the conversation with the client.* [Staff]

Caregivers, staff members, and leaders highlighted the positive impact on caregiver health and well-being. The assessment followed by a tailored care plan prioritizing the most pressing concerns resulted in positive outcomes for clients. Caregivers reported gaining confidence, knowledge and awareness of community resources, better understanding of the care recipient's situation, and better ability to manage the care they provide:

> *The family consultant is such a valuable resource...Helping us to connect to different resources, helping us to remember [that] we, as caregivers, shouldn't forget to take care of our mental, emotional, and physical well-being. I am grateful they can help us to organize and make a plan to help ourselves to be there for our care receivers.* [Caregiver]

The caregiver satisfaction survey explored the impact of CareNav and services on the lives of the caregivers (mean scores are presented in Table 5). The results indicate strong impact in confidence and ability to manage care, increased knowledge and awareness, better access to community resources, enhanced understanding of the disease or disability and issues, improved self-care for their physical and mental health, and reduced feelings of stress.

Table 5. Caregiver satisfaction survey scores: the impact of CareNav and services on caregiver lives (n=2254).

Item	Score, mean (SD)
More confident as a caregiver	4.2 (0.8)
Better able to manage care	4.2 (0.8)
More knowledge and awareness	4.3 (0.8)
Understand the disease, disability, or problem better	4.1 (0.9)
Taking better care of self	4.1 (0.9)
Less stressed	3.9 (1.0)

Discussion

Principal Findings

This paper describes a rigorous evaluation of a complex implementation of a statewide web-based platform to enhance services provided to family caregivers. We presented findings about implementation strategies, implementation outcomes (ie, adoption, fidelity, and sustainment), and the impact on population health (ie, organizational effectiveness and equity as well as caregiver satisfaction, health, and well-being). The platform was fully adopted within 18 months, and the system is advancing toward sustainment through statewide collaboration. The deployment has augmented organizational effectiveness and quality, enhanced equity, and improved caregiver health and well-being.

The CFIR addendum and the dynamic sustainability framework provided a useful approach to explore cross-site variability and the driving forces for implementation and sustainability. A deeper consideration of outcomes can drive meaningful evaluation that includes both implementation and innovation outcomes as well as a consideration of the indicators of sustainability and impact on the population served [19].

The implementation of CareNav occurred during a unique time in history marked by rapid advances in technology in all sectors of society, changing expectations among caregivers as younger generations assumed this role, and a global pandemic. In many ways, these forces accelerated and aided the implementation process. In other ways, these collective changes deepened the divide between those who accept and embrace change and those who prefer to retain the status quo. Early implementation findings suggested that some of the sites, particularly those embedded within larger health systems, experienced a tension between harmonizing workflows with the other CRC sites and also retaining compatibility with the workflows and technologies of partner organizations [13].

Although tension around adapting individual site workflows remained a theme in this longitudinal view of implementation, site-specific technology support and training helped to address logistical barriers, and group learning provided opportunities to build consensus around which modifications were the most important. With the complexity of CRC operations, from client engagement and outreach to creating business efficiencies, it is not surprising that the sites manifest variable patterns of implementation phases across CareNav and service expansion dimensions. As has been suggested previously [20], local contextual factors drive the priority of various strategies to accomplish implementation, an observation amplified across the 11 sites in this evaluation. The variability in developmental implementation patterns is expected across a diverse network of organizations. The tendency to focus on individual client data before engaging in more advanced analytical processes provides evidence for a nonlinear implementation course of a multicomponent health IT adoption. It was helpful to the evaluation to establish the developmental phases of the implementation to consider both site-specific attainment of minimal progress and overall evolution.

The leaders of this initiative used an iterative, continuous, and long-term implementation strategy that advanced the full adoption of CareNav in daily operations. The effort was accelerated by providing appropriate training and technical support and fostering a learning community. The relatively high scores we identified across items on the readiness survey persisted over time, suggesting that these support efforts have helped to prepare CRC staff members effectively for implementation and ongoing operations.

The client adoption rates of approximately 25% exceeded the reported rates of patient portal adoption in health care systems. In a study conducted in the Netherlands, 20% of older adults who were hospitalized activated a patient portal account. The participation rate decreased with age, with approximately 50% more patients aged >76 years declining to create an account compared to those who activated one [21]. Similarly, in a community-based sample of ethnically diverse patients with low-income status attending a rural clinic in the United States, 20.5% reported using their patient portal, with greater odds of engagement for those having higher education and social support coupled with frequent internet use [22]. In the case of CareNav, the most important barrier was a lack of awareness of the opportunity to use a web-based portal. This finding contrasts with a systematic review of patient portal and electronic personal health record use, where the major barriers were privacy and security, access to the internet, and the ability to use technology [23]. Together, these findings suggest that caregiver clients are using the system at a level slightly higher than health system portals and that increasing awareness could be the most important strategy to increase engagement.

The CareNav implementation process fostered statewide system identity and created structures that had a significant role in promoting the sustainability of the implementation. Future efforts should focus on achieving sustainment and realizing population impact. Data-driven strategic decisions have the potential to realize operational efficiencies while prioritizing the most effective efforts of staff members. The system has the potential to support the documentation of population impact and cost-effectiveness as a persuasive strategy to procure sustainable funding for vital programs. Going forward, with a goal of achieving advanced implementation across all sites, training and technical support could focus more attention on enhancing site- and system-level functions and optimizing the use of data to drive both client-level and system-level decisions and priorities.

On the basis of data about the population served and gaps in program offerings, both staff members and leaders articulated the need for broader cultural adaptation of the service model for specific communities, including the linguistic translation of assessment and educational materials. Beyond language, several CRC leaders and staff members recognized the importance of a broader cultural adaptation approach for specific communities (eg, caregivers from tribal communities, underresourced racial or ethnic groups, the LGBTQ+ [lesbian, gay, bisexual, transgender, queer, and similar minority] community; and rural settings) to assure the congruence of programming with client needs and to advance equity. Several leaders cited the dearth of evidence about the best approaches to serve certain underrepresented communities and shared the hope that evaluation of their efforts will contribute to this important knowledge base.

For clients, digital equity occurs at multiple levels, from the availability of internet service in certain communities and the affordability of service to technological literacy. CRC staff members play a vital role in encouraging clients to use the web-based program and providing technical support as they navigate the system, and some of the sites are more effective at promoting web-based engagement than others. Full deployment requires overcoming these barriers and ensuring access to all caregivers who desire to participate in this way.

The limitations of this study included reliance on self-report from staff members and caregivers regarding implementation progress. This limitation was partially offset by the triangulation of actual data entered into CareNav that was analyzed by the evaluation team to identify quality and integrity issues. With the iterative process of engagement among the evaluation team and the sites implementing the program, we were able to identify progress and barriers associated with implementation in real time. The implementation occurred in a state that is more diverse demographically than many other US states, limiting generalizability to all states but providing valuable information related to equity.

Conclusions

The study identified individual and site-level factors related to the CareNav implementation process. Future longitudinal studies should explore long-term adoption trajectories to inform continuous implementation planning, particularly to guide implementation efforts in complex health or social care systems, where one size does not fit all. Further research could examine longer-term outcomes, particularly in the areas of impact on clients served. Finally, the question of the extent to which automating social service processes and using artificial intelligence expands capacity is a vital consideration with the growth of the older adult population and the need for new solutions to increase capacity.

While electronic records are common in health systems and in a variety of industries, community-based agencies have lagged behind in adoption. Advancement in technology in this sector is essential to realize the integration of health and social services for the betterment of population health and to address the growing demand for services. The results of the efforts of the California CRCs provide a compelling use case for the successful implementation and adoption of technology in community-based agencies. Going forward, the California CRCs will grapple with important questions about being a statewide system, advancing technological capacity for clients and staff members, and solving vital equity issues to provide services and supports to all caregivers in need.

Acknowledgments

This work is a collective effort, with many dedicated individuals sharing a vision and contributing their time, energy, and effort to serve the caregivers of California. The evaluation team worked closely with the Family Caregiver Alliance team (represented by Christina Irving and KK) and the Quality Process team (represented by Brad Silen) throughout the evaluation design, data collection, and data verification processes. The authors appreciate the leadership and commitment of the directors of the 11 California Caregiver Resource Centers and the dedicated staff members who participated in the implementation while delivering high-quality services. This study was supported by the California Department of Health Care Services, the California Department of Aging through the Family Caregiving Alliance (A20-3680-002), and the Gordon and Betty Moore Foundation (Family Caregiving Institute, 5968 and Heather M. Young Postdoctoral Fellowship, 7784; fellow: OT).

Abstract

Background: As Alzheimer disease (AD) and AD-related dementias (ADRD) progress, individuals increasingly require assistance from unpaid, informal caregivers to support them in activities of daily living. These caregivers may experience high levels of financial, mental, and physical strain associated with providing care. CareVirtue is a web-based tool created to connect and support multiple individuals across a care network to coordinate care activities and share important information, thereby reducing care burden.

Objective: This study aims to use a computational informatics approach to thematically analyze open text written by AD/ADRD caregivers in the CareVirtue platform. We then explore relationships between identified themes and use patterns.

Methods: We analyzed journal posts (n=1555 posts; 170,212 words) generated by 51 unique users of the CareVirtue platform. Latent themes were identified using a neural network approach to topic modeling. We calculated a sentiment score for each post using the Valence Aware Dictionary and Sentiment Reasoner. We then examined relationships between identified topics; semantic sentiment; and use-related data, including post word count and self-reported mood.

Results: We identified 5 primary topics in users' journal posts, including descriptions of specific events, professional and medical care, routine daily activities, nighttime symptoms, and bathroom/toileting issues. This 5-topic model demonstrated adequate fit to the data, having the highest coherence score (0.41) among those tested. We observed group differences across these topics in both word count and semantic sentiment. Further, posts made in the evening were both longer and more semantically positive than other times of the day.

Conclusions: Users of the CareVirtue platform journaled about a variety of different topics, including generalized experiences and specific behavioral symptomology of AD/ADRD, suggesting a desire to record and share broadly across the care network. Posts were the most positive in the early evening when the tool was used habitually, rather than when writing about acute events or symptomology. We discuss the value of embedding informatics-based tools into digital interventions to facilitate real-time content delivery.

Introduction

Background

Nearly 7 million people in the United States currently live with Alzheimer disease (AD) or AD-related dementias (ADRD), a number that is projected to double by 2050 [1]. AD/ADRD generally progresses slowly; however, as disease symptomology worsens, most people living with AD/ADRD require support from informal caregivers (ie, unpaid family or friends) [1-5]. Recent estimates suggest these caregivers provide roughly 16 billion hours of unpaid care labor annually in the United States. Caring for people living with AD/ADRD is highly complex and has broad psychological, physical, and economic consequences [1,4,6]. Care partners are often underresourced and unsupported [5-8], which has been associated with high levels of care partner stress, burden, burnout, depression, morbidity, and isolation [2,3,9]. The national plan to address AD highlights the need to expand support for people with AD/ADRD and their families [10]. This research aimed to explore the use of a novel care support platform, CareVirtue, by AD/ADRD caregivers, particularly focusing on specific aspects of use for the platform's care journal feature.

Caregiving for Individuals Living With AD/ADRD

AD/ADRD can present with a broad set of behavioral and medical symptoms across an extended time period, contributing to the challenges of caregiving [1,11,12]. Yet, caregivers often remain underresourced and overburdened due to the complexity of AD/ADRD care [7]. Compared with caregivers of people living with other chronic conditions, AD/ADRD caregivers report higher levels of burden, characterized by greater financial, emotional, and physical strain associated with care, aiding with a larger number of activities of daily living, and more difficulty maintaining their own health and well-being [1,7]. Further, a recent review found that many behavioral symptoms of AD/ADRD (eg, sleep disturbances, aggression, and care recipient depression) were directly associated with higher levels of caregiver burden [2]. Not surprisingly, and important to this study, higher levels of perceived burden are associated with increased unplanned hospitalization and poorer quality of life for caregivers [1,2,13,14].

Alleviating suboptimal outcomes (eg, caregiver burden) associated with the progressively changing needs of people living with AD/ADRD often requires a network of multiple care partners including extended family, friends, respite providers, and paid in-home care [4,6,9,15,16]. These care networks engage with and support care partners and the person living with AD/ADRD [4,6,8,9,16-18]. Previous research has advanced a foundational understanding of AD/ADRD care networks demonstrating that (1) many AD/ADRD care partners distribute caregiving in a heterogeneous care network [17]; (2) network members have varying levels of contributions that influence the person living with AD/ADRD and other care partners [8,9,17]; and (3) care networks are currently under supported, leading to factors associated with increased caregiver burden, including role conflict and ambiguity among care network members, communication and coordination challenges, and increased task demands on care partners [4-6,16-21].

Technology Interventions to Support Caregivers

Overview

Systematically connecting and activating care networks through technology interventions is a critical area of need for improving caregiver outcomes [8,22]. As rates of AD/ADRD, and associated need for care, are expected to significantly increase in coming decades, there are increasing calls for scalable interventions to support caregivers, particularly those enabled by technology. There is growing evidence that internet-based tools are an effective and appropriate tool for delivering interventions for older adults, including individuals with some cognitive impairment [23,24]. Further, novel informatics-based tools offer potential capacity as a design feature of internet-based interventions, allowing for real-time participant monitoring and modification to meet user's unique needs in the moment. That is, by embedding certain tools into the design of such interventions, processes for delivering content can be automated to occur in real time [25]. However, to date, there is less research related to technology-based network interventions for AD/ADRD caregivers.

The CareVirtue Platform

CareVirtue is a web-based platform designed to connect a care network of AD/ADRD caregivers around the care of a person living with AD/ADRD [22]. CareVirtue is designed with features for documenting, communicating, and coordinating care needs. CareVirtue's central feature is the care journal in which caregivers can create posts about their daily caregiving experiences, create posts about caregiving updates and logistics, and ask questions that are shared with their care network. Results from a recent feasibility test of CareVirtue indicated that AD/ADRD care networks use CareVirtue's journal feature to document and share information, acquire information, cocreate strategies, and lend support to the care partner [22]. We also found that care networks used the journal to give and receive logistic, social, and emotional support [26]. Additionally, posting in the journal provided individual benefits to caregivers, including the ability to process emotions through posting in the care journal [26].

Given that the initial feasibility results indicate that journaling in CareVirtue has benefits for AD/ADRD caregivers [22], an important next step is to glean design requirements from actual use patterns that can be used to support and sustain engagement with the care journal. Therefore, this study first sought to apply exploratory topic modeling to identify primary themes among journal posts. We then explored relationships between these computer-generated themes and certain post characteristics (ie, word count and text sentiment score). Finally, we explored potential differences in care journal post characteristics based on time of day and caregiver mood, self-reported at the time of posting.

Methods

Ethical Considerations

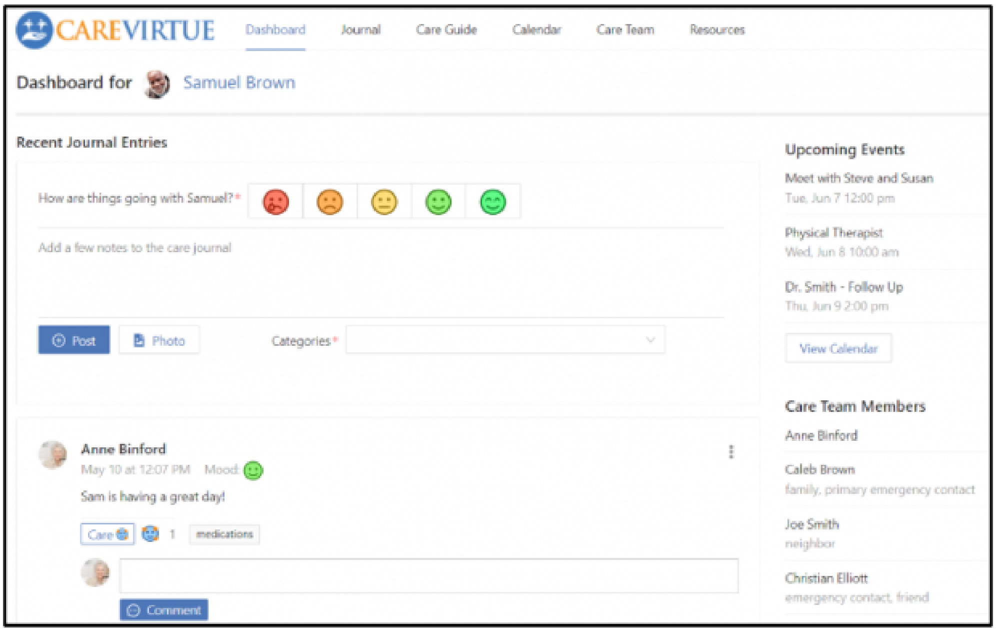
This study is a secondary analysis of the CareVirtue feasibility study (R41AG069607), which was approved by the University of Wisconsin-Madison Institutional Review Board. All participants provided informed consent. Participants were provided compensation via e-gift card for completing each stage of the trial (totaling US $150). All data was deidentified prior to analysis, with personally identifying information removed. To protect participant information, any names or proper nouns represented in text are pseudonyms.

Study Design and Primary Study Procedures

The primary study enrolled 51 caregivers and their network members to use CareVirtue for 60 days. Details of the primary study and its findings are provided elsewhere [22].

Care partners who were enrolled in the primary study first created an account on CareVirtue and then invited their chosen care network members to join their CareVirtue account. Care network members included family members and friends who were involved in the care of the person living with AD/ADRD, wanted information about the daily care of the person living with AD/ADRD, or provided social support to the care partner. Care network members can also include paid care partners such as respite care providers and in-home aides and nurses. Features of the CareVirtue platform include a personal care guide, calendar, geolocated resources, and the care journal [22,26]. As noted, this study focused specifically on CareVirtue's care journal feature. A typical CareVirtue user uses the care journal feature to document and share their daily caregiving experiences and the status of the person living with AD/ADRD with their care network, as well as to communicate with care network members. In addition to posting content using the journal, users are prompted with each post to provide a mood rating using faces as depicted in Figure 1, as well as to assign a relevant "Categories" tag that labels the post for easier search and filter (eg, medication management, behavior related, activities, and hobbies). Journal posts are displayed in the dashboard and shared with all care network members. Anyone in the care network can comment on the journal posts and respond to other network member comments.

Figure 1. CareVirtue journal.



Sam is having a great day!

Participants

Participants for this research (n=51) were AD/ADRD caregivers, recruited to participate in a feasibility study for the CareVirtue care platform. Participants were recruited for this study through flyers distributed by community partners in Wisconsin and California and through the Wisconsin Alzheimer Disease Research Center.

Data Collection

Data were collected in the feasibility study in three parts: the enrollment interview, 60-day use period, and postuse interview. During the enrollment interview, a research team member met with the participant; obtained informed consent; and oriented the participant to CareVirtue, including creating an account, inviting a care network member, and making a journal post. Care network members received an invitation email once an invitation was made in the CareVirtue system that oriented them to the study and electronically obtained informed consent. At the end of the enrollment interview, the participant completed a demographic survey via electronic survey link and then the use period began. To capture actual use, participants were instructed to use CareVirtue as they would like during the use period but were asked to log in at least once per day. At the end of 60 days, a research team member met with the participant to conduct an interview focused on acceptability. Participants were provided compensation via e-gift card for completing each stage of the trial (totaling US $150). For this study, we examine user data generated within the platform (ie, journal entries) across the trial period.

Analysis

Overview

Descriptive statistics for participant demographics were calculated. All journal posts made by enrolled care partners were then exported verbatim to .csv files for analysis. Each journal post represented a separate row in the file, with columns of relevant data including user ID, full post text, time of day, and self-reported mood rating.

Bidirectional Encoder Representations From Transformers Topic Modeling Tool

Bidirectional encoder representations from transformers topic modeling tool (BERTopic) uses a neural network approach to topic modeling. Unlike other established unsupervised topic modeling algorithms and tools such as latent Dirichlet allocation, BERTopic does not approximate topics within data using probabilities alone. Indeed, BERTopic's calculation considers pretrained embeddings from one of many transformer models. These transformer models represent a type of neural network architecture where text entries fed through the program are compared against large-scale language data to better approximate content and meaning. For each entry (ie, journal post), BERTopic then calculates an embedding that converts unstructured language data into a fixed-length and continuous vector. These vectors are then further distilled to generate latent topics for a dataset and other natural language processing (NLP) operations, including semantic meaning, sentiments, and relationships.

Principal Components Analysis and Visualization

Embeddings and vectors calculated using BERTopic are complex and often difficult to interpret. As such, we can apply dimensionality reduction techniques to better interpret the data while retaining its constituent parts. This study used a principal components analysis for this task. Principal components analysis is commonly applied for NLP analyses. This analysis allowed us to extract a range of possible clusters, or topics, and visualize them accordingly. Once we reduced the dimensionality of our vectors, we applied hierarchical density-based spatial clustering of applications with noise, to identify and name our latent clusters. We used CountVectorizer to tokenize each topic and class term frequency–inverse document frequency to extract topic words for each cluster. These additional analyses allowed us to generate various visualizations for our data to help us identify the relative similarities and differences across our topics.

Valence Aware Dictionary and Sentiment Reasoner

Valence Aware Dictionary and Sentiment Reasoner (VADER) is a rule-based lexicon and web-based dictionary that measures the polarity, or sentiment, of words, phrases, and similar text entries. VADER assumes that most words in the English language can be triaged into either positive, negative, or neutral categories. VADER also assumes that certain words may have higher or lower polarity than others, which implicates a wide range of positivity or negativity, such as the word "horrible" being inherently more negative than the word "bad." Text fed through the VADER lexicon receives a score based on the presence or absence of negatively and positively charged words. Negative VADER values (–0.99 to –0.01) largely reflect lower sentiment, mood, and affect. Positive VADER values (0.01 to 0.99) largely reflect higher sentiment, mood, and affect.

Other Measures

User Mood

User mood was measured using a 5-point, self-report item completed at the time of posting. Moods were visually represented with colorful emoji-style pictures (Figure 1), ranging from a red angry face to a green smiling face.

Time of Day

We extracted the time of day at submission for each post to the CareVirtue Journal, which were recorded as Universal Time Coordinated values. We first converted each time to local time based on user's location at the time of posting. We then assigned posts to 1 of 4 categories as follows: Morning (6 AM-12 PM), Afternoon (12 PM-5 PM), Evening (5 PM-10 PM), and Overnight (10 PM-6 AM).

Procedure

We analyzed posts generated by caregivers who used CareVirtue between March and May 2021 using an iterative BERTopic analysis in Python. We first preprocessed our data to remove names, numbers, and dates, which we determined would harm the interpretability of our topic model. Once data were preprocessed, we then iteratively applied the neural network NLP tool (ie, BERTopic) to identify prominent topics within journal entries beginning with 5 topics and concluding with 25 topics, in increments of 5 topics. We calculated coherence scores for each of the iterations as a metric of model fit, selecting the model with the highest overall score for final analysis.

All posts in the dataset were then sorted into groups, based on the topic with which they most closely corresponded. Using computer-generated topics as a grouping variable, we then explored differences in word count and post sentiment (ie, VADER scores). We further explored differences in post word count and VADER sentiment, grouped by caregiver mood and the time of day, respectively. Due to violations of normality assumptions in two outcome variables (word count and VADER sentiment score, Shapiro-Wilk test, $P<.05$), group differences were examined using nonparametric Kruskall-Wallace omnibus tests, with Dunn post hoc procedures to test for individual group differences.

Results

Participant Demographics

We first calculated descriptive statistics for participant sociodemographics. Table 1 below provides a detailed summary of this information.

Table 1. Caregiver sociodemographics.

Characteristic	Primary caregivers (n=51)
Gender (women), n (%)	38 (74.5)
Age (years), mean (SD)	60.3 (9.8)
Race and ethnicity, n (%)	
Asian	2 (3.9)
Black or African American	1 (2.0)
Hispanic or Latinx	2 (3.9)
Native American or American Indian	1 (2.0)
Not reported	1 (2.0)
White	44 (86.2)
Marital status, n (%)	
Married or domestic partnership	37 (72.5)
Divorced	11 (21.6)
Single or never married	2 (3.9)
Widowed	1 (2.0)
Education, n (%)	
Postcollege education	19 (37.2)
4-year college	17 (33.3)
Technical school, vocational training, or community college	10 (19.6)
High school diploma or equivalent	5 (9.8)
Employment, n (%)	
Full-time	21 (41.2)
Retired	19 (37.3)
Part-time	7 (13.7)
Not working	4 (7.8)
Income (US $), n (%)	
>100,000	18 (35.3)
40,000-60,000	8 (15.7)
Do not wish to answer	8 (15.7)
80,000-100,000	6 (13.7)
60,000-80,000	4 (11.8)
20,000-40,000	2 (3.9)
<20,000	1 (2.0)
Location, n (%)	
Wisconsin	29 (56.9)
California	19 (37.2)
Illinois	2 (3.9)
Virginia	1 (2.0)
Location type, n (%)	
Urban	42 (82.3)
Rural	9 (17.7)
Relationship of caregiver to person living with AD/ADRD[a], n (%)	
Child	28 (54.9)

Characteristic	Primary caregivers (n=51)
Spouse/partner	20 (39.2)
Other relative	3 (5.9)
Distance to person living with AD/ADRD, n (%)	
In household	34 (66.7)
<20 min	12 (23.5)
>2 h	3 (5.9)
20-60 min	2 (3.9)

[a] AD/ADRD: Alzheimer disease or Alzheimer disease–related dementias.

Topic Modeling

The final dataset comprised the CareVirtue Journal entries (n=1555 posts; 170,212 words) of 51 AD/ADRD caregivers. The optimal model from our analyses suggested 5 latent topics within the corpus. This model was selected after iterative generation of multiple solutions via BERTopic as it had the highest overall coherence score (0.41), indicating adequate fit to the data. After review, we determined the overarching themes to be general content about individual events, professional and medical care, routine daily activities, nighttime symptoms, and bathroom/toileting issues. Table 2 provides further detail about the composition of each topic, including the number of posts (and percentage of the total sample) associated with each topic, mean VADER sentiment score, keywords, and exemplar posts that reflect each topic. Figure 2 is a topic similarity matrix, wherein darker blue colors indicate highly correlated topics; within our data, the 5 latent topics had limited similarity to each other, indicating distinct topics. Figure 3 offers visualization of our findings through an intertopic distance map; intertopic distance maps reflect relative salience and conceptual relationships between topics. Each circle represents a latent topic in the corpus, with larger circles indicating more salient topics. Further, topics are spatially situated such that highly correlated topics will overlap, while conceptually different topics will be arranged further from each other. In our model, no topics overlap, suggesting minimal collinearity between topics. As seen in Figure 2, the topics are loosely clustered, with topics 1 and 2 (individual events and medical care) on one side, and topics 3-5 (routine daily activities, nighttime symptoms, and toileting) clustered together on the other. We discuss each broad cluster in turn below.

On the left of the intertopic distance map, the two largest topics in the corpus were conceptually linked. The largest overall topic (topic 1), with the most associated posts, was related to a broad swath of specific, individual events; this topic was qualitatively the most diverse with respect to overall content. Messages assigned to this topic generally centered on individual (ie, one-time) activities, with particular emphasis on outings or conversations, and included specific details. As such, this topic was largely defined by breaks in standard routine, with many posts focused on conversations or events that were memorable for a novel or specific reason (eg, learned a new tip, spoke to a new person, and tried a new activity). The second most common topic written about by caregivers on the platform is related to various forms of professional and medical care. These included posts about interactions with in-home health aids and nurses, as well as professional care settings (eg, doctors' offices, nursing homes, assisted living, and memory care). For those discussing in-home professional care, posts were commonly about new instructions for care or updates on patient conditions. Another common subtheme in this topic was the sharing of updates or results from doctor visits, both specific to AD/ADRD (eg, neurologists) and not (eg, dermatologists and dentists).

Figure 2. Similarity matrix demonstrating bivariate relationships between topics.

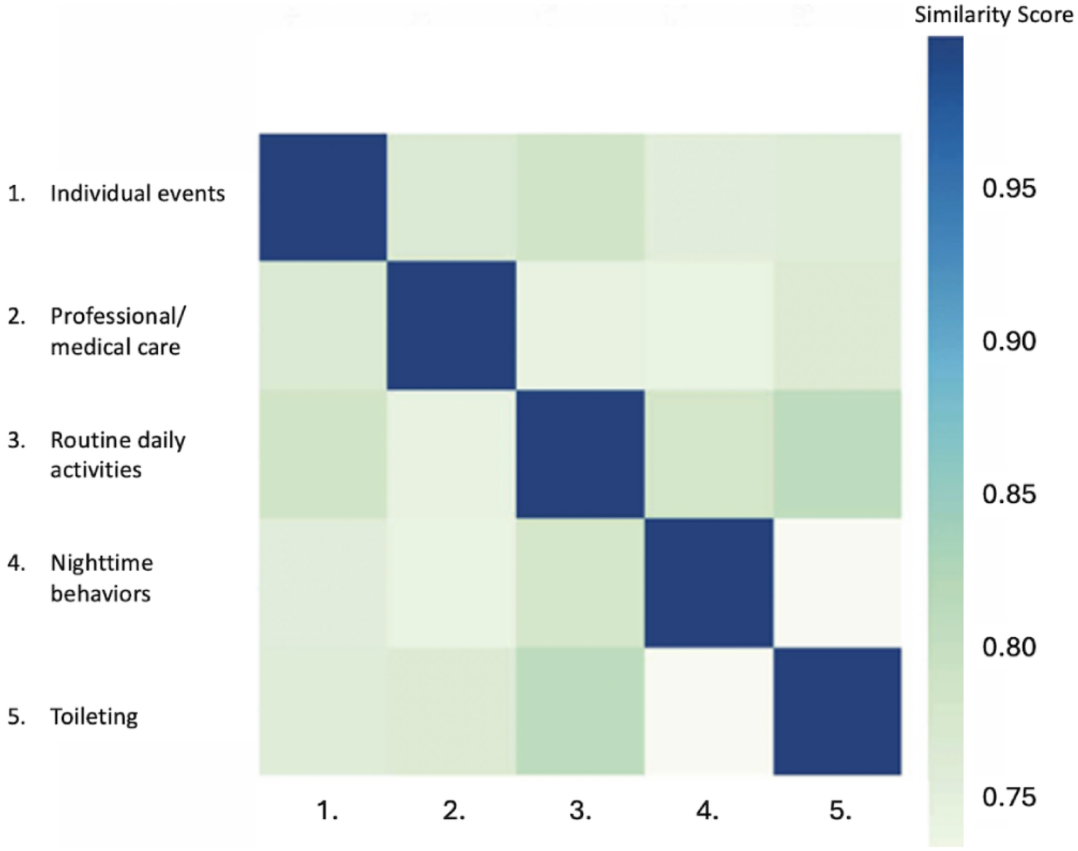


Figure 3. Intertopic distance map visualizing relatedness and relative size of topics observed.

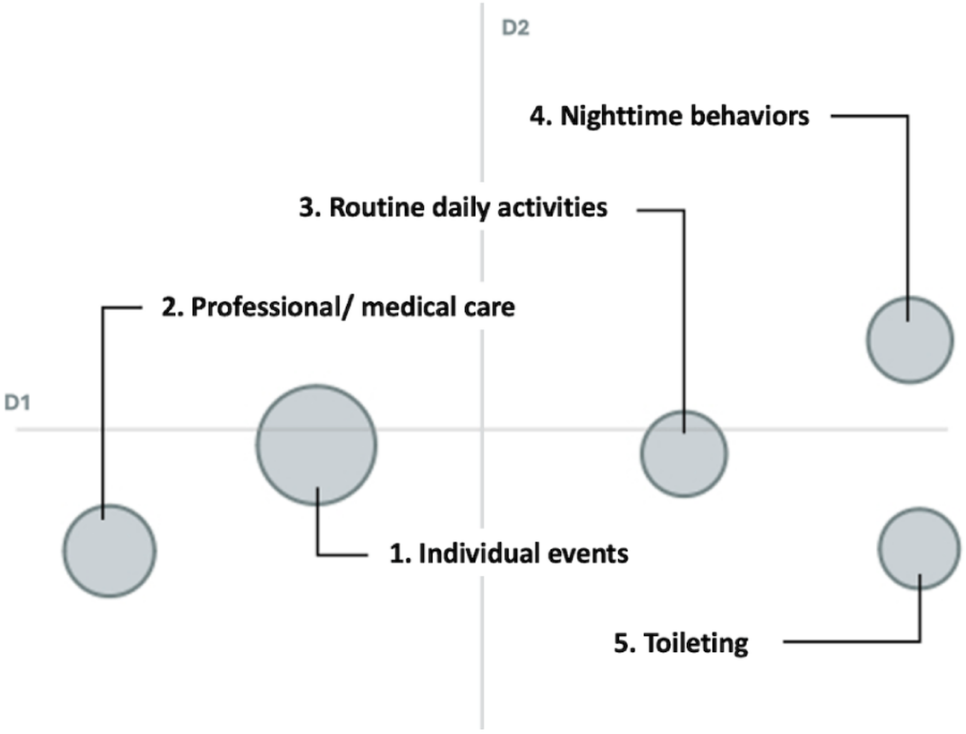

Table 2. Topic model solution for CareVirtue Journal.

Topic ID	Topic name	Post count (n=1555), n (%)	Keywords	Excerpts
1	Individual events	506 (32.75)	Busy, Pastor, Talking, Didn't, Evening, Banging, Day, Told, Work, Doesn't	• I still try to do things like we did a year ago, but the minute I get there I realize it is hard to get back to the old ways. I keep trying Flea markets, but I can't keep up with him. He wants to buy everything and talk to everyone, and I always want to leave the minute we get there. I also realized that my friends don't want to be with him, and I probably have the wrong friends because he is too sweet and good to them. • A very interesting day. The one good thing that happened, the small pot turned up. I found it when I went to make popcorn. She would say she never touched it. • [She] was hesitant at first, but really got into the painting zoom session with [others]. She was able to visualize the correct colors to use based on the image of the final product. Her control of the paint brushes was good. Lisa plans to offer more sessions in the future.
2	Professional/medical care	296 (19.16)	Aunt, Appointment, Mother, Doctor, Nurse, Care, CAN, Hospice Bed	• Was notified by [Name], a caregiver accidentally OVER medicated mom with medication that was NOT hers (Divalproex 125mg in applesauce)! This is the 5th time in 4 months that a medication error has occurred due to caregiver incompetence. Hospice nurse was called and she is being monitored by staff. • I called and spoke with [Name] (a CNA in Memory Care) where my Mom resides. She said my Mom is "tooling around" in her wheelchair. She ate all her dinner last night (fish, asparagus, etc), which is great to hear. Her behavior has been good the past couple days. • Granny has a new primary care "doctor" — [Name], NP, and she's great! She is going to do regular home checkups. In her initial visit she completed a basic memory assessment, the first I think that Granny has ever had, and also ordered a visit with a neurologist—something I've been trying to make happen for years! I am adding [the NP's] contact info to the resources tab. Her next visit is scheduled for 5/20.
3	Routine daily activities	258 (16.70)	Nap, Slept Breakfast, Woke, Morning, Lunch Tired, Bed, Sleep Laundry	• Friday we did not do showers, so the morning was enjoyable. We went to Walmart to buy dirt for the flower beds. We had lunch, naps and devotions and enjoyed the afternoon as well. [She] ate a good supper, we watched our favorite shows and she went to bed without problem. She slept through the nite with waking up only when I got her up to go to the bathroom. • Not much to report. We walked Sunday and Monday and expect to do same daily for the rest of this week. We did Zoom church on Sunday and I played music in the afternoon. Today I played tennis in the morning; [Name] handled laundry. I need to turn on the machine every now and then for her. At dinner she asked four times what was planned for tomorrow, which is very little, pickleball for me. I am waiting for a warmer day, which won't be this week, apparently, so we can go outside for lunch somewhere, maybe the Cupcake place, which has outdoor picnic tables. The TV experiment isn't working […]as she can't figure out the remote. • Tuesday, March 30th ~ Today was [dog]'s grooming appointment. Mom was not sure yesterday if she wanted to go with me to have him groomed. She said she was not feeling well and could I go alone. Today, she was ready when I called to say I was coming to pick him up. She had her cash, her keys and the dog ready. We dropped him off and I took her to Walmart for the two items she had on her list. She liked looking at the Easter Candy and decorations. I kept the trip short and then we drove through McDonalds for her chicken sandwich, one of the only foods that I know she will eat, besides sweet pastries and cookies. Everything went well, she likes [pet]'s grooming, and was happy to get out of the house to get groceries. She called at her 7 PM bedtime and said she was checking all the locks again because it was too quiet outside. I assured her it was all okay and she was safe here in this town.

Topic ID	Topic name	Post count (n=1555), n (%)	Keywords	Excerpts
4	Nighttime behaviors	257 (16.63)	Bedtime, Slept, Restless, Sleep, Sleeping, Morning, Agitated, Woke	• I had to get up every hour to handle [name]. I need to get steady sleep to function well all day. • Up last night for a few hours. She was cold even with electric blanket and extra covers. • Last evening until 2 AM this morning, [name] exhibited Sundowners Syndrome symptoms more than ever before. From when she initially went to bed at 5 PM, she was restless, anxious, fearful and attempted to shadow my every movement. Neither one of us slept much until 2 AM. I'm going to give her her bedtime meds later in the hope she will go to bed later in the evening and sleep better from that point forward.
5	Toileting	228 (14.76)	Nurse, Toilet, Doctor, Poop, Bathroom, Walk, Pee, Care, Bed, Change	• He has diaper rash back in right groin. put something on it that burned?? arthritis cream? anything in a tube he will use. doesn't wash well, just took a shower and doesn't smell good. told him to get in shower and wash off then put on a and d [sic] ointment. will he do?? why is he wearing depends all day? has to go right now! he says. urine the problem? but been in bathroom a lot too for #2 ?? • Came home from Grocery store at 8:15 on Sat and the smell of poop reeked throughout the house. [They] tried to clean up the toilet seat but things were smeared. I tried to look in and ask about it but she locked the door! I got in and she was asleep. I didn't wake her. • Well the past 24 hours have been a poop fest. Dad went from being constipated to having loose stools that have been filling his pants. Lots of showers and laundry. I finally had to put a diaper on him this morning. I hope this ends soon but not with constipation again.

The other three topics (ie, topics 3-5) were clustered together to the right of the intertopic distance map. Topic 3 generally outlined daily routines and common activities; spatially, this topic was situated between topic 0 (relating to specific events) and the two final topics related to AD/ADRD behavioral symptomology (ie, topic 4 [nighttime behaviors] and topic 5 [toileting]). Posts associated with topic 3 (routine daily activities) often included a full walkthrough of the caregivers' day, including any minor events happening throughout the day. This differed from topic 1 in that these posts did not offer details about any single event but tended to be more general in form. Topics 4 and 5 discussed two common challenges associated with AD/ADRD symptomology: nighttime challenges and toileting issues, respectively. In topic 4, caregivers often discussed "sundowning," which is a state of confusion that often occurs in the late afternoon or early evening and can lead to a disrupted sleep schedule [27]. Users also frequently noted that care recipients would wake often throughout the night, sometimes noting confusion or agitation upon waking. The final topic related to bathroom and toileting issues. Journal entries on this topic often described challenges with incontinence, including secondary infections, dirty laundry, or hesitation around the use of disposable underwear. Some posts also related to challenges with constipation or the care recipient's refusal to ask for help in toileting.

Group Differences in Text by Topic, User Mood, and Time of Day

Overview

After exploring topics present in user journals, we then sought to better understand group differences in text features (ie, length of post and VADER sentiment score) associated with topic, users' self-reported mood, and the time of day. Across the whole sample, we found an average of 110.15 (SD 153.41) words per post, with a slightly positive mean VADER sentiment score of 0.23 (SD 0.57).

Differences by Topic

Significant group differences across topics were observed with respect to both word count (χ^2_4=826.11, *P*<.001) and VADER sentiment score count (χ^2_4=212.37, *P*<.001). Descriptive statistics by topic are presented in Table 3. With respect to word count, all groups were significantly different from each other.

With respect to VADER sentiment, topic 3 about routine daily activities had higher average scores than all other groups. A middle tier, including topics 2 and 5 (professional/medical care and toileting) had the next highest sentiment scores, but did not differ from each other. The lowest tier of scores related to topics 1 and 4 (individual events and nighttime behaviors), which did not significantly differ from each other, but were significantly different from all other groups.

Table 3. Descriptive statistics of word count and sentiment score by topic.

Topic	Word count, mean (SD)	VADER[a] score, mean (SD)
1	33.11 (31.34)	0.11 (0.46)
2	71.97 (60.81)	0.24 (0.52)
3	163.88 (82.34)	0.61 (0.53)
4	46.22 (39.09)	0.07 (0.51)
5	341.93 (258.25)	0.27 (0.57)

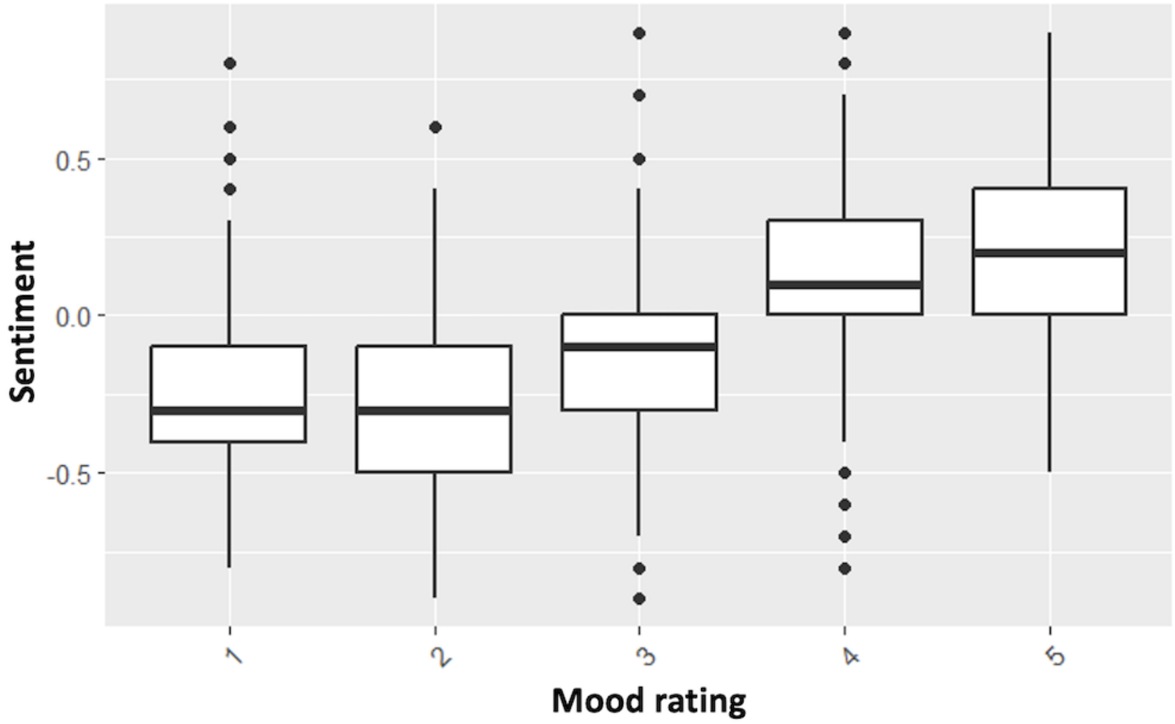
[a] VADER: Valence Aware Dictionary and Sentiment Reasoner.

Differences by User Mood

Mood ratings were self-reported using nonnumbered emojis at the time of posting (Figure 1). For analysis, mood ratings were numbered from 1 to 5, with 1 representing the worst mood state (angry, red face) and 5 representing the best (happy, green face). We observed differences in both word count (χ^2_4=46.15, P<.001) and sentiment (χ^2_4=516.93, P<.001), when grouped by mood rating. The longest overall posts were found in groups 3 (mean 117.71) and 4 (mean 126.55), which were significantly longer than all other groups, but not significantly different from each other. Word count for groups 1 (mean 91.84), 2 (mean 72.11), and 5 (mean 85.61), did not significantly differ from each other.

Text sentiment (ie, VADER scores) also differed between mood groups, following a roughly linear pattern wherein low user mood posts had the low sentiment scores, while higher user reported mood posts had the highest sentiment scores. This can be seen in Figure 4. The only groups that did not differ significantly from each other were groups 1 and 2.

Figure 4. Box-and-whisker plot showing group differences in user sentiment by self-reported mood rating.

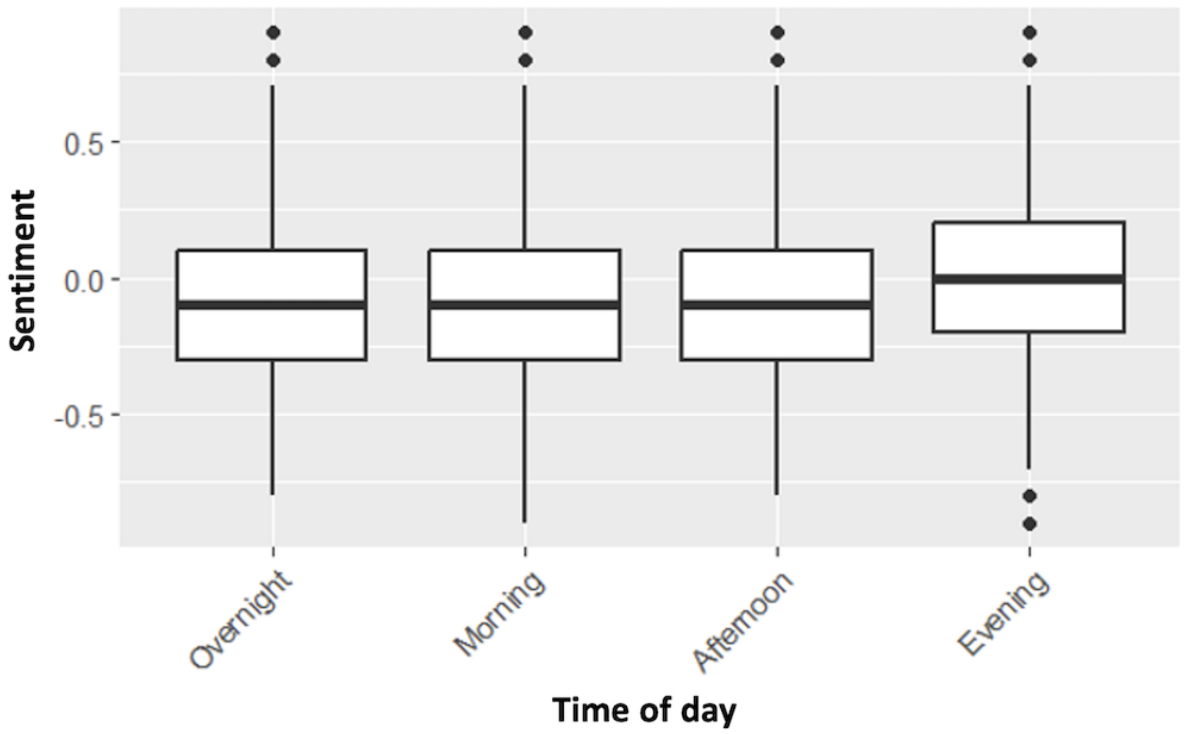


Differences by Time of Day

Finally, we examined differences in word count and sentiment score at different times of day. We again observed significant group differences with respect to both word count (χ^2_3=56.99, P<.001) and sentiment score (χ^2_3=35.71, P<.001). Posts made in the evening (mean 131.05) were statistically significantly longer than all other groups, followed by posts made in the afternoon (mean 110.60) and morning (mean 94.28), which did not significantly differ from each other. Posts made overnight were significantly shorter than all other groups (mean 46.70).

VADER sentiment scores also differed by time of day (Figure 5). Posts made in the evening had significantly higher sentiment than those made at any other time. There were no observed differences in sentiment between other time groups.

Figure 5. Box-and-whisker plot showing group differences in user sentiment by time of day.



Discussion

Principal Findings

This study sought to understand the use of the CareVirtue Journal by caregivers of people living with AD/ADRD [22,26], identifying salient topics within the data and exploring patterns related to the topic of discussion, user mood, and time of day. Using an iterative computational approach to identify the optimal topic modeling solution, we identified 5 primary themes in caregivers' journals. Broadly, these topics related to descriptions of individual events or conversations, professional or medical care, daily activity routines, nighttime symptoms, and toileting behaviors. Across the corpus of posts, users portrayed a generally positive tone, as indicated by a mean VADER score above zero. However, there was a wide deviation in sentiment scores, suggesting there was a variety of content present, including posts that were both highly positive and negative in nature. However, there was a wide deviation in VADER scores, suggesting a wide variety of sentiments across posts in the corpus, including some that were either highly positive or highly negative in nature. In examining post characteristics by time of day, we found posts written in the evening were the most linguistically positive and were longer than posts in all other groups, suggesting a more routine journaling practice at the end of the day. In contrast, the lower sentiment scores and word counts found at other times of day may reflect acute incidents users felt needed to be documented in the moment, or an attempt to fit journal writing into smaller windows of available free time. Broadly, our findings help identify key needs and salient thoughts of AD/ADRD caregivers. These findings have important implications related to increasing support for and improving the well-being of caregivers.

Based on emergent topics in the data, we identified two primary ways users communicated about care tasks and experiences using the Journal feature. These divergent patterns reflect differing approaches or use cases of the Journal feature. The first was defined by sharing information across the care network (ie, much like a social media feed) [17,26], while the other was more individually focused, operating much like a traditional journal for recording personal thoughts and experiences [28,29]. Posts in topic 1 tended to reflect the more social use case of the Journal, often describing a specific event or conversation that was memorable or had useful implications for care. For example, one user wrote, "we did the exersize [sic] class together and [he] was able to participate some of the time. He couldn't answer the question that they asked him about what he is happy about. I guess he is losing his verbal skills."

In this case, description of this event, and particularly the loss of verbal skill, would be of value to others across the care network as it may influence future interactions with the care recipient. These posts also often reflected somewhat more traditional journaling purposes, where users wrote down their experiences, thoughts, and emotions—engaging in real-time reflection or planning for changes in care practices within the post itself. Likely related to their specificity around a particular need or AD/ADRD-related event, these posts were the shortest in length and had the lowest average sentiment score of any topic.

A second latent topic in our data (ie, topic 3) included generalized discussion around care activities, with users describing an entire day or more of activities [18,29]. Posts in this topic reflected the second use case described above, with users treating the tool much like a traditional written journal. These posts generally offered limited detail about any specific activity; rather, posts on this topic seemed to serve the purpose of cataloging daily routines. Posts on this topic did not generally have specific relevance to care and would likely be of limited use to others in the care network [17]. Broadly, the primary use of these posts by other users would be in day-over-day comparisons of daily activities or symptoms. For example, one post said, “Had a busy day yesterday getting ready for a weekend visitor. Went shopping, dropped things off at recyclers, made use of great weather for a walk. [NAME] was pretty worn out by the end of the day. She went to bed early right after supper. Could not remember eating breakfast or lunch.”

These recap-style posts did not generally include the reflection elements common in topic 1, but rather provided the list of activities without further comment. Despite being among the lengthiest posts in the corpus, this topic had the highest average sentiment score, reflecting a lack of symptom-specific or other negative language that may drive down scores in other topic areas.

Caregivers also used the journal to discuss medical care and other professional assistance related to AD/ADRD care (topic 2) [26]. Posts on this topic were diverse in topic and tone, reflected by the wide deviation in VADER score across the topic. Here, there were posts relaying updates from doctors specifically related to AD/ADRD (eg, neurologists) and other medical providers (eg, dentists and general practitioners). This underscores the nature of AD/ADRD caregiving, which is not limited to a single domain, but often requires many hours per day for a wide range of support tasks [4,5]. Additionally, within this topic, users sometimes discussed individual instances related to professional care settings, including mishaps (eg, missed diagnoses and errors in medication management) and praise for individual providers.

Implications for Practice

This work has important implications for organizations seeking to provide support for AD/ADRD caregivers. First, our exploratory findings suggest two distinct use cases for the CareVirtue Journal—one for personal journaling and one for shared communication across the care network—in which users engaged roughly equally. Future refinement of care coordination platforms may provide unique space for each, with clearer instruction related to their different purposes [30]. Given the documented importance of care networks in diffusing caregiver burden and the mental health benefits associated with private journaling [17,26,28], we suggest the maintenance of both functionalities. However, due to time constraints associated with care provision, caregiver support interventions should be tailored to achieve specific tasks in a clear and efficient manner. Relatedly, our findings point to the value of both routinized and as-needed engagement with the Journal. We noted that users often posted longer messages, with a more positive sentiment, in the evening likely as part of a daily routine. By contrast, posts made at odd hours were shorter, more negative, and likely related to an acute instance. Again, however, users seemed to value both capacities of the platform. Future intervention development may consider cues to complete routine posts/engagement, while also providing additional tools to maximize use flexibility (eg, mobile optimization) [31].

In reviewing the content posted to users’ Journals, we found a broad set of general topics. However, some AD/ADRD symptomologies were particularly common among posts; specifically, users often posted about sleep and toileting issues [11,12,32]. There was also a unique topic related to professional medical care, both from physicians and in assisted or long-term care facilities. The frequency with which these topics were discussed may indicate particular stress points for caregivers [4]. This is perhaps, not surprising, as these symptoms less likely to be managed by respite or temporary caregivers, who are not with the care recipient after hours or overnight. Prior research has also found that caregivers often face challenges in determining the appropriate timing to move their care recipient into a long-term care facility [33]. Caregiver interventions and organizations may, therefore, focus efforts on creating novel mechanisms for managing these symptoms and making these determinations. For example, digital care coordination platforms like CareVirtue may nudge local, secondary caregivers in the network to explore options for providing overnight care. Broadly, our findings suggest primary caregivers of people living with AD/ADRD experience myriad, complex emotions and challenges associated with care. Novel technology-based interventions are needed to reduce burden and improve caregiver well-being [26].

One important contribution of this work was to demonstrate the capacity to use large language and machine learning tools in understanding user behavior for digital health tools. A prior study used traditional qualitative content analysis to explore the use of the CareVirtue Journal tool [26]. In that study, primary themes that emerged from the data related to caregivers’ information acquisition, information sharing, strategy development, and information feedback. While similar themes emerged in the current analysis, by using computational tools, we were able to derive additional themes and quantitatively relate these themes to user behavior. This is consistent with prior research suggesting the additive value of such methods in understanding and contextualizing large datasets of unstructured text [34,35].

Beyond uses for retrospective data analysis, the informatics-based tools here could be used within the intervention itself to automate processes for delivering real-time content across the care network [36,37]. For example, embedding a calculation of semantic sentiment score (ie, VADER) at the time of posting, given its significant relationship with user mood, could allow for the identification of caregiver stress in real time. This data could be used to then trigger in-program responses, including curated content for the caregiver related to stress reduction strategies, as well as notifications to others in the care network prompting them to reach out to the principal care provider. This is consistent with other digital health interventions, which have begun to embed artificial intelligence and other informatics-based approaches into digital interventions, including artificial intelligence–enabled chatbots [38,39]. Such applications of these tools are increasingly common, given their relatively low cost to implement and high capacity to make digital tools more immediately responsive to user needs [40].

Limitations and Future Directions

As with all research, this work had certain limitations that limit generalizability and should be noted for consideration. First, this study analyzed the free text responses of AD/ADRD caregivers, who were not given particular prompts or instructions for their use of the Journal tool. As such, individual users perceived differing uses for the CareVirtue Journal feature. While this lack of clarity provided interesting and novel insights for the design process, future research may seek to examine each use case independently. Additionally, those individuals willing to post to the shared Journal space may have certain characteristics (eg, extroversion), which may limit the generalizability of findings to all caregivers. Further, this study was completed with a relatively small sample of predominantly White, female caregivers and may not be generalizable to all caregiving situations. Readers should exercise caution in drawing broad conclusions from this work. Future research may seek to examine Journal use among larger and more diverse samples.

Conclusions

This study examined the use of a novel tool, the digital CareVirtue Journal, by caregivers of people living with AD/ADRD. Using a computational, informatics approach, we identified 5 salient themes in users' free-text journal posts. Two related broadly to the caregiving experience, but with unique use cases: a more traditional journaling approach wherein users chronicled daily routines, and a second approach for recording acute or specific events with relevance for others across the care network. Further, caregivers often journaled about professional medical care and two specific symptomologies of AD/ADRD (ie, sleep disturbance and toileting challenges). We found that users who routinely engage the platform in the evening and who reported a better overall mood also tended toward longer and more semantically positive posts. By contrast, users who engaged in off-hours or who reported poor mood tended to write shorter, semantically negative posts. Taken together, these findings suggest multiple, valuable uses for the CareVirtue Journal tool, which offers AD/ADRD caregivers space to reflect and organize their thoughts, as well as to share important care-related information across their networks.

Acknowledgments

This work was supported by the National Institute on Aging (NIA) of the National Institutes of Health (NIH) under award R41AG069607. Further, recruitment was supported by the NIA (award P30AG062715). ACP is supported, in part, by NIA under award K01AG084930. This work is the responsibility of the authors and does not represent the official views of the NIH/NIA.

Authors' Contributions

JJB, CE, MZ, and NEW conceptualized the larger study and contributed to data collection. ACP, DV, PL, and LAW conducted data analysis. ACP, DV, and NEW drafted the original manuscript, which was reviewed and edited by all authors.

Conflicts of Interest

CE is the founder and chief executive officer of Whiplash Technology and the developer of CareVirtue. MZ is the Customer Service Implementation Manager for Whiplash Technology and supports the development of CareVirtue; is an Associate for HFC, which is a 501(c)3 with a mission of bringing light to Alzheimer; and sits on the Board of Directors for that National Adult Day Services Association (NADSA).

Abstract

Background: Falls pose a significant public health concern, with increasing occurrence due to the aging population, and they are associated with high mortality rates and risks such as multimorbidity and frailty. Falls not only lead to physical injuries but also have detrimental psychological and social consequences, negatively impacting quality of life. Identifying individuals at high risk for falls is crucial, particularly for those aged ≥60 years and living in residential care settings; current professional guidelines favor personalized, multifactorial fall risk assessment approaches for effective fall prevention.

Objective: This study aimed to explore the prognostic validity of the Fall Risk Score (FRS), a multifactorial-based metric to assess fall risk (using longitudinal real-world data), and establish the clinical relevance of the FRS by identifying threshold values and the minimum clinically important differences.

Methods: This retrospective cohort study involved 617 older adults (857 observations: 615 of women, 242 of men; mean age 83.3, SD 8.7 years; mean gait speed 0.49, SD 0.19 m/s; 622 using walking aids) residing in German residential care facilities and used the LINDERA mobile health app for fall risk assessment. The study focused on the association between FRS at the initial assessment (T1) and the normalized number of falls at follow-up (T2). A quadratic regression model and Spearman correlation analysis were utilized to analyze the data, supported by descriptive statistics and subgroup analyses.

Results: The quadratic model exhibited the lowest root mean square error (0.015), and Spearman correlation analysis revealed that a higher FRS at T1 was linked to an increased number of falls at T2 ($\rho=0.960$, $P<.001$). Subgroups revealed significant strong correlations between FRS at T1 and falls at T2, particularly for older adults with slower gait speeds ($\rho=0.954$, $P<.001$) and those using walking aids ($\rho=0.955$, $P<.001$). Threshold values revealed that an FRS of 45%, 32%, and 24% corresponded to the expectation of a fall within 6, 12, and 24 months, respectively. Distribution-based minimum clinically important difference values were established, providing ranges for small, medium, and large effect sizes for FRS changes.

Conclusions: The FRS exhibits good prognostic validity for predicting future falls, particularly in specific subgroups. The findings support a stratified fall risk assessment approach and emphasize the significance of early and personalized intervention. This study contributes to the knowledge base on fall risk, despite limitations such as demographic focus and potential assessment interval variability.

Introduction

Falls represent a major health risk, with a profound impact on both individuals and society, particularly for those aged ≥60 years [1]. They are inherently linked to adverse effects on mobility, concurrent care risks, increased disease burden, and increased mortality rates [2-5]. Falls are the second leading cause of unintentional injury deaths globally, with an estimated 684,000 fatalities annually [6]. The number of falls and their related injuries are estimated to likely increase in the upcoming years [7]. This occurrence can be attributed in part to increasing life expectancy [8] and a rising prevalence of fall risk factors, including but not limited to multimorbidity, polypharmacy, and frailty [7]. Fall-related injuries often lead to severe consequences [9], including hip fractures [10] and head trauma [11], which can increase the risk of death, disability, and institutional care, as well as impose substantial economic strain on the health care system [12]. Falls can also have a significant impact on quality of life. Fear of falling can lead to social isolation, reduced physical activity, and loss of independence [13]. These psychosocial consequences can further exacerbate the risk of falls by creating a vicious cycle.

Identifying individuals at elevated risk of falling constitutes a critical aspect of preventing falls. An individualized approach to screening, assessment, and intervention is highlighted in professional guidelines, exemplified by practices outlined in the German nursing expert standards for fall and fracture prevention [14] and in the World guidelines for fall prevention for older adults [1]. Although no unanimous agreement exists on the precise selection of fall risk assessment methods [15], an emphasis on an individualized, multifactorial, and comprehensive assessment of fall risk is consistent across professional guidelines [1,14], allowing for the development of tailored multifactorial measures to address fall risk. In accordance with these guidelines, a comprehensive assessment should encompass various domains, including mobility, sensory function, activities of daily living, cognitive function, autonomic function, disease history, medication history, nutrition history, and environmental risk. This personalized approach can enable the efficient identification of older adults at risk of falling, facilitating the implementation of targeted interventions to mitigate this risk.

At present, methods for predicting falls in older adults mostly depend on single assessments [15]. These assessments, being singular tools, may lack the scalability and real-time capabilities necessary for widespread multifactorial fall prevention efforts [1,15]. To embrace a multifactorial approach in fall prevention, the incorporation of technology, such as wearables and mobile health (mHealth) technologies, could prove beneficial. These technological tools possess the capability to capture diverse data types, thereby offering the potential for implementing a comprehensive strategy for multifactorial fall prevention. Some mHealth tools have been developed to implement multifactorial fall risk assessments and have focused on validating both their mobile technology (eg, validation of their inertial measurement units against gold standard technologies) and their application in real-world environments (eg, retirement communities) [16]. Most published research related to fall risk assessments has focused on the ability to discriminate between fallers and nonfallers, determining cutoffs, and assessing their sensitivity and specificity [16,17]. Although this is relevant for identifying individuals at an increased risk of falls, the provision of minimal clinically important differences (MCIDs) is missing [16-21]. Such metrics are crucial for identifying responsiveness to fall prevention programs in effectiveness trials using multifactorial risk assessments as a measure of fall risk.

Many of the available mHealth tools use a combination of functional assessments and questionnaires to gather additional risk factors as part of the multifactorial approach to fall risk assessment [16]. For instance, the Steady app incorporates a health history questionnaire alongside a progressive postural stability test, which informs a weighted algorithm to determine the fall risk [22,23]. Similarly, the Kinesis Balance app enables measurements of standing balance, supplemented by a questionnaire addressing further fall risk factors [24]. Another app, the Aachen Falls Prevention App, is based on the Aachen Falls Prevention Scale and evaluates fall risk through a series of questionnaires and a single balance task [25]. The app developed by Taheri-Kharameh and colleagues assesses fall risk based on the Stopping Elderly Accidents, Deaths, and Injuries framework and incorporates a Timed Up and Go test to categorize individuals regarding their fall risk [26]. Most available apps primarily focus on balance assessments and do not incorporate gait-related information, which is relevant for understanding fall risk [15,27]. Although some apps include a Timed Up and Go test [26,28], it focuses solely on the time taken to complete the test, lacking insight into gait parameters. For instance, among other factors, step length, gait speed, and dynamic trunk sway [29-31] have been identified as parameters contributing to fall risk. To the best of our knowledge, the LINDERA Mobility Analysis (LINDERA GmbH) mHealth app uniquely incorporates gait parameters derived from the smartphone camera, and also includes a questionnaire addressing supplementary fall risk factors, providing a multifactorial approach for fall risk assessment.

The LINDERA Mobility Analysis mHealth app comprehensively captures intrinsic (such as comorbidities, incontinence, fear of falling, and prior falls) and extrinsic (including mobility aids, environmental barriers, and home footwear) factors. These factors, recognized as contributors to the risk of falling [1], are seamlessly integrated into the mHealth app's calculation of the Fall Risk Score (FRS). The FRS has been previously detailed and evaluated to ascertain its discriminatory efficacy in distinguishing between fallers and nonfallers within a cross-sectional study design [32]. The FRS exhibits performance metrics that are comparable to those of established assessments commonly used for the evaluation of fall risk [32]. Through this, the mHealth app can provide personalized assessments of fall risk and recommendations for fall prevention [32,33]. However, the prognostic value of the FRS has yet to be reported. This study aimed to investigate the prognostic validity of the FRS based on longitudinal real-world data. It is hypothesized that the FRS serves as a prognostic indicator, suggesting an association with future falls within a predetermined time interval. As a secondary goal, this research aims to establish the clinical relevance of the FRS by identifying threshold values and the MCIDs.

Methods

Study Design

This is an observational, retrospective cohort study in older adults undergoing fall prevention assessment.

Setting

This study focused on nursing facilities for older adults within Germany. These institutions, tailored to the distinctive needs of older adults, adhere to routine fall prevention practices mandated by German legislation. Furthermore, these facilities have incorporated LINDERA into their fall prevention assessment strategy, conducting fall prevention assessments approximately every 3 months, contingent upon the absence of any reported falls.

Participants

Data acquisition involved retrieving data in August 2023 from the LINDERA database. Prior to participant data selection, precise criteria were delineated to identify and incorporate the data relevant to the investigation.

Inclusion criteria were defined as follows: (1) participants should have completed more than one fall risk prevention assessment and (2) participants should be aged 60 years or older. Assessments were exclusively accepted if captured through a uniform app version (versions 10.0.6 to 10.17.0), ensuring consistency in the used FRS calculation, questionnaire version, and gait parameters calculation. Additionally, assessments were considered if they exhibited an interval between 45 and 180 days, corresponding to an initial assessment (T1) and a subsequent follow-up assessment (T2). Repeated assessments (observations) for the same individual were also considered. As the app involved a video-based fall risk assessment, all participants were required to be capable of walking at least 6 meters.

After data retrieval, assessments were included in the analysis only if the gait videos showed the presence of older adults, meaning real human measurements had been collected. To guarantee a dependable documentation of fall history, the analysis focused solely on residents from residential care settings. The study's final sample size comprised 617 older adults (857 observations), with data collected between June 2021 and July 2023.

Description of mHealth App

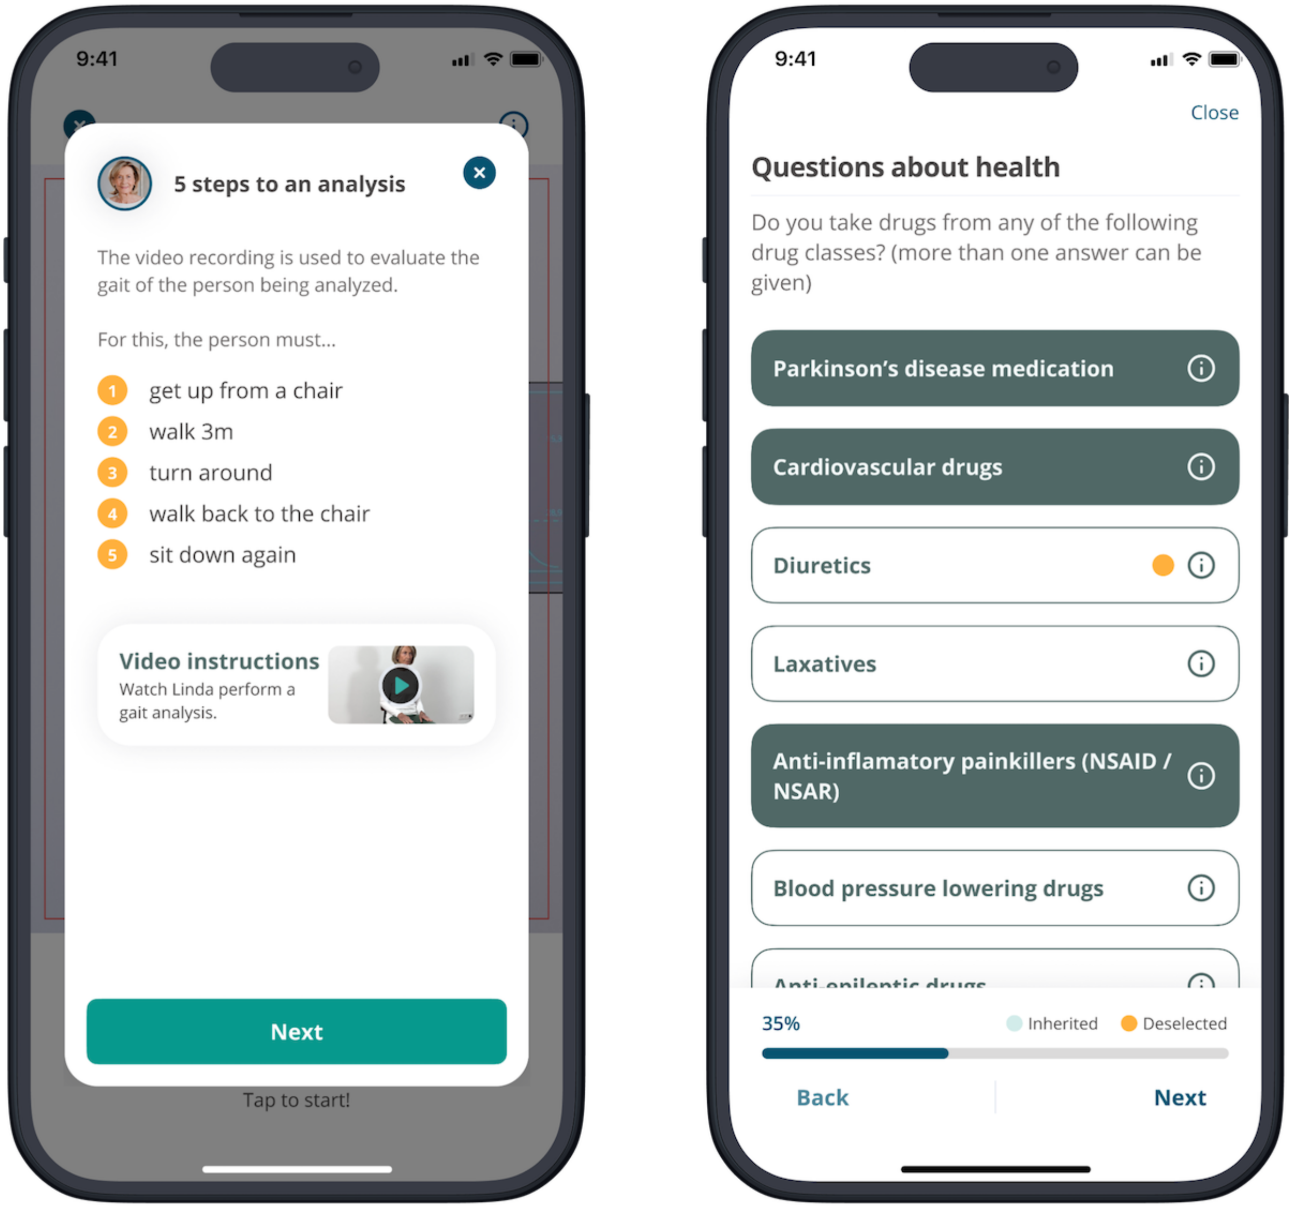
The mHealth app (English version: Figure 1; German version: Multimedia Appendix 1) was used for the evaluation of fall risk among the study participants through the computation of an FRS, as described elsewhere [32]. Briefly, to complete a fall risk assessment, two procedures are required: (1) recording the participants' gait via smartphone-based video to evaluate the gait pattern through a computer vision algorithm [34] and (2) the collection of additional fall risk factors through a standardized questionnaire integrated within the mHealth app.

For the video procedure, participants were required to perform a 3-meter walking test involving the sequence of standing up from a chair, walking approximately 3 meters toward the camera, executing a 180-degree turn, returning to the starting point, and sitting down. Participants were permitted to utilize assistive mobility devices (eg, a cane, crutch, or walker) during the video capture process. The video was recorded by a caregiver, such as a nurse, who simultaneously ensured patient safety. The underlying computer vision algorithm is based on a modular system consisting of a video tester, a skeleton estimator (skeleton estimator 2D, skeleton estimator 3D, skeleton optimization 3D), and processing of mobility parameters [34]. The modular artificial intelligence–based algorithm detects gait cycles during the walking segment of the assessment and computes gait parameters such as step length and gait speed. The accuracy of this algorithm has been previously evaluated through comparison with the GAITRite walkway system elsewhere [34], with reported intraclass correlation coefficient values exceeding 0.90, indicating excellent agreement, as detailed in prior research. Following video capture, immediate quality checks are conducted to confirm that the video complies with the predefined quality criteria (eg, exposure, camera movement). If necessary, a new video recording is requested.

Following the video procedure, participants were required to complete a questionnaire comprised of a maximum of 58 questions that encompassed person-related risk factors and environmental risk factors. Participants had the option to fill out the questionnaire either independently or, if they preferred, with the help of caregivers. Additionally, if cognitive limitations prevent a participant from completing the questionnaire, an alternative version is triggered for external assessment by the caregiver. Nevertheless, the same risk factors are collected.

Assessments were analyzed only if the 2 procedures were carried out and uploaded.

Figure 1. Screenshots depicting the mobile health app during the initialization phase of a new fall prevention assessment.



9:41

5 steps to an analysis

The video recording is used to evaluate the gait of the person being analyzed.

For this, the person must...

1. get up from a chair
2. walk 3m
3. turn around
4. walk back to the chair
5. sit down again

Video instructions
Watch Linda perform a gait analysis.

Variables Extracted From the mHealth App

Fall Risk Score

Utilizing these 2 procedures (video and questionnaire) inherent to the mHealth app, fall risk factors were systematically and automatically gathered. The recorded video exclusively allows an analysis of the gait pattern, which includes key characteristics such as step length and gait speed. The questionnaire screens for a range of additional fall risk factors, including dizziness and visual and acoustic impairments, among others, which are relevant for a comprehensive assessment of fall risk [32]. There are no overlaps between the risk factors derived from the video and those obtained from the questionnaire; each risk factor is exclusively captured from 1 of these 2 sources.

Each risk factor identified through these methods is considered in the FRS calculation, which is quantified on a scale ranging from 0-100 points. A score of 0 indicates the absence of fall risk factors, while a score of 100 represents the complete presence of all identified fall risk factors. The higher the FRS, the more fall risk factors are present. According to established fall-risk models with demonstrated diagnostic accuracy [35,36], such as St. Thomas's Risk Assessment Tool in Falling Elderly Inpatients, the Hendrich II Fall Risk Model, and the Downton Fall Risk Assessment, 9 specific risk factors are assigned double weighting. These factors include limited mobility, dizziness, visual and auditory impairments, medication use, cognitive impairment, depression, urge incontinence, a history of falls, and restlessness. Additional risk factors are assigned single weighting. These include comorbidities that limit mobility, foot disorders, conditions that can cause syncope, fear of falling, the use of walking aids, and environmental hazards.

Number of Falls at Follow-Up Assessment

The number of falls recorded at follow-up, T2, was self-reported by the senior using the mHealth app. Participants responded to a specific inquiry presented in the mHealth app, detailing how often falls occurred since the last analysis. It is noteworthy to highlight that, owing to the nature of the setting being stationary residential, the number of falls is meticulously documented in this environment. Caregivers have ready access to this documented information when conducting the fall risk prevention assessment.

To standardize these reported values and account for variable observation periods, a normalization process was implemented where the number of reported falls was divided by the corresponding number of days covered by the analysis (T1 to T2).

Bias

To address potential biases inherent in the study design [37] that could potentially introduce confusion and affect the precision of association estimates, a series of methodological strategies were implemented to enhance the internal validity of the study findings.

Statistical Analysis

Overview

Descriptive statistics were calculated as mean and standard deviation for continuous data and counts for categorical data. For all statistical evaluations, the significance level was set at α=.05. RStudio (R version 4.3.1; Posit PBC, irr package) and Python (version 3.9; Python Software Foundation) were used to process, analyze, and visualize all data. Specifically for Python, NumPy (version 1.25.2), Pandas (version 2.03), and scikit-learn (version 1.3.0) libraries were used.

Regression Analysis

To determine the relationship between the FRS at T1 and the number of falls at T2, a correlation analysis was performed, with a 3-step approach. First, to enhance data smoothing and establish a more consistent data representation, a running average was computed. This running average utilized the FRS as a grouping parameter, with a window size equivalent to 2% of the FRS value, resulting in the derivation of an average number of falls at T2 for each FRS. Second, multiple regression models were created to identify the function that best fits the data points. To assess the performance of the fitted function, root mean square error (RMSE) was reported. The model exhibiting the lowest RMSE value was selected as the most appropriate. Finally, in the third step, the Spearman rank correlation coefficient was used to evaluate the strength and direction of the monotonic relationships between FRS at T1 and number of falls at T2, both extracted from the running average. This nonparametric test was selected for its ability to handle ordinal data and nonlinear relationships. Correlation coefficients and corresponding *P* values were computed to assess the statistical significance of these associations. This analysis was also conducted in multiple subgroups to identify stronger associations within specific variables. Specifically, the following variables were investigated: time interval (60, 90, or 120 days); number of reported diseases (cancer, arthritis, osteoarthritis, stroke, Parkinson disease, multiple sclerosis, chronic pain, heart disease, lung disease, kidney disease, liver disease, HIV, osteoporosis, dementia, anemia); age (<65, 65-74, 74-85, or >85 years old); gait speed (above or below 0.6 m/s); dementia (with or without); gait speed and dementia (above 0.6 m/s and without dementia, below 0.6 m/s and with dementia); fall history (yes or no); and use of walking aids (yes or no). The subgroups were selected based on risk factors previously mentioned as associated with increased risk of a fall [1,15,38-43]. For each subgroup explored, the RMSE, Spearman correlation coefficients, *P* values, and sample size are reported.

Threshold Values

Following this process, threshold values were determined based on the obtained regression model for the main sample size. The corresponding model’s equation was used to estimate the average number of falls per week. To estimate the threshold values over longer periods—such as 6, 12, and 24 months—the average number of falls per week was multiplied by the corresponding number of weeks in those periods (26, 52, and 104, respectively). This approach enabled the calculation of fall risk thresholds over extended time frames.

Determination of MCID

To determine the MCID for the FRS, a distribution-based approach was used, in accordance with [44]. Consequently, the distribution-based MCID was computed using the following formula: effect size × SD pooled, where the effect size assumes values of 0.2, 0.5, and 0.8, representing small, medium, and large effect sizes, respectively, in accordance with [45]. The pooled standard deviation (SDpooled) is determined as the square root of [(SD baseline)^2 + (SD follow-up)^2/ 2] in [44,46]. The 95% CIs were estimated using bootstrapping methodology. The MCID range was estimated by considering values that span from smaller to larger, as derived from these calculations.

Ethical Considerations

Data acquisition involved retrieving data in August 2023 from the LINDERA database, encompassing participants who had provided informed consent for the collection and utilization of their data for research purposes. Participants were not compensated for their participation. LINDERA adheres to the European Union General Data Protection Regulation, and all data incorporated into the study were pseudonymized. The study was approved by the local ethics committee at Charité - Universitätsmedizin Berlin (EA4/009/21).

Results

Participants

A detailed participant inclusion flowchart before exclusion is provided in Figure 2, illustrating the selection process. Initially, 4577 patients (3146 women and 1431 men) who provided consent to use their data for research purposes were considered for inclusion. The average age of these participants was 81.1 (SD 12.1) years. Among them, 1192 (25.8%) had dementia and 3235 (70.7%) used walking aids.

The details of the full sample at T1 are displayed in Table 1. The FRS for the observations of the full sample size was 29.7 (SD 11.8%; range 1 - 71) at T1 and 29.2 (SD 11.5%; range 4 - 77) at T2. The average time interval between T1 and T2 was 108.5 (SD 31.6) days.

At T1, a total of 190 patients (with a total of 277 observations) could not self-report the fall risks collected through the questionnaire and required an external assessment. Comparisons between this group and the self-reported group showed no statistically significant differences in gender (*P*=.31) and fallers at T1 (*P*=.40). However, statistically significant differences were found for age (*P*<.001), gait speed (*P*=.03), and walking aid usage (*P*<.001). Specifically, the self-reported assessment group was older and slower and had a higher proportion of individuals using walking aids (464/580 observations, 80%) compared to the external assessment group (158/277 observations, 57%).

Figure 2. Participant inclusion flowchart.

Table . Demographic and anthropometric data at initial assessment (T1) for the full sample, the self-reported fall risk questionnaire sample, and the externally assessed fall risk questionnaire sample.

Initial assessment characteristic	Full sample	Self-reported questionnaire	Externally assessed questionnaire
Participants, n	617	427	190
Observations, n	857	580	277
Gender, n	615 women, 242 men	423 women, 157 men	192 women, 85 men
Age (years), mean (SD)	83.3 (8.7)	84.0 (8.8)	81.8 (8.4)
Dementia, n	277	0	277
Fallers, n	125	80	45
Gait speed (m/s), mean (SD)	0.49 (0.19)	0.48 (0.19)	0.52 (0.20)
Using walking aids, n	622	464	158

Regression Analysis

Figure 3A presents a scatter plot illustrating the relationship between the normalized number of falls at T2 and the FRS at T1. The mean (SD) normalized number of falls per week at T2 for the full sample was 0.02 (SD 0.05). A running average was calculated using the FRS as a grouping parameter, with a window size equivalent to 2% of the FRS value. Figure 3B displays the resultant points of this running average computation, revealing a nonlinear relationship in the data.

Multiple regression models were computed to determine the best-fitting function. Three sequential models were tested: linear, quadratic, and exponential, introduced in ascending order of complexity. Among the models, the quadratic model (Figure 3B) was selected as it exhibited the lowest RMSE (0.015). The corresponding quadratic regression model's equation is as follows, where FRS represents the average Fall Risk Score at T1:

$$\text{avg number of falls per week} = 2.9745\times10^{-5}\times FRS^{2} + 3.4612\times10^{-5}\times FRS - 2.4251\times10^{-3}$$

The linear and exponential models exhibited corresponding RMSE values of 0.017 and 0.016, respectively.

Spearman correlation analysis, using the moving average data as the basis, revealed a strong, positive correlation between FRS at T1 and falls at T2 (ρ=0.960, *P*<.001). Subgroup analysis, using the moving average as the basis, was conducted to explore the impact of various variables on the relationship between FRS at T1 and falls at T2. The outcomes of the subgroup analysis are summarized in Table 2.

Table 2 reveals that significant strong correlations were found for the subgroup using walking aids (ρ=0.955, *P*<.001), with a gait speed below 0.6 m/s (ρ=0.954, *P*<.001), and with a time interval of 120 days (ρ=0.934, *P*<.001), indicating robust associations. Moderate yet significant correlations were observed for the subgroup aged 65 - 74 years (ρ=0.437, *P*=.002) and with no diseases (ρ=0.504, *P*=.002). Weak and nonsignificant correlations were found for groups such as those with 3 diseases and gait speed above 0.6 m/s, suggesting no substantial relationship. The results obtained using the raw data are presented in Multimedia Appendix 2.

Figure 3. (A) Scatter plot of the FRS at T1 and normalized number of falls per week at T2. (B) Resultant values for the running average computation for the FRS at T1 and normalized number of falls per week at T2, including of the quadratic model in the resultant values of the running average computation. FRS: Fall Risk Score.

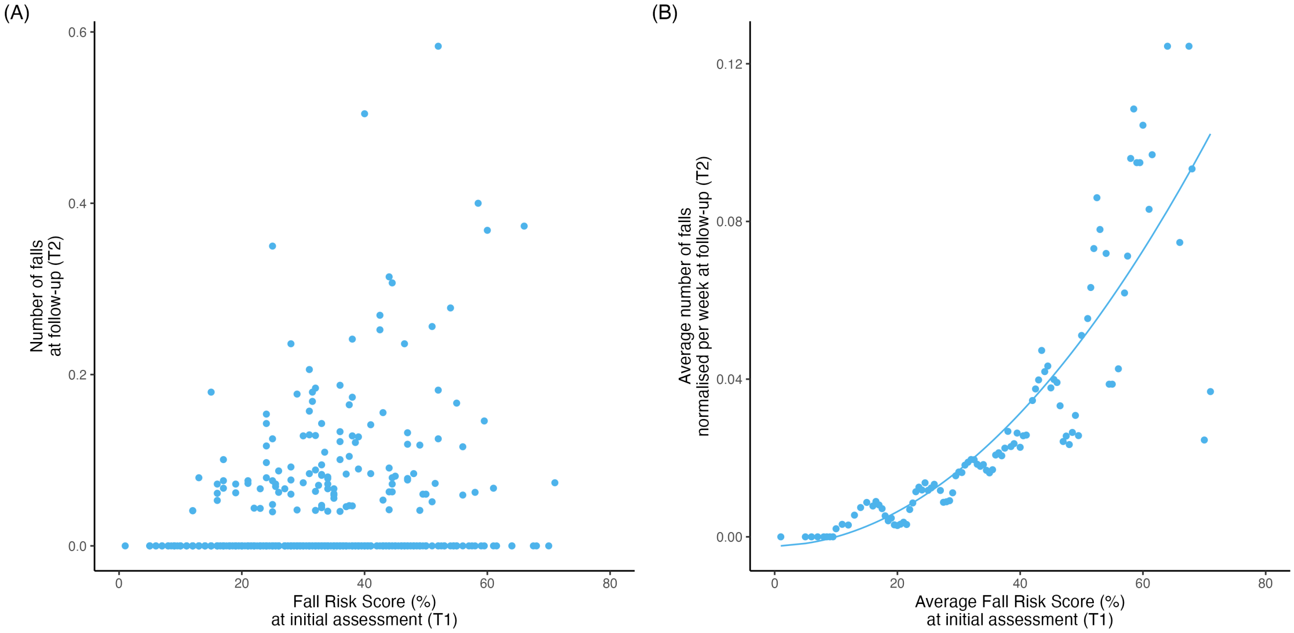

Table . Performance metrics of the models evaluated (running average–based; root mean square error) and Spearman correlation analysis to predict number of falls at T2 based on Fall Risk Score values at T1 for subgroups.[a,b]

Subgroups explored at T1		Root mean square error	Spearman correlation coefficient	*P* value	Fall Risk Score at T1, mean (SD)	Observations, n
Time interval between T1 and T2

[a] T1: initial assessment.

[b] T2: follow-up assessment.

Threshold Values

The threshold values obtained from the quadratic model revealed the corresponding FRS values as follows: an expectation of 1 fall within the next 6 months aligns with an FRS value starting at 45%, while an anticipation of 1 fall within the next 12 months corresponds to an FRS value starting at 32%. Additionally, individuals expecting 1 fall in the upcoming 24 months exhibited an associated FRS value starting at 24%.

MCID Values

Table 3 reports the distribution-based MCID (95% CI) values for the FRS change from T1 to T2.

Table . Distribution-based MCID values for the Fall Risk Score change from T1 to T2.[a,b,c]

Effect size	Distribution-based MCID (95% CI) for Fall Risk Score
Small (effect size=0.2)	2.3 (2.2-2.4)
Medium (effect size=0.5)	5.8 (5.6-6.1)
Large (effect size=0.8)	9.3 (8.9-9.8)

[a] MCID: minimal clinically important difference.

[b] T1: initial assessment.

[c] T2: follow-up assessment.

Discussion

Principal Findings

The study confirms the multifaceted nature of fall risk for older adults from several long-term care facilities (inpatient caregiving) as represented by the FRS. The main findings highlight the prognostic significance of the FRS across different time intervals. Individuals with an FRS exceeding 45% had an increased risk of falling within 6 months, emphasizing the importance of early intervention for those identified at this threshold. The graded risk spectrum, with FRS values of 32% and 24% corresponding to expected falls over 12 and 24 months, respectively, provides a nuanced framework for risk stratification and tailoring of preventive strategies over different time horizons. Additionally, establishing MCID values for FRS offers a robust metric to evaluate the clinical impact of FRS measurement and its corresponding fall prevention programs. By providing MCIDs for small (effect size=0.2), medium (effect size=0.5), and large (effect size=0.8) effect sizes, a framework for interpreting the observed changes in fall risk scores was established, which will help in understanding the results of future prospective studies by evaluating whether observed changes in fall risk scores are meaningful.

Subgroup analyses broaden the understanding of the FRS's contextual applicability, revealing that the use of walking aids, slower gait speed, and the time interval between assessments are important contributing factors influencing fall risk. In contrast, faster gait speeds and a combination of faster gait speeds and no dementia (indicating higher functional levels) do not appear to be significant contributing factors to fall risk. These insights into FRS dynamics underscore the need for a multifactorial approach to fall risk assessment and management, incorporating clinical, behavioral, and environmental factors for optimal outcomes for people exposed to fall risks.

Overall, the study aimed to assess the prognostic validity of the FRS based on longitudinal fall risk assessment data acquired in real-world conditions. The study hypothesis posited that the FRS operates as a prognostic indicator, suggesting an association with future falls within a predetermined time interval. The study's main finding was that the FRS, when assessed at T1 and used in a quadratic model to predict the number of falls at T2, demonstrates a good predictive performance. This is supported by the significant strong correlations detected between the FRS at T1 and falls at T2 ($\rho=0.960$, $P<.001$).

Prognostic Validity of the Fall Risk Score

The best-fitting regression model, characterized by the lowest RMSE, depicted a nonlinear relationship between the FRS and number of falls. These results seemed to be consistent with previous research. Notably, alternative models for predicting falls rely on objective metrics such as gait speed. Quach and colleagues [47] identified a nonlinear, U-shaped relationship between gait speed and the frequency of falls in community-dwelling older adults. Both faster and slower gait speeds were associated with the highest risk of falls. Subsequent subgroup analyses in this investigation revealed that variations in gait speed may influence the magnitude of the association between FRS and fall frequency, as significant, strong correlations were detected for slower walkers (gait speed below 0.6 m/s), in agreement with findings from [47]. Moreover, the mean FRS values of slower walkers (mean 32.3, SD 11.4%) exceeded the threshold indicative of distinguishing fallers from nonfallers (27.5%), as previously determined [32]. In contrast, the mean FRS values of faster walkers (mean 21.9, SD 9.5%) did not surpass this threshold, underscoring the relevance of gait speed in the predictive model.

Spearman correlation analysis revealed differing strengths of correlation across different subgroups. It was most effective for predicting falls among older individuals with slower gait speeds, using walking aids, and with a time interval between fall risk assessments of 120 days. On the other hand, the correlations were weaker among individuals with different disease counts and those with a combination of gait speed and dementia status. These results indicate that, while the predictive model is robust in certain contexts, it may require additional refinement or consideration of other factors to improve its predictive power across all subgroups. For instance, in the disease group with 3 conditions (n=3), the observed low Spearman correlation can be attributed to the presence of observations with high FRS and zero falls (Multimedia Appendix 3). These observations disrupt the rank-order relationship, leading to a reduction in the Spearman correlation coefficient. Nonetheless, the low RMSE indicates that the quadratic model performed well overall for most data points within this subgroup. Individuals with multiple diseases exhibited a descriptively higher fall risk (Table 2), with an even greater fall risk observed in those over 85 years of age (Multimedia Appendix 4). Health care professionals may be more vigilant in monitoring these individuals, paying closer attention to their health conditions, environmental hazards, and behaviors that could contribute to falls. Such heightened awareness has been previously reported to influence their decisions and actions to prevent falls [48], which may help explain the lack of a statistically significant association between the variables in this subgroup.

An increasing number of mHealth solutions are contributing to the growing body of evidence that supports the validity of using this technology for fall risk screening [49]. For example, the Aachen Falls Prevention Scale, a self-assessment tool that combines a short questionnaire with a balance test, has been found to significantly correlate with users' self-reported history of falls [25]. In addition, Ozinga and Alberts [50] evaluated postural stability assessments captured by a tablet, comparing their results to those obtained through a 3D motion analysis system. Their findings indicate that tablet sensors can quantify postural stability with sufficient accuracy. A more recent review also evaluated several digital apps developed for fall risk assessment [16]. The accumulating body of evidence supporting mHealth use for assessing fall risk holds significant potential to optimize fall prevention efforts by not only identifying individuals at high risk but also delivering targeted interventions tailored to the specific needs identified. This opens avenues for older adults to assess their individual fall risk, a crucial step in determining the appropriate type of fall prevention treatment. However, the majority of mHealth tools assessed in the literature only provide support and integration with isolated parts of fall risk assessment and fail to incorporate a multifactorial, multimodal approach.

MCID Findings

The results from the quadratic model established threshold values for the FRS that correlated with the expectation of falls over different time frames, resulting in risk stratification. The calculation of MCID for FRS changes from T1 to T2, with varying effect sizes, enabled clinicians to understand the magnitude of change in FRS that would be considered clinically significant. Subgroup analysis further refined the understanding of how various characteristics influenced the FRS and the implementation of recommendations, highlighting the complex interplay of factors such as disease presence, age, gait speed, dementia status, fall history, and the use of walking aids in fall risk and response to interventions. These findings underscore the importance of personalized approaches in managing fall risk among different populations, which was not part of the real-world usage of the device.

The distribution-based approach allowed for the interpretation of the MCID while taking into consideration its inherent variability [51]. This method informed the estimation of the MCID by incorporating descriptive statistics derived from the observed scores across the sample's distribution [52]. The magnitude of effect sizes varied with the clinical condition under consideration, with small effect sizes holding potential significance for patients with severe disease, while moderate to large effect sizes become relevant for patients with milder conditions [44]. Among distribution-based methods, the standard deviation between participants is one of the most widely accepted [51,53], and both the variability at initial and follow-up assessments should be considered [46].

Distribution-based approaches are validated methods to derive MCIDs [53,54]. These studies support the use of distribution-based MCID methods, demonstrating accuracy and reliability in deriving MCIDs. In this study, distribution-based methods to derive MCIDs from real world baseline data were effectively applied. In the results, the MCID was divided into 3 categories: small change of approximately 2.3 points, medium change of approximately 5.8 points, and large change of approximately 9.3 points. These MCID numbers can be used to evaluate whether the changes in FRS after an intervention (eg, an exercise program) are large enough to be meaningful. If a participant's FRS drops by more than the MCID, it is likely that the program was beneficial. As a result, the distribution-based approach yielded appropriate differences for a meaningful clinical interpretation of FRS changes.

Usage of Real-World Data

Regulatory organizations are progressively acknowledging the utility of real-world data (RWD) in forming real-world evidence. A systematic literature review was recently undertaken to examine the use of RWD for interpreting outcomes from trials lacking control groups [55]. The study examined major regulatory and health technology assessment bodies and underscored the necessity for enhanced guidance on methodological considerations from these bodies. The systematic review articulated essential directives for generating real-world evidence that is appropriate for its intended benefits. The application of RWD is particularly pertinent in areas where randomized clinical trials are not viable, such as in oncology, rare diseases, or nursing homes [56,57]. Here, controls may be derived from historical data and observational studies. Finally, the paper advocated for the exchange of experiences among stakeholders (eg, sponsors and regulatory bodies) to promote learning and refine the application of RWD-derived evidence, aiming to enhance patient care.

Limitations

Study Group

This study included the physical and demographic characteristics of older adults, providing valuable insights for aging populations. However, its focus on older individuals, gender imbalance, and lack of specific details regarding dementia and fall circumstances could limit its generalizability. Notably, there are indications that gender could have a significant influence on fall risk factors [58] and fall awareness behavior should be emphasized among older females to address gender-specific factors that might be crucial in mitigating fall risk in this demographic [59]. Furthermore, variable assessment intervals may affect the reliability of longitudinal comparisons.

Study Type

The study relies on preexisting, retrospective data, which may have limitations in accuracy, completeness, and consistency. There is also a risk of selection bias, as the data might not have been collected with the current research questions in mind (eg, without a control group, it is harder to attribute changes in fall risk solely to the digital interventions studied). This limits the ability to establish cause-and-effect relationships. Although RWD are valuable for their practical relevance, they can introduce confounding factors and variability.

Statistical Methods

The study suggests that, while there were associations between FRS and fall frequency, there were nonlinear relationships, with variable correlations across different subgroups. The prognostic model was most reliable for predicting falls among older individuals with slower gait speeds and those using walking aids. However, its predictive power was less consistent among individuals with different disease counts and those with a combination of gait speed and dementia status. These results indicate that, while the FRS is robust in certain contexts, it may require additional refinement or consideration of other factors to improve its predictive power across all subgroups.

Bias Reduction

Specifically, eligibility criteria were preestablished to ensure consistency in participant selection and minimize the impact of selection bias on the study outcomes. Additionally, quality criteria were defined for both video capture and data collection processes. For video capture, to optimize the reliability of gait parameter calculations from video recordings, predetermined quality criteria—encompassing aspects such as exposure and camera movement—were systematically implemented. After video capture, this quality assurance process was executed to verify adherence to the predefined criteria, ensuring the integrity of the captured data. For the data collection process, to guarantee caregivers' proficiency in utilizing the mHealth app, a regimen of regular and standardized training sessions was administered by the LINDERA Customer Success Team. Finally, to ensure the reliability of the dataset included, a comprehensive review of all videos associated with the analyses was conducted to confirm the presence of older adults in the video recordings.

In summary, the study utilized the FRS as a predictive tool and the MCID for managing individual fall risk. The FRS could screen fall risks among older adults in nursing care, with its real-world application underscoring its practical utility in clinical settings. The MCID enhanced the study's findings, while translating statistical shifts in FRS into meaningful, patient-centric outcomes. This approach can be used to personalize care plans and also offers an objective measure for evaluating the efficacy of fall prevention strategies. The deduction of MCID sets a practical standard in geriatric care research and practice, emphasizing its value in assessing the effectiveness of interventions in fall risk management.

Conclusions

This study investigated the complex nature of falls and fall risk, encapsulated by the FRS and its prognostic value. Elevated FRS values corresponded to an increased risk of falls and future falls. This, along with the obtained threshold, offers a stratified approach to risk assessment and the formulation of preventative strategies tailored to risk projections of falls. The deduction of MCID values for FRS changes provides a metric for assessing the clinical significance of interventions across a spectrum of effect sizes. Despite the stated limitations, the study's insights are a valuable addition to the existing literature on fall risk, suggesting the FRS as a predictive tool that may benefit from further refinement for broader applications in clinical and nursing settings. The fall risk assessment method utilized in this study identified specific fall risk factors for each individual. By targeting the individual fall risk profile with distinct fall risk factors—such as mobility limitations or environmental hazards—this method enables the delivery of tailored and person-centered fall prevention strategies. These strategies are designed to manage and mitigate the fall risks identified by addressing the particular needs and vulnerabilities of each individual based on a holistic, multifactorial fall risk assessment. Future research should focus on evaluating the effectiveness of such fall prevention strategies derived from a comprehensive and multifactorial fall risk assessment among individuals in residential care settings.

Acknowledgments

All authors developed the study concept and contributed to the study design. ST, SAA, and AB processed and analyzed all the data. SAA wrote the first draft of the manuscript under the supervision of AB. SM contributed to the statistical analysis processes. SAA, ST, SM, MK, WP, SW, JZ, and AB had a role in the preparation of the manuscript, overall data analysis and interpretation of data, and critical revision of the manuscript. SAA, ST, SM, MK, WP, SW, JZ, and AB gave final approval of the version to be published. The authors would like to thank all study participants. Additionally, thanks to Menia Ettrich for her support in manuscript coordination and to Peter Woodcraft for proofreading the final draft.

Conflicts of Interest

SAA, ST, SM, and MK are employees of LINDERA GmbH, which is involved in the development of technologies relevant to the study. Author WP has received consulting fees in the past from LINDERA GmbH. AB has served as a consultant for LINDERA GmbH regarding the market access application of the mHealth app. WP and AB did not receive honoraria for participation in advisory meetings related to the scope of this research. JZ and SW declare no conflicts of interest.

Abstract

Background: The duration of sleep plays a crucial role in the development of physiological functions that impact health. However, little is known about the associations between sleep duration and functional disability among older adults in China.

Objective: This study aimed to explore the associations between sleep duration and functional disabilities in the older population (aged≥65 years) in China.

Methods: The data for this cross-sectional study were gathered from respondents 65 years and older who participated in the 2018 survey of the China Health and Retirement Longitudinal Study, an ongoing nationwide longitudinal investigation of Chinese adults. The duration of sleep per night was obtained through face-to-face interviews. Functional disability was assessed according to activities of daily living (ADL) and instrumental activities of daily living (IADL) scales. The association between sleep duration and functional disability was assessed by multivariable generalized linear models. A restricted cubic-spline model was used to explore the dose-response relationship between sleep duration and functional disability.

Results: In total, 5519 participants (n=2471, 44.77% men) were included in this study with a mean age of 73.67 years, including 2800 (50.73%) respondents with a functional disability, 1978 (35.83%) with ADL disability, and 2299 (41.66%) with IADL disability. After adjusting for potential confounders, the older adults reporting shorter (≤4, 5, or 6 hours) or longer (8, 9, or ≥10 hours) sleep durations per night exhibited a notably increased risk of functional disability compared to that of respondents who reported having 7 hours of sleep per night (all $P<.05$), which revealed a U-shaped association between sleep duration and dysfunction. When the sleep duration fell below 7 hours, increased sleep duration was associated with a significantly lower risk of functional disability (odds ratio [OR] 0.85, 95% CI 0.79-0.91; $P<.001$). When the sleep duration exceeded 7 hours, the risk of functional disability associated with a prolonged sleep duration increased (OR 1.16, 95% CI 1.05-1.29; $P<.001$).

Conclusions: Sleep durations shorter and longer than 7 hours were associated with a higher risk of functional disability among Chinese adults 65 years and older. Future studies are needed to explore intervention strategies for improving sleep duration with a particular focus on functional disability.

KEYWORDS

sleep duration; functional disability; activity of daily living disability; instrumental activity of daily living; older population

Introduction

The issue of disability in the older population has garnered significant attention and interest in recent decades [1-3]. Disability—as defined by the International Classification of Functioning, Disability, and Health—encompasses the combined effects of impairments, activity limitations, or participation restrictions [4]. Functional disability is a significant measure of restrictions in activities, specifically referring to challenges in performing basic activities of daily living (ADLs) and/or instrumental activities of daily living (IADLs) [5,6]. ADLs are widely recognized as essential tasks for maintaining independence in one's own residence, such as dressing, bathing, and eating. IADLs refer to more complex tasks that require a higher level of independence and cognitive ability, such as managing financial matters, engaging in shopping activities, and preparing meals [7].

According to the World Health Organization (WHO) survey of 2022, 46.1% of adults 60 years and older worldwide are living with a disability, and this figure is increasing in tandem with the rapid global aging phenomenon [8]. China has one of the highest proportions of older citizens globally, with over 14% of individuals living in China classified as older people (ie, 65 years and older) [8]. This proportion is expected to increase to 30% by 2050, along with a massive drop in the elderly support ratio (defined as the number of people of "working age" [15-64 years] divided by those aged ≥65 years) from 9 in 2010 to 3 in 2050, which is comparable to that of the United States and Germany [9]. A meta-analysis conducted in 2022 reported that the cumulative prevalence of functional disability in China exceeds 30 million [10]. Moreover, the WHO projects that by 2050, the number of older adults living with a functional disability in China will increase to 66 million [11]. Given the high and rising prevalence of functional disabilities among the growing older adult population, exploring the key factors influencing the risk of functional disabilities is crucial to establish appropriate prevention and intervention strategies.

Duration of sleep plays a crucial role in the development of physiological functions that impact health, showing correlations with an increased risk of cognitive decline, depression, cardiovascular diseases, osteoporosis, and stroke [12-17]. However, a consensus has yet to be reached about the association between the duration of sleep and potential risk of functional disability.

In 2016, the National Survey of Midlife Development in the United States presented evidence that insufficient sleep is an independent and important factor contributing to physiological function disability [18]. A cohort study conducted in China with 1798 individuals 90 years or older demonstrated that sleep duration of 8 to 10 hours was associated with the lowest risk of experiencing an ADL disability, whereas a sleep duration exceeding 12 hours was associated with a heightened risk of experiencing ADL disability [19]. However, there is limited knowledge about the correlations of sleep duration with IADL disability. A US study with 136 participants, predominantly comprising older (aged≥65 years) Black individuals from low-income households, revealed a significant correlation between extended sleep duration surpassing 7.5 hours and worse IADL performance [20]. Similarly, evidence from the National Health Interview Survey spanning 2000 to 2015 showed that an extended sleep duration (≥9 hours) was associated with a higher risk of IADL disability [21]. In addition, owing to interactions with historical, ethnic, economic, and sociocultural factors, the association between sleep duration and functional disability may be heterogeneous across different countries and regions [22,23]. Therefore, the aim of this study was to examine the association between sleep duration and functional disability in China using a nationally representative sample of adults 65 years and older.

Methods

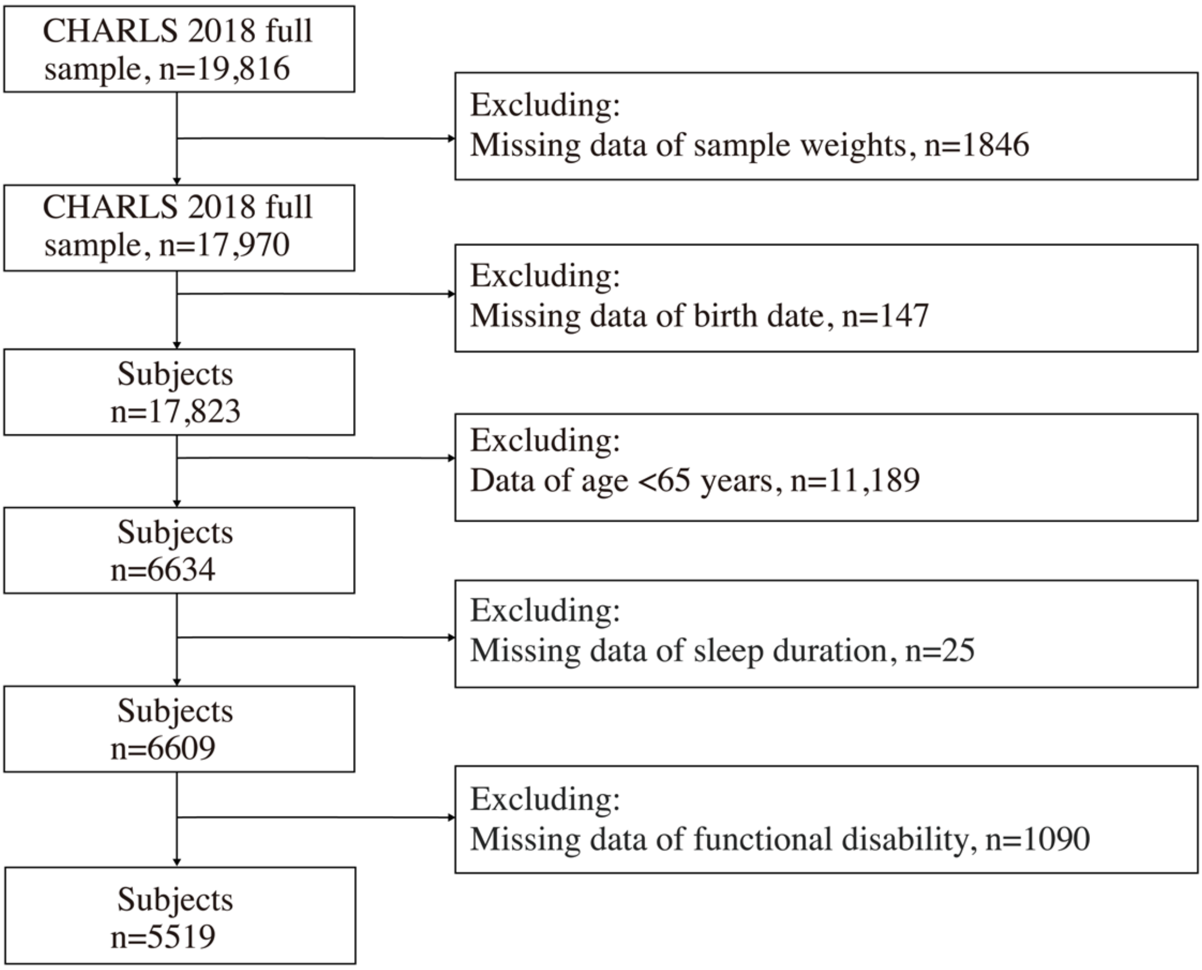
Design and Study Population

This study used data from the China Health and Retirement Longitudinal Study (CHARLS), a comprehensive longitudinal data set designed to provide a representative sample of individuals aged ≥45 years residing in mainland China [3]. The baseline survey of the CHARLS involved a multistage, stratified, probability proportional to sampling method to recruit participants across 150 counties or districts and 450 villages or urban areas throughout the country. Face-to-face interviews were used to obtain the data. A relative or caregiver was asked to complete the survey on behalf of the older adult if assistance was needed. Additional details regarding the CHARLS data set are available elsewhere [3].

The data analyzed in this study were taken from the most recent wave of the CHARLS in 2018, with a sample size of 19,816 participants, to investigate the potential correlation between sleep duration and functional disability. We included only observations without missing values from Chinese older adults aged ≥65 years. The schematic flow of the study sample is depicted in Figure 1. The total sample consisted of 5519 individuals, both with and without functional disability.

This cross-sectional study followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) reporting guideline [24].

Figure 1. Flowchart of the study sample inclusion process. CHARLS: China Health and Retirement Longitudinal Study.



Ethical Considerations

The protocols followed in the CHARLS were aligned with the principles of the Declaration of Helsinki [25]. This study obtained ethical approval from the Institutional Review Board at Peking University (IRB00001052-11015, IRB00001052-11014) [3]. All participants in the CHARLS provided written informed consent. The participants received a physical examination report for their participation. The data were deidentified and treated for confidentiality by anonymization and coding.

Sleep Duration

The self-reported data on sleep duration were obtained from a question about the average number of hours participants slept per night over the course of the previous month. Based on previous research experience of the CHARLS on sleep [26,27], we divided respondents into seven sleep duration groups (≤4, 5, 6, 7, 8, 9, and ≥10 hours per night) in the analyses. In addition to assessing sleep duration, we also explored daytime napping habits and established four distinct groups based on napping duration: 0, <30, 30-90, and >90 minutes [28].

Functional Disability

Functional disability was evaluated by asking participants about their ability to perform several domains of routine tasks included in the ADL and IADL questionnaires without special equipment [29]. The response of each item was categorized into four levels: “No, I do not encounter any problem”; “I experience difficulty but am still able to perform the task”; “Yes, I encounter trouble and require assistance”; and “I am unable to perform the task.” According to previous studies [30-32], respondents were recorded as having a functional disability if they reported any challenge in any of the six ADLs (dressing, bathing, eating, getting in and out of bed, using the toilet, and managing urination and defecation) or the five IADLs (household chores, cooking, shopping, paying bills or managing assets, and taking medications) [29,33].

Covariates

The CHARLS structured questionnaire was completed using in-person interviews to gather participants’ demographic characteristics as covariates, including age (years), gender (man or woman), tobacco use (never and current use), alcohol consumption (never and current use), education level (illiterate, primary or middle school, and high school or higher), residential location (urban or rural area), marital status (married or cohabiting and other statuses), afternoon napping habits, chronic disease status, sampling weights, and depression status. The 10-item Center for Epidemiological Studies Depression Scale was used to differentiate between individuals with and without depression according to a cut-off score of 10 [34-36]. The chronic illness condition of participants was assessed using self-reported noncommunicable diseases (NCDs), including hypertension, diabetes, dyslipidemia, heart issues, stroke, liver diseases, renal diseases, lung diseases, arthritis, and stomach disorders. Based on a recent analysis of CHARLS data on sleep duration [37], individuals were divided into three chronic disease groups: "none" (no NCD), "mild" (1-2 NCDs), or "severe" (more than 3 NCDs). Sampling weights were incorporated based on sets of cross-sectional individual weights that included adjustments for nonresponse by individuals and households.

Statistical Analysis

Participants' characteristics are summarized as numbers and percentages for categorical variables and as mean and SD values for continuous variables and were divided according to the functional disability status (including ADL and IADL disability). Missing baseline data were handled by a multiple-imputation method, which is a widely used approach to compensate for missing data via generating predictions for each missing value multiple times, resulting in a data set containing no missing values [38]. Multivariable generalized linear models (GLMs) were established using a binomial family and log-link functions to investigate the associations between sleep duration and functional disability status. Restricted cubic-splines analyses with four specific knots located at the 5th, 25th, 75th, and 95th centiles of the exposure distribution were performed to assess dose-response relationships between sleep duration and functional disability. The GLM and restricted cubic-spline models were adjusted for potential confounders, including age, gender, education, marital status, tobacco and alcohol use, afternoon napping, residential location, depression status, chronic disease condition, and sampling weights. All analyses accounting for the complex survey design of the CHARLS were conducted using Stata version 14.0 (Stata Corp). Statistically significant findings were defined by a two-sided *P* value below .05.

Results

Sample Characteristics

A total of 5519 participants (2471 men and 3048 women) were included in this analysis with a mean age of 73.67 years, including 2800 (50.73%) participants with a functional disability, 1978 (35.83%) with an ADL disability, and 2299 (41.66%) with an IADL disability.

Table 1 provides a summary of the baseline characteristics of the participants according to disability status. The average sleep duration was 6.04 hours for the total sample, with the majority of respondents reporting sleep durations less than 7 hours. Moreover, individuals with functional disability exhibited an average reduction in sleep duration in comparison to that of individuals without functional disability (5.80 vs 6.28 hours). A similar pattern emerged among individuals with ADL and IADL disabilities. Notably, older participants; women; nonsmokers; alcohol abstainers; those who are single; rural inhabitants; as well as those with lower educational attainment, depression, and a higher burden of chronic illnesses had greater rates of functional disability.

Table 1. Baseline characteristics of participants according to functional disability status.

Characteristics	Total sample (N=5519)	Functional disability		ADL[a] disability		IADL[b] disability	
		Yes (n=2800)	No (n=2719)	Yes (n=1978)	No (n=3541)	Yes (n=2299)	No (n=3220)

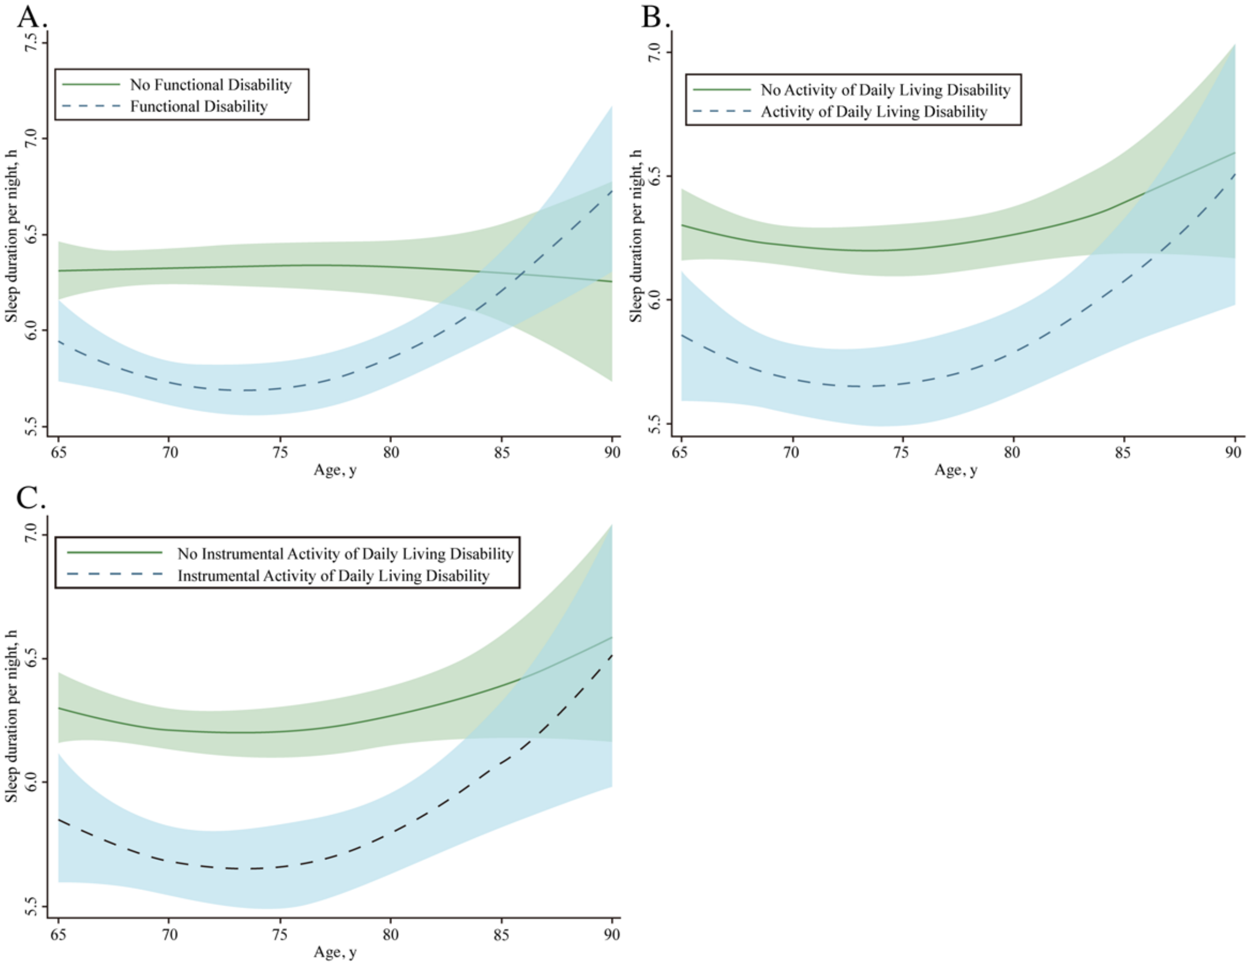
Trajectories for Sleep Duration According to Functional Disability Status

The trajectories of sleep duration for groups classified according to different types of functional disability are depicted in Figure 2. The sleep duration of respondents with no functional disability followed a flat curve, whereas there was a U-shaped association between sleep duration and age among respondents with functional disability (Figure 2A). Individuals in the age range of 65 and 75 years with any functional disability had a substantially shorter sleep duration than those 75 years and older (mean 6.11, SD 2.22 vs mean 5.98, SD 2.43). Respondents with functional disability showed an increasing trend in sleep duration after the age of 75 years (mean change per 1 age point later in life of 0.09 hours). Respondents with ADL disability showed a rapid decline in sleep duration between the ages of 65 and 75 years, which increased after the age of 75 years (Figure 2B). Similar patterns are illustrated in Figure 2C, showing that for respondents with IADL disability, the sleep duration trajectories took on a U shape with age, and the shortest sleep duration was evident around the age of 75 years.

Figure 2. Trajectories of sleep duration across individuals according to functional disability status. Graphs display analog values (lines) of the sleep duration with 95% CIs (shaded areas) for any functional disability (A), activity of daily living disability (B), and instrumental activity of daily living disability (C).



Associations Between Sleep Duration and Functional Disability

Table 2 presents the association between sleep duration and functional disability status. In the unadjusted model (model 1), both individuals reporting shorter sleep durations (≤4, 5, and 6 hours) and those reporting longer sleep durations (8, 9, and ≥10 hours) per night exhibited a significantly increased risk of functional disability compared to the reference group (7 hours of sleep/night). The same trend was observed in the relationship between different sleep durations and IADL. Correspondingly, participants reporting shorter sleep durations (≤4 and 5 hours) or longer sleep durations (9 and ≥10 hours) demonstrated a significantly higher odds of ADL disability compared to the reference group.

After adjusting for other potential confounding factors (model 2), the significant associations between shorter sleep durations (≤4, 5, and 6 hours) or longer sleep durations (8, 9, and ≥10 hours) and functional disability persisted, whereas the association of a longer sleep duration (9 hours) to IADL disability dissipated and the association of a longer sleep duration (8 hours) to ADL disability emerged (Table 2).

Table 2. Associations between sleep duration and functional disability status in participants from the 2018 China Health and Retirement Longitudinal Study.

[a] ADL: activity of daily living.

[b] IADL: instrumental activity of daily living.

[c] OR: odds ratio.

[d] Model 1 was unadjusted.

[e] Not applicable.

[f] Model 2 was adjusted for age, gender, education, marital status, tobacco use, alcohol use, afternoon napping, residence, depression, chronic disease status, and sampling weights.

Subgroup Analyses

The findings of subgroup analyses by gender and age are shown in Figure 3 and Figure 4, respectively, where significant effects specific to gender and age were noted. Compared to men, women who slept for shorter durations (≤4, 5, and 6 hours) or longer durations (8, 9, and ≥10 hours) per night were more likely to experience functional disability (Figure 3). Regarding age-specific effects, participants in the older group (75 years and older) who slept for fewer than 6 hours or more than 8 hours were more likely to develop a functional disability than the younger group (74 years and younger) (Figure 4).

Figure 3. Gender-specific effect of sleep duration on functional disability.

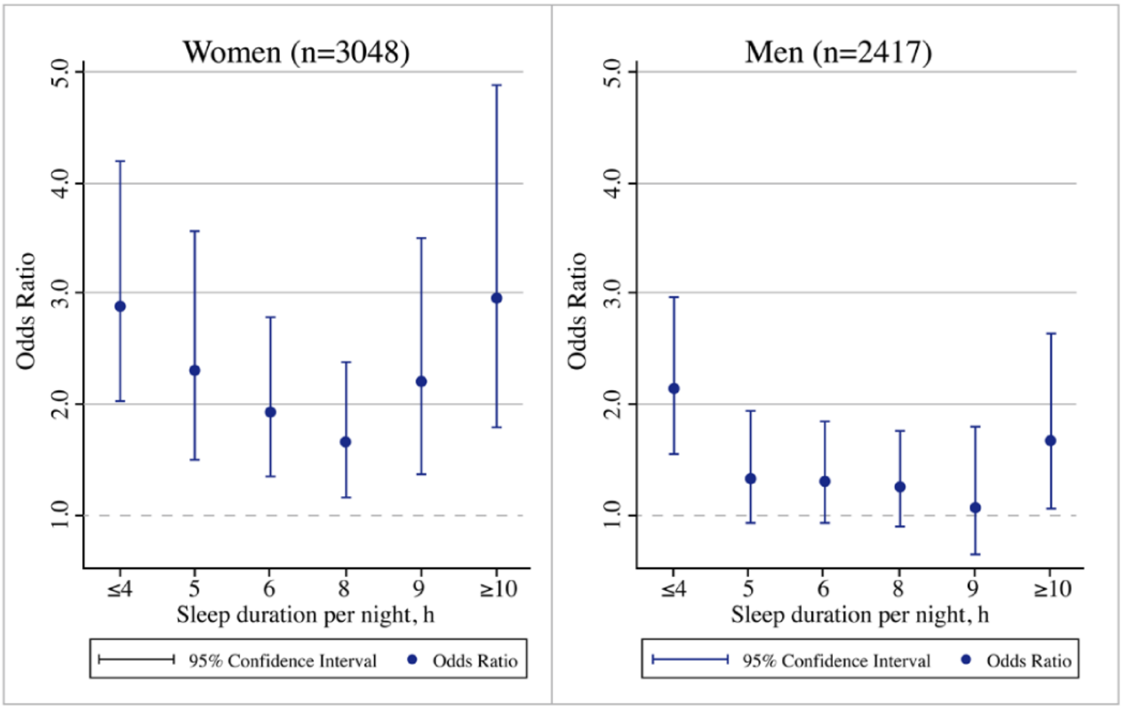

Figure 4. Age-specific effect of sleep duration on functional disability.

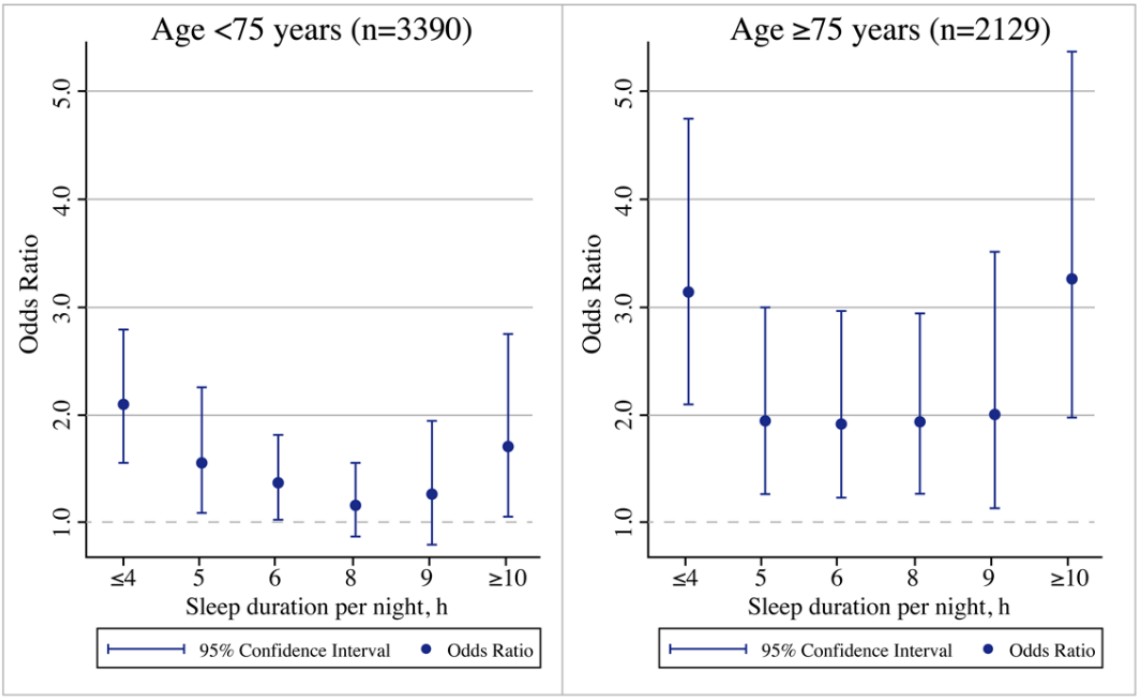
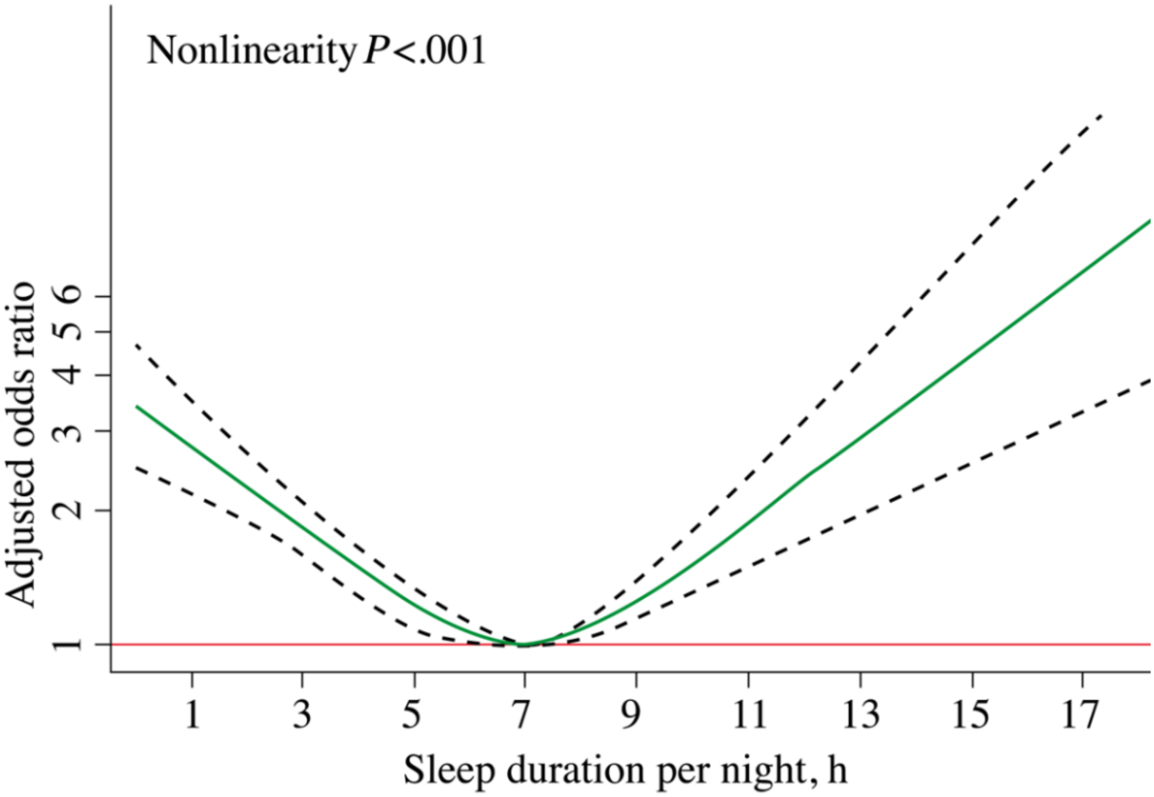


Nonlinear Relationship Between Sleep Duration and Functional Disability

Restricted cubic-splines analyses were conducted to visually represent the associations between the duration of sleep and functional disability. We found a U-shaped relationship between sleep duration and functional disability, even after accounting for confounding factors. As shown in Figure 5, the risk of functional disability was negatively correlated with sleep duration until it bottomed out at 7 hours (odds ratio [OR] 0.85, 95% CI 0.79-0.91; *P*<.001). Nevertheless, there was a substantial increase in the risk of functional disability when the duration of sleep exceeded 7 hours (OR 1.16, 95% CI 1.05-1.29; *P*<.001).

Figure 5. Nonlinear relationship of sleep duration and functional disability status. The adjusted odds ratio is presented accounting for potentially confounding factors (green solid line) in the relationship of sleep duration with 95% CIs (dotted lines) for functional disability. The red solid line is the reference line for the association at an odds ratio of 1.0.



Discussion

Principal Results

Our findings obtained from a nationally representative sample of 5519 participants 65 years and older in China indicated that shorter or longer sleep durations are associated with a higher risk of functional disability, including limitations in ADLs and IADLs. In the case of the older population, a minimum risk of 7 hours of sleep is associated with a reduced likelihood of experiencing functional disability. Based on previous studies highlighting functional disability as a notable risk factor for sleep disorders in the older population [39], the findings of this study suggest that the association between sleep and functional disability can exhibit a bidirectional nature.

Limitations

Our study has several limitations. First, the data of sleep duration and functional disability assessment were collected via self-report by participants, which could be subject to information bias. Second, the sample for this study comprised individuals from China who were 65 years of age or older. This particular demographic characteristic may limit the generalizability of the findings to different age cohorts, geographical areas, or ethnic backgrounds. Third, this study adopted a cross-sectional design, which limits the ability to show a causal association. It is plausible to consider that older adults with functional disability may require prolonged periods of sleep and a reduced duration of sleep could potentially serve as an initial indication of dysfunction. Therefore, it is necessary to conduct further comprehensive cohort studies to validate these findings.

Comparison With Prior Work

Functional ability refers to an individual’s capacity to engage in daily living and social activities according to their own intentions and preference. However, it is discouraging that the prevalence of functional disability was determined to be 41% across the entire sample in China [40]. The aging process is commonly accompanied by disturbances in sleep patterns, which have been linked to notable alterations in brain function and a decline in overall quality of life [41]. Moreover, various population-based studies [42-44], including both cross-sectional and longitudinal study designs, have demonstrated that the prevalence of cognitive decline may be linked to an increased risk of experiencing functional disability. Epidemiological research has also documented a U-shaped association between sleep duration and cognitive decline, indicating a significant trend in the association between sleep duration and functional disability [45-47]. Nevertheless, a definitive consensus has not yet been attained and there is still a dearth of studies examining the association between sleep duration and functional disability.

Despite previous investigations into the association between sleep duration and self-care function, the majority of these studies have primarily concentrated on a single form of functional disability. One study involving nightshift workers in the United States found that individuals with a shorter sleep duration (<7 hours/day) had the highest prevalence of sleep problems (61.8%) and the highest prevalence of an impaired ADL score (24.8%) [48], revealing a correlation between shorter sleep duration and higher risk of ADL disability. Another study focusing on patients with dementia discovered that a longer sleep duration was associated with ADL disability [49].

Similarly, a cross-sectional study that recruited 1798 participants older than 90 years found that a long sleep duration (≥12 hours) may be associated with an increased risk of ADL disability for this population [19]. Peng et al [50] found that after accounting for potential confounders such as age and gender, both longer and shorter sleep durations were linked to a heightened risk of IADL disability, which was consistent with the results of this study. Furthermore, instead of solely focusing on the relationship between shorter or longer sleep duration and functional disability among different sample sets, we simultaneously explored the impact of both shorter and longer sleep durations on functional disability within the same sample group. Additionally, concerning functional disability, we separately explored the associations between sleep duration and ADL and IADL disabilities, demonstrating that both shorter and longer sleep durations have an influence on functional health among the older population.

Implications and Contribution

The mechanism that accounts for the association between sleep duration and functional disability has yet to be fully explained; however, several hypotheses have been proposed. Luo et al [51] demonstrated that inadequate and excessive sleep durations were associated with an increased likelihood of hypertension among Chinese individuals. The increased susceptibility to cardiovascular illnesses associated with this elevated risk can have a direct influence on the overall well-being and functional abilities of older adults. Another recent study revealed that both insufficient and excessive sleep durations are associated with an increased risk of late-life dementia, a condition that significantly impairs the ability of older individuals to perform their daily tasks [52]. Other relevant studies indicated that sleep was correlated with changes in epigenetic mechanisms such as DNA methylation and histone modifications, which can also lead to cognitive dysfunctions such as learning and memory disruption [53-55]. This evidence has provided a new avenue for exploring the mechanism underlying the relationship between sleep duration and functional disability. Interventions aimed at good sleep hygiene may have the capacity to yield favorable outcomes in terms of improving physiological function among older adults. As evidenced by the empirical findings of this study, maintenance of the recommended sleep duration (7 hours) might play a crucial role in the health of older adults.

Our subgroup analyses suggested that women and older adults aged ≥75 years with shorter sleep durations (≤4, 5, and 6 hours) or longer sleep durations (8, 9, and ≥10 hours) per night were more likely to experience functional disability. Gender differences in sleep duration among the older population cannot be ignored. With changes in biological life cycles and the extreme hormonal fluctuations occurring with advancing age, women are at an increased risk for sleep disturbances (including insomnia and hypersomnia) [56]. Further, the sleep disturbances occurring during menopause can be an independent risk factor associated with arterial stiffness, which can result in a higher incidence of osteoarthritis that is in turn highly related to dysfunction [57]. With respect to age-specific effects, changes in sleep duration are a part of the normal aging process and also may enhance cellular aging in the later years of life [58]. According to the findings from an umbrella review [59], extreme sleep durations (including shorter and longer sleep durations) were more likely to be associated with an elevated risk of all-cause mortality, cognitive disorders, and type 2 diabetes in the general population. The circadian oscillations that alter body functions, including sleep, become less pronounced in older age, which can increase the risk of functional disability [60]. Collectively, these results emphasize the importance of addressing the complex needs of the population experiencing functional disabilities, particularly among women and older adults.

Conclusions

In conclusion, more attention should be paid to older individuals with shorter or longer sleep durations than recommended (7 hours). The precise mechanisms underlying the association between sleep duration and functional disability in the older population require further investigation.

Acknowledgments

We thank the China Health and Retirement Longitudinal Study (CHARLS) team for providing data and all the respondents for their contribution. This work was supported by a Beijing University of Chinese Medicine Evidence-based Chinese Medicine Research and Development Fund phase I grant (90020172220020). The funder played no role in the design, methods, subject recruitment, data collection, analysis, or preparation of the article.

Data Availability

The data sets presented in this study can be found in online repositories of the China Health and Retirement Longitudinal Study [61]. The data sets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

HR and YF had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. ML, YD, BF, and XZ contributed to the hypothesis and study design and interpreted the results. HL and CL analyzed the data. ML wrote the manuscript. HR and YF revised the manuscript. All authors contributed to the article and approved the submitted version.

Abstract

Background: The global population of older adults is on the rise. As people age, their physical functions gradually decline, leading to a decrease in the overall functioning of different organ systems. Due to these changes, older individuals are at a higher risk of encountering various adverse health outcomes and complications, such as malnutrition.

Objective: This study aims to investigate the prevalence of malnutrition and its associated factors among older adults dwelling in the western region of Saudi Arabia. We have analyzed these factors separately for both men and women to understand any potential sex differences.

Methods: A nonrandomized cross-sectional study was conducted for older adults aged ≥60 years in the western region of Saudi Arabia. Personal information was obtained through a closed questionnaire. The Mini Nutritional Assessment Short Form was used to determine the malnutrition status of older adults. Consequently, the individuals were divided into 2 groups: normal and malnourished. To assess the risk factors related to malnutrition, the odds ratio (OR) and 95% CI were determined using a binary logistic regression.

Results: The prevalence of malnutrition in men and women was around 7% and 5%, respectively. Potential risk factors related to malnutrition in men were higher age (OR 1.263, 95% CI 1.086-1.468; *P*=.002), being widowed (OR 8.392, 95% CI 1.002-70.258; *P*=.049), and having dental problems (OR 9.408, 95% CI 1.863-47.514; *P*=.007). On the other hand, risk factors associated with malnutrition in women were lower BMI (OR 0.843, 95% CI 0.747-0.952; *P*=.006) and being disabled (OR 18.089, 95% CI 0.747-0.952; *P*=.006).

Conclusions: The findings of this study provide important insights into the risk factors for malnutrition among older adults in the western region of Saudi Arabia. While the overall prevalence of malnutrition was relatively low, the analysis revealed distinct risk factors for older men and women. Interventions developed based on the identified risk factors may prove effective in addressing the issue of malnutrition within this population.

Introduction

The global population of older adults, aged 60 years and older, is considerably large. According to the World Health Organization, the global population of individuals aged 60 years and older was approximately 1 billion in 2019. It is projected to reach 1.4 billion by 2030 and further increase to 2.1 billion by 2050 [1]. Older adults in Saudi Arabia are expected to increase from 5.6% in 2017 to 23% by 2050 [2]. This rapid growth emphasizes the importance of the country to prepare and adapt to the changing demographics.

The process of aging involves a gradual decline in physiological functions, resulting in a decrease in the functional abilities of various organ systems and a reduced ability to cope with physical, cognitive, and mental stressors [3]. The impact of these changes can have a profound effect on the overall well-being of individuals. Additionally, as aging progresses, the prevalence of chronic diseases and multiple chronic conditions increases substantially, placing significant burdens on both individuals and the health care system. Older adults face greater risks of experiencing adverse health outcomes and complications, including malnutrition [4].

The prevalence of malnutrition among older adults is substantial and varies across different countries, ranging from an estimated 13% to 54% globally [5]. According to a recent study conducted in Nepal, the occurrence of malnutrition among a group of 320 older adults was found to be 11.6% [6]. The earlier study found that malnutrition was more common among women (15%) compared to men (9.3%). However, malnutrition is a complex condition influenced by various factors that can vary between countries and even different cities within the same country [3]. Therefore, this study specifically focuses on the western region of Saudi Arabia to examine the prevalence of malnutrition and its associated factors among older adults, taking into account the variations based on sex.

Methods

Participants

This study was conducted in the western region of Saudi Arabia (Makkah, Jeddah, Al-Taif, and Al-Madinah) as a community-based, nonrandomized, cross-sectional study, and was conducted between the periods of October 2022 and December 2022. To be included in the study, participants had to be older adults aged <60 years and living in the western region of Saudi Arabia. However, hospitalized older adults were excluded from the study. Out of 883, 623 were included; 2 were missing data, and 258 were out of the recruited age. As per the latest data from the General Authority for Statistics Report in the Kingdom of Saudi Arabia (KSA), there are approximately 400,000 older adults residing in the western region. The sample size was calculated using the Raosoft website. Based on specific parameters, including a 5% accepted margin of error, a 95% CI, and a 50% response distribution, the minimum required sample size for the study was determined to be 384 older adults.

Study Design

A web-based questionnaire was submitted to eligible participants. Informed consent was meticulously drafted in simple Arabic language to ensure understanding, and it was obtained directly from the older adults or through their immediate family members, as outlined in the procedural instructions prior to questionnaire completion. Personal information was obtained by a closed questionnaire, including age, height (cm), weight (kg), BMI (kg/m^2), nationality, city, social status, educational level, family income, living status, and health status. The Mini Nutritional Assessment (MNA) Short Form was used to determine the malnutrition status of older adults [7]. The MNA Short Form questionnaire includes 6 sections: food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties, weight loss during the last 3 months, mobility, experiencing psychological stress or acute disease in the past 3 months, neuropsychological problems, and BMI (kg/m^2). Each answer to the previous questions is assigned a score, and the total value is the MNA score. Based on this score, we divided the sample into 2 categories: normal (MNA score ranging from 8 to 14), and malnourished (MNA score ≤7 points).

Statistical Analysis

To analyze the data statistically, we applied IBM-SPSS statistics (version 23). We considered a P value less than .05 as statistically significant. For continuous variables, we represented them as the mean and SD. On the other hand, category variables were compared using a chi-squared test to examine their frequencies. The Mann-Whitney test was used to compare the mean ranks between the 2 groups when the distribution was not normal. To evaluate the risk factors associated with malnutrition, we conducted a multivariate binary logistic regression separately for men and women. This analysis allowed us to determine the odds ratio (OR) along with the corresponding 95% CI.

Ethical Considerations

This study was approved by the Ethical Committee of Umm Al-Qura University (approval number AMSEC-6-954-2022), following the Declaration of Helsinki. All participants in the study volunteered and provided informed consent at the beginning. The data collected was made anonymous and did not include any identifiable information. As a token of appreciation, all participants who completed the questionnaire received a US $25 gift voucher.

Results

The findings of this study are presented in Tables 1-3. Table 1 presents the sociodemographic characteristics of the participants in relation to malnutrition in both sexes. Tables 2 and 3 present the findings of logistic regression analysis, which was used to assess the probability of malnutrition occurrence based on the presence or absence of various risk factors in men and women, respectively. As shown in Table 1, of the total sample size (n=623), 36.5% were male and 55.5% were female. The majority of participants (95.3%) were of Saudi Arabian nationality. The prevalence of malnutrition was observed to be slightly higher among men (≈7%) compared to women (≈5%). Age was identified as a non-modifiable risk factor (a trait that cannot be altered or changed) that showed a positive association with malnutrition in older men. This suggests that as men get older, they are more likely to experience malnutrition (OR 1.263; 95% CI 1.086-1.468; P=.002; Table 2). However, no such association was observed among women (Table 3).

As opposed to the positive association detected between malnutrition and age, a negative correlation was observed between malnutrition and BMI in women. Specifically, the incidence of malnutrition was found to be more prevalent among women with a lower BMI compared to those with a higher BMI (mean BMI 25.5, SD 8.1 vs mean 29.4, SD 7; P=.04; Table 1). Logistic regression analysis further supported this finding, indicating that older women with a higher BMI had a 16% lower probability of experiencing malnutrition compared to those with a lower BMI (OR 0.843, 95% CI 0.747-0.952; *P*=.006), as depicted in Table 3.

As presented in Table 1, additional factors were found to be associated with the nutritional status of both male and female older adults. These factors include educational level, social status, and health status. Specifically, individuals with higher levels of education exhibited better health outcomes across both sexes. For instance, a significant proportion of older men (76.3%) who held bachelor's or postgraduate degrees were not affected by malnutrition, whereas only 35% experienced malnutrition (*P*=.001). Similarly, 62.9% of women, with bachelor's or postgraduate degrees did not experience malnutrition, while only 29.4% were malnourished (*P*=.02) (Table 1). Furthermore, malnutrition was less prevalent among financially independent individuals of both sexes. Notably, 93.8% of financially independent men were not malnourished, whereas only 6.2% of them experienced malnutrition (*P*<.001). Likewise, among financially independent women, 79% were not malnourished, while 21% of them exhibited malnutrition (*P*=.005).

Regarding social status, being married was associated with a more favorable nutritional status, with 90.7% of married men not affected by malnutrition. Additionally, the presence of a spouse and children in the household was linked to a significantly lower prevalence of malnutrition among older adults. Around 96% of men living with their wives and children were not affected by malnutrition, while only 3.9% experienced malnutrition (*P*=.006; Table 1). Conversely, being widowed was identified as a risk factor for malnutrition in older men. Interestingly, according to the logistic regression analysis, widowed men had an approximately 8-fold higher likelihood of experiencing malnutrition compared to their married counterparts (95% CI 1.002-70.258; *P*=.049), as depicted in Table 2. However, this association was not evident among women (Table 3).

In terms of health status, the prevalence of malnutrition was observed to be high among men with chronic health conditions. Compared to healthy older men, malnutrition was notably more prevalent among individuals diagnosed with diabetes (15% vs 85%, *P*=.006), hypertension (20% vs 80%, *P*=.007), and heart disease (40% vs 60%, *P*=.001; Table 1). An additional noteworthy factor linked to the likelihood of developing malnutrition in older men was the presence of dental problems. Specifically, older men with dental problems exhibited a significantly higher probability of experiencing malnutrition, approximately 9-fold higher than those without dental problems (95% CI 1.863-47.514; *P*=.007; Table 2). As for women, disability was found to be strongly associated with malnutrition. The probability of experiencing malnutrition in older women with a disability was approximately 18-fold higher compared to their counterparts without a disability (95% CI 2.605-125.626; *P*=.003; Table 3).

Table 1. Relationship between malnutrition and participants' characteristics based on sex.

Variable	Men (n=277)		*P* value	Women (n=346)		*P* value

Discussion

Principal Findings

This study explored the prevalence of malnutrition among older men and women in the Saudi Arabian community in the western province, with an emphasis on its associated risk factors. The study revealed that the occurrence of malnutrition was approximately 7% among men and 5% among women. This is comparable to the findings of studies conducted in the region. For instance, a study conducted in Jeddah city reported that the prevalence of malnutrition among older adults was 5.3% [8]. Another study conducted in Al Madinah Al Munawarah reported a lower prevalence of malnutrition among older adults, accounting for 3.5% [9]. One possible reason for this difference in the prevalence of geriatric malnutrition could be attributed to the different support and health programs provided in each district.

However, a study involving participants from Makkah and Jeddah cities found a higher prevalence of malnutrition among older adults, reaching approximately 13% [10]. This elevated prevalence could be linked to the study's recruitment strategy, which involved recruiting individuals from public places as well as health care clinics. This suggests that the study cohort may have had preexisting health conditions or chronic illnesses that could impact their nutritional status. This is consistent with a further study conducted in Jeddah city, which included hospitalized patients and reported a higher prevalence of geriatric malnutrition, reaching 27% [11].

The association between malnutrition and chronic disease is well established in the literature [12]. This is also confirmed by the findings of this study, which found that the prevalence of malnutrition was higher among older men with chronic health conditions (ie, diabetes, hypertension, and heart disease), which could be attributed to several factors. For instance, symptoms associated with chronic diseases, such as fatigue, pain, or shortness of breath, can impact appetite and food intake, leading to malnutrition [13]. Furthermore, medications used to manage chronic diseases can have side effects that reduce appetite, alter taste perception, or impair nutrient absorption, leading to malnutrition [14]. Therefore, regular monitoring of the old individual's nutritional status as well as any signs of malnutrition is recommended in order to identify and address any deficiencies or imbalances early on.

The significant association between chronic disease and malnutrition observed in men, but not in women, could be partially explained by the higher prevalence of chronic conditions in the male subsample compared to the female subsample. Specifically, the prevalence of diabetes was 85% in men versus 58.8% in women, the prevalence of hypertension was 80% in men versus 52.9% in women, and the prevalence of heart disease was 60% in men versus 23.5% in women. This disparity in chronic disease burden between sexes may have contributed to the stronger link between chronic conditions and malnutrition risk observed in the male participants. The higher underlying chronic disease prevalence in the male group could make them more susceptible to the detrimental effects of chronic illness on nutritional status, leading to the significant association found in the regression analysis. However, further investigation into the complex interplay of sex, chronic disease burden, and nutritional status in this population would be valuable to elucidate the factors contributing to the divergent findings.

Not only were chronic health conditions associated with the prevalence of malnutrition in the participated sample, but disability was also a strong predictor, especially among women. In this study, women with disabilities were 18 times more likely to experience malnutrition compared to healthy individuals. This is consistent with a study conducted in the KSA, which reported that physically dependent older adults had higher scores of malnutrition compared to their independent counterparts [15]. This could be explained by the fact that disability adversely affects the potential to access and consume nutritious food, leading to poor nutritional intake [16]. In contrast to the adverse impact of disability on nutritional status, mobility in older patients was associated with 90% lower cases of malnutrition compared to being bed-bound, as shown by a recent study conducted in the KSA [11]. This is probably because older adults with better mobility are more likely to be independent in performing their daily activities, including shopping, cooking, and eating. This independence allows them to have greater autonomy in their food choices and meal preparation, leading to a higher likelihood of consuming a balanced and nutritious diet [17].

Contrary to the significant negative association observed between disability and nutritional status among women, this study did not detect a comparable adverse effect of physical impairment on the nutritional profile of men. This difference may be partly explained by the slightly higher prevalence of disability among women (46.7%) compared to men (41.5%) in the KSA, based on openly available data from 2015 to 2020 [18]. Another potential explanation for the significant impact of disability on women, compared with the absence of such an association in men, may lie in the social context. For instance, physical impairment might be linked with social isolation and depression [19], which could diminish appetite and subsequently lower nutritional intake, resulting in malnutrition [20]. According to the World Health Organization, rates of depression are higher among women (6%) compared to men (4%) [21]. This discrepancy may elucidate the observed sex differences in the relationship between disability and nutritional status.

According to the findings of this study, dental problems were also identified as a risk factor for geriatric malnutrition. The likelihood of experiencing malnutrition in older men was approximately 9 times higher in participants experiencing dental problems compared to their counterparts who had good dental health. This is in line with the findings of a recent study conducted in Riyadh (central region, KSA), which reported that malnutrition was greater in patients with higher scores of oral health problems compared to those with lower scores [22]. This is expected, as dental and oral problems in older adults could be associated with malnutrition due to difficulties in chewing, pain, and discomfort while eating, leading to poor nutrient intake.

In this study, we investigated the relationship between malnutrition among older adults and BMI as a continuous variable, rather than focusing on a specific weight status category such as underweight or overweight. It is important to note that obesity is prevalent in the KSA [23]; however, there are limited data regarding the associations between weight status and malnutrition among older adults in the country. While low BMI is often used to identify the presence of malnutrition [24], we sought to explore the associations between an individual's BMI, across its entire range, and the likelihood of being malnourished. The analysis took into account the complex interplay of factors that can contribute to malnutrition risk. This allowed us to assess the independent effect of BMI, treated as a continuous measure, on malnutrition, while controlling for other potential confounding variables. It was found that a higher BMI is considered a protective factor against malnutrition in the participated older women. This is in alignment with the findings of several studies conducted in Kuwait [25], Lebanon [26], and Iran [27]. The reduced risk of malnutrition among older adults with a higher BMI could be explained by the fact that a higher BMI implies larger energy reserves and nutrient stores, which can help buffer against periods of reduced food intake or increased nutrient requirements that may occur in situations of illness or decreased appetite [28]. However, a recent review highlighted the absence of comprehensive research on anthropometric cutoffs for older adults in Saudi Arabia, which hampers the development of evidence-based guidelines. Thus, further studies are needed to establish anthropometric cutoffs that align with the Saudi Vision 2030 [29]. This is important for enabling health care professionals to accurately assess and manage the nutritional needs of older adults.

According to the study findings, being married and living with family emerged as potential protective factors against malnutrition in older men. This is expected and could be attributed to the positive influence of social interaction and companionship during mealtimes, which could enhance appetite and enjoyment of food. In contrast, being widowed in men was associated with 8 times greater likelihood of experiencing malnutrition compared to being married. This is in line with the findings of a systematic review and meta-analysis of 40 observational studies, which confirmed that social status is a predictor of geriatric malnutrition [30]. The adverse influence of spouse loss on malnutrition in older adults might be due to a lack of emotional support and companionship, which can contribute to a decline in appetite and skipping meals, leading to poor nutritional status [31,32].

It is worth mentioning that the absent probability of experiencing malnutrition in women compared to men, in this study, might be explained by cultural norms and sex roles. In many societies, traditional sex roles have assigned women the primary responsibility for food preparation, cooking skills, and attention to the nutritional value of food. This has resulted in women having a greater understanding of nutrition and being less prone to malnutrition compared to men who may rely on their wives for meal preparation [33].

The preceding sections discussed the findings of this study in terms of the prevalence of geriatric malnutrition in the KSA and its associated risk factors. This section will briefly discuss the potential solutions to address this pressing issue. It is recommended to consider comprehensive interventions that encompass a range of strategies aimed at mitigating malnutrition among older adults. These strategies may include social support, dietary modifications, nutritional supplementation, meal delivery programs, and nutrition education or counseling [34-36]. Moreover, it is important to consider cultural factors during the development of the intervention, as they play a crucial role in shaping dietary habits, attitudes towards food, and health-seeking behaviors in older adults [37]. By designing an intervention that aligns with the cultural norms, values, and preferences of the target population, the effectiveness and acceptability of the intervention are likely to be enhanced [38]. Therefore, it is recommended to develop culturally tailored interventions that tackle barriers including traditional food practices, religious beliefs, and social norms, as they are likely to have the potential to enhance nutrition outcomes.

Furthermore, it is recommended to leverage the advantages offered by modern technology and widespread internet usage, along with the proliferation of handheld devices. These factors could facilitate intervention delivery to older adults. This is supported by the findings of a systematic review of 70 studies, which indicated that eHealth interventions using mobile apps could be deemed effective in enhancing health outcomes in older adults [39]. Nevertheless, that review underscored heterogeneity in terms of intervention duration, targeted health outcomes, and populations. Therefore, additional research endeavors are warranted in this domain to establish robust evidence concerning the optimal approaches for addressing geriatric malnutrition.

Limitations

It is important to note that this study has a cross-sectional design, which limits its scope. Moreover, older adults were only recruited from certain regions in the KSA, so the findings of this study cannot be generalized to the entire older adults in the KSA. Another limitation of the study involved the self-reported nature of the data. The researchers relied on self-reported information from the participants, which may be subject to recall bias or social desirability bias. This could potentially affect the accuracy of the data collected, particularly regarding factors such as weight loss, food intake, and health status. However, a key strength of the study is that, to the best of our knowledge, it is the first to investigate the sex-based differences in the prevalence and associated risk factors of malnutrition among older adults in the KSA. This represents an important contribution to the limited existing literature on this topic in the KSA.

Conclusions

The findings of this study indicate that malnutrition affects both older men and women in the western region of Saudi Arabia. Importantly, the study identified various risk factors associated with malnutrition in this population. These findings hold significance for informing the development of targeted interventions aimed at addressing malnutrition among older adults. By identifying the specific risk factors, health care providers and policy makers can tailor strategies and interventions to effectively meet the distinct needs and challenges faced by both sexes. Furthermore, understanding the impact of malnutrition on older men and women allows for the consideration of sex-specific factors in the planning and implementation of interventions. This recognition enables the design of interventions that account for the unique circumstances, social dynamics, and cultural norms that may influence nutritional health differently for men and women. In addition, future research is recommended to evaluate the efficacy of digital interventions in mitigating malnutrition within the Saudi Arabian population, considering the potential benefits of technology-based approaches to addressing this issue.

Abstract

Background: China's rapidly aging population necessitates effective strategies for ensuring older adults' quality of life (QOL). While individual factors (IF) and family factors (FF) are known to influence QOL, existing research often examines these factors in isolation or focuses on specific subpopulations, overlooking potential interactions and mediating pathways.

Objective: This study aims to examine both direct and indirect pathways connecting IF and FF to older adults' QOL, focusing on the mediating roles of health risks (HR) and health care service demand (HSD).

Methods: This study uses structural equation modeling (SEM) to analyze cross-sectional data from 8600 older participants in the 2015 China Health and Retirement Longitudinal Study (CHARLS), a nationally representative study using a multistage probability proportional to size sampling method.

Results: Among the 8600 participants, the majority (5586/8502, 65.7%) were aged 60-70 years, with a near-equal distribution of males and females at around 50%. The average PCS score was 76.77, while the MCS score averaged 59.70. Both IF (β=0.165, *P*<.001) and FF (β=0.189, *P*<.001) had a direct positive effect on QOL. Furthermore, the indirect effects of IF (β=0.186, *P*<.001) and FF (β=0.211, *P*<.001) through HR and HSD were also significant. In the direct model, IF and FF had a greater impact on MCS (β=0.841) than on PCS (β=0.639). However, after including the 2 mediating factors, HR and HSD, the influence of IF and FF on MCS (β=0.739) became consistent with that on PCS (β=0.728). Subgroup analyses revealed that the direct effect of IF on QOL was significant in the 60-70 age group (β=0.151, *P*<.001) but not in those over 70 years old (β=0.122, *P*=.074). Comorbidity status significantly influenced the pathway from HR to HSD, with older adults having 2 or more chronic diseases (β=0.363) showing a greater impact compared to those with fewer than 2 chronic diseases (β=0.358).

Conclusions: Both IF (education, per capita disposable income, and endowment insurance) and FF (satisfaction with a spouse and children) directly impact the QOL in older people. Meanwhile, IF and FF have equal influence on QOL through the mediating role of HR and HSD. Recognizing the interplay among these factors is crucial for targeted interventions to enhance the well-being of older adults in China.

quality of life; older adults; individual factor; family factor; structural equation modeling (SEM)

Introduction

Since China transitioned into an aging society around 2000, the aging process has accelerated steadily [1]. It is projected that by 2040, the population aged 60 years and older in China will reach 402 million, with an aging rate exceeding 28%, marking the country's transition into a deeply aging society [2]. The increased number of older adults will inevitably lead to a substantial rise in national financial pressure and family care burden [3,4]. Ensuring a dignified and high quality of life (QOL) for older adults during their later years has evolved into a pivotal focal point within the sphere of social development.

QOL refers to an individual's overall well-being and satisfaction with various aspects of their life [5]. It is directly correlated with overall health outcomes, health care use, and the effectiveness of health interventions. QOL serves as a pivotal benchmark illuminating the living standards of older adults, forming the cornerstone for the implementation of strategies promoting healthy and active aging. The health status of older individuals is a key determinant of their overall physical and mental well-being. While considerable research has been devoted to exploring the risk factors affecting the health status of older adults [6-8], comprehensive studies integrating various sociodemographic factors, such as individual and family factors, which broadly impact their QOL, remain limited. Individual factors (IFs) include socioeconomic and demographic characteristics [9]. In this study, IF is represented by education level [10], per capita disposable income [11], and endowment insurance [12]. Family factors (FFs) include interactions among family members and the broader family environments [13]. In this study, FF is represented by measures of spouse satisfaction [14] and children satisfaction [15].

Existing literature has extensively examined the impact of various individual and family factors on the QOL of older adults, highlighting the importance of maintaining healthy lifestyles and fostering strong social connections to enhance QOL in later life [16,17]. For example, studies by Zhang et al [18] in Shanxi, China, and Chen et al [19] in Hainan, China, delved into the influence of socioeconomic status, health behaviors, and family relationships on the QOL of older adults. However, these studies often either focus on the impact of a single factor or target subgroups with specific characteristics, such as empty nesters and the oldest-old population. This overlooks the potential mutual interactions between variables and the interactive effects on outcomes, potentially resulting in partial and nongeneralizable research conclusions.

Furthermore, previous studies indicated that IFs, such as education and income, impact dietary habits, smoking and alcohol consumption, physical activity levels [20,21], and access to health insurance in older adults [22]. Similarly, FFs, such as marital status and parent-child relationships, affect health risks (HR) and mental well-being in older adults [23,24]. In turn, HR can influence health care service demand (HSD) [25]. Both HR and HSD are known to be associated with QOL [26]. Nevertheless, only a few studies have addressed the potential mediating role of HR and HSD in the relationship between individual or familial factors and QOL. For example, Zhang et al [18] demonstrated the indirect effects of socioeconomic status and family relationships on QOL through health behaviors among empty nesters. Similarly, studies emphasized the importance of addressing health-related issues and improving access to health care services to enhance QOL among older adults in Zhejiang province and Shanghai [27,28]. However, these studies focus on specific regions or populations, and most studies rely on cross-sectional designs, hindering the establishment of causal relationships. There is a need for more comprehensive frameworks that integrate a broader range of personal, familial, and environmental factors and examine their complex interactions and potential mediating roles to provide a holistic understanding of QOL among older adults.

This study uses structural equation modeling (SEM) to analyze the direct and indirect effects of individual and family factors on QOL among individuals aged 60 years and older that cover the entire scope of China. We consider the mediating roles of HR and HSD in the relationship between individual or family factors and QOL. By examining these complex relationships, this study aims to provide valuable insights for policy making and interventions to improve the well-being of older adults in China.

Methods

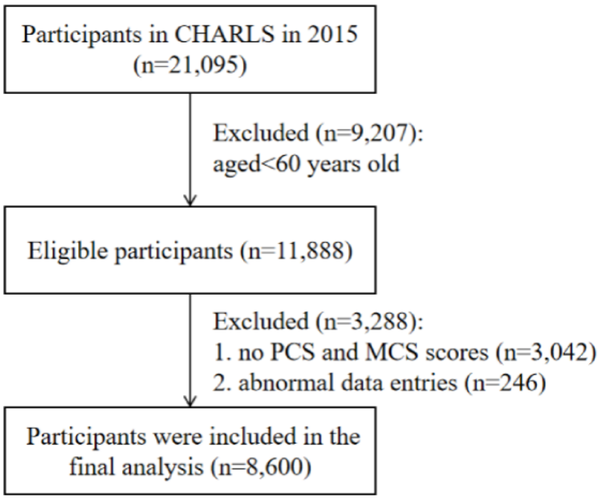
Data Source and Participants

This study used data from the China Health and Retirement Longitudinal Study (CHARLS), the details of which have been documented previously [29]. Briefly, the CHARLS project aims to gather high-quality microdata representing households and individuals aged 45 years and older in China, promoting interdisciplinary aging research. The national baseline survey of CHARLS was conducted in 2011 using a multistage probability proportional to size sampling method. The sample encompassed 450 villages, 150 counties, and 28 provinces, comprising over 17,000 individuals from approximately 10,000 households. CHARLS is an ongoing survey, with assessments conducted every 2-3 years. Participants were interviewed face-to-face in their homes using computer-assisted personal interviewing technology. The survey comprehensively covered basic demographic information of respondents and their families, intrafamily transfer payments, health status, medical care and insurance, employment, income, expenditure, assets, and more. Additionally, CHARLS included 13 physical measurements and collected blood samples. To date, CHARLS has released data from 5 waves: the national baseline survey (Wave 1, 2011), first follow-up survey (Wave 2, 2013), second follow-up survey (Wave 3, 2015), third follow-up survey (Wave 4, 2018), and fourth follow-up survey (Wave 5, 2020) [30]. The CHARLS datasets can be downloaded at the CHARLS home page [30]. The CHARLS survey project received approval from the Biomedical Ethics Committee of Peking University, and all participants have provided informed consent.

This study used data from the third wave of the CHARLS, collected in 2015, with a sample size of 21,095. We excluded 12,495 individuals due to (1) age <60 years (n=9207); (2) missing information on physical component summary (PCS) and mental component summary (MCS) scores (n=3042); and

(3) abnormal data entries (n=246), resulting in a final analytic sample of 8600 participants for this cross-sectional analysis. The detailed flowchart of the sample selection process is shown in Figure 1.

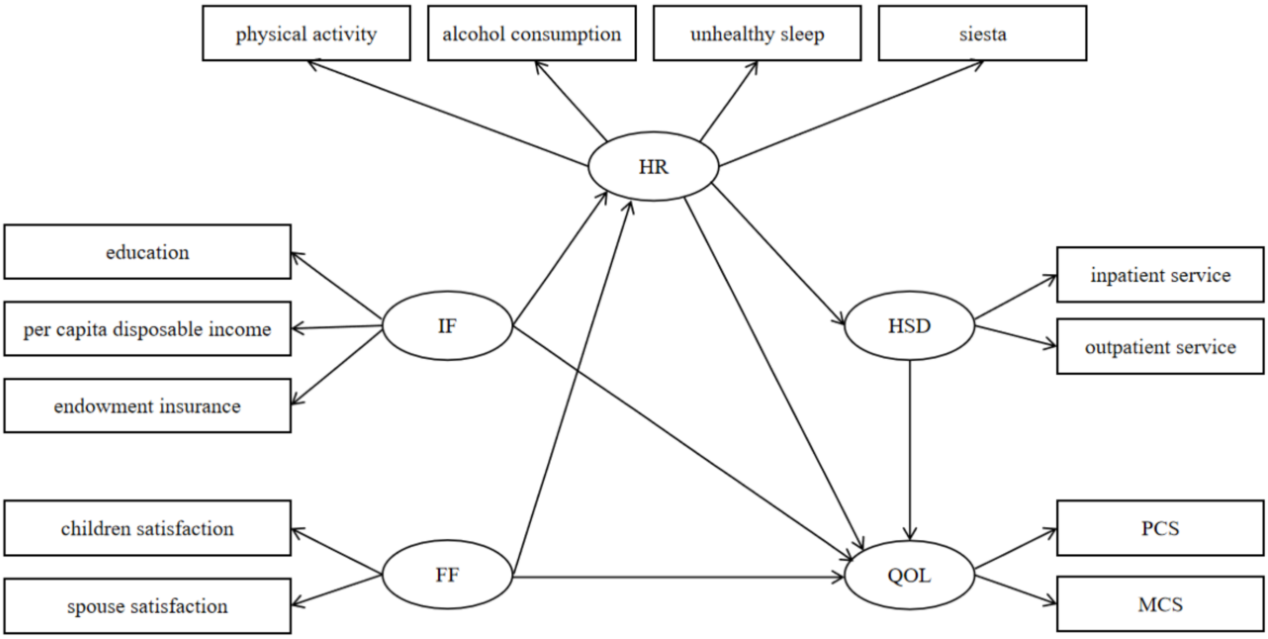
Figure 1. The flowchart of participants through the study. CHARLS: China Health and Retirement Longitudinal Study; PCS: physical component summary; MCS: mental component summary.



Conceptual Framework

Building upon a review of the literature [16,26-30] and informed by medical context, the core components of the conceptual framework in this study include: (1) IF is associated with education [10], per capita disposable income [11], and endowment insurance [12], which directly influence QOL. (2) FF is associated with spouse satisfaction [14] and children satisfaction [15], which directly influence QOL. (3) Individual and family factors indirectly influenced QOL via HR. The reason is that health plays a pivotal role in overall well-being [18]. IFs, such as education and income, also impact dietary habits, smoking and alcohol consumption, and physical activity levels in older adults [31]. Similarly, FFs, such as marital status and parent-child relationships, affect health risks and mental well-being in older adults [23,24]. HR encompasses physical activity, alcohol consumption, unhealthy sleep, and siesta. (4) IF and FF indirectly influenced QOL via HR and HSD. HSD involves both inpatient service and outpatient service. Previous studies have found that HR can influence HSD [25]. Both HR and HSD are known to be associated with QOL [26]. (5) Assessing the QOL through the metrics of PCS and MCS, which is accessed by Short Form 36 (SF-36) [32]. The multiple pathways from IF and FF to QOL and the statistical analysis strategy are shown in Figure 2.

Figure 2. Research framework. IF: individual factors; FF: family factors; HR: health risk; HSD: health services demand; PCS: physical component summary; MCS: mental component summary; QOL: quality of life.



Measures

This study introduced a novel scale construction from variables derived from both SF-36 and the CHARLS questionnaire to measure QOL in older Chinese adults. This scale's development emanated from the 8 dimensions within the SF-36, while we curated pertinent CHARLS variables to appraise these dimensions, encompassing physical functioning (PF), role-physical (RP), bodily pain (BP), general health (GH), vitality, social functioning (SF), role-emotional (RE), and mental health (MH). PF, RP, BP, and GH were computed as PCS, while vitality, SF, RE, and MH were computed as MCS (Multimedia Appendix 1). Each dimension score was converted to a range from 0 to 100, with a high score indicating better levels of functioning. The SF-36 score was obtained from the average of the 8 dimensions. Consequently, higher SF-36 scores indicate better QOL [32].

Drawing on methodologies applied in pertinent literature, the development of this scale mirrored approaches using Cronbach α coefficient to assess reliability between SF-36 and CHARLS variables. Overall, the scale demonstrated robust reliability across dimensions, registering α values exceeding 0.6 for all except vitality (α=0.34) [33]. At both the item (I-CVI) and scale (S-CVI) levels, the content validity index (CVI) was assessed, with I-CVI surpassing 0.83 and an S-CVI reaching 0.94 [33]. These findings suggest that the scale exhibited commendable reliability and validity and has already been used in related research [34].

Demographic characteristics included sex (male or female) and age groups (60-70 years and 70 years or older). We defined comorbidity as the presence of ≥2 chronic diseases [35]. IF was accessed by 3 variables: education [10], per capita disposable income [11], and endowment insurance [12]. The specific definition of each variable is added in Multimedia Appendix 2. It is important to note that per capita disposable income, presented as a continuous variable, was extracted from the 2015 Gotohui data [36], takes into account deductions, such as personal income tax, social insurance contributions, and removes essential living expenses to measure individuals' actual disposable income within an economy [37]. The following 2 variables accessed FF: spouse satisfaction [14] and children satisfaction [15]. HR was accessed by 4 variables: physical activity [38], alcohol consumption [39], unhealthy sleep, and siesta [40,41]. Thereby, HSD was accessed using 2 variables: inpatient service and outpatient service [42].

SEM and the Theory of Inferred Causation

First, SEM allows for constructing latent variables using other observable variables and models causal relationships between latent and observed variables [43]. Second, within SEM, causal paths are explicitly represented as directed arrows between variables in a path diagram [44]. These paths represent hypothesized causal relationships based on theory or prior research [44]. Finally, SEM evaluates how well the specified model fits the observed data to evaluate the validity of hypothesized causal relationships [45]. A well-fitting model indicates that the hypothesized causal relationship model can effectively explain or predict the observed variability in the data [44]. Additionally, the magnitude of each path parameter signifies the strength and direction of the causal paths between variables [43]. In cases of poor model fit, researchers can refine models based on empirical data and theoretical insights, enhancing the accuracy of causal inferences [44].

Statistical Analysis

Continuous variables are presented as mean and SD, and categorical variables are presented as frequencies and percentages. Scores of QOL are presented as mean and SD. Pearson correlation analysis is used to examine the correlations among the IF, FF, HR, HSD, and QOL variables. The missing data were imputed using nonparametric missing value imputation based on the random forest procedure in R. Detailed missing rates for the essential factors used in this study are provided in Multimedia Appendix 3.

To verify the suitability of the SF-36 scale based on the CHARLS database for the construction of SEM, we performed confirmatory factor analysis (CFA) [46]. In CFA, CR is used to demonstrate composite reliability, and average variance extracted (AVE) is used to establish the convergent validity of the model. The model exhibits strong internal consistency and convergent validity, as indicated by the CR exceeding 0.7 and the AVE surpassing 0.5, and the AVE between 0.36 and 0.5 is also acceptable [47].

SEM was used to ascertain the direct and indirect effects among outcome, observed, and latent variables. Among them, the observed variable refers to a variable that can be directly observed with specific values. In contrast, the latent variable is a variable that cannot be directly observed and requires inference through other variables. The total effect represents the sum of direct and indirect effects, mathematically expressed as follows [48]: $c = c' + ab$, where c = total effect, c' = direct effect, ab = indirect effect. Subsequently, bias-corrected bootstrapping (using 2000 bootstrap samples) was used to gauge the statistical significance of both direct and indirect effects within each pathway of the SEM. Various modification indices were used to refine and adjust the model, aiming to achieve the optimal fit [49], including the comparative fit index (CFI), incremental fit index (IFI), standardized root-mean-square residual (SRMR), goodness of fit index (GFI), adjusted goodness of fit index (AGFI), and the root-mean-square error of approximation (RMSEA). The RMSEA and SRMR ≤ 0.08, CFI, IFI, GFI, and AGFI > 0.90 indicated an acceptable model [50]. Due to the sensitivity of chi-square values to large sample sizes, they were excluded from the analysis [50]. Main effect values are presented by β, representing standardized regression coefficients. $P< .05$ indicated statistical significance. In addition, given that approximately 50% of the data on physical activity were missing, we conducted an additional sensitivity analysis to assess the robustness of the results by excluding participants with missing physical activity data.

Finally, we conducted subgroup analyses to examine the applicability of the model across gender, age, and comorbidity groups and to assess whether there were significant differences in the β values of different paths among the subgroups. In subgroup analyses, an absolute critical ratio for a difference of more than 1.96 was considered to indicate a significant difference between the groups [51]. $P<.05$ for β indicates its statistical significance. All data were analyzed using the statistical software IBM SPSS Statistics (version 26.0; IBM Corp), IBM SPSS Amos (version 26.0), and R (version 4.3.2; R Foundation for Statistical Computing).

Ethical Considerations

This study used secondary data from CHARLS. The agency responsible for the survey is Peking University.

Results

Participant Characteristics

Table 1 summarizes the results of descriptive statistics. Among the 8600 samples, the gender distribution was nearly equal. Participants aged 60-70 years outnumbered those aged over 70 years (n=5586 vs n=2916). Concerning comorbidity, a modest proportion (3171/8600, 36.9%) of the participants had more than 2 chronic diseases. Most participants reported their educational attainment as less than the secondary level and did not have endowment insurance. The mean annual per capita disposable income in the study population was ¥ 17,715.97 (SD ¥ 10,131.80; US $2852.27, per the 2015 average annual exchange rate). A significant number of participants reported satisfaction with their spouses and children.

Table 1. Descriptive statistics of the variables at baseline.

Variables	Overall, n (%)
Age (years), (n=8502)	
60-70	5586 (65.7)
≥70	2916 (34.3)
Gender, (n=8599)	
Male	4297 (50.0)
Female	4302 (50.0)
Comorbidity, (n=8600)	
Fewer than 2 chronic diseases	5429 (63.1)
Having 2 or more chronic diseases	3171 (36.9)
Education, (n=8598)	
Below secondary education	7912 (92.0)
High school and vocational training	534 (6.2)
Higher education	152 (1.8)
Endowment insurance, (n=8550)	
Having endowment insurance	1097 (12.8)
No endowment insurance	7453 (87.2)
Spouse satisfaction, (n=6939)	
Satisfied with spouse	6355 (91.6)
Dissatisfied with spouse	584 (8.4)
Children satisfaction, (n=8494)	
Satisfied with children	8080 (95.1)
Dissatisfied with children	414 (4.9)
Alcohol consumption, (n=8596)	
Drinking alcoholic beverages in the past year	6403 (74.5)
Not drinking alcoholic beverages in the past year	2193 (25.5)
Physical activity, (n=4259)	
Engaging in any physical activity in the past week	2990 (70.2)
Have not engaged in any strenuous physical activity in the past week	1269 (29.8)
Unhealthy sleep, (n=7915)	
Sleep less than 5 hours or more than 9 hours per night	3084 (39.0)
Sleep duration is within 6-8 hours	4831 (61.0)
Siesta, (n=7982)	
Having a habit of taking midday naps	4606 (57.7)
Absence of the habit of taking midday naps	3376 (42.3)
Outpatient services, (n=8588)	
Received outpatient or home care services in the past month	1767 (20.6)
Not attending outpatient or home health services in the past month	6821 (79.4)
Inpatient services, (n=8588)	
Inpatient service use in the past year	1436 (16.7)
No inpatient service use in the past year	7152 (83.3)

In terms of lifestyle factors, most participants engaged in physical activity and reported alcohol consumption in the past year. Healthy sleep patterns were prevalent. More than half of the individuals indicated good sleep quality and had regular siestas. Health care use patterns indicated that only a minority of the participants had received inpatient services in the past year and used outpatient or home care services within the past month during the baseline period.

Status Quo of the Older Chinese Adults' QOL

Table 2 displays the total scores and dimensional scores of SF-36. Among the 8600 participants, the PCS score averaged 76.77, and the MCS score averaged 59.70. Among the 4 dimensions of PCS, role physical obtained the highest score, followed by bodily pain and physical functioning. The general health dimension had the lowest score. In the realm of MCS, vitality, role emotional, and mental health scores were similar, all above 70.00, while social functioning scored lower.

Table 2. Scores for quality of life (n=8600).

Dimensions	Scores, mean (SD)
PCS[a]	76.77 (14.50)
PF[b]	85.54 (17.61)
RP[c]	94.99 (13.70)
BP[d]	87.90 (22.80)
GH[e]	38.66 (26.08)
MCS[f]	59.70 (17.83)
Vitality	77.29 (27.05)
SF[g]	13.18 (13.63)
RE[h]	72.35 (31.66)
MH[i]	75.97 (23.51)

[a] PCS: physical component summary.

[b] PF: physical functioning.

[c] RP: role-physical.

[d] BP: bodily pain.

[e] GH: general health.

[f] MCS: mental component summary.

[g] SF: social functioning.

[h] RE: role-emotional.

[i] MH: mental health.

Correlation Between Variables

The correlation analysis results between IF, FF, HR, HSD, and QOL variables are detailed in Multimedia Appendix 4. The results indicate that the observed IF, FF, HR, and HSD variables significantly correlate with the outcome indicators. Meantime, the significant correlation coefficients between each observed variable ranged from –0.007 to 0.307, which did not meet the standard of strong correlation [52].

CFA Results

The detailed results of the CFA performed to assess the suitability of the SF-36 scale based on the CHARLS database for the construction of SEM are presented in Table 3. According to the results, the standardized regression coefficients, ranging from 0.132 to 0.839, were statistically significant in the 2-factor model. The CR and AVE of the PCS and MCS were within the acceptable range. These findings indicate that the model exhibited excellent reliability and validity, rendering it suitable for SEM analysis. The fit indexes for the entire sample model, as shown in Table 4, suggest a good model fit.

Table 3. Standardized regression coefficient, composite reliability, and convergent validity of the CFA[a].

Path	β[b]	*P* value	CR[c]	AVE[d]
PCS [e]		<.001	0.726	0.412
PCS→physical function	0.831			
PCS→role-physical	0.692			
PCS→bodily pain	0.526			
PCS→general health	0.448			
MCS[f]		<.001	0.704	0.419
MCS→vitality	0.650			
MCS→social functioning	0.132

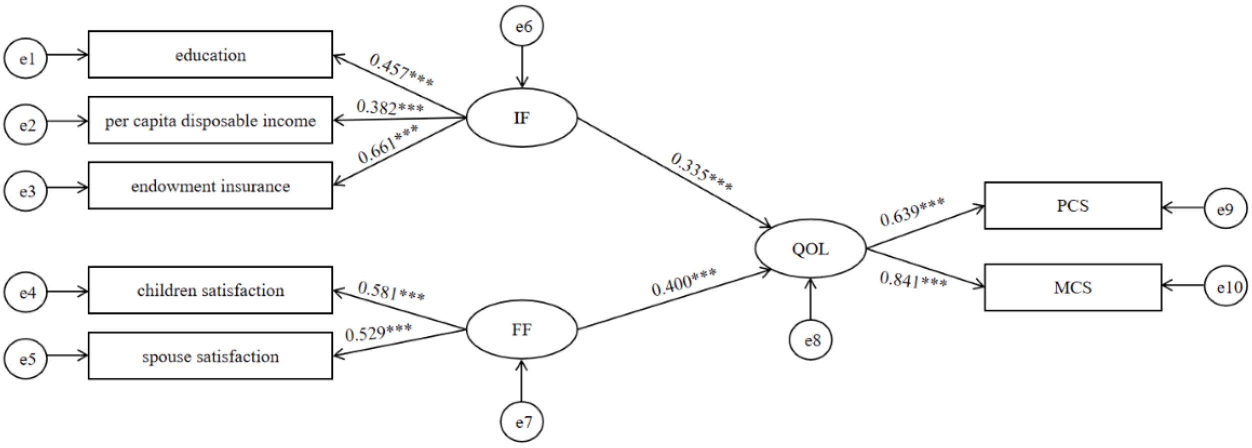
SEM Results

Direct Effects Model

Before analyzing the intermediary effects model, we used a total direct model to assess the effect of IF and FF on the QOL (Figure 3). The fit index of the direct model is acceptable (Table 4). In the direct effects model of individual and family factors on the QOL of older adults, IF and FF have significant positive direct effects on MCS and PCS, thereby promoting an improvement in QOL. It is worth noting that the impact of FF on QOL is greater than that of IF (0.400 vs 0.335; Figure 3). Moreover, the β value of endowment insurance to QOL in IF is much higher than the β values of education and per capita disposable income (0.661 vs 0.457 and 0.382). Additionally, in QOL, the β value of MCS is greater than the β value of PCS (0.841 vs 0.639), indicating that the direct impact of individual and family factors on MCS is greater than that on PCS (Figure 3).

Figure 3. The direct effects of IF and FF on QOL. IF: individual factors; FF: family factors; PCS: physical component summary; MCS: mental component summary; QOL: quality of life.



Multiple Indirect Effects Model

Second, we formulated a multiple intermediary effects model to explore how IF and FF influence the QOL among older adults through mediators—specifically, HR and HSD (Figure 4 and Multimedia Appendix 5). Table 4 illustrates the detailed information on model fit indices, revealing an acceptable fit for the multiple mediation mode. Table 5 further presents the total, direct, and indirect effects of IF and FF on QOL and their corresponding 95% CI.

Figure 4. Multiple mediation model between IF, FF, and QOL with HR and HSD as mediators. IF: individual factors; FF: family factors; HR: health risk; HSD: health services demand; PCS: physical component summary; MCS: mental component summary; QOL: quality of life.

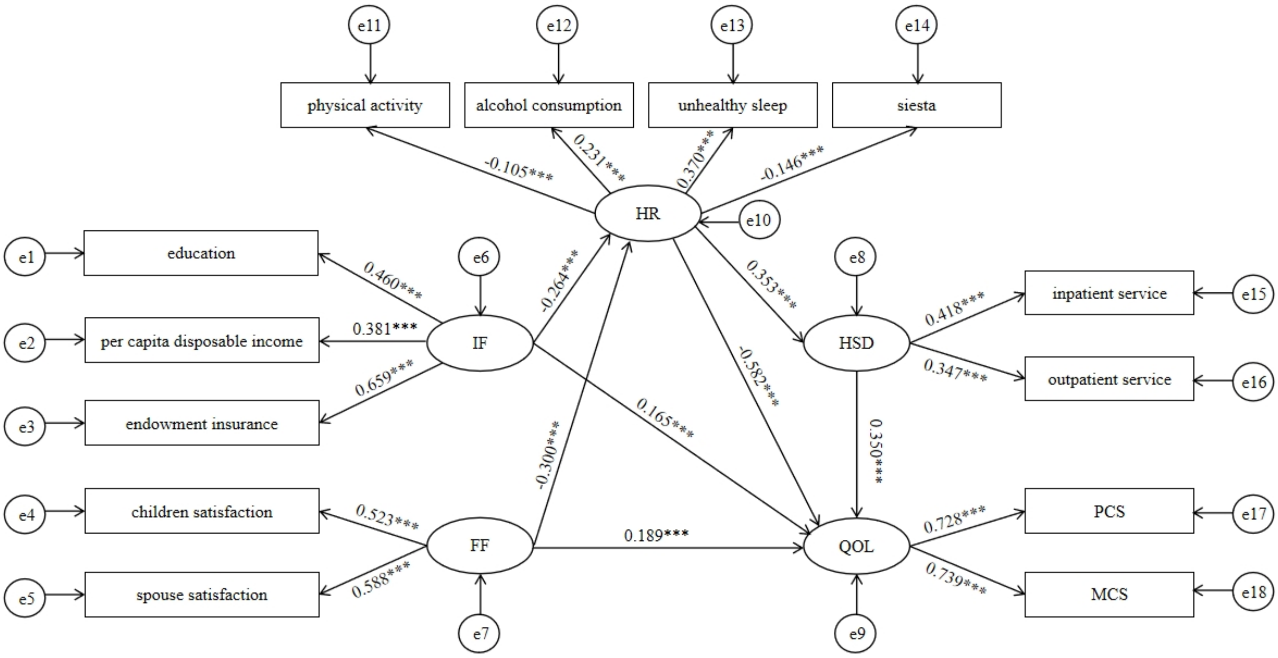


Table 5. Standardized total, direct, and indirect effects of the variables on QOL[a].

Mediation Effect	β[b]	Lower[c]	Upper[d]	Ratio of indirect to total effect, %	Ratio of direct to total effect, %
IF[e]→HR[f]→QOL	0.154	0.104	0.219	44	—[g]
IF→HR→HSD[h]→QOL	0.033	0.023	0.048	9	—
Total indirect effects: IF→QOL	0.186	0.128	0.254	53	—
Direct Effects: IF→QOL	0.165	0.100	0.219	—	47
Total Effects: IF→QOL	0.351	0.321	0.381	—	—
FF[i]→HR→QOL	0.174	0.119	0.240	44	—
FF→HR→HSD→QOL	0.037	0.025	0.054	9	—
Total Indirect Effects: FF→QOL	0.211	0.150	0.282	53	—
Direct Effects: FF→QOL	0.189	0.112	0.258	—	47
Totally Effects: FF→QOL	0.400	0.359	0.443	—	—

[a] QOL: quality of life.

[b] β: standardized regression weights.

[c] Lower: lower limit of confidence interval.

[d] Upper: upper limit of confidence interval.

[e] IF: individual factors.

[f] HR: health risk.

[g] Not applicable.

[h] HSD: health services demand.

[i] FF: family factors.

Specifically, the indirect effects of IF and FF on QOL mediated by HR accounted for a similar proportion of the total effect, both approximately 44%. Similarly, the proportions of the total effect attributed to the indirect effects mediated by HR and HSD were also comparable, around 9%. The CIs corresponding to each mediation path did not include 0, indicating that the multiple mediating effects between IF, FF, and QOL were valid. Additionally, the β values for PCS and MCS were similar in the multiple indirect effects model compared with the direct model (0.728 and 0.739 vs 0.639 and 0.841). This suggests that the impacts of IF and FF on PCS were strengthened following the inclusion of the mediation effect, gradually aligning with the effect observed for MCS. In conclusion, the indirect effects of IF and FF on QOL play equally significant roles as the direct effects, and the indirect effect through HR surpasses that through both HR and HSD. This indicates the pivotal role of HR in mediating the impact of IF and FF on QOL.

Subgroup Analyses

The model fit indices for subgroup analysis are presented in Multimedia Appendix 6. All fit indices across different subgroups fall within the acceptable range, indicating that the model is equally applicable across different genders, age groups, and comorbidities.

The detailed results of the subgroup analysis are presented in Table 6. In the gender subgroup analysis, all path coefficients (β values) are significant, and the absolute values of critical ratios for difference are all below 1.96, indicating no significant differences in the paths across different gender groups. In the age subgroup analysis, the absolute values of critical ratios for difference are all less than 1.96, indicating no significant differences in other paths across different age groups. It is worth noting that in terms of the effect of IF on QOL, the β value in the 60-70 age group was significant, and the β value in the group older than 70 years was not significant, indicating that for older adults aged 60-70 years, IF has a direct impact on QOL, but for older adults older than 70 years, IF has no direct effect on QOL. In the comorbidity subgroup analysis, the absolute value of the critical ratio for difference (–3.011) for the path from HR to HSD is greater than 1.96, indicating a significant difference in comorbidity for the HR to HSD path. Specifically, the effect of HR on HSD for older adults with 2 or more chronic diseases (0.363) is greater than for those with fewer than 2 chronic diseases (0.358). However, the absolute values of critical ratios for difference for other paths are all less than 1.96, demonstrating no differences in β values among paths due to comorbidity status.

Sensitivity Analysis

Due to the high missingness in physical activity data, we conducted an additional sensitivity analysis to evaluate the robustness of our findings. A total of 4259 participants with physical activity data were included in the analysis. The results indicate that the model fit indices are within acceptable ranges, and all path coefficients of the structural model are significant, suggesting that the missing physical activity data have minimal impact on the overall robustness of the multiple indirect effects model. Detailed results can be found in Multimedia Appendices 7 and 8.

Table 6. Standardized regression coefficients (β) with *P* values for the components of subgroup analyses.

Path	Gender			Age			Comorbidity		
	Male	Female	Critical ratios for difference	60-70 years old	≥70 years old	Critical ratios for difference	≥2 chronic diseases	<2 chronic diseases	Critical ratios for difference

Discussion

Principal Findings

To our knowledge, this study is the first to comprehensively assess the impact of IF and FF on QOL in a representative Chinese population aged 60 years and older. We used latent variable modeling to estimate the combined effects of various factors on QOL among older adults. Additionally, we investigated potential mediating pathways beyond the direct effects of IF and FF on QOL. Our findings indicate that both IF and FF have a positive direct impact on QOL. FF showed a greater influence on QOL than IF. Notably, endowment insurance emerged as a significant determinant of QOL among IF. Moreover, indirect effects mediated by HR and HSD were found equally significant as direct effects, with HR playing a pivotal role among the mediators. While individual and family factors had a notably greater direct impact on MCS compared to PCS, their influence converged when considering mediators. Furthermore, we identified differential effects among subgroups with different age and comorbidity status.

Our study aligns with previous studies identifying factors influencing QOL, including education, income, and family relationships [19,28]. However, previous studies often focused on the impact of individual or family factors in isolation or on specific subgroups, such as solitary older adults [27] and community-dwelling older adult populations [53]. In contrast, our study uses structural equation modeling to consider the interactions between variables and their mutual influences on outcomes. Additionally, our study encompasses a nationwide sample of older adults aged 60 years and above in China, enhancing the representativeness and generalizability of the findings. Furthermore, we compared the combined effects of individual and family factors on QOL and found that FF has a greater direct influence than IF. Notably, our study is the first to investigate the impact of pension insurance on the QOL of older adults, highlighting its significance among personal factors. Consistent with the findings of Zhang et al [18], our study incorporates HR and showed its substantial impact on QOL. We further introduce HSD, enriching the mediating pathways through which individual and family factors influence QOL. Our findings underscore the moderating effects of HR and HSD, demonstrating that the indirect effects of individual and family factors on QOL are equally important as their direct effects. Moreover, the influence on mental and physical health exhibits a similar trend across variables.

Our study found that endowment insurance plays a significant role in IF. Endowment insurance may enhance the QOL among older adults through various aspects, such as providing economic security, medical coverage, fostering social engagement, and enhancing psychological well-being [54]. Additionally, endowment insurance could potentially reduce older adults' financial dependence on their children, improve family relationships, and elevate their social status and self-esteem, thus influencing their physical and mental health and enhancing their QOL [55,56]. Our study offers valuable insights for policy makers and social welfare institutions for improving the survival and well-being of older adults.

HR is an important mediating factor for the QOL in older adults. Individual and family factors can indirectly influence the QOL of older adults by moderating HR [54]. Higher education and income levels promote easier access to nutritious food and health care services for older adults, leading to the adoption of healthier lifestyles, thus reducing their HR and enhancing their QOL [18]. Strong family relationships can provide emotional and social support for older adults, helping them cope with stress and challenges, lowering their HR and improving their QOL [57].

The impact of HSD on the QOL of older adults is relatively minor. While QOL can assist older adults in accessing necessary medical services, it cannot eliminate the influence of HR. This may be attributed to the natural decline in physiological functions as individuals age, where certain diseases or health issues may result in permanent physical damage or functional decline, thus potentially affecting the physical and mental well-being of older adults [58]. Furthermore, HSD may also be influenced by individual and family factors such as economic status and medical insurance [59]. Additionally, there may be a lag effect in the impact of HR on HSD, meaning that the influence of HR may take some time to manifest in terms of HSD [60].

In direct effect analysis, we observed the direct impacts of individual and family factors on MCS, which are significantly greater than those on PCS. This may be attributed to the multifaceted influences on MCS, including personal, social, and environmental factors [61], with these factors more likely to directly affect MCS than PCS, when not considering related intermediary effects such as health risks [62]. For instance, factors such as educational attainment and family satisfaction are more closely associated with MCS [63]. Tense family relationships, economic pressures, social discrimination, and similar factors may also contribute to MCS [64]. In contrast, PCS is more influenced by biological factors and is relatively less susceptible to direct impacts from the social environment [65]. However, incorporating HR and HSD as mediators, the impact of individual and family factors on MCS and PCS tends to converge. This could be explained by the moderating role of HR and HSD in individual and family factors and mental or physical health [66]. For instance, unhealthy dietary habits, lack of physical activity, smoking, and other health risk factors, as well as accessibility and use of medical services, which all substantially impact MCS and PCS [67]. This finding contributes to a deeper understanding of how individual and family factors affect the mental and physical health in older adults.

The subgroup analysis indicated that the influence of IF on the QOL in older adults may vary with age. This variation may be associated with increased reliance on family and social support, declining health conditions, and changes in values and life goals among older adults. First, with advancing age, older adults may experience a decline in economic and social resources, leading to increased reliance on family and social support, thereby the impact of IF on QOL declined [68,69]. Second, deteriorating health conditions in old age are characterized by a higher prevalence of chronic diseases and physical impairments, which negatively influence their QOL [70]. Although the influence of IF on health conditions may persist, the overall decline in health status might diminish the significance of IF on QOL [71]. Third, as individuals age, their values and life goals may change [72]. In the age group of 60-70 years, older adults may still have an active lifestyle and self-actualization, thus making the impact of IF on QOL more pronounced. However, in the age group of 70 years and above, older adults may prioritize family and social relationships, leading to a relatively diminished impact of IF on QOL. Consequently, to enhance the QOL among older adults, tailored policies and interventions need to be devised based on the characteristics of different age groups. For individuals aged 60-70 years, efforts can be focused on enhancing their personal capabilities and social resources, such as providing education and training and increasing employment opportunities. For those aged 70 years and older, emphasis can be placed on providing family and social support, such as establishing comprehensive older adult care systems and strengthening community-based older adult care services.

Additionally, within the context of considering comorbidity status, we found that older adults with 2 or more chronic disease conditions tend to require a greater HSD compared to those without such conditions. This may be attributed to the fact that older adults with multiple chronic diseases tend to bear a greater burden of health risks compared to those who are relatively healthy [25]. The Health Belief Model proposes that individuals are most likely to take preventive actions when they perceive a health risk as a serious threat to their own health [73]. Moreover, older adults with a greater number of chronic diseases tend to experience comparatively poorer overall physical conditions, thereby resulting in a heightened HSD [74]. Based on this, it is imperative to emphasize the cultivation of self-management awareness of comorbidities and implement additional health interventions for older adults with multiple chronic diseases. This may involve tailored health education initiatives aimed at enhancing healthy behavior and disease prevention, thereby reducing health risks and enhancing overall QOL. Furthermore, communities should develop comprehensive care service systems that cope with the varying health conditions of older adults, ultimately improving QOL.

Strengths and Limitation

A strength of this study is the use of a large sample covering different regions of China to explore the associations between individual and family factors and QOL in older people. Furthermore, the statistical analysis was conducted using SEM based on a conceptual framework, which is an advanced statistical approach to estimate direct and indirect effects from exposure to outcome, including latent variables. This is the first study using SEM to analyze the pathways from individual and family factors to QOL via HR and HSD over the entire older adult population in China. The findings suggest potential avenues for policy and intervention to improve the QOL among older individuals.

The limitations of the study must be taken into account when interpreting the results. First, the data used in this study is from a cross-sectional survey; although the hypotheses of this study are supported by theory, experience, and statistical data, caution is still warranted in inferring causal relationships. Future research using prospective, longitudinal cohorts is needed to further validate these findings. Second, due to the constraints of the CHARLS database, there are limitations regarding the selection of variables for constructing individual and family factors, and the relevant data on the personal income data of older adults in the database are missing, so we chose per capita disposable income at the city level as a substitute, which may cause bias in the results. Third, for the physical activity data, there is a 50% missing data rate, and our sample does not include individuals with disabilities. Although sensitivity analyses indicated that the absence of physical activity data did not affect the robustness of the model, caution is advised when extrapolating conclusions to individuals with disabilities. Finally, this study included all older adults with spouses and children, caution is needed when extrapolating the conclusions to older individuals who are unmarried or without children.

Conclusions

Both IF (education, per capita disposable income, and endowment insurance) and FF (satisfaction with a spouse and children) directly impact the QOL in older people. Meanwhile, IF and FF have equal influence on QOL through the mediating role of HR and HSD. Therefore, it is imperative to enhance social support and prioritize home care for older adults in future interventions. Enhanced access to financial and emotional support can mitigate health risks and facilitate access to quality health care, thereby improving QOL for older adults.

Acknowledgments

We are grateful to the National Development Research Institute at Peking University for providing us with the CHARLS data. This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

Abstract

Background: The societal burden of cognitive impairment in China has prompted researchers to develop clinical prediction models aimed at making risk assessments that enable preventative interventions. However, it is unclear what types of risk factors best predict future cognitive impairment, if known risk factors make equally accurate predictions across different socioeconomic groups, and if existing prediction models are equally accurate across different subpopulations.

Objective: This paper aimed to identify which domain of health information best predicts future cognitive impairment among Chinese older adults and to examine if discrepancies exist in predictive ability across different population subsets.

Methods: Using data from the Chinese Longitudinal Healthy Longevity Survey, we quantified the ability of demographics, instrumental activities of daily living, activities of daily living, cognitive tests, social factors and hobbies, psychological factors, diet, exercise and sleep, chronic diseases, and 3 recently published logistic regression–based prediction models to predict 3-year risk of cognitive impairment in the general Chinese population and among male, female, rural-dwelling, urban-dwelling, educated, and not formally educated older adults. Predictive ability was quantified using the area under the receiver operating characteristic curve (AUC) and sensitivity-specificity curves through 20 repeats of 10-fold cross-validation.

Results: A total of 4047 participants were included in the study, of which 337 (8.3%) developed cognitive impairment 3 years after baseline data collection. The risk factor groups with the best predictive ability in the general population were demographics (AUC 0.78, 95% CI 0.77-0.78), cognitive tests (AUC 0.72, 95% CI 0.72-0.73), and instrumental activities of daily living (AUC 0.71, 95% CI 0.70-0.71). Demographics, cognitive tests, instrumental activities of daily living, and all 3 recreated prediction models had significantly higher AUCs when making predictions among female older adults compared to male older adults and among older adults with no formal education compared to those with some education.

Conclusions: This study suggests that demographics, cognitive tests, and instrumental activities of daily living are the most useful risk factors for predicting future cognitive impairment among Chinese older adults. However, the most predictive risk factors and existing models have lower predictive power among male, urban-dwelling, and educated older adults. More efforts are needed to ensure that equally accurate risk assessments can be conducted across different socioeconomic groups in China.

Introduction

China's aging population has led to cognitive impairment becoming increasingly burdensome to society [1,2]. In 2020, more than 68 million Chinese older adults had mild cognitive impairment, dementia, or Alzheimer disease [3]. The economic and social burden of cognitive impairment has led to calls for improving risk assessments and prioritizing early diagnoses [1,3]. Given China's limited number of geriatric psychiatrists, researchers have turned to developing prediction models to identify older adults at risk of cognitive impairment for preventative interventions [4-8]. However, no study has compared the predictive ability of known risk factors side by side, and our understanding of which factors are the most useful for developing prediction models is limited. Furthermore, population characteristics vary widely across China, but it is unknown which risk factors are the most predictive in different socioeconomic groups, and existing prediction models have primarily been tested in the general population alone. To understand how to best predict future cognitive impairment and to develop more targeted prediction models for population subgroups, the predictive ability of known risk factors and existing prediction models must be quantified and compared across different subsets of the Chinese population.

A plethora of modifiable and nonmodifiable risk factors that are associated with cognitive impairment among Chinese older adults have been identified. Previous studies have found that increased age, limited functional independence, alcohol consumption, hypertension, and depression are significantly associated with cognitive impairment [3,9-12]. Protective factors have also been identified, namely, good sleep quality, sleeping sufficiently for many hours per night, exercise, and increased social participation [3,9,13-17]. It is also known that the prevalence of cognitive impairment in China differs across population subsets such as male and female individuals, rural and urban dwellers, and older adults with different levels of education [3]. Explanations for such discrepancies include different social patterns and literacy rates across the sexes and across regions with varying degrees of rurality, rates of depression in rural areas, and levels of education [3]. More years of education has also been associated with a greater cognitive reserve, which protects against future impairment [3]. Nevertheless, it is unclear which risk factors are the most useful for predicting future cognitive impairment across different subpopulations in China. Although we have a reasonable understanding of which characteristics make a person more likely to develop cognitive impairment, our understanding of which parts of a person's health profile most accurately predict their risk of developing cognitive impairment is limited.

In addition to known risk factors, it is unclear if existing prediction models for future cognitive impairment are equally accurate across different socioeconomic groups in China. Several published models have reported areas under the receiver operating characteristic curve (AUCs) greater than 0.80 in their development cohorts [5,7,8], but each model has only been tested on the general population. Nearly all existing models make predictions by leveraging measures of cognition, age, and education. Additional covariates vary from model to model and include factors such as instrumental activities of daily living (IADL), hobbies such as gardening and watching television, marital status, and others. Examining the predictive ability of existing models across population subsets would allow us to identify where more efforts are needed to improve risk assessments for cognitive impairment, further our understanding of which subpopulations are more difficult to conduct risk assessments within, and provide a more thorough evaluation of existing prediction models than has been reported previously.

In this study, we quantified the ability of 9 risk factor groups and 3 existing models to predict future cognitive impairment among Chinese older adults. We examined how well demographics, IADL, activities of daily living (ADL), cognitive tests, social factors and hobbies, psychological factors, diet, exercise and sleep, chronic diseases, and 3 recently published models predict future cognitive impairment in the general population and among male, female, rural-dwelling, urban-dwelling, educated, and not formally educated older adults. To our knowledge, this study is the first to comprehensively compare the ability of known risk factors to predict future cognitive impairment and the first seeking to identify which subsets of the Chinese population need greater attention to improve the accuracy of risk assessments.

Methods

Data Source and Study Design

The Chinese Longitudinal Healthy Longevity Survey (CLHLS) is a prospective cohort study of Chinese older adults that contains information on demographics, cognitive function, lifestyle factors, chronic diseases, and more [18,19]. The CLHLS began in 1998, and follow-up surveys have been conducted every 2-3 years since. The data include older adults from 23 of China's provinces that together make up 85% of the country's total population.

We used the 2011 and 2014 CLHLS waves in our study. Baseline characteristics were gathered from the 2011 survey and used to predict if an individual became cognitively impaired by 2014. CLHLS participants younger than the age of 60 years or those with cognitive impairment at baseline were excluded. Sample size calculations were conducted following the methodology for multivariable prediction models by Riley et al [20]. This study is presented following the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) guidelines where appropriate [21,22].

Ethical Considerations

The CLHLS received ethics approval from the Duke University Institutional Review Board (Pro00062871) and Peking University's Biomedical Ethics Committee (IRB00001052–13,074). Written informed consent was given by all participants prior to the survey interviews. This study secondarily analyzed anonymized data from the CLHLS.

Measuring Cognitive Function

Cognition was assessed through the Chinese-language version of the Mini Mental State Examination (MMSE) [23]. MMSE scores range from 0 to 30, with lower scores indicating worse cognitive function. We adopted education-specific cutoffs that have been previously validated in the Chinese older adult population to indicate cognitive impairment [24]. Those with no formal education and MMSE scores less than 18 were labeled as cognitively impaired, as were those with 1-6 years of education with scores less than 21 and those with more than 6 years of education with scores less than 25 [24].

Risk Factor Groups

Overview

A total of 9 groups containing known risk factors for cognitive impairment were considered in this study: demographics, ADL, IADL, cognitive tests, social factors and hobbies, psychological factors, exercise and sleep, diet, and chronic diseases. The risk factor groups were chosen by selecting parts of a person's health profile previously found to be associated with developing cognitive impairment [9]. Each group is briefly described below, and a complete list of the variables in each group can be found in Multimedia Appendix 1.

Demographics Group

The demographics group contained each individual's age, sex, years of education, household income, marital status, and residence location (city, town, or rural area).

ADL Group

The ADL group included each person's ability to bathe, get dressed, use the toilet, get in and out of bed, control urination and bowel movements, and eat food.

IADL Group

The IADL group covered tasks that require thinking, organizational, and physical independence. The IADL group included an older adult's ability to visit neighbors, go shopping, cook, wash clothes, walk continuously for 1 km, lift a bag of groceries, crouch and stand up, and take public transportation.

Cognitive Tests Group

The cognitive tests group included scores from each subsection of the MMSE: orientation, naming, registration, calculation, attention, recall, and language. Scores from each section were included as separate variables.

Social Factors and Hobbies Group

The social factors and hobbies group included whether a person grows vegetables, gardens, reads newspapers and books, looks after pets or animals, plays cards or mahjong, and participates in social activities.

Psychological Factors Group

The psychological factors group included the following factors that primarily relate to depression and anxiety: whether a person is generally optimistic, keeps their belongings organized, is generally anxious, is often lonely, makes decisions independently, feels useless with age, was happier when they were younger, and felt sad for more than 2 consecutive weeks over the past year.

Exercise and Sleep Group

The exercise and sleep group included whether someone currently exercises, whether they used to exercise, as well as the self-reported duration and quality of sleep.

Diet Group

The diet group contained information on each person's staple food; if they eat fresh fruits and vegetables; the main flavor of the dishes they cook; how frequently they consume meat, fish, eggs, sugar, and tea; if they consume alcohol; the type of alcohol they consume; and the frequency of alcohol consumption.

Chronic Diseases Group

The chronic diseases group included the presence or absence of hypertension, diabetes, heart disease, blood disease, and cardiovascular disease.

Recreating Existing Prediction Models

Prediction models were selected based on the following criteria: the model was developed for use in China, was reproducible using the CLHLS, and had an AUC of >0.75 during development. We selected 3 models published in Zhou et al [8], Hu et al [5], and Wang et al [7]. Each model was developed for use in the general Chinese population and showed excellent predictive performance (AUC>0.80) during development. All the models we recreated were based on logistic regression, which returns predictions by summing weighted values of each covariate before the sum is passed through the logistic function to produce predicted probabilities between 0 and 1. The logistic regression model recreated from Zhou et al [8] included age, a functional independence score based on ADL, baseline MMSE score, chewing ability, visual function, history of stroke, whether the participant watches TV or listens to the radio, and whether the participant grows flowers or raises pets. From Hu et al [5], the recreated model included age, marital status, IADL, and baseline MMSE score. Lastly, the model from Wang et al [7] included age; education; sex; ADL; baseline MMSE; and whether the participant gardens, reads newspapers or books, plays mahjong or cards, watches TV, or listens to the radio.

Statistical Analysis

All analyses were performed using the R Statistical Software (version 4.0.5; R Foundation for Statistical Computing), and all code required to reproduce the analyses presented herein can be found on the web [25]. Predictive ability was quantified using AUC, sensitivity, and specificity. We assessed the predictive ability of each risk factor group using logistic regression models evaluated through 20 repeats of 10-fold cross validation, which has been recommended to obtain optimism-corrected performance metrics for prediction models [26]. This resulted in 200 training sets and 200 validation sets. All "I don't know" or "refused" responses in the CLHLSs were set to missing, ordinal variables were integer encoded, and nonordinal categorical variables were dummy encoded. Missing values were imputed on each training and validation set separately using *k*-nearest neighbors imputation [27]. During each iteration of cross-validation, the data were split into training and validation sets before 9 logistic regression models, each containing all covariates in 1 particular risk factor group, were fit to the training data. Thereafter, each model was used to make predictions on the validation set for the general population and 6 subpopulations: male, female, rural-dwelling, urban-dwelling, educated, and not formally educated older adults. The same procedure was also followed for evaluating the prediction models from Zhou et al [8], Hu et al [5], and Wang et al [7]. Average AUCs and accompanying 95% CIs were calculated across the 200 validation-set AUCs for each model in this study. Sensitivity and specificity curves, 1 from each validation set, were also plotted for the risk factor group models.

Results

Given a binary outcome, a population-level prevalence of 0.20, a conservatively estimated Cox-Snell R^2 of 0.09, and 24 predictors in the largest risk factor group, the sample size required for this study was determined to be 1065 with 213 events to minimize the risk of overfitting, reduce the chance of overly optimistic performance metrics, and ensure that the models have sufficient data to estimate the overall risk of cognitive impairment in our sample. After excluding CLHLS participants with cognitive impairment at baseline and those younger than the age of 60 years, a cohort of 4047 Chinese older adults were included, of which 337 (8.3%) developed cognitive impairment. The average age of the cohort was 79.8 (SD 9.4) years, and 2037 (50%) were male. The group that developed cognitive impairment was older at baseline (89.1 vs 79.0 years) with a lower average baseline MMSE score (25.1 vs 27.7). A full description of the cohort's characteristics can be found in Table 1, and the distribution of variables in each risk factor group can be found in Multimedia Appendix 2.

[a] MMSE: Mini Mental State Examination.

As shown in Figure 1A and Table 2, demographics had the best predictive ability in the general population (AUC 0.78, 95% CI 0.77-0.78), followed by cognitive tests (AUC 0.72, 95% CI 0.72-0.73) and IADL (AUC 0.71, 95% CI 0.70-0.71). Social factors and hobbies had a moderate predictive ability (AUC 0.67, 95% CI 0.66-0.68), whereas diet, psychological factors, exercise and sleep, ADL, and chronic diseases all had average AUCs less than 0.60. Demographics, cognitive tests, and IADL also had the best sensitivity and specificity tradeoffs, as shown in Figure 2. By contrast, the sensitivity and specificity curves for the chronic diseases group showed that such risk factors only sometimes resulted in better-than-random predictions.

[b] IADL: instrumental activities of daily living.

[c] ADL: activities of daily living.

Figure 2. Sensitivity and specificity curves for predictions made in the general population. ADL: activities of daily living; IADL: instrumental activities of daily living.

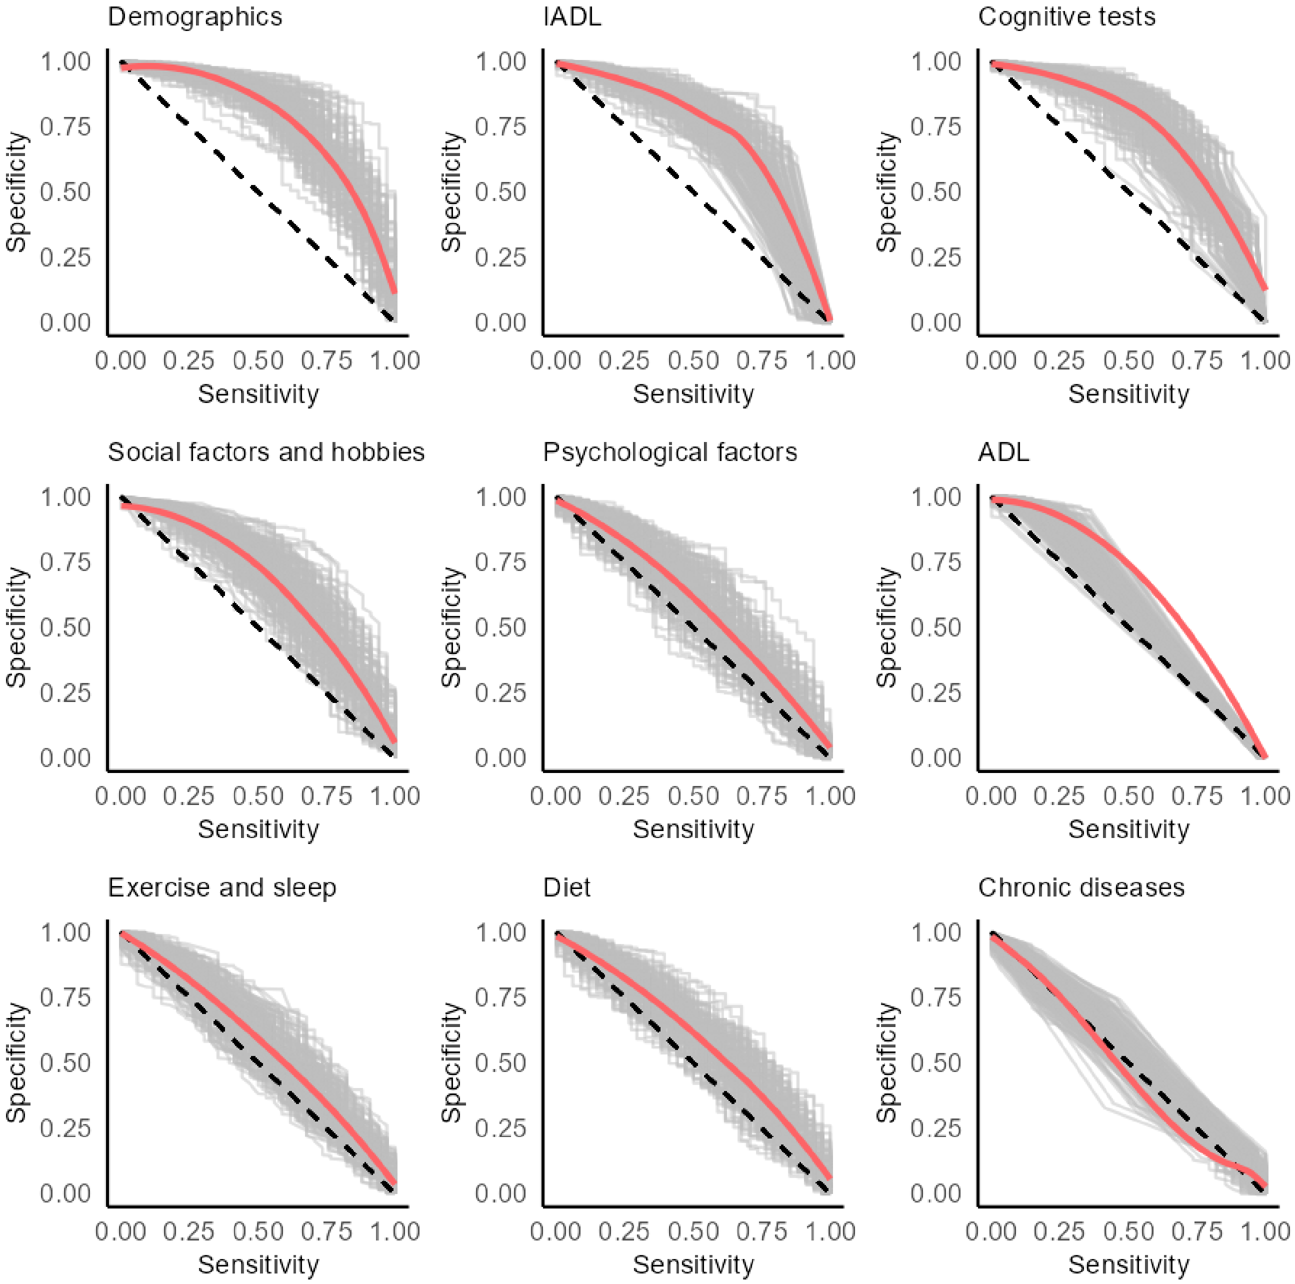

Figure 1D shows that most risk factor groups had significantly higher AUCs when making predictions among older adults with no formal education compared to those with some education. The only exceptions were the ADL and exercise and sleep groups. Among those with no formal education, demographics, cognitive tests, and IADL had AUCs of 0.79 (95% CI 0.78-0.79), 0.72 (95% CI 0.72-0.73), and 0.71 (95% CI 0.70-0.71), respectively. When making predictions among those with some education, demographics, cognitive tests, and IADL had average AUCs of 0.73 (95% CI 0.72-0.74), 0.64 (95% CI 0.63-0.66), and 0.64 (95% CI 0.62-0.65), respectively.

The existing prediction models recreated in this study all had good predictive ability in the general population. Each model had an average AUC of 0.80 (95% CI 0.80-80.1). However, each model had significantly higher AUCs when making predictions in female individuals compared to male individuals, in rural dwellers compared to urban dwellers, and in those with no formal education compared to those with some education. Complete results can be found in Table 2 and Figure 3. The TRIPOD checklist for this study can be found in Checklist 1.

Demographics had a significantly better predictive ability when making predictions among rural dwellers (AUC 0.80, 95% CI 0.79-0.81) compared to urban dwellers (AUC 0.74, 95% CI 0.73-0.75). Similarly, IADL showed a higher average AUC among rural dwellers (AUC 0.73, 95% CI 0.72-0.73) compared to urban dwellers (AUC 0.68, 95% CI 0.67-0.69). As shown in Figure 1C and Table 2, significantly higher AUCs among rural dwellers were also observed for the diet, psychological factors, and chronic diseases groups.

Demographics, cognitive tests, and IADL also had the highest average AUCs when making predictions for male and female individuals, although the predictive ability varied between the

2 sexes. The demographics group had a higher average AUC when making predictions in female individuals compared to male individuals (0.81, 95% CI 0.80-0.82 vs 0.72, 95% CI 0.71-0.73), as did the IADL group (0.72, 95% CI 0.71-0.73 vs 0.66, 95% CI 0.65-0.67) and the cognitive tests group (0.72, 95% CI 0.71-0.73 vs 0.70, 95% CI 0.69-0.71). The dietary group had a significantly higher AUC when making predictions among male individuals (0.61, 95% CI 0.60-0.62) compared to female individuals (0.57, 95% CI 0.56-0.58). No significant differences were observed for the social factors and hobbies group, and all other remaining groups has AUCs less than 0.60 for both male and female individuals. Full results can be found in Figure 1B and Table 2.

Figure 3. Predictive ability of existing models [5,7,8]. AUC: area under the receiver operating characteristic curve.

Discussion

Principal Findings

In this study, we quantified the ability of 9 risk factor groups and 3 prediction models to predict future cognitive impairment in the general Chinese population and 6 population subsets: male, female, rural-dwelling, urban-dwelling, educated, and not formally educated older adults. In the general population, the risk factor groups with the best predictive ability were demographics (AUC 0.78, 95% CI 0.77-0.78), cognitive tests (AUC 0.72, 95% CI 0.72-0.73), and IADL (AUC 0.71, 95% CI 0.70-0.71). The most predictive risk factors and the existing models performed inconsistently across socioeconomic groups and had significantly higher AUCs when making predictions for female individuals and older adults with no formal education compared to male individuals and older adults with some education.

Our study showed that the 3 existing prediction models had significantly lower AUCs when predicting future cognitive impairment among male, urban-dwelling, and educated Chinese older adults compared to female, rural-dwelling, and not formally educated older adults. Despite the only shared risk factors in all 3 models being age and baseline MMSE score, significant differences in predictive ability were consistent across every model. One explanation is that risk factor differences between those who developed cognitive impairment and those who did not were larger among the groups where more accurate predictions were made. For example, the difference in average age between female older adults who did and did not become cognitively impaired was 11.8 years, whereas for male older adults, it was 7.0 years. Similarly, among those with no formal education, the difference in baseline MMSE score between those with and without cognitive impairment at follow-up was 2.67 compared to 1.45 among those with some education. In addition, the prevalence of cognitive impairment in our sample was higher among female, rural-dwelling, and not formally educated older adults, meaning that the models had more events to learn from. Indeed, previous studies using nationally representative data have also reported higher prevalence estimates among these groups [3]. Our results indicate that targeted prediction models for specific socioeconomic groups are needed in China to make equally accurate risk assessments across sex, residential status, and education level. Several studies have called for such models [28,29], but as of this writing, none have been developed in China.

Out of the 9 risk factor groups, we found that demographics, cognitive tests, and IADL best predict future cognitive impairment in the general Chinese population and across sex, residential status, and education level. Demographics are often included in prediction models for cognitive impairment [28,30-32], and we suggest that they continue to be leveraged because of their predictive power and ease to collect. Associations between chronic diseases, ADL, psychological factors, and diet with cognitive impairment among Chinese older adults have been established [13,33-39], but such factors showed moderate predictive ability in our study. To our knowledge, dietary factors have not been incorporated into existing prediction models in China, but they had higher AUCs than commonly used risk factors such as psychological factors, ADL, and chronic diseases. In fact, chronic diseases did not make significantly better than random predictions among male (AUC 0.50, 95% CI 0.49-0.51), urban-dwelling (AUC 0.50, 95% CI 0.50-0.51), and not formally educated (AUC 0.51, 95% CI 0.49-0.52) older adults. Hence, in addition to providing a ranking of the most predictive risk factor groups, our study is the first to show that dietary factors warrant consideration when predicting future cognitive impairment among Chinese older adults.

Many risk factor groups had significantly different AUCs across population subsets. Similar to the existing models we recreated, our study revealed that the most predictive risk factors (demographics, cognitive tests, and IADL) had significantly higher AUCs when making predictions among female and not formally educated older adults compared to male and educated older adults. As was the case with the recreated models, this likely resulted from the distributions of risk factors being more separable between those who developed cognitive impairment and those who did not in the groups where more accurate predictions were made. Given the lack of available evidence, it is unclear whether the discrepancies in predictive ability found in our study generalize outside of China, and future work may seek to perform similar analyses elsewhere.

Limitations

Our study has several limitations. The source code was not available for the models we selected to recreate in this study, but we explicitly followed all preprocessing, variable derivation, and model creation procedures described in the original papers during the model replication process. The AUCs of each model in the general population in this study were consistent with the reported AUCs in the original papers, suggesting that the models were properly recreated from scratch. To facilitate future research, we have further made our code publicly available. Second, the CLHLS is not nationally representative, although it does include older adults from 23 of China’s provinces. The exercise and sleep group did not include objective measurements of physical activity and sleep. Self-reported exercise and sleep are often inaccurate, and we suggest that the results be interpreted with caution for the exercise and sleep group. Lastly, the data used in this study were from 2011 to 2014. Future studies may wish to collect new data and further validate the results presented herein.

Conclusions

Out of the 9 risk factor groups, our study found that demographics, cognitive tests, and IADL best predicted future cognitive impairment among Chinese older adults and had significantly better predictive ability among female and not formally educated older adults compared to male and educated older adults. Similarly, every existing model we recreated made significantly better predictions among female, rural-dwelling, and not formally educated older adults. Our study suggests that more targeted predictions models for cognitive impairment are needed to make equally accurate risk assessments across different socioeconomic groups in China and provides foundational evidence that can support variable selection for such models.

Abstract

Background: As the population of individuals with HIV ages rapidly due to advancements in antiretroviral therapy, virtual care has become an increasingly vital component in managing their complex health needs. However, little is known about perceptions of virtual care among older adults living with HIV.

Objective: This study aimed to understand the perceptions of older adults living with HIV regarding virtual care.

Methods: Using an interpretive, qualitative, descriptive methodology, semistructured interviews were conducted with 14 diverse older adults living with HIV. The participants lived in Ontario, Canada, self-identified as HIV-positive, and were aged 50 years or older. Efforts were made to recruit individuals with varying experience with virtual health care. Reflexive thematic analysis was conducted with the interview transcripts to identify prevalent themes.

Results: The identified themes included (1) the importance of relationships in virtual care for older adults living with HIV; (2) privacy and confidentiality in virtual care; and (3) challenges and solutions related to access and technological barriers in virtual care. These themes highlight the perceptions of diverse older adults living with HIV concerning virtual care, emphasizing the fundamental role of trust, privacy, and technology access.

Conclusions: By embracing the unique perspectives and experiences of this population, we can work toward building more inclusive and responsive health care systems that meet the needs of all individuals, regardless of age, HIV status, or other intersecting identities.

Introduction

The increased uptake in virtual care in response to the COVID-19 pandemic represents a shift in health care delivery worldwide [1-4]. This expansion of virtual care necessitated numerous assessments of its efficacy and suitability for patients with different disease states and demographics [5,6]. Among these studies, the emerging and concerning trend of older individuals lacking access to health care, including timely care, became notable [7], presenting a potential added risk of morbidity and mortality [7]. In contrast, the use of virtual care has continued to be advocated for following the pandemic to provide options and to increase the availability and accessibility of health care services for older adults [7,8]. We define virtual care as "the interaction between patients and/or members of their circle of care, occurring remotely, using any forms of communication or information technologies with the aim of facilitating and maximizing the quality and effectiveness of patient care," in accordance to the Canadian Women's College Hospital Institute for Health System Solutions and Virtual Care [9]. Virtual care can encompass various modalities, including teleconsultation, remote monitoring, and mobile health applications, among others [10,11].

Older adults represent a patient demographic with distinct health care needs and challenges who might benefit from virtual care [12]. As individuals age, they often experience age-related health conditions, chronic diseases, and functional limitations that necessitate frequent interactions with the health care system [13,14]. Moreover, older adults may face logistical obstacles, such as transportation challenges, lack of time, mobility limitations, and caregiver responsibilities, which can impede their access to in-person health care services [15-18]. Virtual care interventions tailored to older adults can offer numerous advantages, including improved access to care [19-21], enhanced convenience for homebound older adults [22] and those who live in rural and remote areas [23,24], cost-effectiveness [22], and the potential for early detection and intervention of clinically adverse events [25]. Thus, virtual care for specialized populations is valuable, as it increases access to specialists who might otherwise be inaccessible.

Older adults living with HIV are accessing virtual care services more commonly [26,27]. As the population of individuals with HIV ages, their complex health needs require specialized management [28]. The intersection of HIV and aging poses unique health care challenges [29-32], and as this population grows rapidly due to advancements in antiretroviral therapy, virtual care has become an increasingly vital component in managing their complex health needs [32]. However, little is known about the experiences and perceptions of older adults living with HIV regarding virtual care [26,33]. Addressing this knowledge gap may inform improvements to virtual care delivery by highlighting the unique health care needs of this population [26].

The goal of this study was to understand the perceptions of diverse older adults living with HIV regarding virtual care. Specifically, we aimed to explore the perceptions of diverse older adults living with HIV on (1) how virtual care supported age-related conditions experienced by older adults living with HIV; (2) perceived obstacles, pathways, and needs encountered in virtual care; and (3) recommendations for improving virtual care to support diverse older adults living with HIV.

Methods

Ethical Considerations

The study received ethics approval from the Mount Sinai Hospital Research Ethics Board (REB: 23-0106E).

Methodology

We used an interpretive qualitative descriptive methodology for this study [34]. This methodology was selected as it is geared toward generating knowledge applicable to clinical practice, which aligns with our objectives [34].

This work was part of a broader research program[35] that involved a diverse advisory team of 10 individuals working within nonprofit community-based organizations, clinical settings, with lived and living experience, and working within policy, and research sectors. As such, an integrated knowledge translation approach was applied throughout this study [34]. This collaborative effort aimed to generate relevant and practical knowledge aligned with our study objectives. The advisory committee played a key role in identifying participants, analyzing data, reviewing the manuscript, and disseminating findings. Our team includes academic researchers and clinicians from geriatric, social work, and infectious disease programs, as well as partners from community organizations, lived experience of HIV, and policy sectors. Some individuals informed this project through their dual roles as researchers and lived experience representatives.

Participants

The participants were not known to our research team in any personal, professional, or academic capacity before the study. All interactions with participants were strictly limited to the context of the research project. To be eligible, individuals had to self-identify as HIV-positive, be 50 years of age or older, and reside in Ontario. This geographic specificity facilitated a targeted examination of health care resources available to older persons living with HIV in this province.

Recruitment

Our advisory committee's websites and social media platforms were used to promote the study. We also recruited through HIV clinics, geriatric clinics, and other health care facilities catering to older individuals living with HIV, to engage potential participants already involved in health care services in Ontario. Representation was purposively sought across various areas to ensure diversity in perspectives [36], including sex and gender, age, ethnicity and race, socioeconomic status, prior usage of virtual-geriatric care, geographical location (rural vs urban), non-English first language, and level of educational attainment. This involved targeted recruitment from community-based organizations, including churches, mosques, temples, shelters, community centers, senior groups, health centers, libraries, and senior living buildings [37]. At these community-based locations, organizational staff posted flyers and circulated newsletters regarding the purpose of the study. Interested participants reached out to the research team via email or telephone. After the principal investigator or the research coordinator contacted interested persons to determine eligibility and to confirm interest via voluntary verbal consent, the participants were provided a written consent form and scheduled a time and location for the interview. The participants were given the option of an in-person, Zoom for Healthcare, or telephone interview. The participants were also offered the opportunity to bring a support person to the interview.

Data Collection

Individual interviews (n=14) were conducted by a trained research assistant (n=10) or a peer researcher with lived experience (n=4) to enhance participants' comfort in expressing their candid thoughts and opinions about virtual care. Interviews were guided using a semistructured interview guide that was developed by the research team in consultation with an advisory committee and took place between November 2023 and April 2024.

The semistructured interview guide (Table S1 in Multimedia Appendix 1) explored participants' experiences with virtual care, including obstacles, pathways, and needs encountered in virtual care. Interview questions also examined their reasons for choosing or avoiding virtual care, the types of health care providers and conditions they consulted in their virtual appointments, and their overall care experiences during and after the COVID-19 pandemic when much care shifted to virtual formats.

The participants also had the option of completing an optional demographic form, either before, during, or after the interview.

Recruitment continued until data saturation was achieved [38]. Data saturation was determined through an ongoing review of the interviews by the research team to ensure no new data themes emerged [38]. The participants received a CAD $25 (US$ 17.80) gift card honorarium as a token of appreciation for their time. All interviews were recorded, professionally transcribed, and reviewed for accuracy by a research assistant.

Data Analysis

Transcripts were analyzed and organized using NVivo 12 software [39]. The reflexive thematic analysis process outlined by Braun and Clarke was followed [40]. The research assistants and principal investigator read each transcript thoroughly, coded the data, and collaborated regularly with the co-investigators to develop and fine-tune the coding scheme. This involved recursive coding and theme development, including immersion in the data, review of relevant literature, and deep reflection [40]. Quality and reporting were guided by checklists provided by Braun and Clarke [41], including Braun and Clarke's 15 questions for evaluating thematic analysis papers for publication (see Table S2 in Multimedia Appendix 1 [42,43]), and the Standards for Reporting Qualitative Research [44].

The sociodemographic characteristics of the participants were summarized using descriptive statistics.

Rigor

To ensure methodological rigor, several strategies were used. These included building rapport with participants, seeking feedback on the interview guide, presenting direct quotes, engaging in team discussions to interpret data, and maintaining reflective notes throughout the analysis process. In addition, a collaborative and inclusive approach was maintained with participants, prioritizing open discussions and considering practical constraints such as scheduling, arranging interviews through a modality convenient to the participant, and the duration of interviews. This approach facilitated authentic exchanges, contributing to enhanced data quality.

Results

Overview

A total of 14 participants participated in this study. Of this, 4 identified as women and 10 as men. The participants were 63 years old on average (SD 10). Overall, 9 participants resided in urban settings, 2 in suburban settings, and 3 in rural settings. In total, 9 participants identified as low income (CAD $0-$29,999). Further details on participants are given in Table 1. Additional details are provided in Table S3 in Multimedia Appendix 1.

Theme 1: Importance of Relationships in Virtual Care for Older Adults Living With HIV

Privacy and data security emerged as key factors influencing the acceptance of virtual geriatric care, with some participants appreciating the privacy of virtual consultations while others preferred in-person visits to ensure confidentiality. Access to technology and internet connectivity were identified as significant obstacles, and participants noted the need for technology training and mutual understanding between patients and health care providers. Stigma associated with registering for age-related virtual care services was also a concern, with suggestions to integrate these services into existing health care frameworks to mitigate this issue. The findings are highlighted using participant quotes cited by the study participant ID, gender of the participant, and age.

All participants described experiencing unique health care challenges that intersect with both aging (eg, memory loss and frailty) and their HIV status (eg, stigma and risk of infection), making supportive and trustworthy relationships with health care providers crucial. The participants noted that the same health care providers should be accessible through virtual care to build effective communication, trust, and a sense of security. The participants who described having strong, positive relationships with their health care providers resulted in them being more likely to engage in open communication about their health concerns and feel supported in managing their condition(s). For example, one participant shared how trust in her relationship with her family physician allowed her to be tested for HIV:

> *I could finally be honest of what was happening in all areas of my life and trusted [family doctor] enough to finally go and get tested anonymously* [Participant 09, woman, 70 years]

On the other hand, when participants lacked a trusting relationship with their health care provider, they seldom adhered to their treatment or appointment schedule. One participant shared:

> *It's hard to want to go to the doctor when you feel like they are judging. The stories and stuff I have been told by doctors. Why would I ever go back and show up? Maybe I should put my pride aside, but it's enough to make you rather be sick* [Participant 11, male, 52 years]

The participants recognized feelings of discomfort during their interactions with new health care providers. One participant shared that he disliked having to "break in new doctors," when discussing his experiences living with HIV (Participant 02, Man, 57 y old). The participants, therefore, emphasized that one of the critical aspects of building strong relationships in virtual health care is the consistency of health care providers. In addition to clinical discussions, the participants emphasized the importance of exploring social and emotional needs with their virtual health care provider. However, the participants who had experience with virtual care of any kind before the interview noted that the physical distance and lack of face-to-face interaction in virtual care made them feel disconnected from their care team, and sometimes challenged the trust that they had in their health care provider, questioning whether the health care provider was truly engaged in their care. One participant shared, "why would I just go and disclose all this to someone I never met and get their judgement" (participant 02, man, 57 years), highlighting the importance of consistent health care providers for discussing personal and sensitive health issues.

The participants noted that if they received care from a consistent health care provider, whether a physician or nurse, they would be willing to access other virtual care services (eg, from a geriatrician or therapist). Adding additional services and health care providers was often accompanied by discussions about who should be involved in a health care team. The integration of various health care providers into a patient's care team emerged throughout the interviews, as the participants noted that they had some trusted health care professionals that they would continue to interact with in-person (eg, pharmacists), even if they saw the same or new health care providers virtually. The participants noted that other members of the care team need to be managed thoughtfully to support trusting relationships between patients and their health care providers.

> *You can tell when a doctor really cares about me. Like when they just know me and actually remember things. So if I had a doctor who I knew actually cared, I'd be more open to using virtual services because I know they would tell me if I needed to come in. They care enough to be honest, not whatever is easiest for them. But like would I go to everyone virtually? Probably not.* [Participant 06, female, 57 years]

Theme 2: Privacy and Confidentiality in Virtual Care

Privacy emerged as a key theme that influenced participants' acceptance of and preference for virtual care. Some participants noted that they would prefer virtual care, particularly phone consultations, over in-person care, as they would not have to see the care provider and thus, privacy and some degree of anonymity could be maintained. For example, one participant said:

> *sometimes, I worry about them knowing me. So if I could just call someone with a question, maybe I'd appreciate it.* [Participant 09, woman, 70 years]

These participants noted that they appreciated the enhanced privacy that virtual care could provide, such as the ability to discuss sensitive issues like menopause and sexual health, from the comfort and security of their own homes, without the risk of being overheard or recognized in a clinical setting. On the other hand, other participants, particularly those who spoke about living in close proximity with others (eg, partner or family members), noted that they preferred in-person appointments to ensure that their privacy and confidentiality were maintained from others in their lives. One participant shared:

> *Even if you live with a partner you trust, there are things you want to say alone* [Participant 01, man, 55 years]

In relation, some participants noted distrust in virtual care platforms as they were skeptical that these platforms could keep their information secure and private. These participants often shared that they heard from friends or family that companies sometimes sold patient health data. For others, despite being aware of the confidentiality and security measures in place for virtual care across Canada, the participants still harbored concerns that they could not ascertain what a provider would discuss with other health care providers.

Subtheme: Stigma of Registration

A few participants expressed that actively registering for a new virtual geriatric care service could heighten their sensitivity to stigma, as it marked them as individuals with an age-related issue, even if they did not see themselves as older. One participant noted:

> *Bad enough they call the doctors infectious doctors, and now I have to see an old person doctor* [Participant 10, man, 79 years]

To mitigate this, the participants suggested integrating the virtual clinic seamlessly with other primary health care services that they were already receiving. They proposed that all individuals living with HIV should be able to register for a virtual clinic, alongside other existing health care services, allowing them to be able to speak to someone about age-related concerns in a private manner.

Theme 3: Access and Technological Barriers in Virtual Care: Challenges and Solutions

Almost all the participants reported that the COVID-19 pandemic had discouraged them from seeking or attending in-person health care, with less than half of the participants noting that they used virtual care. Despite this, most participants noted that they could access a telephone or computer to access virtual care, even if they had to share the technology with other individuals. For many participants, virtual care allowed them to reduce the time taken off from work to attend appointments and associated costs of appointments, such as gas and parking costs. Other participants, expressed that not having a strong internet connection or personal devices presented an obstacle to virtual care. The participants, without the appropriate technology to access virtual care, noted concerns about accessing a secure location to connect to virtual appointments. These participants also spoke to challenges associated with virtual care due to poor internet connectivity, audio problems, and outdated technology, particularly affecting those in rural areas or without access to high-speed internet. One participant explained:

> *People need to think on a spectrum. Sometimes I may have Wi-Fi, sometimes I may not, sometimes I can't afford my phone bill and that will be turned off. We need to consider something that can always be there.* [Participant 14, man, 50 years]

Subtheme: Technology Training That Goes Both Ways

The participants expressed mixed feelings about the use of technology to access geriatric care. Some highlighted difficulties due to limited technological literacy and hoped health care providers could help them navigate virtual care and electronic health information. However, others were concerned that health care providers might assume they lacked technological skills based solely on their age or HIV status. They also expressed a need for guidance on effectively communicating relevant information to health care providers in virtual settings, especially without nearby support or written instructions. One participant said:

> *My English isn't great so I don't even know how to ask for help. Sometimes in person I can write it down, but online, I don't know.* [Participant 04, male, 82 years]

Despite these concerns, the participants acknowledged that virtual care could play a role in educating health care providers about HIV. They believed that while virtual care might help facilitate this education, sharing personal experiences and knowledge in person was often more effective due to fewer distractions and a more direct communication channel. One participant emphasized this point, stating:

> *They [physicians] can't know everything, even if they read it in a textbook. They need to listen to people like us who are aging and who have HIV and sometimes a lot more* [Participant 03, woman, 74 years]

This reflects a preference for in-person interactions when discussing complex, lived experiences, despite recognizing the potential benefits of virtual care.

Discussion

Principal Findings

The study examined the perceptions of diverse older adults living with HIV regarding virtual care, focusing on supporting age-related conditions and identifying obstacles and pathways. Key findings highlighted the importance of consistent and trustworthy relationships with health care providers, emphasizing the need for continuity in virtual care to build rapport. Privacy was a significant concern, with preferences for virtual or in-person care varying based on individual privacy needs and concerns about data security. Access to technology was another critical issue, with obstacles including poor connectivity, audio problems, and outdated devices, particularly affecting rural participants. The participants also highlighted the need for technological assistance and the opportunity to educate geriatric care providers about the intersection of aging and HIV. The study emphasizes that older adults living with HIV can offer valuable insights to enhance virtual care, helping to overcome obstacles such as distance, mobility, and transportation. Our themes, while addressing important aspects of virtual care, highlight that many issues transcend age demographics and are more specifically related to the virtual aspect of care itself rather than being uniquely tied to geriatric care.

Many of the themes uncovered in this study resonate with findings from prior research conducted among the general older adult population. Other studies with older adults have noted that the potential advantages reported by participants included enhanced convenience, and the ability to conduct consultations within the familiar setting of patients' homes, supporting their comfort [45-47]. Similarly, studies noted that older adults have privacy concerns about the use of their health data [46,48,49]. Moreover, some older adults noted challenges due to a lack of technology and/or technological literacy [24,28]. While our study aligns with previous research on the general older adult population, it offers unique insights by focusing specifically on older adults living with HIV. As such, their perspectives on the importance of privacy and trust-building with health care providers during virtual care may differ from those of the general older adult population. Therefore, health care providers offering virtual care to this population must prioritize strategies to ensure the privacy and confidentiality of patient information, thereby fostering a sense of trust and confidence among older adults living with HIV. In practice, health care organizations offering virtual care should implement policies and protocols designed to safeguard patient privacy and promote trust-building between health care providers and patients, such as allowing additional time for visits and follow-up, and communicating with older adults where the provider is situated during calls [50]. These efforts strive to ensure that virtual care delivery is respectful, nonjudgmental, and tailored to the unique circumstances of each patient.

The study participants expressed a strong desire for consistency in their health care providers, underscoring the importance of trust and familiarity in managing their health conditions. This finding aligns with existing literature, which highlights that continuity of care is crucial for building patient-provider relationships, improving patient satisfaction, and enhancing health outcomes, especially for older adults with complex health needs [51-53]. However, given the scarcity of geriatricians [54,55], relying solely on geriatricians for consistent care is impractical. Older adults living with HIV can benefit from receiving care from specialized geriatric interprofessional teams [55], but the success of such care hinges on the establishment of trust and rapport between patients and health care providers. As a viable alternative, a system of "soft handovers" can be implemented. Soft handovers involve a thorough and empathetic transition process between health care providers, ensuring the new provider is well-informed about the patient's history, preferences, and needs [56]. This approach can minimize disruption and maintain continuity of care, addressing the gap caused by the limited number of geriatric specialists. Implementing soft handovers can ensure that older adults living with HIV receive consistent and comprehensive care, despite the limited availability of specialized geriatricians. However, prior to the handoff, fostering trusting relationships between patients and members of the geriatric interprofessional team, including geriatricians, nurses, social workers, and other specialists, is essential. To build trust, geriatric interprofessional teams must prioritize patient-centered care, empathy, and cultural sensitivity [57,58]. This involves actively listening to patients' concerns, respecting their autonomy, and involving them in decision-making regarding their care [59]. In addition, health care providers should be knowledgeable about the unique needs and experiences of older adults living with HIV, including the physical, psychological, and social dimensions of aging with a chronic illness [60]. By demonstrating competence and understanding in addressing these needs, health care providers can establish credibility and foster trust with their patients in a virtual space.

Numerous studies document how stigma associated with HIV can deter individuals from seeking care or disclosing their condition, leading to disparities in health care utilization and outcomes [61]. Moreover, research on age-related stigma highlights how societal perceptions of aging can influence individuals' self-perception and willingness to engage with services tailored for older adults [62,63]. Strategies proposed by the participants in this study, such as integrating virtual clinics with existing health care services to reduce the visibility of age-related concerns, align with recommendations from previous studies in the realm of mental health aimed at destigmatizing health care access [64]. By incorporating virtual care into comprehensive health care delivery models, health care providers can create inclusive environments where individuals feel comfortable addressing their health needs without fear of judgment or discrimination. However, it is important to recognize that challenges to access may persist, particularly for the most marginalized populations. Individuals facing intersecting forms of stigma and discrimination, such as older adults living with HIV, may still encounter challenges in accessing virtual care services due to systemic inequalities, digital divides, and social determinants of health [65]. Future research should prioritize understanding efforts to address stigma and discrimination within health care settings to be integrated into virtual care initiatives, ensuring that all individuals, regardless of their background or health status, feel valued and respected in their interactions with health care providers. Collaborative partnerships between researchers, health care providers, policymakers, and community organizations are essential for identifying and codesigning solutions that address these obstacles effectively, ultimately advancing equity and accessibility in virtual care delivery.

Limitations

Despite the valuable insights gained from this study, several limitations should be acknowledged. First, the sample consisted of older adults living with HIV in Ontario, which may limit the transferability of the findings to other geographic locations or populations with different health care systems. Another limitation is that all participants had access to technology for virtual care. In addition, most were younger than 60 years, and the majority had been living in Canada for over 10 years. These factors may not be representative of the older adult living with HIV population. In addition, the recruitment strategy primarily relied on community-based organizations and health care facilities, potentially introducing selection bias toward individuals already engaged in health care services. Despite challenges, such as participant availability and interest, efforts were made to encompass diverse perspectives in this study, although our sample may limit the transferability of the findings to other contexts. Furthermore, the study did not explore the perspectives of health care providers or other stakeholders involved in the delivery of virtual care, which could provide complementary insights and perspectives. Finally, the study did not assess the long-term impact of virtual care on health outcomes or health care utilization, which warrants further investigation to fully understand the effectiveness and feasibility of virtual care for this population.

Conclusion

In conclusion, this study illuminates the perceptions of diverse older adults living with HIV concerning virtual care, emphasizing the pivotal role of trust, privacy, and technology access. Using an interpretive qualitative descriptive methodology, we gleaned nuanced insights into participants' preferences and experiences, offering actionable implications for practice and policy. Our findings underscore the imperative of cultivating trusting relationships between health care providers and older adults living with HIV in virtual care settings, necessitating strategies to ensure patient privacy, confidentiality, and cultural competence. Moreover, equitable access to technology emerges as a crucial consideration, with efforts needed to address obstacles such as poor connectivity and technological literacy. Moving forward, collaboration between health care providers and policymakers is essential to develop inclusive virtual care models that meet the diverse needs of this population, ensuring continuity of care, providing technological support, and integrating virtual care seamlessly into existing health care services. While the study's findings provide valuable insights, limitations such as sample scope and generalizability underscore the need for further research to comprehensively understand the long-term impact of virtual care on health outcomes and health care utilization among older adults living with HIV. By embracing the unique perspectives and experiences of this population, we can work toward building more inclusive and responsive health care systems that meet the needs of all individuals, regardless of age, HIV status, or other intersecting identities.

Abstract

Background: In our aging population, primary care is under pressure to remain accessible to all. Effective use of digital health care could potentially lower general practitioners’ (GPs) workload. Some general practices are already implementing a digital health platform as a primary method to contact their patients. However, it is unknown how older people experience this novel way to communicate with their GP.

Objective: The aim of this study was to study the experiences of patients aged 65 years and older in general practices who use digital health as a primary communication tool. The secondary aims were to identify barriers and facilitators for the use of digital health care and whether a practice focus on digital health influences older patients’ choice to enlist.

Methods: We invited all patients aged 65 years and older at 2 general practices in Amsterdam that work with a novel digital health platform. We used purposive sampling to select a heterogeneous group of patients in terms of age, sex, level of education, digital literacy, and experiences with the digital app of their general practice. We conducted 18 semistructured interviews from May through July 2023. All interviews were audio-recorded, transcribed, coded, and thematically analyzed.

Results: We generated three themes: (1) experiences of older people with digital health care in general practice, (2) impact of individual factors on digital health experiences, and (3) reasons for choosing a digitally oriented general practice. Participants reported both positive and negative experiences. The main perceived advantages of the digital health platform were increased accessibility, direct GP contact without an intermediary, and saving time through asynchronous communication. The disadvantages mentioned were log-in difficulties and problems with the automated explanatory questionnaire. Individual factors such as age, digital literacy, and expectations of general practice care seemed to impact people’s experiences and could act as barriers or facilitators for using digital health. Reasons for older patients to enlist at a general practice were mainly practical. The digital orientation of the practice hardly played a role in this choice.

Conclusions: Older patients in general practice see benefits to using a digital health platform that offers 2-way chat-based communication between the patient and GP. We found that individual factors such as skills, norms and values, attitudes toward digitalization, and expectations of general practice care impacted older patients’ experiences with digital health care. For many older participants, the digital profile of the general practice did not play a role in their choice to enlist. Further improvement of digital health platforms will be necessary to ensure digital health for all in general practice.

KEYWORDS

digital health care; digital health platform; general practice; qualitative research; older adults; primary care; mobile phone

Introduction

Primary care is under pressure. The population in Europe is aging, and the prevalence of multimorbidity rises, which will increase the demand on primary care services [1-3]. These developments will be difficult to address by the current capacity of health care professionals. Compared with 2015, British general practitioners (GPs) in 2023 already had to care for 19% more patients [4]. In a Dutch representative survey among GPs in 2022, a total of 82% of participants reported that the current workload was too high [5]. Digital health care is often mentioned as a possible solution to meet increased demand and reduce high workload [6,7].

Digital health can be defined as “the proper use of technology to improve the health and wellbeing of people, as well as enhancing the care of patients, through intelligent processing of data” [8,9]. In 2022, the majority of Dutch general practices already used digital platforms for written e-consults and reorders of medication, with similar use in urban and rural areas [10,11]. Digital health has the potential to improve both efficiency and quality of health care. However, there are risks and challenges in using digital health through these platforms. The main concern is digital inequity since digital health is less accessible for people with lower digital skills, lower (health) literacy, and lower financial status [7,8,10,12-17]. By transforming primary care without regard for digital inequity, we risk further increasing health inequity in society [8,12,13,18]. Older people, aged 65 years and older, relatively often require general practice care while they are less likely to use the internet [19,20]. Issues such as lower digital device skills, difficulties evaluating the quality of information on the internet, and concerns about privacy have been reported as barriers for older people to use digital health [10,13,21]. In designing new digital health platforms for primary care, it is therefore vital to understand and address the difficulties older patients face.

In Swedish primary care, digital health platforms that allow 2-way (asynchronous) chat-based communication between the patient and GP, (synchronous) video communication, and self-registration of patient data using automated questions have been researched in recent years [22-26]. Although proper implementation represents many challenges, these digital health platforms improve accessibility across time and space and are seen as a useful addition to current practice both by patients and GPs [22-26]. However, these studies have not specifically focused on the experiences of older adults with this novel way of communication between patients and GPs.

Recently, a few general practices in the Netherlands have started using a similar digital health platform that offers 2-way chat-based communication. To our knowledge, no scientific studies have been conducted to assess this novel form of digital health in the Netherlands. Our main aim in this study was to investigate the experiences of older patients with this digital health platform. Secondary aims were assessing barriers and facilitators for the use of the app and investigating if a practice focus on digital health influences older patients' choice to enlist.

Methods

Study Design

A qualitative study was performed using semistructured interviews to get an in-depth understanding of the experiences of older people with a novel digital health platform in Dutch general practice. We followed the COREQ (Consolidated Criteria for Recording Qualitative Research) to conduct this study (Checklist 1).

Setting

We performed this study in 2 general practices in Amsterdam, Doccs Slotervaart and Doccs Amstel III. As is common in Dutch general practice, enlisting in these practices as a patient is only possible for people who live in the same postal code area. Both practices have worked with a digital health platform (doccs app; doccs BV) since their start in 2021. The doccs app allows 2-way (asynchronous) chat-based communication between the patient and GP and is designated to be the primary way for patients to contact the GPs. The app is solely a communication tool in which patients can chat with their GP, make appointments, or order repeat medications. The app does not have an automated role in the diagnostic or treatment process and is not linked with the electronic patient record. The app has a 2-factor authentication log-in process and is secured with end-to-end encryption to comply with the General Data Protection Regulations. The app can be used on a smartphone or tablet. The patient starts a chat conversation with the GP through the app when they want to make an appointment or ask a question. The patient is automatically asked several explanatory questions about the complaint (shown in Multimedia Appendix 1) that help the GP provide an answer to the patient's question or prepare for a face-to-face consultation. It is possible for patients to skip these questions. Within practice hours, one of the GPs of the practice will review and provide a direct answer within 1 hour. To ensure accessibility for all, it is made clear to patients that use of the app is not required to enlist as a patient because appointments can also be made by telephone or by visiting the practice.

Recruitment of Participants

At the time of recruitment, the total number of patients in the practices was 5055. We approached all patients aged 65 years and older in both practices (N=163) by postal mail. We sent the first invitation on May 19, 2023, and a reminder letter on June 8, 2023. Both letters contained an invitation, study information, and an informed consent form. In total, 54 (33%) patients responded that they wanted to participate. We called all respondents and used purposive sampling to select a group that was heterogeneous in age, sex, level of education, digital literacy, and experiences with the digital health platform. The level of education was assessed according to the Dutch Statistical Office [27]. Perceived digital literacy was assessed by using the eHealth Literacy Scale (eHEALS) questionnaire, which is validated for use in older Dutch adults [28-30]. All respondents provided written informed consent. Within reflexive thematic analysis, the term data saturation is deemed less useful since there are always new theoretical insights possible when data continue to be collected [31]. Regarding the breadth of our research questions and pragmatic considerations, we hypothesized that we would need to conduct 10 - 20 interviews. The final sample size was determined in the process of data collection and reviewing data quality. Recruitment continued until the research team agreed that the data set contained enough richness and complexity to address the research questions.

Interviews

All interviews were performed in Dutch from May through July 2023. We compiled the topic list based on discussions within the research team and previous research [8,10]. During the interviews, the interviewer constantly revisited the topic list and added items when relevant (final topic list in Multimedia Appendix 2). Most interviews took place at the patient's home or the general practice, 1 interview took place at the Amsterdam University Medical Centers. The interviews lasted 22 to 66 minutes. The lead author (HRK) performed all interviews. She explained to patients beforehand that she was not linked to the doccs general practice and guaranteed patients that their audiotape would be deleted after transcription. All interviews were audiotaped and transcribed verbatim.

Analysis

We used a reflexive thematic analysis approach according to Braun and Clarke [32-34]. After reading the transcripts several times, the data were coded by 2 authors (HRK and HTNN) with an inductive orientation. At the time, HRK was a medicine master student in her final year of training, and HTNN was a general practice resident and PhD student. HRK had an open view toward digital health for older adults in general practice but was mindful of the dangers it may pose to the accessibility of care, especially for older patients. HTNN shared those concerns, but as a PhD candidate who researched the implementation of a web-based treatment for chronic dizziness in general practice, she also had a lot of positive experiences with older patients using digital health. HRK and HTNN separately coded the first 2 transcripts and then reflected together on the story within the data. After their discussion, HRK continued coding the other transcripts to further analyze the data. Next, HRK assigned codes to generate initial themes and subthemes which were visualized in a mind map. This preliminary analysis was discussed in a meeting with HRK, HTNN, and VAvV. Afterward, HRK continued analyzing the data, also performing selective coding, in which she conceptualized each theme further, searched for relations across cases, and analyzed variation within and between the cases. She visualized this in mind maps, code matrices, and code-relation matrices to gain insight into the spectrum of different factors influencing patients' experiences. The final results were discussed with the project team (HRK, VAvV, and ORM). Interviews were analyzed in Dutch using MAXQDA (version 2022; Verbi Software). After completion, all themes, subthemes, codes, and quotes were translated into English by the authors.

Ethical Considerations

The study received institutional research board approval by the medical ethics committee of the VU University Medical Center (2023.0001). The study was conducted in accordance with the ethical standards of the responsible committee. All participants included in the study provided written informed consent. Data were deidentified after collection and handled in accordance with the Amsterdam Public Health research institute code of conduct, following General Data Protection Regulation rules. Participants received no financial compensation to participate, but travel costs, when applicable, were reimbursed.

Results

Overview

We conducted and analyzed a total of 18 interviews with older patients before the research team agreed the data set was rich and complex enough to answer the research questions. Characteristics of participants are described in Table 1.

Table . Participant characteristics.

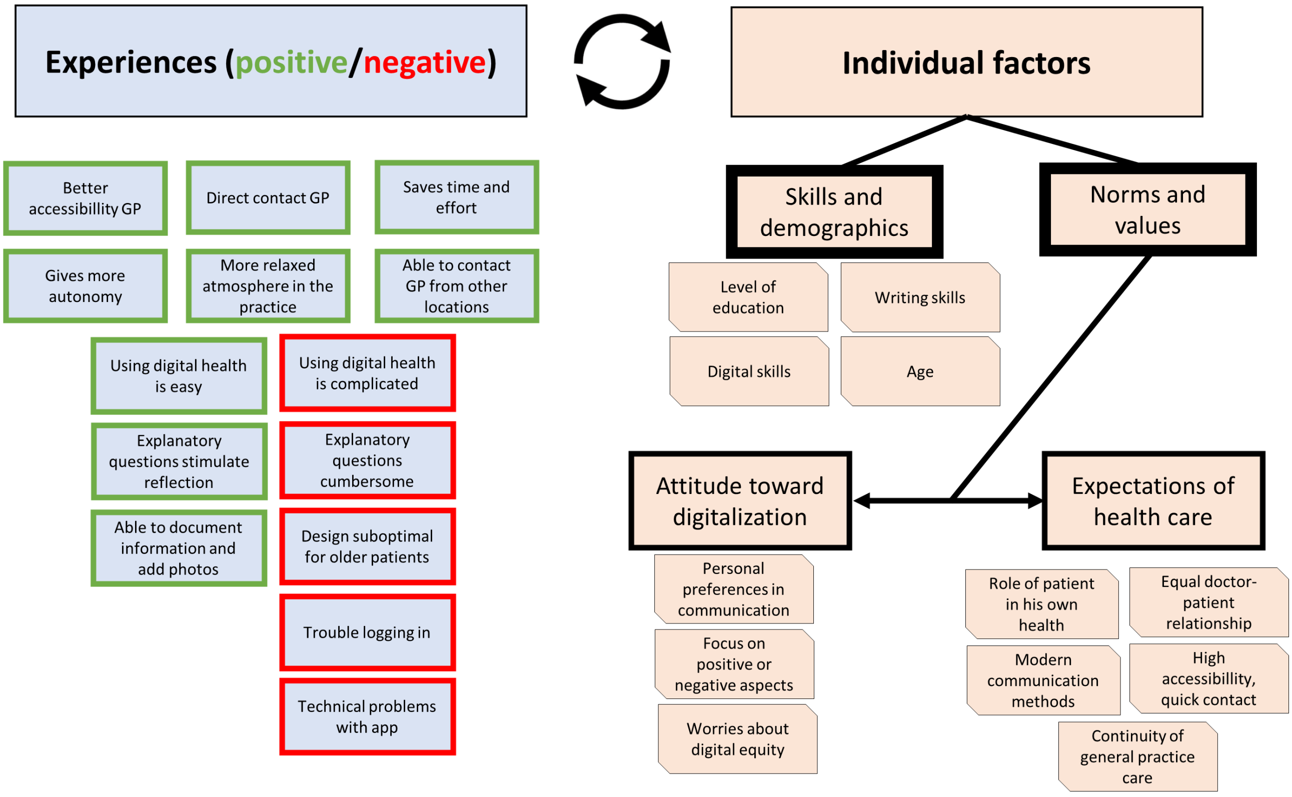
Participant	Sex	Age (years)	Digital literacy[a]	Level of education[b]
A	Male	69	29	High
B	Female	68	39	High
C	Male	77	31	High
D	Female	69	40	High
E	Female	70	36	High
F	Male	70	30	High
G	Female	69	33	High
H	Female	71	26	Intermediate
I	Female	84	14	High
J	Female	79	27	Intermediate
K	Male	71	32	High
L	Male	68	35	Intermediate
M	Female	69	27	Intermediate
N	Male	73	29	Intermediate
O	Female	71	33	Low
P	Male	83	22	Low
Q	Female	68	29	Intermediate
R	Female	89	18	Intermediate

[a] eHealth Literacy Scale score is used to measure digital literacy. Range 8 - 40 points; a higher score indicates better perceived digital literacy [28-30].

[b] Level of education is divided into low, intermediate, and high in accordance with the national Dutch Statistical Office [27].

We generated three main themes: (1) experiences of older people with digital health care in general practice, (2) impact of individual factors on digital health experiences, and (3) reasons for choosing a digitally oriented general practice. The first theme is divided into (1a) positive experiences with digital health care and (1b) negative experiences with digital health care. The second theme is divided into (2a) skills and demographics and (2b) norms and values. In Figure 1, we show a graphical overview of themes 1 and 2 with their subthemes.

Figure 1. Digital health for older patients in general practice. GP: general practitioner.



Theme 1: Experiences of Older People With Digital Health Care in General Practice

Subtheme 1a: Positive Experiences With Digital Health Care

Several participants had good experiences with the digital health platform of their general practice. They found the app easy to navigate and user-friendly. The speed with which they came into contact with a GP was one of the main advantages.

> *Because, I have to say, when I send a message, they respond almost immediately.* [Participant B]

Several participants found having more direct contact with their GP (without an intermediary) beneficial. Participants value the time and effort that they save by having digital asynchronous contact instead of calling or visiting the practice.

> *I don’t always have to call, do I? So I can just ask questions and get answers. Yes, I like that very much. [Interviewer: And why do you prefer this instead of calling?] That takes too long. Then I first get an assistant, and either the GP is busy, or he is talking to someone else. That’s nice, I believe all that, but I have a question. And now I can ask him and I will get an answer. So I like that.* [Participant L]

Other positive experiences were mainly due to opportunities that are specific for using a digital health platform to communicate with the practice, such as sending photos for dermatological issues, easily coming into contact with a GP when on holiday, and experiencing autonomy by making appointments and viewing laboratory results on the web. In addition, a few participants liked to have some time to reflect before they reply to a doctor, which is harder during a physical consultation. By chatting digitally, they have the opportunity to ask questions that would not always come to mind during a consult. A few participants liked the explanatory questions upfront because it helped them reflect on why exactly they contact the GP and activated them in their own health as well. A few participants experienced a more relaxed atmosphere in these general practices compared with other practices, due to an empty waiting room, the doctor being on time, and not constantly hearing ringing phones and assistants talking on the phone.

Subtheme 1b: Negative Experiences With Digital Health Care

Some participants experienced the app as complicated, and a few participants found the app too difficult to use at all. The main issue was logging in with different passwords and using a 2-factor authentication process. One of the other things that some participants experienced negatively is the automated explanatory questionnaire that they were asked to fill out at the start of each new contact with the practice. Participants found it either not relevant to their question (eg, they wanted to ask for test results and first had to answer questions like “at which moments do you experience your symptoms?”) or cumbersome because of the number of questions.

> *I just find it a bit cumbersome....I’m not just going to ask nonsense.* [Participant L]

Some minor issues also impacted participants’ experiences negatively. A few participants would prefer the app to open with a clear menu with different options instead of a direct question “how can we help you?”. In addition, a few participants experienced some technical hiccups, mainly when the practice just started. Furthermore, a few participants suggested the design of the app should be better suited to older patients, with big font size, buttons in the middle of the screen rather than in the corners, and multiple-choice options for ordering medication instead of typing. In addition, a few participants would have liked the possibility to use the digital app on a computer rather than a smartphone or tablet, so it is easier for older people to type longer messages.

Theme 2: Impact of Individual Factors on Digital Health Experiences

Subtheme 2a: Skills and Demographics

Perceived digital skills seemed to play an important role in experiences with digital health. The eHEALS questionnaire can produce scores between 8 and 40, with higher scores representing higher self-perceived digital literacy [28-30]. The digital literacy of participants varied much, with eHEALS scores ranging from 14 to 40. One participant did not use a smartphone or other digital devices and therefore did not use the app at all.

> *I don’t use the app myself....Then I should need to know how to make contact in the first place, therefore I need a password and, oh well... [Wife: he is a computer illiterate, and this is way too complicated for him.]* [Participant P]

One participant, who scored 29 points relatively high on the eHEALS scale, was afraid that he could not keep up with the speed of digitalization.

> *Because the speed of electronics and stuff, it goes so fast and so quick. And as long as we can follow it, through the apps and iPad and iPhone, I think it’s fine, very well. But it’s something that frightens me, that the moment may come when I can no longer keep up.* [Participant N]

Next to digital skills, also reading and writing skills determined people’s experiences, as using the digital health platform mainly consists of reading and writing messages. None of the participants had difficulty reading, but a few had difficulties putting their symptoms into words while typing in the app.

> *Well I think, you have to be able to clarify, as a patient. You have to...Yes, actually be able to clearly tell...what you have and what you want. But I think in that situation, I would call the front desk receptionist, if I really couldn’t figure it out, I would call.* [Participant G]

Finally, we saw that few participants who were the oldest (age 79 years and older) more often reported bad experiences or did not use the app at all. In younger participants (younger than 78 years), the experiences differed, but all of them used the app (to some extent). Next to that, we observed that the people with a high level of education had predominantly more positive experiences than negative ones. In contrast, participants with a lower level of education more often had negative experiences with the app.

Subtheme 2b: Norms and Values

Attitude Toward Digitalization

Personal preferences in communication seemed to be a factor in experiences with digital health. Many participants considered chat-based communication to be of added value because it is fast, they can do it in their own time (asynchronous communication), and it is accessible. However, several participants preferred contact via telephone or face-to-face. These communication methods were more familiar to them and were viewed as more personal. In contrast, a few participants stated chat-based communication was something they would participate in with family and friends but not with a doctor. Many of the participants thought video calling was not of added value; however, some saw it as an added value for situations in which they are immobilized. Furthermore, participants’ attitude toward digitalization in society and health care appeared important. Almost half of the participants liked digitalization because it makes information more accessible and improves communication. Some people focused on disadvantages, for example, dangers in privacy and a more individualized society. Some participants simply found it redundant.

> *Well I don’t think it’s necessary. It’s more, the nonsense...You are often talked into needs. You have to do this now, you have to do that now.* [Participant D]

A few participants worried that in digital interaction, relevant emotions such as fear are lost. Opinions on the topic of searching for digital health information varied. Most participants seek information to some degree, but a few do not, mostly because digital health information can scare them. Opinions about receiving digital health information from their GP varied as well. Some liked it because it is efficient and easy, while others found it the GP’s task to inform the patient instead of sending information.

> *Do I have to read what he studied for? Come on...* [Participant J]

A factor that impacted some participants’ experiences is problems with accessibility, leading to digital inequity. To several participants, it did not impact their own experiences, but it did worry them that other older adults might not be able to access care if communication would be (solely) digital. Participants mentioned different forms of possible digital inequity. Two of those are the difficulty of digital apps (discussed in Subtheme 1b) and the level of digital skills (discussed in Subtheme 2a). Other concerns that were mentioned were that assistance with using digital health care is hard to arrange, learning and remembering new things are harder for older patients, the use of digital tools can be complicated by medical issues, and certain monitors (eg, blood pressure monitor) needed for home measurement may not be affordable or easy to use by all patients. However, some participants also mentioned that to them accessibility was increased by digital care due to easier contact, the possibility to have contact while abroad, and having insight into their own test results.

Expectations of Health Care

Participants' expectations of health care in general also affected how they viewed digital health care. Some participants mentioned that they expect their GPs to apply modern communication methods.

> *At the previous general practitioner, prescriptions were still sent to the pharmacy by fax. And...you couldn't email, you couldn't chat. You were purely like "there are so many people waiting in front of you" on a landline phone. So yeah, their way of doing things was a little outdated, if you know how things are here.* [Participant F]

Many participants said that they expect their GP to listen carefully, take them seriously, and provide solutions. Some participants talked about valuing an equal doctor-patient relationship, in which a doctor empowers a patient by involving them in the diagnosis and decisions. They found that the app increased empowerment because when chatting, both patients and GPs use first names, the GP sends information for the patient to read themselves and involves them with different options for the next steps (eg, come to practice, wait, try lifestyle changes, and try medication). In the general practices, messages by patients were answered by the team of GPs, depending on who worked that day, to ensure each question in the app was answered as soon as possible. Some participants who valued continuity of care found it a disadvantage that the messages were not always answered by their own regular GP. However, other participants who valued accessibility and logistics more did not see this as a problem.

> *[Interviewer: what is important to you in contact with your GP?] Accessibility. For this the app is fantastic because they don't have to be open at all....As long as they respond. Right? Well, they do within 24 hours. What else do you want? Well, I think it's great.* [Participant D]

The way older participants viewed self-management of health varied. A few participants mentioned they did not want to play an active role in their own health management. They preferred to let the GP decide which actions were needed and preferred to have all measurements conducted in the practice. However, many participants preferred an active role in their health in some way. For instance, they were open to perform measurements at home and send them to the GP via the app. One participant stated that he saw his health as his own responsibility.

> *Yes exactly! Yes, it's my health. And I think it's great that I can talk to a doctor about that. Not only can, but sometimes must....But it's still my thing.* [Participant C]

Theme 3: Reasons for Choosing a Digitally Oriented General Practice

For many participants, the digital health platform of these practices did not play a role in their choice of practice. Most participants chose their practice because of practical reasons (location of practice, room to enlist new patients, and partner joined the practice) or because they were unsatisfied with their previous GP. Some participants chose these practices because they wanted a more modern practice (different ways of communication and young doctors) or they wanted more accessible communication. For some participants, however, the presence of digital tools was one of the reasons to enlist.

> *To me it is easier to write something down if I have something, than to go to the doctor right away. So now I am more in contact with the doctor than I would have if I had to go to a normal doctor.* [Participant M]

The reasons for choosing the digitally oriented general practices did seem to affect patients' experiences. Participants for whom the digital tools did not play a role in their choice or who chose the practices because of different reasons (eg, the partner enlisted so they joined) were slightly more negative about the digital health platform and mainly found it complicated. In contrast, participants who enlisted in these practices because they had bad experiences with their previous GP or wanted an improvement in communication had predominantly positive experiences with the digital health platform. The same applies for participants who enlisted in these practices specifically because they wanted to use more digital health tools.

Discussion

Principal Results

Our main aim in this study was to investigate the experiences of older patients in general practice with a digital health platform that offers 2-way chat-based communication between the patient and GP. As expected, participants reported both positive and negative experiences with the digital app. The most important advantages of the digital health platform were described by participants as increased accessibility of the general practice for different health complaints, direct contact with the GP without an intermediary, and saving time because of asynchronous communication between the patient and GP. Disadvantages were that for some participants, use of the platform was complicated, logging in with 2-step authentication was difficult, and filling out the automated explanatory questionnaire was found to be cumbersome or irrelevant to their care request.

Our secondary aims were to assess barriers and facilitators for the use of the app and investigate if a practice focus on digital health impacted older patients' choice to enlist. Our findings suggest that many different individual factors impacted people's experiences with digital health care. Barriers to the use of the digital health platform in general practice appeared to be low digital and writing skills, higher age, and a low level of education. Negative attitudes toward digitalization in general, a preference for face-to-face contact with the GP, and a wish for all health questions to be handled by their own regular GP were also seen as barriers to use the app in its current form. There were also some app-related barriers in details of design and user-friendliness such as small font size. Facilitators for using the digital health platform were being digitally skilled, being highly educated, having a preference for an equal patient-GP relationship, the good accessibility of a GP, and a wish to unburden the GP. Surprisingly, for many older participants, the special focus of the practice on digital health (which was also advertised on the website) did not play a role in their choice to enlist. Logistical reasons or bad experiences with their previous GP were the main reasons to switch to their current general practice.

Strengths and Limitations

Our study has several strengths. First, to find a representative sample of older patients who used the digital health platform, we invited all patients aged 65 years and older who were enlisted in the general practices. To find a more heterogeneous sample, we conducted a second invitation round so we were able to select more patients who were relatively old, less digitally skilled, and less educated. In the end, by using purposive sampling and continuing until the research team decided the data set was rich and complex enough, we were therefore able to attain various samples in terms of age, sex, level of education, and digital literacy. Second, all interviews were performed by the same interviewer, and the interview location was chosen by the participant. This assured that there was no interrater difference and helped participants speak freely during the interviews.

There were also some limitations. First, some participants did not use the digital app but answered how they think they would experience the functions of the digital health platform. Therefore, not all participants were able to comment on all aspects of the digital health platform. However, because expectations of experiences of older patients with digital health may help guide the development of future digital health platforms, we decided to also describe these hypothetical experiences separately. Second, our conclusions on the digital literacy of our participants should be interpreted with care. Digital literacy is a complex concept to measure. We chose to use the eHEALS because this is the only widely used questionnaire that is validated for use in Dutch older adults [28-30]. However, the eHEALS only focuses on perceived literacy as stated by patients and misses questions about skills like logging in with passwords. For future studies, we would consider complementing the eHEALS questionnaire with another established questionnaire such as the Mobile Device Proficiency Questionnaire to measure digital literacy more accurately [29,35].

Interpretation of the Results and Comparison With Prior Work

As far as we know, this is the first study to assess the experiences of older patients with a digital health platform that offers 2-way chat-based communication in Dutch general practice. The willingness for older patients to digitally communicate with their doctor has been often described [10,15,36]. The advantages of digital health platforms mentioned by our older participants, such as increased accessibility of the general practice [37], direct contact with the GP without an intermediary [38], and time-saving because of asynchronous communication [37-39], were also found in previous studies. The problems participants in our sample experienced with logging in are considered a barrier for many digital health platforms [40]. Our participants mentioned that at a high age, it is already hard to remember passwords, while a 2-step authentication is even more complicated. However, for data security reasons, this 2-step authentication is legally obligated by the Dutch General Data Protection Regulations [41]. Although the importance of privacy of health care data cannot be overstated, current requirements limit accessibility of digital health for older patients and may therefore increase digital inequity [40]. Developing methods to ease the log-in process for end users, while still attaining adequate data security, will be essential to ensure digital health for all in the future. Swedish studies that evaluated the GP perspective of a digital health platform with 2-way chat-based communication were very positive about using automated questionnaires to better triage and prepare visits to the general practice [24,42]. This could be an important tool in reducing workload in general practice. However, in our study, some participants experienced the automated questionnaire as cumbersome or not relevant. Explaining to patients why these questions matter and attempting to keep this questionnaire as succinct and to the point as possible will be necessary to achieve broad implementation.

In our study, we found potential barriers and facilitators for the use of digital health by older patients in general practice. Because this is a qualitative study, no inferences can be made about the prevalence of phenomena, and further quantitative research will be necessary to further explore these findings [43]. However, the impact of age, digital literacy, and level of education on digital health has been often described in previous studies and implies a digital divide in which people have unequal access to important parts of society [15-17,44]. A more novel finding in our study is the way how expectations of older patients from general practice care affected their experience with digital health. We found that valuing an equal doctor-patient relationship that causes patient empowerment may be a facilitator. However, patients who wanted all health questions to be handled by one regular GP were less happy with the current form of the digital health platform. This is an important finding because personal continuity of care is a core value of general practice and offers multiple benefits to both patients and GPs [45]. When general practices use a digital health platform, choices have to be made when handling care requests. The digital health platform we assessed allowed all care requests to be primarily answered by a GP who was on duty, even when this was not the patient's regular GP. This ensured that questions that request immediate care could also be asked digitally but limited personal continuity of general practice care. The value of personal continuity of care in general practice has been well demonstrated for both patients and GPs [46,47]. However, the optimal way to achieve personal continuity in a digital health context is still mostly unknown and deserves further study [37,48]. Early in development, future digital health platforms in general practice should view improving personal continuity of care as an essential feature.

By focusing on strengthening this core value of general practice, the introduction of digital health can change from a threatening development to a protective factor. Our study showed that the reasons for older patients to enlist in a practice were mostly practical. Surprisingly, for most older participants, the option of digital health care did not influence their choice for the practice. This is at odds with previous studies that stated that digitally oriented practices attract only digitally minded, young, and skilled patients [37,38,49]. This is further confirmation that digital health platforms for general practice should be designed to be accessible to all to reduce the risk of increased health disparities by the digital divide.

Implications for Research and Practice

For Practice

This research shows that a digital health platform in general practice with 2-way chat-based communication can offer benefits to older patients, but nondigital routes remain important. When developing digital health platforms, it is important to think of details that improve user-friendliness for older patients. An automated explanatory questionnaire may help make the GP work efficiently, but for patients, it should be succinct and to the point, and its importance should be explained clearly. When general practices consider implementing digital health platforms, it is good to know that for older patients this aspect may not play a role in enlisting in a practice.

For Research

To ensure digital health for all, future studies should focus on other patient groups who may struggle with the use of digital health platforms in general practice. Interviewing younger patients with a low socioeconomic position, low level of education, or low (digital) literacy could complement our findings. Furthermore, we found several potential barriers and facilitators for older people in using digital health. Large-scale quantitative research could be helpful to further assess the effects of these factors in daily practice. Finally, continuing scientific work on the effects of digital health platforms on the core value of personal continuity of care will be essential to ensure that digital health can be sustainably implemented in general practice.

Conclusions

This qualitative study showed both positive and negative experiences of older patients in general practice with a digital health platform that offers 2-way chat-based communication between patients and GPs. In assessing barriers and facilitators for the use of the app, we found that individual factors impacted older patients' experiences with digital health care such as skills, norms and values, attitudes toward digitalization, and expectations of general practice care. For many older participants, the digital profile of the general practice did not play a role in their choice to enlist. Further improvement of digital health platforms will be necessary to ensure digital health for all in general practice.

Acknowledgments

The authors thank all participants and general practitioners who participated in the study. The general practitioners received funding from the "Future proof general practice" program of the Regional Organisation of General Practitioners in Amsterdam (ROHA) to cooperate in the study. The authors received no specific funding for this study.

Authors' Contributions

VAvV conceived and designed this study. HRK included the participants and collected the data. HRK and HTNN performed the data analysis. HRK drafted the first version of the manuscript, HTNN, VAvV, and ORM provided feedback and input.

Conflicts of Interest

HRK, HTNN, and ORM have no competing interests to disclose. VAvV is employed both as a researcher at the Amsterdam UMC and as a general practitioner in one of the general practices where the digital health platform was tested. He was not involved in the primary development process of the digital health platform.

Abstract

Background: eHealth literacy is an essential skill for pursuing electronic health information, particularly for older people whose health needs increase with age. South Korea is now at the intersection of a rapidly digitalizing society and an increasingly aged population. eHealth literacy enables older people to maximize the effective use of emerging digital technology for their health and quality of life. Understanding the eHealth literacy of Korean older adults is critical to eliminating the gray digital divide and inequity in health information access.

Objective: This study aims to investigate factors influencing eHealth literacy in older Korean adults and its impact on health outcomes and eHealth use.

Methods: This was a cross-sectional survey. Community-dwelling older adults 65 years and older in 2 urban cities in South Korea were included. eHealth literacy was measured by the eHealth Literacy Scale. Ordinal logistic regression was used to analyze factors associated with eHealth literacy and multivariate ANOVA for the impact of eHealth literacy on health outcomes and eHealth use.

Results: In total, 434 participants were analyzed. A total of 22.3% (97/434) of participants had high eHealth literacy skills. Increasing age, higher monthly income, and time spent on the internet were significantly associated with eHealth literacy ($P<.001$), and social media users were 3.97 times (adjusted odds ratio 3.97, 95% CI 1.02 - 15.43; $P=.04$) more likely to have higher skill. Higher eHealth literacy was associated with better self-perceived health and frequent use of digital technologies for accessing health and care services ($P<.001$).

Conclusions: Disparity in socioeconomic status and engagement on the internet and social media can result in different levels of eHealth literacy skills, which can have consequential impacts on health outcomes and eHealth use. Tailored eHealth interventions, grounded on the social and digital determinants of eHealth literacy, could facilitate eHealth information access among older adults and foster a digitally inclusive healthy aging community.

Introduction

Declining fertility rates and longer life expectancy primarily contribute to the demographic transition into an aging population worldwide. This transition is more prominent in Asia, where Japan, South Korea, China, and Singapore entered the aged society within a period of 20 years. In 2021, South Korea hosted 8.71 million people aged 65 years and older (16.8% of the total population), and the proportion increased by 5.1% compared to 2020 [1]. The rapid increase in the older population underscores the importance of an age-friendly environment in which older people can think or do what they value and age in a place to which they are attached.

Nowadays, with technological integration in every aspect of life, digital inclusiveness has become a basic component of an age-friendly environment. Traditional health promotion and long-term care systems could be upgraded into more productive and efficient systems with the diffusion of technology and digital devices. Gerontechnology, an emerging scientific field applying technological advances in the aging sector, is now used to improve health and social connections among older adults [2]. It is more evident in the COVID-19 pandemic, where physical distancing was inevitable. Digital health promotion activities and exercise videos were used to maintain over 20-year-old community exercise programs in Japan and preserve older people's functional mobility [3]. The application of robotic technology for social connections of residents also showed better engagement and positive user perception in long-term care facilities compared to conventional methods such as telephone communication [4]. Additionally, older adults have a positive attitude toward using digital technology and are willing to use it for health purposes and to maintain activities of daily living [5,6].

Although older people have a positive attitude and are willing to use digital health interventions and devices, they face challenges and limitations when adopting digital technology. First, having access to digital devices and networks is the initial step in adopting digital technology and its associated interventions [7]. Aged countries, such as Japan, South Korea, and Singapore, prioritized digitalization and promoted and implemented policies for digital inclusiveness [8]. Due to government efforts, the gap in access to digital devices and the internet has narrowed. In 2022, the digitization level reached 76.2% among South Korea's vulnerable populations (older people, low-income individuals, people with disabilities, fishermen, and farmers), and digital access was as high as 96% of the total population [9]. Regarding older people, 69.9% had access to digital information in 2022, increasing from 69.1% in 2021 [9]. Ownership of digital devices and access to the internet do not guarantee the actual application of digital technology for health. Another barrier for older adults to fully embrace the benefits of technology is not knowing how to acquire and use information obtained in the digital context to make effective health decisions [10].

According to Norman and Skinner [11], eHealth literacy is defined as "the ability to seek, discover, evaluate and appraise eHealth information and apply the acquired knowledge to solve health problems." Older adults often see eHealth literacy as a barrier to successfully using electronically delivered health information and interventions [10]. Due to technological advancements, health information is one-click away, and older adults are faced with information overload, in which misleading information could be exposed physically and digitally. On the other hand, internet use for health-related searches by older American adults increased from 24.8% in 2009 to 43.9% in 2018 [12]. Due to the prevalence of chronic diseases and age-related disorders in older age, there are pros of searching health information on the web. However, older adults could be harmed by fake information on the web if they lack adequate skills to identify the correct source and facts. Therefore, being eHealth literate is essential, and exploring the factors associated with older adults' eHealth literacy is crucial.

Extensive research has shown that age, sex, level of education, marital status, economic conditions, and social support contribute to the eHealth literacy of older adults [13]. Arcury et al [14] stated that internet use is positively associated with eHealth literacy. Little published data exist on the relationship between social media and eHealth literacy, especially in older populations. In addition, having a good command of eHealth literacy skills enhances the physical, mental, and social well-being of older people [15]. Higher eHealth literacy skill is a protective factor against cognitive decline and is positively associated with health-promoting behaviors and better health outcomes [16,17]. There have been few attempts to investigate the impact of eHealth literacy on perceived health status and the use of digital devices and the internet for health, particularly in the older population. The need for scientific literature in this field is more urgent in South Korea, which is becoming a super-aged society, and the proportion of older adults is expected to be as high as 44% in 2050 [18]. Additionally, the Ministry of Health and Welfare in South Korea started a pilot project to use artificial intelligence and the Internet of Things to improve the health care of older adults [19]. Advanced technology is readily diffused into the daily lives of older Korean adults, and knowledge of embracing eHealth information becomes inevitable. Therefore, this study aims to fill the gap by exploring the factors associated with eHealth literacy in community-dwelling older Korean adults and the impact of eHealth literacy on health-related outcomes and digital technology use for health purposes.

Methods

Participants, Setting, and Data Collection

It is a community-based survey conducted in 2 urban cities of the Republic of Korea, Wonju-si and Yeoju-si, in 2022. This cross-sectional study is part of the digitally inclusive healthy aging communities study, a cross-cultural study in 4 rapid aging countries: Japan, the Republic of Korea, Singapore, and Thailand [20]. After obtaining ethics approval, participation in the study was announced in the study area. It was accomplished through the cooperation of local senior welfare centers and senior citizen centers. Community-dwelling older adults aged 65 years and older, both male and female adults with ongoing health promotion activities in residing communities, were included in the study.

The sample size was calculated by 1 sample estimation of proportion in Stata SE (version 16.0; Stata Corp) based on the proportion of internet use among older adults in South Korea. The calculated sample size was inflated by 20% for nonresponses. A sample of 444 participants responded to the questionnaire, and 434 were analyzed after excluding 10 participants who were younger than 65 years.

Ethical Considerations

The Juntendo University Ethical Committee (approval E22-0057-M01) and Yonsei University Institutional Review Board (approval 1041849 - 202304SB-073-02) approved the ethics of the digitally inclusive healthy aging communities study. Participation in the study was completely voluntary. The study’s purposes and procedures were thoroughly explained, and written informed consent was obtained. Data were collected using a structured questionnaire in the participants’ native language (Korean). The data were anonymized and identifiable features were not included. The participants were compensated with a financial incentive equivalent to US $10 for answering the questionnaire.

Measures

Demographic Characteristics

Demographic characteristics of age, sex, education, living arrangements, and financial status were investigated. Age was described as a continuous variable for distribution and divided into 4 categories (65-70, 71-75, 76-80, and >80 years) for eHealth distribution and regression analysis. Education was asked for the highest level of completed education, with 4 groups (did not go to school, primary school completed, junior high school completed, and high school and above). For living arrangements, the participants were asked whether they lived alone or with someone and categorized into living alone, living only with a spouse, and living only with children or grandchildren. Financial status included average income per month based on the 4 income quartiles in South Korea, which is divided into 2 groups of low (less than or equal to 1 million Won; a currency exchange rate of ₩ 1=US $0.0008 is applicable) and high (more than 1 million Won) and a dichotomous question on receiving a pension of any type.

Internet Use and Social Media Use

We determined internet use by a dichotomous question about the internet use derived from the internet environment and digital devices used to access the internet. The frequency is then determined by number of hours per day and number of days per week spent on the internet. Negative responses in the dichotomous question, 0 hours and 0 days of using the internet, were defined as internet nonusers. Positive responses in the dichotomous question, more than 0 hours and 0 days of using the internet, were defined as internet users. Engagement in 1 or more social media platforms prevalent in South Korea determined social media use.

Health-Related Outcomes and eHealth Use

Self-perceived health status was measured using a single-item 4-point Likert scale (1=very healthy to 4=not healthy at all). A single-item 4-point scale has been used to reflect the subjective health status of community-dwelling older adults in longitudinal and cross-sectional studies and to predict mortality, health outcomes, and digital use among older adults [21-24]. Annual medical checkup was measured using a 5-point Likert scale ranging from 1=never to 5=always, and the participants were asked how frequently they participated in regular medical checkups. The technology used in health was measured by how often participants used the internet and digital technology to improve eating habits and access health care and long-term care services. The scale was a 5-point Likert scale ranging from 1=never to 5=always. For analysis, annual medical checkups, digital technology, and internet use for health purposes were regrouped according to their participation and frequency of use as never or nonuser, low participation or low user, and frequent participation or frequent user.

eHealth Literacy

eHealth literacy was measured by an 8-item 5-pointed eHealth Literacy Scale (eHEALS) developed by Norman and Skinner [25]. The scale was developed using the Lily model of eHealth literacy, which consisted of 6 aspects (healthy, traditional, information, scientific, media, and computer literacy). The scale tends to measure perceived skill and comfort with eHealth rather than the actual skill itself [25]. Although eHEALS was primarily developed for using computers for health purposes, it has been validated with the use of mobile devices and social media and shows good reliability [26,27]. In this study, the scale has a Cronbach α reliability coefficient of 0.99, which indicates high internal consistency and reliability. For distribution, eHealth literacy is categorized into 3 groups: lack of eHealth literacy (eHEALS 8 - 15.9), low to moderate eHealth literacy (eHEALS 16 - 31.9), and high eHealth literacy (eHEALS 32 - 40) [28].

Statistical Analysis

The statistical analysis was done by using Stata SE (version 16.0; StataCorp). Sociodemographic characteristics, the use of the internet and social media, eHealth literacy, self-perceived health, annual medical checkups and eHealth use for improving eating habits, and access to health care services and long-term care services were described by descriptive statistics. Frequency and percentage were used to describe categorical data and mean and SD for continuous data. The normality of the data was checked by using the Shapiro-Wilk test. The distribution of eHealth literacy across sociodemographic factors, internet, and social media use were described by descriptive statistics. A Kruskal Wallis H test and Mann-Whitney *U* tests analyzed the difference in mean scores.

Ordinal logistic regression was used to identify factors influencing eHealth literacy. Univariate ordinal logistic regression treated eHealth literacy as the dependent variable and age, sex, education, monthly income, pension receiving status, living arrangement, internet use, and social media use as independent variables. The statistically significant variables (*P*<.2) and conceptually relevant variables were included in the multivariate analysis. Association was reported as an adjusted odds ratio (aOR) and 95% CI. Statistical significance is defined as a *P* value ≤.05 with a 95% CI. Age, sex, income, and education were included as covariates in the multivariate analysis.

Furthermore, multivariate analysis of variance was applied to assess the difference in health-related outcomes such as perceived health status, annual medical checkup, and eHealth use to improve eating habits, access to health care, and long-term care services among the different orders of eHealth literacy. The covariates for the impact of eHealth literacy on health outcomes and eHealth use were age and sex.

Results

Overview

The mean age was 76.8 (SD 6.6) years, and participants 80 years and older occupied 30% (131/432) of the total sample. Of the total sample (N=434), 315 (72.6%) were female, and 192 (44%) participants of the sample had primary school education or lower. A total of 136 (31.5%) older people lived alone, 341 (78.6%) had monthly income lower than or equal to 1 million Won, and 385 (88.7%) received a pension (Table 1). Regarding digital technology use (N=434), 208 (47.9%) participants used the internet, and 184 (42.4%) engaged in social media. The mean days of internet use in a week were 2.4 (SD 2.9), and the mean hours of internet use in a day were 0.8 (SD 1.4). Over one-third of the sample population spent more than 3 days a week (142/404, 35.2%) and 1 - 2 hours a day (155/404, 38.4%) on the web. The mean of the eHEALS score was 15.4 (SD 10.8). Over half of the participants (289/434, 66.6%) lacked eHealth literacy, and 97 (22.4%) had high eHealth literacy (Table 2).

Regarding health-related outcomes, almost every participant had an annual medical checkup (n=423, 97.9%). Over half of the participants (n=242, 55.8%) reported not being in good health. Regarding eHealth use, 353 (81.3%) participants did not have experience using digital technology to improve eating habits. A total of 350 (80.6%) and 370 (85.3%) users did not use digital technology to access health care services or long-term care services, respectively (Table 2).

Table 3 shows the distribution of eHealth literacy across different groups of sociodemographic factors and digital technology use. The results showed significant differences in mean eHEALS scores across all variables except for receiving pension. The level of eHealth literacy descends with older age and ascends with daily time spent on the web (Figure 1).

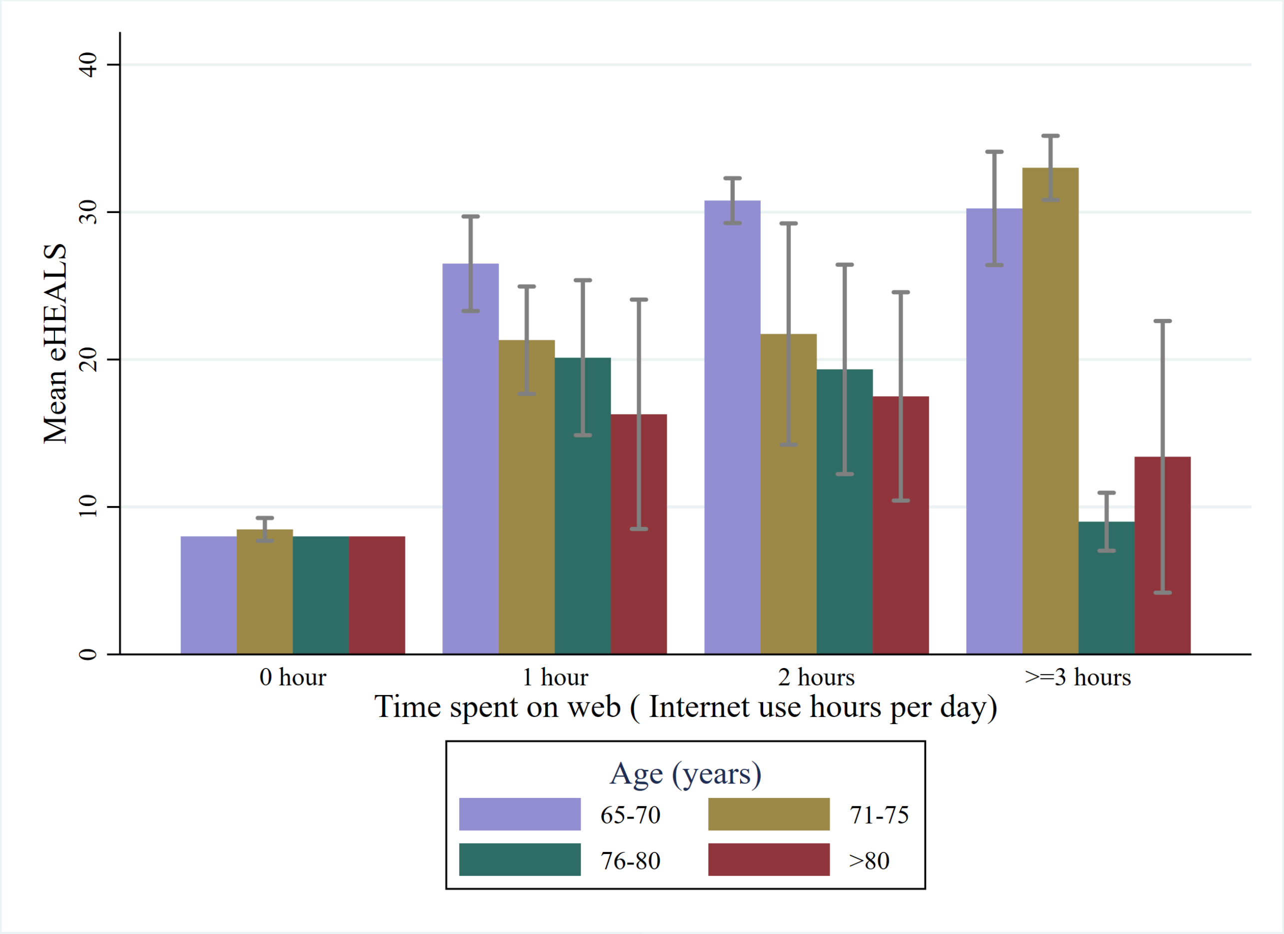
Figure 1. Level of eHealth literacy of different age groups by different categories of daily time spent on the web among older Korean adults. eHEALS: eHealth Literacy Scale.



Social and Digital Determinants of eHealth Literacy

Ordinal logistic regression predicted eHealth literacy from sociodemographic factors and the use of digital technology. eHealth literacy was associated with age, income, internet use, and social media use, while other variables were controlled. Compared to the 65 - to 70-year age group, the odds of having high eHealth literacy were decreased by 76% (aOR 0.24, 95% CI 0.1 - 0.6) for the 76 - to 80-year age group and 88% (aOR 0.12, 95% CI 0.03 - 0.42) for the >80-year age group. A monthly income of more than 1 million Won per month increased the odds of having a higher eHealth literacy 2.8 times (aOR 2.8, 95% CI 1.35 - 5.8) than a monthly income of less than or equal to 1 million Won. Univariate analysis showed that internet users had significantly higher eHealth literacy (odds ratio 108.57, 95% CI 42.63 - 276.54; *P*<.001). In multivariable analysis, hours spent on the web daily were significantly associated with eHealth literacy. Users who spent an hour per day had 19.2 times (aOR 19.2, 95% CI 2.33 - 158.81; *P*=.006), 2 hours per day had 25.7 times (aOR 25.72, 95% CI 2.83 - 233.47; *P*=.004), and 3 hours and more had 35.3 times (aOR 35.39, 95% CI 3.70 - 338.63; *P*=.002) higher eHealth literacy than nonusers of the internet. Social media users had 3.9 times (aOR 3.97, 95% CI 1.02 - 15.43; *P*=.04) higher eHealth literacy than nonusers (Table 4).

Impacts of eHealth Literacy on Health-Related Outcomes and eHealth Use

Self-perceived health was significantly better in participants with higher mean eHealth literacy scores (very healthy groups: mean 22.2, SD 12.0 and unhealthy groups: mean 11.6, SD 8.1; *P*<.001). Participants with higher mean eHealth literacy scores attended annual medical checkups frequently. Regarding the use of digital technology for health, frequent users had a statistically significant higher mean in all 3 measures: the use of the internet and digital technology for improving eating habits (mean 25.4, SD 11.8; *P*<.001), access to health care services (mean 28.4, SD 10.4; *P*<.001), and long-term care services (mean 23.3, SD 14.1; *P*=.004; Table 5).

The influence of eHealth literacy on health-related outcomes was analyzed using multivariate ANOVA (Table 6). The result showed eHealth literacy had an effect at the multivariate level on self-perceived health status, digital technology, and internet use to improve eating habits to access health care and long-term care (*P*<.001). In multivariate analysis, the eHealth literacy level did not significantly influence participation in annual medical checkups.

Table . eHealth Literacy Scale (eHEALS) and different levels of health outcomes and digital technology use for health in older Korean adults (N=434).

Health outcomes and eHealth use		eHEALS score, mean (SD)	*P* value
Perceived health status			<.001
	Very healthy	22.2 (12.0)	
	Moderately healthy	18.8 (11.6)

Discussion

Principal Findings

Competent in eHealth literacy skills is a characteristic of older people with healthy behaviors and those with better health knowledge and attitudes [15]. This study fills the gaps in eHealth literacy evidence by identifying social and digital determinants of eHealth literacy in community-dwelling Korean older adults and its consequential impact on subjective health status and digital technology application for lifestyle improvement and health needs.

In this study, older age, monthly income of lower or equal to 1 million Won, internet nonusers, and those not engaged in social media have a higher risk of having poor eHealth literacy (Table 4). Furthermore, the findings indicated that eHealth literacy has a significant effect on self-perceived health and eHealth use. It was also associated with lifestyle behaviors using digital resources for promoting health (Tables 5 and 6), such as improving healthy eating habits. Using smartwatches in physical activity promotion is an ideal recent example globally [29]. Additionally, eHealth literacy enabled older persons to seek health care services digitally and access long-term care services digitally (Tables 5 and 6). Integrating all these findings, we can highlight the significant influence of eHealth literacy upon general well-being, self-care, and opportunity to use health and social care services and health promotion through multiple evidence. The findings in other recent publications agreed with our findings [30,31].

The eHealth literacy of community-dwelling older Korean adults is relatively low, and 66.6% (n=289) need support and facilitation to improve their skills (Table 2). Since eHealth literacy is a predictor of eHealth information seeking, the disparity could result in inequity in health information access. Incompetency in eHealth literacy skills in older adults reflects lower self-efficacy in the effective use of electronically delivered information and services and the risk of exclusion from these services [10]. Therefore, regarding the country's high-paced demographic and digital transition, urgent interventions in eHealth literacy promotion targeting high-risk groups should be prioritized to ensure older adults' healthy and inclusive aging.

The effect of age on eHealth literacy varies among different age groups (Table 4). The skill increases with age in young and middle-aged adults and declines with age in older adults [32,33]. Younger older adults are more likely to have better eHealth literacy than those who are older. This may be due to an age-related decline in physiological and cognitive ability to access eHealth information. A qualitative study stated that younger older adults adopt digital technology considering literacy, benefits, and support from relatives and families, while those who are older are more likely to adopt with support from friends and relatives [34]. Therefore, older adults are not homogenous, and improving eHealth literacy in older adults should consider age-specific interventions tailored to the needs of different older adults.

Previous studies have stated that economic status has a significant association with eHealth literacy, which is concurrent with this study [35]. Older adults with higher incomes are more likely to adopt digital devices and have more autonomy in internet use [36]. Lower-income older adults may face poor access to digital technology, leading to skill disparity. As South Korea ranked highest in old age poverty among Organization for Economic Co-operation and Development countries [37], the relationship between financial security, social support for older adults, and eHealth literacy needs in-depth investigations to prevent the potential loss of the silver economy in a digitalized society.

Regarding other socioeconomic factors, there is inconsistency in the relationship between sex and eHealth literacy, and this study did not find any significant differences among different sex (Table 4). Level of education is a significant predictor of eHealth literacy in several studies [33,38]. However, this study did not find favorable relationships between education level and eHealth literacy, except that those with a high school education or above were more likely to have higher eHealth literacy in univariate analysis (Table 4).

Internet and social media use had a strong association with eHealth literacy. The frequency and time spent on the internet lead to different levels of eHealth literacy among older people, and those spending 3 hours or more have 35 times higher eHealth literacy than nonusers (Table 4). The internet penetration of older people is around 90% of the general population [39] in South Korea, which means that Korean older adults have favorable environmental access to the internet, and they are more likely to adopt digital devices [40]. In addition, having confidence in using the internet promotes the use of the internet for seeking health information and thus improves eHealth usability [41]. Therefore, comprehensive internet coverage serving as a foundation, boosting older adults' self-efficacy with digital technology and comfortability with eHealth skills, is a promising way to narrow the usability gap.

The eHEALS was developed before the widespread use of social media, and there were few studies regarding the validity of eHEALS on social media use. This study showed that social media users had 3.97 times higher eHealth literacy than nonusers (Table 4), which is concurrent with Tennant et al's [42] findings. The diffusion of social media into people's daily lives has become a channel to distribute health information and promote health, especially during the COVID-19 pandemic. South Korea and China have effectively used social media for disease notification, updating health information, and promoting preventive behaviors [43,44]. People who use social media frequently are more likely to keep abreast with updated health information, have better eHealth literacy, and be able to adopt healthy behaviors.

This study also found that eHealth literacy significantly impacts the self-perception of health (Table 6). Better levels of eHealth literacy are related to better-perceived health through access to quality health information and prompt and adequate health-related decisions [45,46]. Healthy behavior, such as participation in annual medical checkups, is not associated with eHealth literacy in this study population. The study population's participation in annual medical checkups is 90% (Table 2), higher than the national level of 80.3% in the group older than 40 years [47]. Due to the well-established health screening programs and high participation, this study could not find a significant impact of eHealth literacy on participation in health screening programs.

In addition, this study found that eHealth literacy influences digital technology use for health and care purposes (Table 6). People with better eHealth literacy can navigate the required information correctly, whereas people with poor eHealth literacy skills lack eHealth self-efficacy and pose a barrier to the adoption of eHealth services. Moreover, a higher eHealth literacy level increases the positive impact on perceived usefulness and ease of use in technology and facilitates the adoption of digital health technology [45]. Recently, a municipality in South Korea has introduced an artificial intelligence–featured call to prevent social isolation in the older population [46]. Such development affirmed that digital technology would narrow the unmet needs of health care and long-term care services in the future, provided that the users have the proper knowledge and self-efficacy in eHealth. Therefore, promoting eHealth literacy for the older population is fundamental in expanding eHealth services and eliminating the gray digital divide.

Limitations

Due to the demographics and aging rate of the sample population and the location of the study site, generalizing the findings may underestimate internet use in the older Korean population. In addition, eHEALS measures perceived eHealth skills rather than the actual performance of using digital technology. The possible gap between perceived skill and actual application of eHealth literacy could not be excluded.

Conclusions

eHealth literacy is an essential skill in the rapidly digitalizing world. It is important to learn about the factors associated with eHealth literacy in community-dwelling Korean older adults and the impact of eHealth literacy on health-related outcomes and digital technology use for health purposes. With the application of the results from this study, interventions to improve the eHealth literacy skills of older adults can be tailored to high-risk populations and narrow the gap in the usability of eHealth services by older adults.

Acknowledgments

This research was funded by the Japanese Ministry of Education, Culture, Sports, Science and Technology, Grant-in-Aid for Scientific Research, 21H00795 and 23K20657, entitled “Digitally inclusive, healthy ageing communities (DIHAC): A cross-cultural study in Japan, Republic of Korea, Singapore, and Thailand” [48].

Authors' Contributions

MNA, MYK, MY, and YK conceptualized the research. MYK and MNA performed the formal analysis and visualization and were involved in writing the original draft. MNA contributed toward using the software. MNA, MY, SM, and TNNA supervised the project. MNA and MY were responsible for funding acquisition. MNA, YK, EWN, MY, HKCM, and TNNA administered the project, and MYK, MNA, YK, SM, TNNA, EWN, HL, and HKN were responsible for validation. All authors were responsible for investigation, methodology, writing, reviewing, and editing of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: During COVID-19 lockdowns, older adults' engagement in daily activities was severely affected, causing negative physical and mental health implications. Technology flourished as a means of performing daily activities in this complex situation; however, older adults often struggled to effectively use these opportunities. Despite the important role of older adults' social environments—including their families and health professionals—in influencing their technology use, research into their unique perspectives is lacking.

Objective: This study aimed to explore the daily activity performance, health, and technology use experiences of healthy independent Israeli adults (aged ≥65 years) during COVID-19 from a 3-dimensional perspective: older adults, older adults' family members, and health professionals.

Methods: Nine online focus groups, averaging 6-7 participants per group, were conducted with older adults, family members, and health professionals (N=59). Data were analyzed using thematic analysis and constant comparative methods.

Results: The intertwining of daily activity performance and health emerged as a central theme, with differences between the groups. Older adults prioritized their self-fulfilling routines based on motivation and choice, especially in social-familial activities. In contrast, family members and health professionals focused on serious physical and mental health COVID-19–related consequences. A consensus among all three groups revealed the meaningful role of technology use during this period in bridging functional limitations. Participants delved into technology's transformative power, focusing on the need for technology to get engaged in daily activities.

Conclusions: This study illustrates the profound interplay between daily activity performances, physical and mental health, and technology use, using a 3-dimensional approach. Its focus on technology's uses and benefits sheds light on what older adults need to increase their technology use. Interventions for improving digital activity performance can be tailored to meet older adults' needs and preferences by focusing on motivational and preference-related activities.

Introduction

Background

Occupational scientist Ann Wilcock [1] claimed that "occupation and health are inseparable," meaning that a person's ability to function and perform in daily activities and occupations, especially meaningful ones, directly affects their health [2]. Previous studies have emphasized the substantial role of daily activity performance in maintaining and enhancing older adults' health. More information should be gathered to explore the unique daily experiences of older adults during a crisis such as the COVID-19 pandemic, since they cope with specific age-related changes, including physical, psychological, and social factors [3].

Although COVID-19 presented additional major challenges to older adults' daily activity performance and health, some remained active, most notably by using technology [4,5]. Since technology has become integral to modern life, it is essential to understand technology use among older adults in terms of their daily activity performance and health [6]. One major factor affecting older adults' success in daily functioning and adopting technology is their social environment [7,8], including family and health professionals [9]. For example, family members can support technology challenges (choosing suitable devices and introducing basic functions), and health professionals can suggest appropriate technology [8]. Thus, a deep understanding of daily activity performance and technology use necessitates consideration of family members' and health professionals' experiences.

Nevertheless, previous studies focused almost entirely on older adults' perspectives regarding daily activity performance. For example, Israeli studies of activity performance during the COVID-19 pandemic focused on adults (18 years and older) in general without addressing the specific needs and experiences of older adults (65 years and older) [5,10]. It remains unclear how older adults adjusted their daily activity performance in the face of the COVID-19 outbreak. Similarly, a study conducted among family members and health professionals regarding technology use did not specifically address the needs of older adults in terms of using technology to promote health in times of crisis [11]. Therefore, it is necessary to gain greater insight into Israeli older adults' experiences of their daily activity performance and technology use during COVID-19 through the various perspectives of older adults, family members, and gerontology health professionals. In this study, technology is considered with daily activity performance. Hence, the term technology refers to devices that adults already own (eg, mobile phones, computers, and tablets) for carrying out these activities.

Prior Studies

Older Adults' Daily Activity Performance and Health During the COVID-19 Pandemic

Globally, people are living longer, with more options to discover new interests, such as education or professional training. Alternatively, they might contribute positively to their families and society by caring for their grandchildren or volunteering for various charitable activities. Despite this empowering perspective, a central aspect—health—strongly influences their ability to engage in daily activities [12].

Extraordinary circumstances such as the COVID-19 pandemic present a substantial concern for older individuals' health. Worldwide, they reported restrictions on daily activities, such as banking, shopping, hiking [13], and leisure activities [14]. These changes negatively affected their physical and mental health [15,16]. Hence, exploring older adults' daily experiences during the COVID-19 pandemic can provide insight into their needs.

The occupational perspective, which provides an in-depth view of human doing, highlights the contribution of daily activity performance to health. This perspective further emphasizes the impact of the activities' context, time, and role in doing, being, becoming, and belonging [17]. Situations like COVID-19 may negatively affect older adults' ability to function (doing) and their sense of self (being). It can present obstacles to achieving future goals (becoming) and particularly affect older adults' ability to participate socially (belonging) [18]. The occupational perspective can demonstrate how humanity adapted to COVID-19 changes by adapting activities to what was available at the time.

Studies in numerous global regions showed that older adults adjusted to the COVID-19–related activity changes in various ways. They may have acquired a new skill or knowledge (eg, learning a foreign language), modified the nature of their activities, or adjusted the time allocated to each activity. Thus, they might have engaged in social, leisure, physical, and educational activities throughout the pandemic—but in new ways. Maintaining routines and participating in such meaningful activities regularly facilitated individuals maintaining their mental health [19,20].

Israeli Society's Distinctive Characteristics

Previous cross-sectional studies among Israeli adults (18 years and older) during COVID-19 highlighted the importance of maintaining daily routines. Their findings showed that Israeli adults discontinued some activities and modified their environment, often opting for solitude or staying home [5,10]. Cultural influences greatly determine how older adults navigate daily activities and use technology [21], thus requiring insight into their experiences. Despite the earlier studies, Israeli older adults' experiences of their performance in daily activities during crises still require clarification.

Technology-Supported Daily Activity Performance During the COVID-19 Pandemic

Previous studies focused mainly on older adults' self-reports on their technology use [4,19-26]. However, because social support, often provided by family members or health professionals, can overcome gaps between technology and barriers to using it [8], it is also vital to explore the person's social environment. The studies that were conducted among family members and health professionals focused on issues like assistive technology [27], robots allowing aging in place [28], technology for care services [11], strategies and barriers for communication technologies [29], and accepting personal alerting devices [30]. None directly addressed the older adults' specific needs for using technology in meaningful daily activities to promote health in crisis periods.

This Study's Goal

This study aimed to fill the literature gaps by exploring daily activity performance and technology use experiences among healthy, independent, older Israeli adults during COVID-19 using a 3-dimensional perspective (including older adults, their family members, and health professionals).

Methods

Overview

This study is part of a larger project, Empathic Platform to Personally Monitor, Stimulate, Enrich, and Assist Elders and Children in Their Environment (ESSENCE). The ESSENCE used opportunities arising during the COVID-19 pandemic to study vulnerable populations, including older adults and children. This paper provides the results of focus groups exploring older adults' daily activity performance experiences with technology in the COVID-19 pandemic context. The focus groups provided a multi-perspective window through diverse daily communication, allowing us to learn more about human experiences, desires, and concerns.

Ethics Approval

This study was approved by the University of Haifa Faculty Ethics Committee (086/21).

Procedures

Recruitment

We recruited participants using snowball sampling and social media. Participants received information about the study, signed online consent forms, and completed a short demographic questionnaire. We honored their willingness to share their experiences with gift certificates.

Data Collection

The data were collected between February 2021 and July 2022 (Israel was in lockdown part of this time). Using three types of focus groups (older adults, family members, and health professionals) allowed for triangulation, strengthening the results' validity [31].

The 9 focus group sessions were conducted by the first and third authors. We calculated the focus group size (6-7 participants each) according to Krueger and Casey's [32] guidelines. The moderators created a relaxed and friendly environment, encouraging participant interaction and continued data collection until the main issues were repeated and theoretical saturation was reached [33].

Participants

The 9 focus groups comprised 3 clusters. The clusters were:

1. Older adults (65 years and older) living independently at home and able to use a computer and Zoom software (n=20)
2. Family members of older adults deeply familiarized with the older adults' routines (n=19)
3. Health professionals with at least 5 years of experience working with older adults (n=20)

Table 1 presents each group's sociodemographic characteristics.

Table . Sociodemographic characteristics of study participants.

Characteristic		Older adults (n=20)	Family members (n=19)	Health professionals (n=20)
Gender, n (%)

[a] Not applicable.

Each focus group lasted approximately 60-70 minutes. They were conducted via Zoom videoconferencing software, video- and audio-recorded in Hebrew, and stored on the researchers' password-protected computers. The recordings were transcribed without details that could identify the participants. Once transcribed, the original records were deleted to maintain anonymity and confidentiality.

The researchers wrote reflective comments capturing verbal and nonverbal interactions during each focus group. Because the groups were conducted online, particular attention was paid to the older participants' needs. For instance, we offered support for difficulties in using technology. Support included help setting up an internet connection in another room and repeating the conversation issues. The broad perspective on older adults' use of technology during the focus group further enhanced the study's credibility.

Research Tools

The moderator's questions were customized for each group. However, the session structure, developed based on findings in the relevant literature [34], was similar for all three focus group types. It was designed to create a relaxing environment where participants felt free to share their experiences and thoughts. We invited the participants to introduce themselves and asked a general opening question to encourage active participation in the discussion: "What is your most enjoyable activity in your free time?" Additional questions were asked related to older adults' general daily function and routines, for example, "Would you be able to summarize your ordinary day, starting from the moment you wake up to the moment you go to sleep,” daily activity performance during the COVID-19 period (“How has the COVID-19 affected your daily activity performance in comparison to the routine before the COVID-19?”), and technology (“Which technology devices do you use and how do you use them?” and “How has the use of technology changed since the COVID-19?”).

Data Analysis

The data were analyzed according to thematic analysis and the constant comparative method [35] using Word (Microsoft Corporation) and Excel (Microsoft Corporation) worksheets. The researchers repeatedly reread the transcripts and reflective comments to familiarize themselves with the data and used the Office software to create memos related to the text. The data were then sorted, highlighted, and categorized by cases, and comparisons were made. Comprehensive coding was conducted to produce themes, and selective coding was performed to fit the theme precisely. Last, the quotations were rearranged into new categories and translated into English. We paid particular attention to the similarities and differences between participants’ experiences in each group and between the three groups [33,34,36,37]. In-depth discussions of any disagreements among the researchers were held in a series of research meetings with a researcher in the field and a qualitative researcher [38], improving the findings’ trustworthiness [36].

Results

Overview

We identified two main themes, with two subthemes each:

- Daily activity performance and health are intertwined.
    - Changes in daily activity performance affect health.
    - Meaningful activities shape a healthy routine.

Whereas older adults described how they adapted during the pandemic and used it for self-fulfillment, the family members and health professionals discussed its devastating effect, especially relative to physical and mental health.

- Technology use bridges functional limitations.
    - “It forced them to use technology.”
    - Opportunities to engage in daily activities.

While the COVID-19 pandemic was underway, technology allowed solutions to some challenges older adults faced. Thus, this extended period provided a window into their technology needs.

Daily Activity Performance and Health Are Intertwined

Changes in Daily Activity Performance Affect Health

Miriam (a 69-year-old female participant) illustrated the older adults’ changing daily activity performance during the lockdown period when they were required to stay home:

> *My previous routine included the whole culture thing. And I miss it very much...I live in a private house in Israel, and we saw the grandchildren. We were careful...We were restricted from going for a walk. Now, we can do a little more. It is very lacking, and it greatly affects my mood that I can’t go to the theater or plays or concerts. It is a central part of my life.*

Although she met with others, Miriam’s inability to participate in cultural activities, which she considered vital, affected her mood.

Racheli exemplified the family members’ descriptions of emotional reactions, changes in daily activity performance, and concerns about their older family members:

> *The Corona interrupted [my mother’s] blossom and somewhat stole the joy of her retirement...It was also very frustrating for her...It seems we cared more about her than she cared about herself...And suddenly, all the classes and everything moved to Zoom...It was also hard for her to follow, so [she lost] all her fun from “brain strength” or [other] kinds of things...She was keeping herself, feeling that she was suddenly deteriorating, and she struggled terribly with it—with this feeling and with trying not to be a burden on us, not expressing her loneliness so that we didn’t feel it, too.*

Racheli portrayed her mother’s frustration during this crisis period, in which activities were reduced, compared to her earlier delight in retirement. Although the situation and her loneliness affected Racheli’s mother, she did not share her feelings with the family.

The professional therapists’ perspectives added to this dimension while foregrounding the health-related implications. One physiotherapist referred to medical treatment, stating, “I don’t think we’ve even talked about all the medical treatments that people forgo in order not to go to, I don’t know what, hospitals, even dental treatments.”

A family therapist expounded, “I think the last year brought death closer to older people in a very present way,...and they are very busy with their physical health and fears that were not there before.”

The professional therapists included physical health alongside the fear, exemplifying how this crisis affected both physical and mental health and how they intertwine. A geriatrician described how the mental state caused stressful reactions:

> *I saw terrible examples of loneliness and anxiety...In the beginning, it really was all of us, even the children who, every day before Corona, would come in and hug their parents, and parents, as usual, would get along. Here, they came to the door of the house because they said it was forbidden to enter and it was forbidden to meet, and they left the food for them—left it for them. Rang the bell, but it wasn’t enough. I had terrible examples of people who were afraid, all the time using alcohol gel, and came [to me] with wounds on their hands and all kinds of terrible anxiety.*

Meaningful Activities Shape a Healthy Routine

Lea's (66-year-old woman) words illustrated how the older adults described adaptations that helped them cope with challenges in the COVID-19 period:

> *I also had a difficult time when everything was closed. In the more serious lockdowns, the children refused to come. I told them, "Come, I'm right at the limit in terms of age," but they didn't agree. On Passover, they came and put something for me by the door. And they told me, "We left something for you by the door." Flower...It was really...wow. On the other hand, I had a dog, so I would go for walks. So it helped because the dog took me for a walk in a way, so that was good. The garden saved me. The garden and the dog, and that's it; some phones.*

Daily meaningful outdoor activities such as walking her dog and tending her garden supported Lea during this challenging period. Similarly, Rebecca (a 70-year-old woman) demonstrated adaptation to the new situation to the point where she enjoyed it:

> *Compared to before? Obviously, I haven't left the house since the end of February. I was at home. And I'm telling you the truth, I really enjoyed it. I picked up, arranged, got to a lot of things that I hadn't gotten to in years...I adapted myself to the thought that this is what there is.*

The health professionals' focus groups discussed reasons for the shift in activities and their meaning. A paramedic described:

> *Until now, they were really assisted. First, their day would have been filled with grandchildren who would come,...you know, there would be a reason to go to the kitchen and make the meatballs this child loves...There was this thing, now, because of the whole last year that was not created, so they simply look for the meaning in other forms.*

According to that paramedic, these circumstances forced older adults to find solutions to their difficulties and continuity in routine, such as preparing meals for grandchildren, which supported their coping.

Technology Use Bridges Functional Limitations

"It Forced Them to Use Technology"

The COVID-19 pandemic restrictions required individual adjustments in daily activity performance. One prominent change was how technology was used in daily life. Michel (a 67-year-old man) described needing technology to perform social and leisure activities:

> *I don't know how I would have gotten through this period without technology. I started taking a course that stopped due to the Coronavirus. But during all these periods, there are, of course, Zooms and all kinds of lectures, even WhatsApp conversations between groups of friends.*

Rebecca described keeping her life active with technology while learning new skills:

> *This (virus) is unknown...It has stopped the whole world, and [we] just wait for it to pass and learn how to behave afterward. I was very active every day. And even now in Corona, I participate in Zoom, learning new things. There is nothing to be done; you must realize that this is the situation, and that is what there is.*

She described COVID-19 as a period of inactivity but also emphasized the need to acquire new skills, especially those related to technology.

The family members' and health professionals' groups also demonstrated how technology use became a necessity during COVID-19. Olivia, the daughter of an older adult, explained:

> *My father retired a short time before the Coronavirus, and then the Coronavirus started, and it really worried us; it was huge. And we said, "Okay, even this [retirement] transition, which seemed difficult for him, and then Corona." And it seemed way too much. But surprisingly—maybe because it was something worldly—my father really found himself. Like maybe because there was no alternative, and everyone was now in some kind of madness, so he really surprised us for the better. As if he really found himself. He is not a technological person, but he really found himself in Zooms, one after the other, such as lectures and all. Even to the extent that they hang up on us because they now have some Zoom.*

Olivia's quote shows that even though her father apparently had no knowledge of technology before the COVID-19 pandemic, he learned to use it because it was necessary and there was no alternative. The restrictions and lockdowns decreased communications with the outside world. A gerontology social worker noted technology use as a communication issue to consider:

> *We knew this even before the Coronavirus. There was a lot of work in this area, but obviously, during the Coronavirus, [digital literacy] jumped by hundreds of percent. And it was a sudden realization that it's something almost existential,...that it's nice fun, and it's enriching. You need a real existence for connection with the world.*

A nurse added, "It forced them to use [technology] because, otherwise, there is no option to communicate with the world." The social worker and the nurse emphasized that technology use becomes a virtual requirement for not only engaging in meaningful activities but also staying connected with the outside world.

Opportunities to Engage in Daily Activities

The older adult participants depicted their technology use according to their desires for meaningful activities, divided into three main domains: instrumental activities of daily living (IADL), leisure, and social activities.

Aharon (a 66-year-old man) described how COVID-19 affected IADL, especially shopping:

> *A notable thing that changed is a funny thing: Yes, shopping in the supermarket has become the whole of the Corona only through the Internet. It...yes, continues with it, almost never physically visiting the store.*

Jacob (a 79-year-old man) described technology use for leisure activities:

> *We tried to compensate (which was not possible in the pre-Corona period) during the Corona period...We play bridge online; there is an online option to play bridge with opponents from all over the world who enter the table and open and play for an hour or so...In the game of bridge, both partners play but do not see the cards each has. We arranged the two computers, so we sit back-to-back and don't see the partner's cards, and that's how we play, and it's very nice. Sometimes, when you lose, you get quite frustrated, but that's the game.*

Although Jacob played the game on an online platform, it seemed to provide the same experience as regular gaming. It made him feel he was compensating for activities he could not perform.

The availability of technology seemed to provide older adults more opportunities to participate in lessons than they were used to. Shira (69-year-old woman) described:

> *The timing of Corona was good for me. I felt I was already very tired when this rest came to me, and what helped me with Corona was Zoom. I am alone at home, and I have a son who lives with his partner. It helped me overcome this period. From morning to evening, on Zoom all the time. You don't have to sit in front of the screen; you also listen to the lectures.*

Shira described the benefits of the COVID-19 period, bringing her opportunities to rest and interact using Zoom.

Emma, a daughter of an older adult, added:

> *Now, during the Corona period, we bought [my mother] a smartphone that she didn't have before, and this made it very accessible for us to share with her...Every time she would send pictures by email, and when everyone is on WhatsApp and presses a button and forwards to everyone, then an email is already something a little more like sending a letter by post with a stamp. And she didn't always understand: "What's so hard for you? Well, send." The phone was a gift from us. We bought it for her birthday, but it gave us the option to share with her more and gave her another tool to help her orient herself.*

Communicating through advanced technology apparently provided Emma's mother opportunities to not only stay in touch with family but also feel a sense of belonging.

The health professionals described opportunities for older adults' remote health care. A paramedic explained:

> *They receive remote medical treatments...like they were sitting in front of doctors once upon a time. Who thought of it? So, coming from a generation connected with a wire to the wall, like a curled phone, everything was so terrible when talking face-to-face. Suddenly, they learned the whole young generation of today, and they are inside it. And I say up to higher studies, which is beautiful...They know how to use a computer at such a level as the Open University.*

The paramedic exemplified the incredible changes in the older population receiving health care during COVID-19, adjusting their habits to the realities of the COVID-19 period when people were required or encouraged to stay home.

Discussion

Principal Findings

COVID-19 had a substantial impact on people's health. Technology use supported the daily lives of Israeli older adults (65 years and older) and affected their health during the pandemic. Findings based on a 3-dimensional perspective (older adults, family members, and health professionals) highlight the overlaps and differences between perspectives and provide explanations of these findings. Overall, the findings point to older adults' need to stay active as a factor motivating their technology use.

Older Adults: Meaningful Activities Shape Healthy Routines

The participants described changes in daily activity performance, emphasizing COVID-19 constraints as causing emotional difficulties. Their descriptions demonstrate the effects of time and context on their activities and how *doing* and *being* interrelate from an occupational perspective [17]. Older Japanese adults described similar pain and fear emotions regarding their daily activity limitations [39]. The aging process alone includes substantial changes in routine (like retirement) and in the ability to engage in some activities due to biological, psychological, and social changes [3,40]. These aging characteristics, magnified in a crisis, underscore the importance of offering emotional support to older adults with daily activity performance limitations resulting from varying causes.

Despite limitations preventing them from reaching their aspirations and *becoming*, older adults seek adaptions and opportunities to remain active. They become involved in new activities, gain new skills, and find alternative methods (like using technology) to carry out their daily tasks. In line with previous research [19,20], this study's participants describe how staying engaged in leisure, educational, and outdoor activities (eg, gardening and walking) supported their daily routines during COVID-19.

Interestingly, the older adult participants tend to emphasize engaging in *secondary routines*, associated with preference and motivation (eg, leisure and social activities) rather than *primary routines*. *Primary routines* are behaviors vital for survival (eg, sleep and personal hygiene) and establish the general pattern of daily life [41,42]. The participants stressed the benefits of meaningful activities of pleasure, social interaction, and mental health, which motivate them to participate [43].

Specifically, older Israeli adults frequently mentioned social activities with family members, including religious rituals. The activities perceived as meaningful vary across cultures [21]. Older adults in Brazil, Italy, Portugal, and the United States viewed their social environment, including family and friends, and religious rituals as coping mechanisms. They underlined the crucial role of the family as a support system during the COVID-19 pandemic [13]. Somewhat differently, the older Israeli adults in this study often referred to activities with their families, indicating that maintaining contact with their relatives was paramount and composed a substantial part of their daily routines. Even with cultural differences, the value of the family to older adults in times of crisis is cross-cultural.

Family Members: Close Social Environments and Caring for a Loved One

Like the older participants, the family members described changes they noticed in their daily activity performance, including leisure, educational, and social activities. However, they exhibited greater concern for the older members of their families, prioritizing their loved ones' safety and emotional support. For instance, they worried about the older adults' increased vulnerability to the virus, the potential consequences to their health [7], and particularly their loneliness and unwillingness to share their struggles. Witnessing their loved ones' health deterioration and accelerated aging while experiencing their own COVID-19 challenges could increase the family members' mental burdens. Since they are a source of support for older adults [7], professional involvement is warranted in supporting both older adults and their family members during times of crisis.

Health Professionals: Health Implications

Similarly, to older adults and family members, health professionals outlined changes in meaningful activities. However, they added a main focus on ensuring the health and safety of older adults, drawing upon their expertise and knowledge [44]. Notably, the professional participants represented a wide range of fields; several were older than 60 years, allowing for valuable and unique insights. They assessed the situation accurately and objectively from a medical perspective, being equipped with knowledge of the aging process, and addressed health consequences, including mental and physical implications. They particularly noted loneliness, anxiety, and physical health symptoms associated with COVID-19 in older adults and stressed the importance of maintaining meaningful activities to enhance older adults' health. Consideration of these factors can contribute to older adults' health and well-being whenever they are faced with similar situations.

Focus Group Consensus: Technology Use Promotes Health

All focus groups agreed on technology's necessity. The need for technology during the COVID-19 pandemic might have played a role in the rise of older adults adopting and using technology [21]. Technology is indispensable for motivating them and meeting their needs in routine and crisis periods. During the COVID-19 pandemic, older adults had to cope with an unknown situation requiring them to use technology. Adapting to unfamiliar situations and using technology effectively require higher-order cognitive abilities of executive functions (eg, inhibition, working memory, cognitive flexibility, planning, and problem-solving) [45]. Although possibly the first affected by the cognitive dysfunction associated with aging, executive functions have a remarkable ability to maintain physical and mental health [46,47]. Therefore, it is vital to leverage the COVID-19 period by creating opportunities for older individuals to engage in unfamiliar digital activities, which could benefit executive functions and improve physical and mental health.

Technology benefits include opportunities for daily activities, especially IADL (eg, shopping and receiving remote health care), education, leisure, and social activities. As in previous research, this study's participants described how engaging in digital activities fostered a sense of belonging [48]. Focusing on technology's uses and benefits sheds light on older adults' needs, allowing them to increase their use of technology.

Limitations and Future Research

It is important to acknowledge this study's limitations. First, participation in online focus groups requires high functional abilities. Thus, the study might present a limited perspective on digital activity performance because potential participants with less technology proficiency were not included. Further, most participants in all groups were female, possibly introducing gender bias and limiting the diversity of perspectives represented in the study. Finally, the snowball sampling method increased the likelihood that some participants, particularly health professionals, had preexisting relationships.

Future studies should include participants with a more diverse range of technological proficiency and gender. Because participating in digital technology is vital to physical and mental health among the older adult population, further research should be conducted in both a qualitative and quantitative manner exploring technology's downsides, including its disadvantages and challenges for older adults. This could identify key principles for interventions to promote older adults' technology use.

Conclusion

This study illustrates the profound interplay between daily activities, physical and mental health, and technology use among Israeli older adults (65 years and older) using a 3-dimensional approach. Specifically, it delves into the perspectives of older adults, their family members, and health professionals. In light of an occupational perspective, older adults emphasize family connection activities as a significant aspect of their lives. Thus, when activities are restricted, it is imperative to provide emotional support to them and their families. All three groups emphasize the importance of digital activities for coping with changes in routines and activities and promoting emotional and physical health during crises. These findings apply to various circumstances that older adults may encounter, ranging from health conditions to crises. Whether facing personal challenges such as the loss of a loved one or coping with social upheavals like war, their daily lives may be affected. The focus on technological uses and benefits during COVID-19 sheds light on what older adults need to increase their technology use. Interventions for improving digital activity performance can be tailored to meet their needs and preferences by focusing on their secondary routines.

Abstract

Background: Informal caregivers are called upon to provide substantial care, but more needs to be known about technology use among older adult and caregiver dyads.

Objective: This study described technology use among older adults and their caregivers, explored potential correlates of technology use, and highlighted implications for practice.

Methods: A cross-sectional survey was conducted among unpaid caregivers of older adults (n=486). Primary outcomes were self-reported technology (devices and functions) use among caregivers and their oldest care recipient. The concordance of technology use among caregivers and care recipients was also examined. Multivariable regression models were conducted separately for caregivers and care recipients.

Results: Greater proportions of caregivers used all examined technologies, except for the medication alerts or tracking function, than care recipients. Caregivers used an average of 3.4 devices and 4.2 functions, compared to 1.8 devices and 1.6 functions used by their care recipients. Among caregivers, younger age, higher income, and higher education were associated with more technology use (*P*<.05). Among care recipients, younger age, not having cognitive dysfunction, and caregiver's technology use were associated with more technology use (*P*<.05).

Conclusions: Understanding technology use patterns and device adoption across diverse caregiver and care recipient populations is increasingly important for enhancing geriatric care. Findings can guide recommendations about appropriate technology interventions and help providers communicate and share information more effectively with patients and their caregivers.

Introduction

Aging is occurring in most parts of the world [1]. Driven by the large baby boomer generation, the American population is aging rapidly [2], with 1 in 4 Americans estimated to be 65 years or older by 2060 [3]. Although healthy aging may be the "new normal" for some [4], normative age-related decline in physical and cognitive functions exists and often results in the need for assistance with daily household and self-care activities. Among 53 million American adult informal caregivers, nearly 42 million cared for adults aged 50 years or older [4,5]. Despite the many hours devoted to informal caregiving [4,5], many older adults face adverse consequences of unmet needs for assistance with daily activities [6,7]. In addition to inadequate caregiving resources for older Americans, the negative impacts of caregiving on caregivers' health and quality of life have raised significant programmatic and policy concerns [8-10].

An array of innovative technology solutions exists to support older adults' health, independence, and quality of life, enabling them to age in place [11-14]. These technologies also support caregivers and enhance caregiving for older adults in areas such as fall alert notifications, social supports, communication, and medication scheduling [15,16]. However, older age is frequently considered a prominent factor associated with diminished interest in, and adoption of, technology [17-19]. This can be attributed to unique barriers associated with older age, including the lack of experiences or familiarity and declining physical, cognitive, and sensory functions [20,21]. Although recent data suggest a narrowing of the age-based gap in the digital divide [5,22,23], data also show that older adults may not use technology to its full potential [5].

The latest national surveillance data showed that about 24% of baby boomers provided informal care [24], with older caregivers tending to provide care for care recipients at similar or older ages [25]. The existence of any age-related difficulty in accessing or using technology is relevant for understanding health technology use among older adults in need of care, as well as their older caregivers who can use technology for caregiving. Although abundant literature discusses technology use among older adults or caregivers [5,25-27], few studies have examined technology use among both older adults and their caregivers [28,29] and the potential relationship between older adults and their caregivers' technology use [16].

The relationship between older adults and their caregivers is interdependent, extending to their use of technology. Knowing the pattern of technology use in older adults and their caregivers can inform the development of technology-based interventions that are accessible and usable to the aging community. For example, a qualitative study involving patients with type 1 diabetes and their spouses revealed that continuous glucose monitoring technology can enhance spousal engagement in diabetes care, yet it may also introduce sources of tension within the relationship [30]. The qualitative study provided preliminary data to guide the development of a technology-based intervention, called SHARE plus [31]. In another recent study, Shih et al [32] focused on the different types of digital devices and categories of smartphone functions used by caregivers and care recipients compared to those with no caring roles. Shih et al [32] developed a health-related smartphone app for older adults and their caregivers, and their recent work was conducted to improve the design of their smartphone app.

Our study sought to further our understanding of how the use of technology by caregiver and care recipient dyads can guide intervention outlets (eg, digital platforms) and support efficient deployment of the technology interventions, including expanded access and use of technology functions. Therefore, technology use was broadly defined in this study to enable research into the use of diverse types of devices and functions. Devices and functions represent different aspects of technology use. Devices encompass the equipment or hardware of technology, whereas functions pertain to the specific tasks one can perform using technology. For instance, an individual may possess a smartphone, tablet, and computer but only use them for internet browsing. In contrast, another person with access solely to a smartphone may use it for various functions such as email and texting, internet browsing, web-based banking, and more. Analyzing devices and functions independently can offer more precise insights to inform future technology-based interventions for the aging community.

Our key aims were (1) to describe the use of various technologies (ie, both devices and functions) for caregivers and older adult care recipients; (2) to compare technology use among caregivers and older adult care recipients; and (3) to examine potential correlates of caregivers' and older adult care recipients' technology use. A study by Lindeman et al [33] offers a conceptual framework for identifying and addressing the challenges in technology-enabled solutions for family caregivers. While not yet a theoretical basis to study and analyze caregivers' and care recipients' use of technology, the conceptual framework by Lindeman et al [33] pointed to several factors that influence the caregivers' technology adoption. The individual-level moderators involved user capacity and family, and socioeconomic moderators encompassed race and ethnicity, income, and geographic location [33]. Rather than directly assessing user capacity, we explored factors potentially linked to user capacity, such as age and education for caregivers, and cognitive dysfunction for care recipients.

Methods

Data Source and Study Population

This study collected cross-sectional data from a web-based survey about technology use among paid and unpaid caregivers of older adults who were recruited through a Qualtrics panel. To be eligible to participate in the web-based survey, the respondents must have provided 8 or more hours of weekly care for at least 1 adult care recipient aged 50 years or older (N=626). Recognizing that caregivers may be caring for multiple individuals, the caregiver was asked to respond to the survey questions in the context of the oldest person to whom they provided at least 8 hours of care. Quota sampling was used to ensure data were collected from a diverse sample reflecting the general characteristics of the US caregiving population.

Predetermined targets were set: 75% of the recruited sample were to be female, 50% at least 50 years old, and no more than 60% White. Geographic targets were also set to represent the regional population proportion (ie, 17.2% in the Northwest, 20.9% in the Midwest, 23.8% in the West, and 38.1% in the South [34]). This study focused on unpaid caregivers (n=486). The web-based survey commenced with a set of screening questions to identify eligible individuals. Those who were not screened out were provided with study information necessary for informed consent. Only those who agreed to participate were invited to complete the web-based survey.

This study differentiated between technology devices and technology functions. The respondents were asked whether they used each of the 7 devices (ie, cell phone, smartphone, tablet, computer, e-reader, voice-activated assistant, and wearable or smartwatch for activity tracking) and 8 functions (ie, communication, ride-sharing, online shopping, online banking, navigation, online entertainment, medication alerts or tracking, and physical activity tracking). The types of devices and functions were determined based on the 2020 AARP *Tech and the 50+ Survey* report [25]. We dropped some of the minimally used devices (eg, virtual reality device, 1%) and combined functions (eg, instead of individually assessing games, music, and video or movie streaming, they were consolidated into the "online entertainment" category) [25]. The respondents were also asked about their oldest care recipients' use of the same devices and functions. The total numbers of devices (ranging from 0 to 7) and functions (ranging from 0 to 8) used were calculated separately for caregivers and care recipients.

Socioeconomic and demographic characteristics of the respondents were collected using the web-based survey: age (years), sex (male or female), race and ethnicity (Non-Hispanic White or others), household income (less than US $50,000 or US $50,000 or more), and education (high school graduate and lower educational attainment or higher). The web-based survey also asked about the respondents' place of residence (zip code), and rural-urban commuting area codes were used to classify the place of residence into rural or urban areas. The respondents were also asked about their oldest care recipient's age and place of residence (rural or urban areas classified based on the care recipient's zip code). Respondents who reported being aware of their care recipient's chronic conditions were also asked about their care recipients' cognitive dysfunction (eg, dementia) and sensory impairment (eg, severe vision or hearing problems).

Statistical Analysis

Frequencies and percentages or means and SDs were used to describe the caregivers' and their care recipients' background information and use of technology devices and functions. Cohen κ statistics were estimated to examine the concordance of technology use among caregivers and care recipients. The magnitude of matching was classified into poor ($\kappa<0.20$), fair ($\kappa=0.21$-0.40), moderate ($\kappa=0.41$-0.60), good ($\kappa=0.61$-0.80), and very good ($\kappa=0.81$-1.00) matching categories. Along with Cohen κ coefficient estimation, the McNemar test was performed to compare the marginal proportions of caregivers and care recipients using or not using each technology. Next, separate multivariable Poisson regression analyses were performed to predict the total number of devices and functions used among caregivers based on caregivers' age, sex, race and ethnicity, household income, education, and place of residence. Separate multivariable Poisson regression analyses were performed to predict the total number of devices and functions used among care recipients based on the care recipients' age, place of residence, cognitive dysfunction, and sensory impairment and the total number of devices and functions used among caregivers. Only 438 (90.1%) out of 486 respondents were aware of their care recipients' chronic conditions; therefore, the regression models for predicting care recipients' technology use included a smaller sample size than the regression models for predicting caregivers' technology use. All statistical analyses were performed using SAS 9.4 (SAS Institute Inc), and a significance level of .05 was used.

Ethical Considerations

The informed consent document was integrated at the outset of the web-based survey, and only those who agreed to participate proceeded to the subsequent sections of the survey. Given the web-based nature of the study, a waiver of documentation of informed consent was requested. Upon the completion of the study, any personally identifiable information (zip code) was deleted and age was truncated to 90 years old. Within Qualtrics, participant stipends were integrated into the survey, and each participant received a stipend upon the completion of the study. Based on the estimate provided Qualtrics, each participant was paid between US $7 and US $8. The study has been reviewed and approved by the Texas A&M University Institutional Review Board (IRB2019-1128M).

Results

Study Participants

The average age was 60.8 (SD 12.11) years for caregivers and 74.9 (SD 11.61) years for their oldest care recipient (Table 1). The majority of caregivers were female (363/485, 74.8%) and non-Hispanic White (331/483, 68.5%). Nearly 50% (241/486) had a household income less than US $50,000, and 20.6% (100/486) had high school or lower educational attainment. In all, 9.1% (44/483) of caregivers and 9.5% (46/482) of care recipients resided in rural areas. Of the 438 care recipients with available information, 43.2% (n=189) had cognitive dysfunction and 32.9% (n=144) had sensory impairment. On average, the caregivers used 3.4 devices and 4.2 functions, and their oldest care recipients used 1.8 devices and 1.6 functions.

Table . Characteristics of caregivers and care recipients and their technology use (n=486).

Characteristics	Caregivers	Care recipients
Age (y), mean (SD)	60.8 (12.11)	74.9 (11.61)
Female, n/N (%)	363/485 (74.8)	N/A[a]
Non-Hispanic White, n/N (%)	331/483 (68.5)	N/A
Household income less than US $50,000, n/N (%)	241/486 (49.6)	N/A
High school or lower educational attainment, n/N (%)	100/485 (20.6)	N/A
Rural residence, n/N (%)	44/483 (9.1)	46/482 (9.5)
Having cognitive dysfunction, n/N (%)[b]	N/A	189/438 (43.2)
Having sensory impairment, n/N (%)[b]	N/A	144/438 (32.9)
Number of devices used, mean (SD)[c]	3.4 (1.35)	1.8 (1.49)
Number of functions used, mean (SD)[d]	4.2 (1.73)	1.6 (1.92)

[a] N/A: not available.

[b] Cognitive function and sensory impairment information was only available for care recipients and reported by 556 (88.8%) out of 626 total eligible caregivers.

[c] Number of devices used ranged from 0 to 7.

[d] Number of functions used ranged from 0 to 8.

Comparing Technology Use Among Caregivers and Care Recipients

McNemar tests showed that significantly greater proportions of caregivers used all examined technologies than their care recipients (all $P<.05$), with the exception of the medication alerts or tracking function ($P=.45$; Table 2). κ coefficients ranged from 0.09 to 0.42 (Table 3), indicating a poor to moderate degree of matching (ie, concurrent use or no use) of technology among caregivers and care recipients. For example, there were 84% (404/481) of dyads in which the caregiver used a computer, yet there were only 31.2% (150/481) of dyads in which both the caregiver and care recipient used a computer.

Table . Use of different devices and functions among caregivers and care recipients (n=486).

Variables		Caregivers, n/N (%)	Care recipients, n/N (%)	*P* value[a]
Devices				
	Cell phone	268/481 (55.7)	231/481 (48)	.002

	Communication	168/481 (34.9)	64/481 (13.3)	0.12
	Ride-sharing	20/480 (4.2)	376/480 (78.3)	0.25
	Online shopping	127/481 (26.4)	82/481 (17)	0.12
	Online banking	105/480 (21.9)	108/480 (22.5)	0.11
	Navigation	75/479 (15.7)	132/479 (27.6)	0.09
	Online entertainment	122/480 (25.4)	203/480 (42.3)	0.39
	Medication alerts or tracking	22/481 (4.6)	397/481 (82.5)	0.34
	Physical activity tracking	20/481 (4.2)	370/481 (76.9)	0.22

[a] Poor (κ>0.20), fair (κ=0.21-0.40), moderate (κ=0.41-0.60), good (κ=0.61-0.80), and very good (κ=0.81-1.00) matching.

Correlates of Technology Use Among Caregivers

The multivariable Poisson regression analyses suggested that the expected number of devices used among caregivers with household incomes less than US $50,000 was 0.88 times the number of devices used among those with household incomes of US $50,000 or more (*P*=.02; Table 4). Using a separate regression analysis, the results indicated that the adjusted mean number of functions used among caregivers decreased by 0.8% for every 1-year increase in the caregivers' age (*P*<.001). Additionally, the adjusted mean number of functions used among caregivers was negatively associated with household income (b=−0.097; *P*=.04) and educational attainment (b=−0.188; *P*=.002). The estimated number of functions used among caregivers in the lower household income and lower educational attainment categories was significantly lower than that of caregivers with higher socioeconomic status.

Table . Multivariable Poisson regression analysis for predicting the total number of devices and functions used among caregivers (n=486).

Outcome and variables		b[a] (SE)	IRR[b] (95% CI)	*P* value

Correlates of Technology Use Among Care Recipients

For care recipients, age and cognitive dysfunction were negatively associated with number of devices (b=−0.024; *P*<.001 and b=−0.394; *P*<.001, respectively) and functions (b=−0.032; *P*<.001 and b=−0.370; *P*=.002, respectively; Table 5). In contrast, caregivers' technology use was positively associated with care recipients' technology use (b=0.184; *P*<.001 for devices and b=0.238; *P*<.001 for functions; Table 5).

Table . Multivariable Poisson regression analysis for predicting the total number of devices and functions used among care recipients (n=438).

Outcome and variables		b[a] (SE)	IRR[b] (95% CI)	*P* value
Number of devices				
	Age	−0.024 (0.003)	0.976 (0.970-0.983)	<.001
	Rural residence	−0.102 (0.125)	0.903 (0.707-1.154)	.41
	Cognitive dysfunction	−0.394 (0.080)	0.675 (0.577-0.789)	<.001
	Sensory impairment	0.002 (0.082)	1.002 (0.854-1.176)	.98
	Number of devices used by caregiver	0.184 (0.027)	1.202 (1.142-1.267)	<.001
Number of functions				
	Age	−0.032 (0.005)	0.969 (0.960-0.979)	<.001

Discussion

Principal Findings

Based on the data analysis and results analyzed in the above section, some key findings provide a fuller and more specific understanding of older adults' and their caregivers' use of digital technologies and highlight the contextual factors that may either affect resistance or enhance accessibility and receptivity of technology-based interventions in a broader caregiver population.

Key findings and reflections on current and parallel research are presented below.

Use of Technology and Comparison

This study examined unpaid caregivers' use of various technology and their reports of their older adult care recipient's use. It was observed that a greater proportion of caregivers reported using technologies themselves than being used by their care recipients. In our study, although 82.5% (396/480) and 84% (404/481) of caregivers reported using smartphones and computers, only 43.5% (209/480) and 33.3% (160/481) of older adults used smartphones and computers, respectively. This implies greater access to technology by caregivers than their older adult care recipients. Furthermore, although caregivers reported a higher number of functions used than the number of device types used (eg, 3.4 devices and 4.2 functions), their older care recipients reported a fewer number of functions than the number of device types used (eg, 1.8 devices and 1.6 functions). These findings imply that caregivers are more likely to maximize the potential of a technology than their care recipients, who are typically older and in poorer health [20,21]. Our findings support the 2020 AARP tech trend report [5], which pointed out that despite older adults' high engagement with their devices, "many are not using the technology to its full potential." For example, fewer than half of smart home assistant or smart speaker owners used the device daily according to the 2019 national survey [5]. Although the proportion increased to about 57% in 2023 [35], the rate has still remained relatively low. The value of technology in enabling aging in place and reducing caregiver burden will only become further enhanced when these devices can be used to their fullest potential by older adults.

The age-related discrepancy in technology adoption is likely to be associated with skills in using technology but also with attitudes related to technology. For example, "perceived needs" is an important attitudinal factor in behavior adoption [36]. In this study, there was the lack of statistically significant differences between caregivers and their care recipients in medication management technology. These findings are consistent with research by both Abrashkin et al [28] and Portz et al [37], who also found that older adults in an advanced illness management program had significantly less access to and confidence in using technology (eg, computer, internet, tablet, and cell phone) than the program enrollees' caregivers, except for medical alert devices such as medication management systems [28,37]. While the reasons underlying these findings have not been fully examined yet, this could be related to a similar level of perceived needs by both parties.

Correlates of Technology Use in Caregivers

Among caregivers, older age and lower socioeconomic factors (household income and education) were negatively associated with the number of technological devices or functions used. This finding is consistent with extant literature [38-41]. Our study further explores this relationship by revealing a difference between devices and functions. Although the number of technological devices used by caregivers was only significantly associated with household income, the number of technological functions in use was associated with multiple factors (ie, age, household income, and education).

Regarding ownership or access to technological devices, the age and socioeconomic aspects of the digital divide seem to be narrowing [5]. However, the age and socioeconomic aspects of the digital divide appear to remain in technology use [42]. Among the more critical issues facing many older adults in using digital devices such as smartphones and tablets, they lack the basic digital literacy required to use multimedia interactive devices with touchscreen technology [43,44], and their digital literacy level is likely to diminish with age [35]. Assumptions in the past were that if access to devices and basic training were provided, the "grey span" of the digital divide could be eliminated. For older adults, each new operating system revision or interface for existing devices can be a traumatic event, as what worked before no longer does. Cao et al [45] described the information overload and system feature overload of new digital applications that resulted in increased fatigue and technostress of the older adult users, further increasing their resistance to technology adoption. These findings align with the AARP national survey findings indicating a limited set of tasks performed by older adults on technology [5,35]. This continuing of the digital divide can disproportionately impact caregiving for older care recipients, especially those whose primary caregivers are often older adults.

Correlates of Technology Use in Care Recipients

Our study found that, for care recipients, age and cognitive dysfunction were negatively associated with the number of devices and functions. In contrast, care recipients' use of a device or function was positively associated with the use of the technology among their caregivers. Along with the previous findings about the correlates of technology use in caregivers, these findings align with Baishya and Samalia's [46] assertion that technology adoption is contextual. This study's findings emphasize the need for additional research to identify and understand the contextual factors to enhance the accessibility and receptivity of technology-based interventions in a broader aging community.

Limitations

This study is not without limitations. Efforts were made to diversify the convenience Qualtrics panel sample by specifying the proportion of sample characteristics of respondents to ensure heterogeneity in key factors such as age, gender, race and ethnicity, and geographic region. However, this study did not use probability sampling and is subject to a potential nonprobability sampling bias. For example, given the nature of web-based recruitment, the study population already has access to the internet. Although the majority of caregivers have access to the internet (eg, 78% in 2018 [47]), the study findings may not be generalizable to a group of caregivers without access to the internet. Additionally, this study used proxy responses for care recipients' technology use (ie, as reported by their caregivers). Further, some key sociodemographic characteristics of care recipients were not collected.

Our restriction to unpaid caregivers who provided at least 8 weekly hours of care was intended to ensure that caregivers were familiar with their care recipients. However, it is important to note that previous literature indicates that caregivers tend to underestimate care recipients' physical and cognitive functions and certain activities [48,49] and may also be imprecise in reporting technology use. In this study, many care recipients had cognitive impairments or sensory impairments, which might have adversely affected caregivers' perception of care recipients' user capacity and actual use of technology. However, we also note that many older persons do experience these functional limitations and impairments and their inclusion is important for reflecting health conditions and technology use in this population, albeit recognizing reporting limitations. This study was not able to differentiate the cross-use or whether the technology was used explicitly for caregiving functions. Future studies can benefit from the specification of the purpose of different technologies related to caregiving tasks and more precise measurement of care recipients' technology use, such as daily diary use of technology devices and functional use over a specified period of time or digital tracking of technology use.

This study was conducted prior to the onset of the COVID-19 pandemic; hence, it does not reflect what might have changed in attitude toward or use of technologies, as well as the evolution of technologies. However, it differentiates between technology use and function among both caregivers and care recipients and provides important insights related to disparities in access to technology, which was a critical factor in access to health care and other social services during the COVID-19 pandemic. Furthermore, despite the increase in technology use in older adults since the COVID-19 pandemic, this study's findings align with the more recent report on older adults' technology use pattern regarding the use of functions and socioeconomic correlates (eg, income) [35].

Conclusions

With the increasing use of technology solutions for caregiving that are becoming available on the market, it is important to be aware of factors associated with the current digital divide in technology use—both in terms of the number and diversity of devices and their functional use. It is critical to look forward to what the future might hold regarding the technology being used to reduce caregiver burden and enhance care recipients' health, independence, and quality of life. A digital divide among older adults can exacerbate greater health disparity since technology is a powerful source for obtaining information and communicating with health care and social service providers [50].

A major finding from this study was the existence of significant disparities in the use of technological devices and functions among caregivers and their older adult care recipients. Among caregivers, significant differences were observed in technology use based on age and socioeconomic factors. In addition, this study suggested that caregivers' technology use is an enabling factor for older care recipients' technology use, independent of advanced age and cognitive impairment, which depressed use, indicating pathways for clinical intervention.

This study was conducted before the onset of the COVID-19 pandemic, which demonstrated the growing importance of connecting on the web for basic health care. The extent to which observed relationships between individual and socioeconomic moderators and technology use have changed since COVID-19 is a question for further study. The importance of technology use has become more salient during the recommended "physically distant stay at home" orders for older adults to stay socially connected with loved ones or professional social connectors, whether living at home, in assisted living facilities, or even nursing homes [51]. Additionally, familiarity with or access to technology can facilitate or act as a barrier to obtaining COVID-19 vaccinations. For example, the reach of a digital platform to track vaccinations and make follow-up interactions among older adult populations, who would benefit greatly from such technology, will depend largely upon the extent telecommunication or telehealth is used or accepted by older adults or their caregivers.

In summary, this study adds to the rapidly expanding field of technology in the health and aging realm by describing potential contextual factors in technology use, which may contribute to the disparities in technology use among older adults and their care recipients [52,53]. Further efforts are needed to expand the understanding of how these contextual factors contribute to technology adoption among caregivers and their care recipients and the benefits and costs of such technological innovations [54]. Especially relevant is how social workers, health professionals, educators, and the community can facilitate and maintain appropriate use of new and emerging technology for critical interactions normally and enable access to the needed caregiver and social resources during the COVID-19 pandemic or after it subsides. Furthermore, future research could gain additional benefits by concentrating on broader categories of functions. This approach would enable a more targeted investigation into particular functions related to specific outcomes, such as economic functions and financial health.

Acknowledgments

We thank all the caregivers who participated in our web-based survey, which formed the basis of this research. The caregiver survey was funded by contributions from DVD Associates LLC, Clairvoyant Networks Inc, and The Texas A&M Center for Population Health and Aging. Clairvoyant Networks Inc was not involved in the manuscript's conceptualization, data analyses, interpretation, or development.

Authors' Contributions

MGO lead the study conceptualization and manuscript development. SL conducted all statistical analyses. All authors contributed to the study conceptualization, data collection, and development and revision of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The potential benefits of IT for the well-being of older adults have been widely anticipated. However, findings regarding the impact of internet use on depressive symptoms are inconsistent. As a result of IT's exponential growth, internet skills have supplanted internet access as the source of the digital divide.

Objective: This study evaluates the effect of internet skills on depressive symptoms through an instrumental variables (IV) approach.

Methods: Data from the China Health and Retirement Longitudinal Study's wave 4 (2018) were used. This included 16,949 community residents aged 45 years and older. To overcome the endogeneity issue, we used an IV approach.

Results: Our results reveal the emergence of a second-level digital divide, the disparity in internet skills, among Chinese middle-aged and older adults. Liner regression suggests that a 1% increase in internet skills is associated with a 0.037% decrease in depressive symptoms (β=−.037, SE 0.009), which underestimates the causal effect. As expected, internet skills are an endogenous variable (*F* test *P* value <.001). IV regressions indicate that a 1% increase in internet skills reduces 1.135% (SE 0.471) to 1.741% (SE 0.297) of depressive symptoms. These 2 IV are neither weak (F_{-1}=16.7 and 28.5; both >10) nor endogenous (Wu-Hausman test *P* value of .10; >.05 or >.01).

Conclusions: Better mental health is predicted through improved and higher internet skills. Consequently, residents and policy makers in China should focus on bridging the digital divide in internet skills among middle-aged and older adults.

KEYWORDS

internet skills; depression; second-level digital divide; instrumental variables

Introduction

Background

By 2050, there will be 2.1 billion individuals aged 60 years or older, with 80% of them living in low- and middle-income countries [1]. Late-life depression is a major public health challenge for this population because of its high prevalence and poor outcomes [2,3]. China, one of the low- and middle-income countries, is predicted to reach nearly 400 million older adults by 2050 [4]. Approximately 20%-31% of individuals aged 45 years or older in China had depression in 2015, with the highest risk among all age groups [5,6]. In 2013, the annual cost for individuals with mental disorders in China was US $3665, with depression and depressive symptoms accounting for 54% of the total [7,8]. With a rapidly aging population, late-life depression may damage the well-being of older adults; it also brings more burden to the family as well as the community. China accounts for nearly 17% of the global mental health burden [9]. In contrast, China's mental health system has only 8.75 mental health workers per 100,000 residents [10], which calls for novel approaches with low cost and wide access to reduce depressive symptoms among middle-aged and older adults.

Given that the internet can improve one's mental health by reducing social isolation and loneliness, it has attracted marked attention among researchers [11]. Prior work has investigated the correlation between depression symptoms and the frequency, type, and purpose of internet use, and identified potential mechanisms from the perspective of social connectedness [12-16]. Overall, these studies suggest that internet use among older adults offers new opportunities to prevent, support, and treat late-life depression in family and community contexts.

We aim to complement this research topic in 2 ways. First, previous studies have mainly measured internet use from the perspective of the first-level digital divide, that is, whether respondents have access to the internet [12,16,17]. With the rapid penetration of IT, internet skills (the capability of internet use) have replaced internet access as the most essential variable in characterizing IT use [18-20]. We believe that we have now entered the second level of the digital divide and thus chose internet skills to measure internet use. Second, the existing literature has derived results mainly from correlation analysis and yielded mixed evidence [13,16,21,22]. However, the findings of correlation analysis cannot provide interventional insights; only causal findings can do so [23]. Several modern economic approaches have been used in empirical studies to estimate the causal relation, such as the instrumental variables (IV) approach. Joshua D Angrist, who shares the 2021 Nobel Prize for methodological contributions to the analysis of causal relationships, adopted and developed the IV approach to quantify the impact of educational attainment on wage growth [24]. In the face of rising public health challenges in an aging society, policy makers and the public need robust insights. Therefore, our goal is to uncover the causal effects of internet skills on depressive symptoms in middle-aged and older adults and provide practical implications for promoting mental health through daily IT use.

Overall, IT-based mental health promotion programs could be an essential means to address the high prevalence of depression in older adults when they lack specialized medical resources [25]. As the internet spreads to older adults, we should pay more attention to their differences in internet skills rather than in internet access [20,26]. We should also focus on causal effects to provide more valuable evidence for public health practices [23]. Therefore, this study examines the causal effect of internet skills on depressive symptoms among middle-aged and older Chinese adults by using data from the 2018 China Health and Retirement Longitudinal Study (CHARLS). We used the IV approach to address the endogeneity issue and guide daily internet use practices among middle-aged and older adults to improve their mental health.

Literature Review

Internet Use and Depressive Symptoms Among Middle-Aged and Older Adults

Numerous studies have examined the relationship between internet use and depressive symptoms in older adults using national representative data sets. Table S1 in Multimedia Appendix 1 summarizes the key findings from these studies. Several insights are worth noting. First, analyses of the correlation between internet use and depressive symptoms yielded inconsistent conclusions. Jun and Kim [27] reported in 2015 that internet use was associated with lower levels of depressive symptoms among Korean older adults. Lee et al [28] showed that older adult cancer survivors in the United States used the internet to complete personal tasks or handle health-related matters, but internet use was unrelated to their depressive symptoms. Lifshitz et al [17] found that the use frequencies of 4 web-based functions (interpersonal communication, information seeking, task performance, and leisure) were not associated with depressive symptoms among Israeli older adults.

Second, some studies have focused on the potential mechanism underlying the association between internet use and depressive symptoms. Internet use is related to a decrease in depressive symptoms among socially inactive older adults [15], and this association is mediated by social isolation [12] and loneliness [22]. Internet use also reduces the negative effect of disadvantageous socioeconomic status (SES) on depressive symptoms [16,29]. However, most studies have used correlation analyses, and only a few studies have revealed a causal effect of internet use on depressive symptoms.

Cotten et al [30] used the propensity score matching method and the cross-sectional Health and Retirement Survey and found that internet use reduced the probability of a depressed state by about 20%-28% among retired older adults in the United States. Subsequently, Cotten et al [12] used a longitudinal design and lagged variables to handle the causal effect, and found that internet use reduced the probability of a depressed state by about 33% among retired older adults in the United States. Nie et al [31] used the IV approach and 2010 cross-sectional China Family Panel Studies (CFPS) data and found that internet use was associated with higher levels of depressive symptoms among Chinese individuals aged 16-60 years. Xie et al [32] also used the CHARLS and propensity score matching method and reported that internet use increased depressive symptoms in Chinese older adults.

This study also uses a nationally representative data set, CHARLS, to examine the effect of internet use on depressive symptoms. We extend the concept of IT use by focusing on the second-level digital divide, which emphasizes the critical role of internet skills. We also attempt to identify causal effects by applying an IV approach to quantify the impact of internet skills on depressive symptoms. In the next section, we elaborate on the second-level digital divide in internet use among older adults and ways to address the endogeneity of internet skills.

Internet Skills

The digital divide refers to certain groups having better opportunities than others to benefit from IT. Prior studies have suggested three stages of the digital divide [18,20,26]: (1) economic divide, which implies that some people cannot afford access to IT; (2) usability divide, which emphasizes that IT remains so complicated that some people cannot use it even if they can afford it; and (3) empowerment divide, which refers to inequality of outcomes after IT use. As internet use becomes prevalent among older adults, it is increasingly important to look at who uses the internet and distinguish their internet skills [18,33]. For depression among middle-aged and older adults, the existing literature has primarily discussed the first-level digital divide, which refers to the impact of internet use on depressive symptoms. We further examine the second-level digital divide, namely how internet skills influence depressive symptoms among middle-aged and older adults.

IV of Internet Skills

On examining how internet skills affect depressive symptoms, endogenous issues may be raised for two main reasons: (1) internet skills and depressive symptoms are simultaneously affected by unobserved factors such as personality traits, and (2) mentally healthier individuals are more prone to use the internet and have better internet skills. We have used the IV approach to handle potential endogeneity and obtain reliable causal effects.

A few studies have applied the IV approach to capture the effect of internet use. Hong and Chang [34] used the geographical distance to the nearest telecommunication station for each household as an instrumental variable to estimate the impact of internet use on household income at forestry farms in Fujian Province in China. Gao et al [35] applied provincial internet penetration rates as an instrumental variable to capture the effect of computer penetration on Chinese rural farmers' income. Nie et al [31] used the number of provincial internet broadband access terminals as an instrumental variable to examine the relationship between internet use and depressive symptoms among 16- to 60-year-old Chinese individuals.

This study adopts the above-described "resources accessibility" approach by using the following 2 IV: mobile phone penetration and the performance of government websites. Specifically, higher mobile phone penetration in a city implies that residents have easier access to IT resources, which implies a higher level of IT acceptance and internet skills [31,35]. Similarly, better performance of government website operations indicates higher informatization of the city, which implies higher internet skills of residents in that city [34]. Furthermore, there is no evidence that city-level mobile phone penetration or government website performance is directly associated with individual depressive symptoms. Overall, mobile phone penetration and government website performance correlate with each resident's internet acceptance and skills, while not being directly correlated with individual depressive symptoms. Therefore, these variables satisfy the principle of IV selection logically [24,36]. Furthermore, when considering the population of older adults in each city, both variables are multiplied by the proportion of the city's population aged 60 years and older.

Methods

Sample and Data Collection

We analyzed data from CHARLS, a nationwide survey designed to provide comprehensive and high-quality data on the demographics, household characteristics, health status and functioning, work, and retirement information of Chinese residents aged 45 years and older [37]. CHARLS is a longitudinal study that used a 4-stage, stratified, cluster sampling design to enroll community-dwelling residents from 450 villages and 150 counties in 28 provinces in China. The national baseline study (wave 1) was conducted in 2011. The last public survey (wave 4) was conducted in 2018, with information obtained from 19,816 respondents.

Since IV regression can investigate the causal effects of independent variables on dependent variables in cross-sectional data, we selected 16,949 participants from CHARLS wave 4. The sampling process is as follows: (1) respondents aged 45 years and older (excluded 178 samples); (2) provided information on internet skills and depression (excluded 2689 samples).

The 2018 Yearbook of China Communication and the 2017 China Government Website Performance Evaluation database provide information on IV. The Yearbook of China Communication provides annual updates on the development of the Chinese telecommunication industry by city. The China Government Website Performance Evaluation contains performance evaluations of government websites for all cities in China, with the latest version being publicly available in 2017.

Variables

Depression

The 10-item Center for Epidemiologic Studies Depression Scale (CES-D-10) is used to examine depressive symptoms. The respondents were asked about their positive feelings, negative emotions, and somatic symptoms during the past week. Scores for each question ranged from 0 to 30, with high scores indicating severe depressive symptoms. Our study considers 12 as a cutoff point to describe the prevalence of depression [38], using the CES-D-10 score in IV regression.

Internet Skills

New questions about internet skills have been added in wave 4 of CHARLS. Respondents were asked whether they would use the following web-based functions on their mobile phones: (1) chat on social media (such as WeChat); (2) post on social media (such as WeChat moments); and (3) mobile payments (such as Alipay or WeChat). Respondents provided binary responses, denoting "yes" or "no." Subsequently, based on the perceived complexity associated with these distinct functions, this study assigned numerical scores to gauge respondents' internet skills. Respondents capable of using mobile payment systems were assigned a score of 9, those adept at posting on social media received a score of 5, individuals proficient in social media chat were assigned a score of 1, while those abstaining from all the aforementioned functionalities received a score of 0. The cumulative internet skills score was derived by evaluating respondents' competencies across various functions, within a scale spanning from 0 to 15 points. Higher scores herein signify enhanced internet aptitude.

To reinforce the dependability of our findings, we incorporated an additional measurement strategy, using both a Likert scale with scores ranging from 1 to 5 and a cumulative scoring method as alternative approaches for assessing internet skills. An IV analysis was conducted using these supplementary metrics of internet skills. The inferences drawn from this analysis are in concordance with the foundational model's findings. Detailed information on the measurements and the corresponding results can be found in Tables S1-S4 in Multimedia Appendix 1.

Mobile Phone Penetration and Performance of Government Websites

The first instrumental variable is mobile phone penetration: the number of mobile phone subscribers at the end of the year in a city multiplied by the proportion of individuals aged 60 years and older in each city. Another instrumental variable is the performance of government websites: the score is the sum of the operational scores of each city's government website, ranging from 50 to 100.

Potential Confounding Variables

Potential confounding variables are shown in Table 1.

Table . Definition/codes of the potential confounding variables.

Variable	Codes/definition
Age	Continuous variable
Gender	0=male; 1=female
Marital status	0=single (divorced, widowed, or single); 1=partnered (married or partnered)
Retirement	0=no; 1=yes
Education	0=less than lower secondary (no formal education, did not finish primary school but can read, private tutoring, elementary school, or middle school); 1=upper secondary (high school or vocational school); 2=tertiary (2- or 3-year college, college graduate, or postgraduate degree)
Total household per capita consumption	Total household consumption or number of people living in the household (skewed distribution, logarithmically transformed)
Residency	0=urban; 1=rural
Ever had a memory problem	Ever had doctor-diagnosed memory-related diseases, including dementia, brain atrophy, and Parkinson disease (0=no; 1=yes)
Ever had a psychological problem	Ever had doctor-diagnosed psychiatric problems, such as emotional, nervous, or psychiatric problems (0=no; 1=yes)
Mobility	A 9-item summary of any difficulty with mobility activities. The mobility activities are walking 100 m, climbing several flights of stairs, getting up from a chair, stooping or kneeling or crouching, extending arms up, lifting 5 kg, and picking up a small coin. Continuous variable: 0-27 (skewed distribution, logarithmically transformed)

Ethical Considerations

This investigation constitutes a secondary analysis of publicly available data sets; hence, prior registration was not deemed necessary. The foundational data used herein are obtainable via the official portal of the CFPS [39]. Ethical approval for the CFPS was granted from the Biomedical Ethics Committee at Peking University (IRB00001052-14010).

Statistical Analysis

To examine the effect of internet skills on depressive symptoms, we performed an IV regression to control for possible endogeneity issues. Given that both the dependent and independent variables have skewed distributions, it is meaningful to understand the impact of internet skills on depressive symptoms in terms of percentage change. Thus, we estimate a log-log specification presented in the two-stage least squares model as follows:

(1)

(2)

where refers to CES-D-10 scores for individual , denotes internet skill scores for individual , indicates potential confounding variables, is the mobile phone penetration in city , and are error terms.

We carried out regression analysis to evaluate the association of individual depressive symptoms with individuals' internet skills and the mobile phone penetration in the city. For another instrumental variable, the first stage of the two-stage least squares model also can be written as follows:

(3)

where is the government website performance of city .

Diagnostic tests including correlation, overidentification, and weak IV tests supported the validity of the aforementioned IV. The data were analyzed using R package AER (version 1.2; R Foundation for Statistical Computing).

Results

Descriptive Statistics

The demographic characteristics of the sample are shown in Table 2. There are 16,949 participants, and the mean age in wave 4 (2018) was 62.3 (SD 9.9) years. Most participants are female (n=8735, 51.5%), have a partner (n=14,672, 86.6%), have less than a lower secondary level of education (n=14,619, 86.2%), are currently employed (n=11,086, 66.5%), and are rural residents (n=10,095, 60.7%). In addition, internet skills have significant differences across demographics, including age, gender, and education levels.

Table . Characteristics of the selected respondents. The total percentage may not equal to 100 due to rounding.

Characteristics	Full sample (n=16,949)	Scores for IT skills					*P* value
		0 (n=14,601, 86.1%)	1 (n=312, 1.8%)	6 (n=558, 3.3%)	10 (n=272, 1.6%)	15 (n=1206, 7.1%)

[i] CES-D-10: 10-item Center for Epidemiologic Studies Depression Scale.

Table 1 reveals a distinct profile among individuals with elevated internet skill scores. These individuals are predominantly younger, hail from higher-income households (higher total household per capita consumption), are more likely to be male, have partners, are nonretired, and are predominantly urban residents. Additionally, this cohort is characterized by superior health outcomes, evident from lower incidences of memory-related issues, psychological problems, and reduced mobility challenges.

Further analysis of internet skill scores underscores a stark digital divide. A significant 86.1% of participants do not engage with the internet, thereby receiving a score of 0. Conversely, within the subset of internet users, those with advanced internet skills form the majority, representing 7.1% of the overall sample and 51.4% of internet users (1206 out of 2348 individuals). This disparity highlights not only a first-level digital divide but also a pronounced second-level digital divide within the middle-aged and older demographic, marked by a dual extremity of complete absence or high proficiency in internet skills.

Prevalence of Depression in Residents

The prevalence of depression varied among participants with different levels of internet skills. Respondents with lower-level internet skills are at higher risk of depression than those with higher-level internet skills (30.23% vs 20.51% vs 17.38% vs 13.24% vs 15.17%).

The Effect of Internet Skills on Depressive Symptoms in Residents

The association between internet skills and depressive symptoms was estimated using ordinary least squares (OLS) regression, and the effect of internet skills on depressive symptoms was subsequently estimated using IV regression (see Table 3). OLS regression suggests that a 1% increase in internet skills is associated with a 0.037% decrease in depressive symptoms (β=–.037, SE 0.009), which underestimates the causal effect. As expected, internet skills are an endogenous variable (*F* test *P* value <.001). IV regressions indicate that a 1% increase in internet skills leads to a 1.135% (SE 0.471) to 1.741% (SE 0.297) reduction in depressive symptoms. The 2 IV were neither weak (F_{-1}=16.7 and 28.5 both being >10) nor endogenous (Wu-Hausman test *P* value of .10; being >.05 or .01). Detailed results of the controls can be found in Table S5 in Multimedia Appendix 1.

Table . The results of ordinary least squares (OLS) and instrumental variables (IV) regression analyses. The potential confounding variables are controlled in all models.

	OLS	IV	
		Mobile phone penetration	Performance of government websites
Log (internet skills), β (SE)	–0.037 (0.009)[a]	–1.741 (0.471)[a]	–1.135 (0.297)[a]

[b] Demographic variables and health status have been controlled for in the model. To maintain the conciseness of the model's results, the coefficient estimates for demographic and health status variables are shown in Table S6 in Multimedia Appendix 1 rather than in the main text.

[c] Not available.

Sensitivity Analysis

We applied multiple imputation techniques to missing values, assuming that missing variables are missing at random. To examine the robustness of the results, we conducted OLS and IV regressions with missing values and compared the results. Our findings yielded no difference between complete cases and the prior sample. Detailed results can be found in Table S6 in Multimedia Appendix 1.

Discussion

This study explored the impact of internet skills on depressive symptoms. Our findings revealed that (1) internet skills are relatively low among Chinese middle-aged and older adults and (2) improvement of internet skills can reduce depressive symptoms.

Impact of Internet Skills on Depressive Symptoms

Our results suggest that for middle-aged and older Chinese adults, a 1% increase in their internet skills leads to a 1.1% to 1.7% reduction in depressive symptoms. Our main finding is consistent with those of Cotten et al [12,30], who reported a positive outcome of internet use reducing risk of depression by 20% to 33% among retired older adults in the United States. We used internet skills (0~15 points) to measure IT use rather than using dummy variables. In addition, since the CES-D-10 scores are a continuous variable, we could estimate the effect of internet skills on depressive symptoms.

Some studies have reported that internet use increases depressive symptoms in the context of China [31,32]. Nie et al [31] used the IV approach and 2010 CFPS data and found that internet use was associated with higher levels of depressive symptoms among Chinese individuals aged 16-60 years. Notably, in 2010, internet access among middle-aged and older Chinese individuals was limited [40], and some residents were even prejudiced and resistant to the internet [31]. These reasons may lead to a negative impact of internet use on depression. The existing literature predominantly addresses the first-level digital divide, examining the effect of internet use on depressive symptoms [31,32]. Our study expands on this by delving into the second-level digital divide, revealing that enhanced internet skills significantly mitigate depressive symptoms. This observation, divergent from prior studies, suggests a possible shift in the perception of the internet among the middle-aged and older Chinese individuals as it becomes more ingrained in various facets of society [31]. Proficiency in internet use potentially enables more effective usage [13,16,19], leading to positive psychosocial outcomes. For instance, improved internet skills facilitate web-based social interactions and content sharing, thus increasing social support and reducing isolation and loneliness [11,15,22,27]. Further skill enhancement allows these individuals to more efficiently perform daily activities such as shopping and bill payments on the web, fostering a greater sense of inclusion and autonomy in the digital era [14,16,19]. Such psychosocial benefits potentially alleviate depressive symptoms and bolster mental health.

Our study additionally revealed that populations with a higher SES and superior health tend to exhibit more advanced internet skills. While it has been acknowledged that SES can create disparities in resource access and health outcomes [29,33], our research indicates that the improvement of internet skills might mitigate depressive symptoms, even in scenarios where SES and health factors are consistent. This finding suggests that diminishing the second-level digital divide could play a role in lessening health disparities. Consequently, future research should delve into the potential mechanisms by which internet skills influence depressive symptoms and examine the interplay between this subject and health equity concerns.

Improving Internet Skills Among Middle-Aged and Older Residents

This study delves into the usage of the internet among middle-aged and older adults in China, analyzing it through the digital divide framework. As of 2018, around 86% of respondents either demonstrated limited internet skills or lacked access altogether. This figure represents an improvement from the 98% and 97% non–internet use rate observed between 2011 and 2015 [38], indicating a gradual increase in both internet usage and skill acquisition among this demographic. Such a trend suggests an ongoing closure of the first-level digital divide, marked by a shift from nonuse to initial internet engagement. Despite this progress, a second-level digital divide is apparent among those who have embraced the internet and acquired specific skills, with a substantial segment showing advanced internet skills, underscoring an uneven skill distribution. The variability in internet skills may be attributed to individual IT preferences and the consistent support from family and peers in IT usage and learning [20,31,41]. Considering the beneficial impact of internet skills on the mental health of middle-aged and older individuals, and in light of increasing internet penetration rates, it becomes crucial for society and policy makers alike to focus on bridging this second-level digital divide.

IT training programs can reduce anxiety in older adults, increase their interest and efficacy in IT, and improve their IT capability [42]. A community or senior university that provides courses on internet use can follow three guidelines: (1) provide regular long-term training: older adults prefer long-term guidance on IT use and a stable context for experience exchange [42]; (2) leverage the influence of those with good internet skills [43]: interacting with more qualified peers and obtaining guidance from them will reduce the attrition rate of courses; more skilled older adults are important role models and mentors for older adults to improve their skills [43]; and (3) develop web-based participation projects to encourage older adults to establish, maintain, and participate in their own web-based communities [44].

Technical support from the younger generation is vital: young people are “impatient” with older IT learners and lack an understanding of older adults’ special needs [41]. We need to educate younger generations about the benefits of internet use among older adults to inspire families and communities to bridge the digital divide for older adults. Improving internet skills also requires gerontological software design improvements. The Chinese government is actively promoting the gerontological design of internet-based applications [45]. The initial stages of the project mainly focus on interface design and function simplification. Follow-up studies should develop tools and applications that specifically support older adults' current activities and goals. Finally, older adults may have negative attitudes toward the internet [31]. It is necessary to reduce the negative connotations surrounding internet use and emphasize that web-based activity can be meaningful and manageable rather than just a form of entertainment.

Limitations

This study has several limitations. First, our findings are based on self-reported data, which implies potential self-reported bias. Second, we assume that the data are missing at random and used multiple imputations to resolve this issue. However, the excluded individuals are more likely to be older, less educated, have a severe disability, and more likely to have higher levels of depressive symptoms. Thus, we cannot exclude this bias. Third, while CHARLS provides a substantial sample size for investigating the relationship between internet skills and depressive symptoms, it is imperative to acknowledge certain shortcomings inherent in the measurement items within the secondary data. This study delineates and quantifies internet skills, differentiated by the level of difficulty associated with various functionalities. Future research should aim to explore more robust measurement methodologies to enhance the reliability of these findings. Lastly, in 2018, a significant majority (98.6%) of Chinese internet users accessed the internet via their mobile phones [46]. Consequently, this study used the rate of mobile phone penetration at the city level as an instrumental variable. This approach was further nuanced by incorporating the percentage of residents aged 60 years and older in each city. Future research should aim to enhance the precision of this instrumental variable by integrating data on city-level internet usage. Additionally, examining the segment of the population aged 45 years and older may offer more relevance, closely mirroring the age range of our study's sample. Future research can address these issues and explore the formative mechanisms of the second-level digital divide among older adults.

Conclusion

Understanding the role of IT in fulfilling the well-being of older adults has been limited. This study evaluates the effect of internet skills on depressive symptoms through the IV approach. The results reveal the emergence of a second-level digital divide—the disparity in internet skills among middle-aged and older Chinese adults. A 1% improvement in internet skills reduces depressive symptoms by 1.1%-1.7%. This study contributes to the literature on the societal impacts of the internet.

Abstract

Background: As the population ages and the prevalence of long-term diseases rises, the use of telecare is becoming increasingly frequent to aid older people.

Objective: This study aims to explore the use and adoption of 3 types of telehealth services among the older population in Israel before, during, and after the COVID-19 pandemic.

Methods: We explored the use characteristics of older adults (aged ≥65 years) belonging to Clalit Health Services in several aspects in the use of 3 types of telehealth services: the use of digital services for administrative tasks; the use of synchronous working-hours telehealth visits with the patient's personal physician during clinic business hours; and the use of after-hours consultations during evenings, nights, and weekends when the clinics are closed. The data were collected and analyzed throughout 3 distinct periods in Israel: before the COVID-19 pandemic, during the onset of the COVID-19 pandemic, and following the COVID-19 peak.

Results: Data of 618,850 patients who met the inclusion criteria were extracted. Telehealth services used for administrative purposes were the most popular. The most intriguing finding was that the older population significantly increased their use of all types of telehealth services during the COVID-19 pandemic, and in most types, this use decreased after the COVID-19 peak, but to a level that was higher than the baseline level before the COVID-19 pandemic. Before the COVID-19 pandemic, 23.1% (142,936/618,850) of the study population used working-hours telehealth visits, and 2.2% (13,837/618,850) used after-hours consultations at least once. The percentage of use for these services increased during the COVID-19 pandemic to 59.2% (366,566/618,850) and 5% (30,777/618,850) and then decreased during the third period to 39.5% (244,572/618,850) and 2.4% (14,584/618,850), respectively ($P<.001$). Multiple patient variables have been found to be associated with the use of the different telehealth services in each period.

Conclusions: Despite the limitations and obstacles, the older population uses telehealth services and can increase their use when they are needed. These people can learn how to use digital health services effectively, and they should be given the opportunity to do so by creating suitable and straightforward telehealth solutions tailored to this population and enhancing their usability.

Introduction

Background

Telehealth is the practice of providing patients with long-distance clinical health care through various communication technologies (television, email, telephone, videoconferencing, internet, and radio) when a patient and physician cannot be present simultaneously [1,2]. Telehealth, a more general term, encompasses health-related education programs such as diabetes management and nutrition seminars. It is distinct from telemedicine, which is more particularly concerned with the delivery of clinical care via the internet [3]. Telemedicine, which uses current information and communication technology, blends patient requirements with technological progress, going beyond the boundaries of traditional health care systems [4].

Telecare combines professional remote health care services with technological tools and assistive technologies. It offers a range of services, including training, monitoring, consultation, communication, and consultation to preserve users' autonomy and improve their quality of life. It is particularly valuable for those who live in remote areas, groups considered vulnerable, and aging populations [1,5].

The world's population is aging quickly, especially in Europe, according to demographic statistics. Aged populations are now more prevalent than ever in many countries, particularly in the more high-income areas. The percentage of people aged >60 years in the world will double between 2000 and 2050, from approximately 11% to 22%. It is predicted that between 2000 and 2050, the number of persons aged >80 years will double [6]. The aging of the population has resulted in many older people living alone in our communities. Because of instances such as the death of a spouse, older people are increasingly being compelled to singularize or live in a single home [4].

Telecare is used more frequently to assist older people in maintaining their independence and carrying on with their current way of life as the population ages and the prevalence of long-term conditions rises. It appears to be one of the most effective strategies for promoting independent living in a community-dwelling setting because it gives an older person a sense of security and comfort [1,7].

Older people have emerged as one of the primary target demographics for telecare technology in recent years, with a variety of gadgets available for those with long-term medical illnesses as well as for those who have limited mobility or memory issues associated with aging [4,8]. Living at home is associated with a superior quality of life, dignity, and independence, and there is a growing trend among older people to do so rather than age in a health care facility [9,10].

A sizeable portion of the population of older adults have at least 1 chronic illness that necessitates routine monitoring and some level of self-management [11]. However, older patients are less likely to notice signs of an exacerbation before being admitted to the hospital, have less awareness of their disease, and engage in fewer self-management activities [12]. The issue may be resolved by evolving technologies that can notify patients to monitor health status information that can help with at-home self-management [7,13,14]. Although there has been general success for many of the telehealth systems already in use, these technologies are sometimes created without considering how easy they will be for patients and caregivers to use. Although telemedicine offers a way to deliver equitable health care, many people with disabilities find it difficult and challenging to access and use telehealth services [15].

Patients participating in video visits must have the technical knowledge and aptitude to connect to the internet, use and troubleshoot audio-visual equipment, and converse without in-person cues. Due to their limitations or lack of technological skills, many older people might be unable to perform this. In addition, older individuals frequently resist using new technology, especially when it comes to gaining knowledge and learning the skills required to operate computers and other electronic devices [4,16]. Older people may also have changes in their eyesight, hearing, and dexterity in addition to the symptoms of chronic illnesses, which could make it difficult for them to use different telehealth devices [17,18].

Although phone consultations are not ideal for care that necessitates visual assessment, they may increase access for the estimated 6.3 million older people who are unfamiliar with technology or have vision impairment [19]. To safeguard both patients and medical staff during the COVID-19 pandemic, there has been a substantial shift to telemedicine, with video visits being encouraged to see patients at home [3,11].

Telehealth, which allows patients to consult with medical professionals in real time and receive advice on their health issues, has become a basic requirement for the public, especially for those who are in quarantine. Telehealth was the most often used method of service delivery during the pandemic, according to a recent report from the World Health Organization [20]. The study also revealed a trend of rise in telehealth uses as income levels rise; even low-income nations, where 42% of people experienced service interruptions during the COVID-19 pandemic, reported using this technology.

The prevalence of telemedicine unreadiness among Medicare beneficiaries aged ≥65 years in the United States during the COVID-19 pandemic was studied in cross-sectional research in community-dwelling individuals and reported by Lam et al [16]. Patients who met the criteria for unreadiness included those who were older, male, single, Black, or Hispanic; lived in a nonmetropolitan area; and had less education, less income, and worse self-reported health. In total, 72%) of adults aged> 85 years met those criteria.

Despite the difficulties with using technology mentioned earlier, there is a misperception about older adults that they either lack interest in using technology or are unable to use technological platforms. Contrary to that belief, most older persons (70%) own and regularly use a computer, smartphone, or tablet with an internet connection at home [21]. However, just a small percentage of older people are comfortable using telehealth (11%) [21].

Objectives

Considering the growing phenomena of our aging society and the need to implement telecare for this age group, specifically, this study aimed to explore the use and adoption of 3 types of telehealth services among the older population in Israel before, during, and after the COVID-19 pandemic. Using a quantitative approach, the data have been extracted before the COVID-19 pandemic, throughout the pandemic, and during the months after the peak of the epidemic in Israel.

In addition, we wanted to determine whether the COVID-19 pandemic had an impact on how older adults used telehealth services and, if so, whether those changes would last once the pandemic concluded. The results of this study will enable us to emphasize to health care decision makers the necessity for tailored telemedicine-based care that considers the needs, abilities, and preferences of the older population and adapts over time as those needs change.

Methods

Study Population

Clalit Health Services, the largest integrated health care service provider and payer system in Israel, has >4 million active members. Clalit Health Services has a comprehensive health care data warehouse, which integrates hospital and community medical records, laboratory and imaging information, pharmaceutical records, health care expenses, and Ministry of the Interior vital statistics of all the members. Clalit Health Services experiences membership turnover of <1% annually, making it easier to track population trends over time. The inclusion and exclusion criteria are presented in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Membership in Clalit Health Services for at least a year
- Aged ≥65 years at each period

Exclusion criteria

- No Clalit Health Services membership
- Aged <65 years at each period

Ethics Approval

The study was ethically approved by the boards of the Clalit Health Services on January 18, 2021 (reference numbers 826 and COM-0113-21).

Study Design

This study is a repeated cross-sectional analysis. This type of study looks at data collected at a single point in time, rather than over a period, which is useful for comparing and analyzing the effect of different factors on one another or describing a sample.

Data Extraction

We explored the telehealth use characteristics of older adults (aged ≥65 years) belonging to Clalit Health Services in several aspects:

1. The use of digital services for administrative tasks such as web-based medical appointment scheduling and physician request submission. This category of eHealth services was named *administrative*.
2. The use of synchronous web-based, telephone, or digital visits with the patient's personal physician during clinic business hours (through video or telephone), initiated by the patients themselves. This type of consultation was named *working hours telehealth consultations*.
3. The use of web-based or telephone consultations (not with the personal physician) during the evenings, nights, and weekends when the clinics are closed, including the use of a phone, video camera, or "tytocare" equipment [22]. The term *after-hours consultations* was used to describe this form of consultation.

Data Extraction Periods

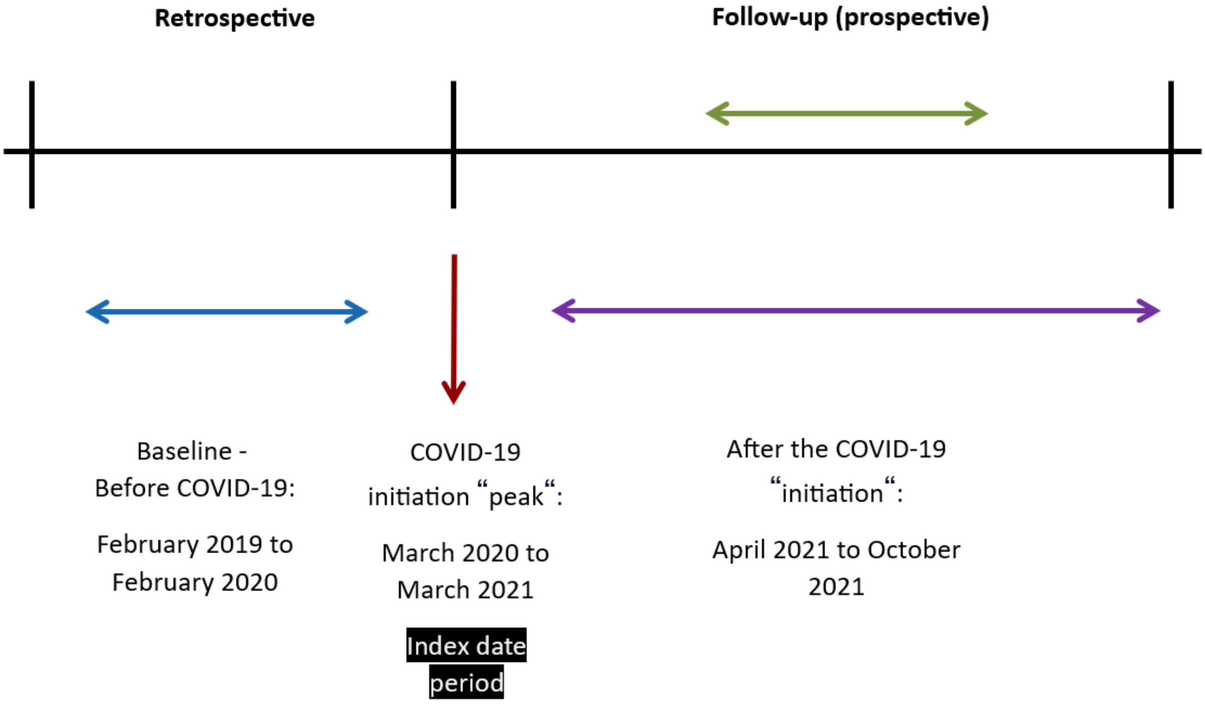
Three separate periods were used to collect and analyze the data:

1. Baseline—from February 1, 2019, to the end of February 2020, the period before the COVID-19 pandemic in Israel, which was labeled period 1 (*before*).
2. Initiation—from March 1, 2020, to March 31, 2021, when lockdowns were implemented during the COVID-19 pandemic in Israel. Period 2 (*during*) was used to designate this time frame.
3. Follow-up—from April 1, 2021, to the end of October 2021, following the COVID-19 pandemic peak in Israel. Period 3 (*after*) was used to designate this time frame.

Study Timeline

Figure 1 describes the timing scheme. The "index date period" refers to the time from March 1, 2020, to March 31, 2021, which is considered the peak of COVID-19 pandemic in Israel. The study was designed and planned during this period.

Figure 1. Study design timeline.



We planned to gather certain data retrospectively from February 1, 2019, to the index date period and the rest of the data prospectively from the index date period to the end of the follow-up period date, which was October 31, 2021. As intended, and previously indicated, the participant files were recruited from February 1, 2019, to October 31, 2021.

Finally, after gaining approval from all committees of Clalit Health Services, the raw data were accessed for research purposes between February 20, 2022, and May 16, 2022.

Study Outcomes

As previously indicated, the main outcomes (dependent variables) measured were as follows: (1) The use of digital services for *administrative* tasks, such as web-based medical appointment scheduling and physician request submission, named *administrative services* (2) The use of video or telephone calls with a personal physician conducted during clinic business hours at the patients' request, named *working-hours telehealth consultations* (3) The use of web-based consultations (not with the personal physician) during the evenings, nights, and weekends when the clinics are closed, including the use of the telephone, video camera, or Tytocare device, named *after-hours consultations*

Covariables (Covariates)

The inpatient and outpatient data warehouses of Clalit Health Services have provided the data. The information covered the use of telemedicine and digital health services during the aforementioned 3 periods. The variables can be described as dichotomous (use of telemedicine and digital health; yes or no) and as categorical in the aspect of which digital services were used: (1) administrative only use; (2) consultations with the personal physician—*working-hours telehealth consultations*; (3) consultations during the after hours of the clinic—*after-hours consultations*.

Multiple patient variables, such as sociodemographic information (age, sex, place of birth, place of residence, socioeconomic status [SES], ethnicity, country of birth, etc), clinical information (chronic diseases, habits, etc), and use of chronic medications have been examined for each period.

The different features were extracted and categorized as follows: (1) sociodemographic parameters, including sex, age, SES, country of birth (coalesced into regions when necessary), ethnicity by country of individual's or parents' birth, sector (clinic level data—predominantly Arab or Jewish), marital status and number of children, Clalit Health Services affiliation by district, subdistrict, and clinic; (2) clinical markers or comorbidities, such as smoking status, alcohol use (and related diagnoses), BMI, height, weight, Charlson comorbidity index (the most widely used comorbidity index used to determine survival rate [1 year and 10 year] in patients with multiple comorbidities), presence of chronic diseases such as active malignancy, cardiovascular diseases (ischemic heart disease, cerebrovascular disease, hypertension), asthma, diabetes, neurological diseases (Alzheimer disease and Parkinson disease), psychiatric disease, diagnosis of COVID-19 since the index period; (3) use of chronic medications, especially antianxiety, antidepression, and sleep-aid medications.

Statistical Analysis

We analyzed the data according to the type of telehealth use (working hours telehealth consultations, after-hours consultations, and administrative), the time frame in which it was used (before, during, or after the COVID-19 pandemic in Israel), and the amount of use (how often it was used) according to 2 categories (0 or ≥1 time).

We used appropriate descriptive statistics to characterize the study population. The association between telemedicine use and each available socioeconomic factor was studied using univariable analyses while comparing participants who used telemedicine at least once during the specific period with patients with zero use (Pearson χ^2 test). We have used nonparametric related samples Cochran *Q* test to compare telemedicine use during the 3 periods.

Post hoc analysis with the Dunn and McNemar post hoc tests was conducted (with a Bonferroni correction applied) to access both between-subjects and within-subjects effects, analyzing each pair of periods. In addition, we performed a set of multivariable binary logistic regression models to estimate the association between telemedicine use and socioeconomic factors during each period. These models were used to calculate odd ratios (ORs) and 95% CIs. A *P* value <.05 was considered statistically significant. SPSS IBM Statistics for Windows, predictive analytics software (version 28.0 [28.0.1]), was used for data analysis.

Privacy

Data extraction was conducted by the research room team at Clalit Health Services. The deidentified, raw extracted data were stored on the virtualization desktop infrastructure (VDI), a secure setting. Data were analyzed on the VDI, and only aggregated nonidentifiable results were moved out of the VDI for publication.

As discussed earlier, we did not have any access to identified information. We had limited and restricted access only to unidentified data. A confirmation from the special committee for data mining from Clalit Health Services authorities was received on August 25, 2021.

Results

General Characteristics

There were 669,349 patients in total who met the inclusion criteria at the start of period 1 (2019). In 2020, a total of 642,223 patients met the criterion for inclusion, whereas in 2021, only 618,850 patients met the requirements. Various analyses were carried out on this population. The general characteristics are presented in Table 1.

The mean Charlson score was 5.59 (SD 2.57), with a median of 5.00 (range 2-22). The mean age in 2019 was 75.16 (SD 7.64) years, with a median of 73.00 (range 65-110) years.

Table 1. General characteristics (N=618,850).

Telehealth Use Characteristics

Overview

Table 2 lists the visit counts (per person) according to the telehealth use type (administrative, working hours, or after hours) and time frame. For telehealth administrative purposes, we can observe that the mean count (per person) was 4.39 (SD 5.56) before the COVID-19 pandemic (period 1), increased to 5.55 (SD 6.71) during the COVID-19 pandemic (period 2), and decreased to 3.07 (SD 4.11) after the peak of the COVID-19 pandemic in Israel (period 3).

Regarding working-hours telehealth consultations with the personal physician, the mean number (per person) was 0.49 (SD 1.43) before the COVID-19 pandemic (period 1), it increased dramatically to a mean of 2.23 (3.54) during the COVID-19 pandemic (period 2), and then it decreased to a mean of 1.00 (1.95) after the peak of the COVID-19 pandemic in Israel (period 3), but still higher than that in period 1.

The mean after-hours telehealth use (per person) was 0.03 (SD 0.02) before the COVID-19 pandemic, increased to 0.07 (0.46) during the COVID-19 pandemic, and decreased again after the peak of the COVID-19 pandemic to 0.03 (SD 0.33).

The visit counts were also analyzed in a dichotomic manner into 2 categories: “no” or “yes,” that is, 0 visits versus ≥1 visit, respectively.

The comparison of telemedicine use (at least once) during 3 periods and the results of Cochran Q test are presented in Figure 2 and Table 3, respectively. The pairwise comparisons of telemedicine use (at least once) during the 3 periods, results of the Dunn and McNemar post hoc tests (with Bonferroni correction), between and within subjects, respectively, are presented in Tables 4 and 5.

Table 2. Telehealth use (visit counts) according to types and periods.

Telehealth use	Visits, mean (SD)	Visits, median (IQR)
Period 1 (before)		
Administrative	4.39 (5.56)	3.00 (0-191)
Working hours	0.49 (1.43)	0.00 (0-66)
After hours	0.03 (0.02)	0.00 (0-83)
Period 2 (during)		
Administrative	5.55 (6.71)	4.00 (0-208)
Working hours	2.23 (3.54)	1.00 (0-104)
After hours	0.07 (0.46)	0.00 (0-96)
Period 3 (after)		
Administrative	3.07 (4.11)	2.00 (0-107)
Working hours	1.00 (1.95)	0.00 (0-50)
After hours	0.03 (0.33)	0.00 (0-96)

Figure 2. Percentage of Telehealth Services Usage During 3 Periods.

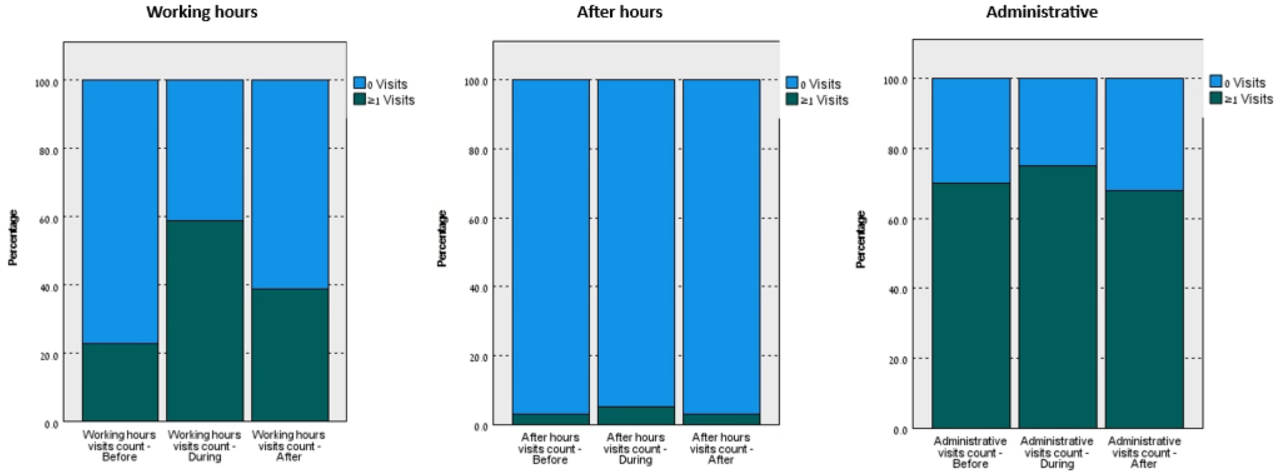

Table 3. Comparison of telemedicine use (at least once) during 3 periods, results of the Cochran Q test (N=618,850).

Period	Working-hours telehealth visits, n (%)[a]	After-hours visits, n (%)[a]	Administrative, n (%)[a]
Before	142,936 (23.1)	13,837 (2.2)	427,295 (69)
During	366,566 (59.2)	30,777 (5)	459,622 (74.3)
After	244,572 (39.5)	14,584 (2.4)	420,209 (67.9)

[a] $P<.001$.

Table 4. Pairwise comparison of telemedicine use (at least once) during 3 periods and results of the Dunn post hoc test (between-subjects analysis with Bonferroni correction).

Sample 1/sample 2	Working-hours telehealth visits		After-hours visits		Administrative	
	Test statistic	Adjusted *P* value	Test statistic	Adjusted *P* value	Test statistic	Adjusted *P* value
Before/after	−0.164	<.001	0.001	1.000	−0.011	.975
Before/during	−0.361	<.001	0.027	<.001	0.052	<.001
After/during	0.197	<.001	−0.026	<.001	−0.064	<.001

Table 5. Pairwise comparison of telemedicine use (at least once) during the 3 periods and results of the McNemar post hoc test (within-subjects analysis with Bonferroni correction).

Sample 1/sample 2	Working-hours telehealth visits		After-hours visits		Administrative

[a] Continuity corrected.

Working-Hours Telehealth Visits (During the Regular Work Hours, With the Personal Physician)

During the first period, 23.1% (142,936/618,850) of the study population used working-hours telehealth services at least once. The percentage of use increased to 59.2% (366,566/618,850) during the second period and then decreased to 39.5% (244,572/618,850) during the third period (still higher than that in period 1).

Pairwise comparisons were performed using the Dunn [23] procedure (between-subjects analysis) with a Bonferroni correction for multiple comparisons. Adjusted *P* values are presented in Table 4. Compared to the percentage of working-hours telehealth services use during the first period, there was a statistically significant increase in the percentage of use during the second period (*P*<.001) and during the third period (*P*<.001). There was also a statistically significant decrease in the percentage of the study population that used working-hours telehealth services at least once during the third period compared to the second period (*P*<.001).

Similar results were demonstrated using the McNemar post hoc test (within-subjects analysis with Bonferroni correction), as demonstrated in Table 5.

After-Hours Telemedicine

During the first period, 2.2% (13,837/618,850) of the study population used after-hours telemedicine services at least once. The percentage of use increased to 5.0% (30,777/618,850) during the second period and then decreased to 2.4% (14,584/618,850) during the third period (still higher than that in period 1).

Pairwise comparisons were performed using the Dunn [23] procedure (between-subjects analysis) with a Bonferroni correction for multiple comparisons. Adjusted *P* values are presented in Table 4. Compared to the percentage of after-hours services use during the first period, there was a statistically significant increase in the percentage of use during the second period (*P*<.001), while there was no statistically significant difference compared to the third period. There was also a statistically significant decrease in the percentage of the study population that used after-hours telemedicine services at least once during the third period compared to the second period (*P*<.001).

When using the McNemar post hoc test (within-subjects analysis with Bonferroni correction), significant differences were demonstrated between all 3 pairs of periods, as demonstrated in Table 5.

Administrative Telemedicine

During the first period, 69% (427,295/618,850) of the study population used administrative telemedicine services at least once. The percentage of use increased to 74.3% (459,622/618,850) during the second period and then decreased to 67.9% (420,209/618,850) during the third period. Pairwise comparisons were performed using the Dunn [23] procedure (between-subjects analysis) with a Bonferroni correction for multiple comparisons. Adjusted *P* values are presented in Table 4. Compared to the percentage of administrative services use during the first period, there was a statistically significant increase in the percentage of use during the second period (*P*<.001), while there was no statistically significant difference compared to the third period. There was also a statistically significant decrease in the percentage of the study population that used administrative telemedicine services at least once during the third period compared to the second period (*P*<.001).

When using the McNemar post hoc test (within-subjects analysis with Bonferroni correction), significant differences were demonstrated between all 3 pairs of periods, as demonstrated in Table 5.

Univariate Analysis of Working-Hours Telehealth Visits

According to the dichotomous classification into 2 categories (0 uses versus ≥1 uses), a univariate analysis was conducted using Pearson χ^2 tests on the various types of telehealth use, and the results are shown in Multimedia Appendices 1-3. Multimedia Appendix 1 demonstrates the significant factors associated with the working-hours telehealth visits (telehealth services with the personal physician), with the 2 categories classification (0 visits vs ≥1 visits).

Gender

A higher percentage of female individuals than male individuals used the web-based visits at all periods. In addition, both male individuals and female individuals increased their working-hours telecare use during the COVID-19 pandemic period, which was followed by a decline, though at a higher level than before (period 1).

Age Group

The age group of 75 to 84 years had used the web-based services to a greater extent, compared to the other age groups (65-74 years and >85 years), at all the 3 periods. In addition, during the COVID-19 pandemic, all age groups significantly boosted their use of working-hours telehealth services; following the COVID-19 pandemic, the use reduced but remained significantly greater than it was before the COVID-19 pandemic (period 1).

Country of Birth

Before the COVID-19 pandemic, persons who were born in Israel used working-hours telehealth services more frequently than those who were born elsewhere. However, this tendency shifted during and after the COVID-19 pandemic, when those born outside of Israel had a larger use. Both groups had increased their use of working-hours telehealth services during the COVID-19 pandemic, and it had declined after that time to a greater level than it had been before the COVID-19 pandemic.

SES Level

Persons belonging to a higher SES level had a higher level of working-hours telehealth services use, compared to persons with lower SES, at all periods. Here also, we see that during the COVID-19 pandemic, persons in all SES levels greatly expanded their use of working-hours telehealth services; this use eventually declined, but it remained higher than it had been before the COVID-19 pandemic.

Demographic Sector

If we ignore the "unknown" portion (which accounts for only 3.6% of the populations included), we see that the religious Jewish population (followed by the general Jewish population) had higher use of working hours telehealth services, as compared to other sectors, at all periods. Here again, persons in all demographic sectors greatly expanded their use of working hours telehealth services during the COVID-19 pandemic period; this use eventually declined, but it remained higher than it had been before the COVID-19 pandemic.

District

People from the northern region of Israel had more working hours telehealth visits than people from other districts before the COVID-19 pandemic (period 1). Those from the center districts, however, made many more working-hours telehealth visits to their physician both during and after the COVID-19 pandemic. As stated in the factors described earlier, all subgroups had increased their use of working-hours telehealth services during the COVID-19 pandemic period, and it had declined after that time to a greater level than it had been before the COVID-19 pandemic.

Smoking Status

Those who were past smokers used the working hours telehealth visits more frequently than people who are currently smokers or even people who had never smoked. This held true throughout all periods. All subgroups had increased their use of working-hours telehealth services during the COVID-19 pandemic, and it had decreased after that time to a greater degree than it had been before the COVID-19 pandemic, as reflected in the factors mentioned earlier.

The Presence of a Chronic Disease

Across all periods, those with chronic diseases significantly used working-hours telehealth visits to a greater extent (more than twice as often as people without chronic diseases). Both groups had expanded their use of working hours telehealth services during the COVID-19 pandemic, and use declined after that period to a larger extent than it had before (period 1).

Univariate Analysis of Administrative Telehealth Use

Multimedia Appendix 2 shows a univariate analysis, outlining the important variables that were significantly linked to administrative telehealth use in accordance with the 2 categories used (0 visits vs ≥1 visits).

Sex

At all 3 periods, a greater proportion of female individuals than male individuals used the administrative web-based services. In contrast to the situation outlined for web-based visits, the administrative telehealth use (for this parameter and all other parameters described here) did increase throughout the COVID-19 pandemic before declining to a level below that of the before period (period 1).

Age Group

The age group of 75 to 84 years had used the administrative web-based services in a greater extent, compared to the other age groups (65-74 years and >85 years), at all the 3 periods. In addition, as reported earlier, during the COVID-19 pandemic, all age groups significantly boosted their use of web-based services, but the use reduced following the COVID-19 pandemic, to a lower level than it was before the COVID-19 pandemic.

Country of Birth

Throughout all periods, those born outside of Israel used administrative web-based services more than those who were born there. Both groups had increased their use of web-based services during the COVID-19 pandemic, and it had declined after that time to a lower level than it had been before the COVID-19 pandemic.

SES Level

Persons belonging to a higher SES level had a higher level of administrative web-based services use, compared to persons with lower SES, at all periods. Here also, we see that during the COVID-19 pandemic, persons in all SES levels greatly expanded their use of web-based services; this use eventually declined to a lower level than it had been before the COVID-19 pandemic.

Demographic Sector

Throughout all periods, the Cherkess (Circassians) had the higher use of administrative web-based services, as compared to other sectors. In this instance, as well, people in all demographic groups significantly increased their use of administrative web-based services during the COVID-19 pandemic; nevertheless, this use gradually decreased to a level that was lower than it had been before the COVID-19 pandemic.

District

People from Israel’s southern region used administrative internet services to a greater extent than residents from other districts at all times. All subgroups had increased their use of administrative web-based services during the COVID-19 pandemic, and it had decreased after that time to a lower level than it had been before the COVID-19 pandemic, as was shown in other factors mentioned earlier.

Smoking Status

People who had previously smoked used the administrative web-based services more than those who smoke now or even those who have never smoked. This was accurate at all times. All subgroups had grown their use of administrative web-based services during the COVID-19 pandemic and had declined after that period to a lesser extent than it had been before the COVID-19 pandemic.

The Presence of a Chronic Disease

Throughout all periods, persons with chronic conditions significantly used the administrative web-based services more frequently (more than twice as often as people without chronic diseases). Both groups had expanded their use of web-based services during the COVID-19 pandemic, and use decreased after that period to a lower extent than it had before (period 1).

As demonstrated in Table 2, the overall use of after-hours telemedicine services (during the evenings, nights, and weekend days) was considerably lower than that of administrative telehealth and working-hours telemedicine services (with the personal physician during opening hours).

Univariate Analysis of After-Hours Telemedicine Use

In accordance with the 2 categories used (0 visits vs ≥1 visits), Multimedia Appendix 3 presents a univariate analysis summarizing the relevant variables that were significantly associated to after-hours telemedicine use:

Sex

At all 3 periods, a greater proportion of females than males used the after-hours telemedicine services. During the COVID-19 pandemic, both men and women increased their use of after-hours telemedicine services, which was followed by a fall, but at a greater level than previously (period 1), in a manner similar to the trend outlined for the working-hours telehealth services.

Age Group

Only on the COVID-19 pandemic, the age groups of 65 to 74 years and 75 to 84 years had significantly greater use of after-hours telemedicine services, compared to the third age group (>85 years). In addition, as previously mentioned, during the COVID-19 pandemic, all age groups increased their use of after-hours services; however, after the COVID-19 pandemic, use decreased, though it remained at a higher level than it had been before the COVID-19 pandemic.

Country of Birth

During the COVID-19 pandemic and the period after the COVID-19 pandemic, those born outside of Israel significantly used after-hours telemedicine services more than those who were born there. Both groups had increased their use of after-hours telemedicine services during the COVID-19 pandemic, and it had declined after that time (for people born outside Israel, it declined to a higher level than it was before the COVID-19 pandemic).

SES Level

Similar to how it was with the other telehealth services, those with higher SES levels used after-hours telemedicine services more frequently than people with lower SES levels did always. In this area as well, the use of after-hours services by people of all SES levels significantly increased during the COVID-19 pandemic. Eventually, this use decreased but it did so at a greater level than it had been before the COVID-19 pandemic.

Demographic Sector

As described for the use of working-hours telehealth visits, here also, the religious Jewish population and the general Jewish population had the higher use of after-hours services, as compared to other sectors, at all periods (the religious Jews had a higher use during the COVID-19 pandemic). Here again, people in all demographic sectors greatly expanded their use of after-hours services during the COVID-19 pandemic, which declined after that period.

District

Contrary to the previously mentioned telehealth services, persons from Israel's central area were much more likely to use after-hours telemedicine services than those from other regions during all periods. The use of after-hours internet services had surged across all subgroups during the COVID-19 pandemic and had fallen thereafter to a greater level than it had been before the COVID-19 pandemic (except for the south region in which it declined to the same level as before).

Smoking Status

As was the case with the other telehealth services, people who had previously smoked used more the after-hours services than those who do so now or even those who have never smoked. This was accurate at all periods. All groupings had increased their use of after-hours internet services during the COVID-19 pandemic and had decreased after that typically to a greater extent than it had been before the COVID-19 pandemic.

The Presence of a Chronic Disease

Similar to other telehealth services mentioned earlier, those with chronic conditions significantly used the after-hours web-based services more often across all periods (more than twice as often as people without chronic diseases). During the COVID-19 pandemic, both groups (with and without chronic diseases) increased their use of web-based services, and after that time, use decreased but to a higher level than it had previously (period 1).

Multivariate Analysis

In the multivariate analysis, using a set of multivariable binary logistic regression models, several parameters were found to be significantly associated with the different types of telehealth use during each period: male sex (decreased use of all types of telehealth services, during all periods); country of birth–Israel (increased use of working-hours telehealth visits and after-hours visits during all periods but decreased administrative use at all periods); presence of any chronic disease (highly increased use of all types of telehealth services during all periods); Charlson comorbidity score (increased use of all types of telehealth services during all periods); medium and high SES (increased use of all types of telehealth services during all periods); Jewish religion (highly increased use of all types of telehealth services during all periods); southern district—place of residence (people living in this district used fewer working-hours telehealth services and fewer after-hours services during all periods but used more administrative services before and after the COVID-19 pandemic); northern district (people living here used more working-hours telehealth services before the COVID-19 pandemic but used less working-hours telehealth services during periods 2 and 3 and used fewer administrative services and fewer after-hours services at all periods); central east district (people living here used fewer of all types of telehealth services during all periods); current or past smokers (these people used more working-hours telehealth services, more after-hours services, and more administrative services during all periods); older age groups of those aged ≥75 years (used fewer working-hours telehealth services, fewer after-hours services, and fewer administrative services during all periods).

The multivariate analysis is demonstrated in Table 6 (for working-hours telehealth visits), Table 7 (for after-hours visits), and Table 8 (for administrative uses). The Nagelkerke R^2 values for each type of telehealth service and each period are also provided in the tables.

Discussion

Principal Findings

In this study, we examined the use and uptake of 3 distinct telehealth services among the older population who were members of Clalit Health Services before, during, and after the COVID-19 pandemic in Israel. Data of 618,850 patients who met the inclusion criteria were extracted. Telehealth services used for administrative purposes were the most popular. The older population significantly increased their use of all types of telehealth services during the COVID-19 pandemic, and in most types of services, this use decreased after the COVID-19 peak but to a level that was higher than the baseline level before the COVID-19 pandemic. The three telehealth service types that were investigated in the study were as follows: (1) "working-hours telehealth visits" refers to video or telephone consultations with a personal physician during clinic business hours; (2) "administrative" refers to the use of digital services for administrative tasks (such as scheduling appointments or submitting requests to the physicians on the web); and (3) "after-hours visits" refers to the use of web-based consultations in the evenings, weekend days, and other nonbusiness hours (with other physicians)

A quantitative method was used to extract the data at three different time points: (1) "before" was before the COVID-19 pandemic; (2) "during" was during the COVID-19 pandemic's emergence; and (3) "after" was during the months after the peak of the pandemic in Israel.

Our main objectives were to assess how the older adults in Israel used various telehealth services, considering the challenges and difficulties they encountered; to determine what factors were associated with increased or decreased uptake; and to determine whether the COVID-19 period had any impact on use patterns and whether those patterns persisted after the period had ended.

Tables 2 and 3 show that, throughout the study periods, the telehealth services used for administrative purposes were the most popular among the older population. This was followed by "working-hours telehealth visits"—telemedicine consultations with the personal physician—during the regular business hours of clinics. Among the other services mentioned earlier, "after-hours" telemedicine visits came in last.

Another intriguing finding was that during the COVID-19 pandemic, the older population significantly increased their use of all telehealth services, and this use decreased after the peak of the COVID-19 pandemic (period 3), in all types of telehealth uses (Tables 3 and 4). However, concerning the working-hours telehealth visits, and the after-hours visits—this decrease was found to remain significantly higher than the baseline level before the COVID-19 pandemic.

These findings support our assumptions that as expected, the use of all telehealth services was increased during the COVID-19 pandemic. The working-hours telehealth visits, which are the primary telemedicine meetings (with the personal physician), prospered during the COVID-19 pandemic, but even after this period, they remained at a higher level than they had before the COVID-19 pandemic period.

These findings confirm our hypothesis that older adults are interested in and capable of using telehealth services, given the opportunity and accessibility to do so—factors that were noticeably improved during the COVID-19 pandemic—despite their hesitations and barriers and the medical system's mistaken belief that there is no point in teaching this population how to use digital health services.

In the univariate analysis, after classifying the number of telehealth services used into 2 categories (0 visits vs ≥1 visits), we found several factors that were significantly associated with increased telehealth use among the older individuals (Multimedia Appendices 1-3). Furthermore, we conducted a multivariate analysis**,** using a set of multivariable binary logistic regression models, which revealed that several parameters were significantly associated with the different types of telehealth utilization during each period (Tables 6-8).

Women were found to significantly use more working-hours telehealth visits with the personal physician, more after-hours telehealth visits, and more administrative telehealth services across all periods compared to men. This finding was supported by the multivariate analysis, showing that among men, there was decreased use of all types of telehealth services, during all periods. This finding may be explained by women's greater general health literacy, eHealth literacy, and health awareness, as previously reported [24-26].

The findings for telehealth use by age groups in the univariant analysis were somewhat unexpected because it would be reasonable to presume that younger age groups (aged 65-74 years) would use telehealth the most. The findings indicate that the older age groups used telehealth services more frequently. Specifically, those aged 75 to 84 years used more working-hours telehealth visits during opening hours, more administrative telehealth use, and more after-hours visits following the COVID-19 pandemic. However, in the multivariate analysis, older age groups (aged ≥75 years) were found to use fewer working-hours telehealth services, fewer after-hours services, and fewer administrative services, during all periods.

These findings are consistent with the general belief that "younger, more highly educated and affluent seniors use technology more readily and across broader platforms than the older old, who as a group tend to be less affluent, less educated, and often have a significantly greater burden of chronic illness and disability," as reported by Greenwald et al [21]. These authors claimed that younger seniors, who are more physically and psychologically integrated into the technological modern world, may have a more positive attitude toward the benefits of technology than older seniors. In contrast, the use of automated telephone menu systems, medical-related purchases on the internet (such as medical supplies or medications), and telemedicine videoconferencing with health care providers were all found to be more common among older adults than among younger adults in a 2011 study that looked into the type and frequency of technology use for a variety of health care activities [27].

The findings relating to SES in the univariate analysis were as expected: higher SES was significantly associated with increased telehealth use of all services investigated (working-hours telehealth visits, after hours, and administrative use) at all periods. This was also demonstrated in the multivariate analysis, in which people in medium and high SES significantly had increased use of all types of telehealth services during all periods. This could be ascribed to higher levels of education; increased knowledge and awareness of digital health services; increased income enabling the acquisition of computers, smartphones, and digital devices; and increased eHealth literacy linked to higher SES levels. These findings are in line with earlier studies, which found that people with lower median household incomes and less favorable insurance situations used web-based visits less frequently [26]. Another study also found a correlation between declining SES and declining probabilities of using telemedicine during elective surgery visits [28]. According to comparable findings among 16,000 patients with a new cancer diagnosis, those with the greatest SES were more likely to use telemedicine within 30 days of diagnosis [29].

The demographic sector findings in the univariate analysis were also a little surprising: the religious Jews, compared to other groups, had more working-hours telehealth visits with their physician, at all periods, and more after-hours visits (followed by the general Jewish population), before and during the COVID-19 pandemic. However, only in case of the administrative use, the Cherkess (Circassians) had greater use at all periods. These findings are unexpected given that using telehealth solutions in ultraorthodox communities offers several difficulties given their restricted access to virtual communication as well as their reluctance to engage in this novel modality of therapy. For many of these populations, receiving therapy through the web is strange and foreign, and it may be seen as going against their religious principles [30,31]. Nevertheless, in the multivariant analysis, those of the Jewish religion demonstrated highly increased use of all types of telehealth services during all periods.

The findings regarding the district that the older people belong to (where they reside) in the univariate analysis were inconsistent: before the COVID-19 pandemic, more working-hours telehealth visits were observed in the northern district; however, during and after the COVID-19 pandemic, more working-hours telehealth visits were made in the central areas. In addition, during all periods, more after-hours visits were made by residents of central regions. However, throughout all periods, people from the southern district used telehealth more frequently for administrative functions.

Using the multivariate analysis, we saw that people living in southern district used fewer working-hours telehealth services and fewer after-hours services during all periods but used more administrative services before and after the COVID-19 pandemic; people living in the northern district used more working-hours telehealth services before the COVID-19 pandemic but used less working-hours telehealth services during periods 2 and 3 and used fewer administrative services and fewer after-hours services in all periods; and people living in the central east district used less of all types of telehealth services during all periods. In general, we may conclude that a more peripheral place of residency was associated with reduced use of telehealth services. These findings are unexpected because one may anticipate that telehealth services would be used more frequently in remote places, where there are typically fewer health care personnel and resources.

The association of smoking status with telehealth use in the univariate analysis was interesting: for all types of telehealth services (working-hours telehealth visits with the personal physician, after-hours visits, and administrative telehealth use), people who had smoked in the past and stopped smoking (past smokers) substantially used more services compared to other groups (even more than nonusers) at all periods. This may be accounted for by such people's greater health awareness, which led to a major change in their health-related behaviors. However, the multivariate analysis demonstrated that current or past smokers used more working-hours telehealth services, more after-hours services, and more administrative services during all periods. These findings could be additionally explained by the notion that current smokers have greater health problems, necessitating more frequent appointments with health care providers.

Finally, compared to persons without chronic diseases, people with chronic diseases significantly used digital services more frequently for administrative tasks, after-hours telehealth visits, and working-hours telehealth visits during business hours. This was true throughout all periods (including those before, during, and after the COVID-19 pandemic). This group's rising use of telehealth was more than twice as high as that of people who were ordinarily healthy. These findings were also supported by the multivariate analysis demonstrating that the presence of any chronic disease was significantly associated with highly increased use of all types of telehealth services during all periods; in addition, the Charlson comorbidity score was found to be significantly associated with increased use of all types of telehealth services during all periods. This is not unexpected given that individuals with chronic illnesses or comorbid conditions may require additional help from health care professionals, and they frequently experience accessibility issues, making telehealth services particularly desirable to them.

In this study, we investigated the use of telehealth by older people who are still living at home to communicate with their clinic (administrative requests); individual physicians; or other medical professionals on evenings, weekend days, and holidays when clinics are closed. Nevertheless, there are telecare options available globally that enable the monitoring of patients with a chronic illness, such as heart failure, hypertension, diabetes, asthma, chronic obstructive pulmonary disease, or stroke [32-34]. In addition, more health care systems are using telemedicine video communication as a tool for health maintenance after discharge to lower hospital readmissions as well as expedited consult services (stroke, trauma, mental health screening, and surgical second opinions) [21]. Evaluation of telehealth programs for individuals, particularly the older adults, with chronic medical issues has yielded conflicting outcomes. Glycemic management and the use of health care services both benefited patients with diabetes [35].

The research on telemedicine-enhanced emergency care for older people has been concentrated on residents of older people living community centers and has shown that high-intensity telemedicine services for acute illnesses have been effectively carried out, believed to be acceptable by older patients, and offered definitive care without needing a referral to the emergency department or urgent care [36]. An analysis of the impact of home-based telehealth interventions on the use of secondary care and mortality in a cohort of patients with COPD (chronic obstructive pulmonary disease), diabetes, and heart failure, most of whom (70%) were aged >65 years, led to lower emergency admission rates and lower mortality. [37] However, a different analysis of the same data revealed no impact on psychological outcomes or quality of life over a 12-month period [38].

Benefits of Telemedicine

It is well agreed that telemedicine-based care offers many benefits and advantages for older people. Older adults who use eHealth services can maintain their freedom and continue to live in their own familiar homes, where they feel secure and at ease. Their sense of security and quality of life are improved by being aware that they are constantly being watched and monitored [39-41]. According to Chou et al [40], older people who frequently used their telecare program and had better social welfare and health status also embraced using technology and had a higher quality of life. Their findings also showed that older people who believed telecare could help them with their health issues and were prepared to use it had a higher opinion of their quality of life, particularly in terms of their social interactions and home environment.

When an older person has decreased mobility, easy and quick web-based communication with a health care facility or professional becomes particularly crucial. This reduces travel time, speeds up diagnosis, reduces the need for repeat diagnostic tests and clinical services, and allows for older adult triage that is appropriate [42]. By offering some medical services at the patient's home, telemonitoring and telerehabilitation help to decrease the frequency of hospitalizations and shorten their length, and the patient who is chronically ill can benefit by reducing the number of follow-up visits required at the medical facility [42-44]. In addition, due to telecare systems using eHealth services, an older person who is housebound can sign up via the web for a physician's appointment, choose to receive a reminder of a due date for a medical consultation, receive straightforward remote medical recommendations or test results (via SMS text messaging or email), and buy ongoing prescription drugs from the pharmacy of their choice [45,46].

By allowing patients to develop and select the tools they will use as well as how they will use them, telecare fosters increased involvement [47]. Patients can actively participate in their own care through the use of telecare systems rather than just receiving it as a passive benefit. They become partners on an equal footing with their physicians, capable of making choices for their health on their own while being cognizant of the repercussions [48,49].

Through telemedicine, proactive healthy behaviors are formed. During an emergency, telemonitoring can identify pathological signs and symptoms and abnormal test results earlier than during or before a typical physician's visit or examination, enabling prompt preventive action [42]. Telemonitoring also has a substantial impact on education. Patients who are conscious of their health status frequently begin to educate themselves on their disease and how to self-manage it. They have a better understanding of their body and are more motivated to modify unhealthy behaviors and live healthier lifestyles [42,50].

Telecare lessens socioeconomic and regional inequities in access to care as well as the uneven distribution of care quality. With the help of telecare technologies, older people can easily connect with a variety of functionally and geographically dispersed health care professionals at times that are convenient for both the patient and the health care provider [42].

Physicians in varied practice settings can easily access evidence-based medicine and effective clinical decision-making tools, such as knowledgeable colleagues in tertiary care facilities. In addition, patients can get the right type of care close to where they live, which is crucial for older people with chronic illnesses or disabilities because it affects their quality of life and level of care [42,51]. According to Chae et al [52], telecare was successful in lowering the frequency of clinic visits and also increased patient satisfaction in a trial of home health services for older people.

Barriers to Telecare Use

Although telecare offers undeniable advantages, it is important to understand that it also has limits, some of which are due to the older people themselves. The use of new technologies is frequently resisted by older individuals. Although computers and the internet have become important tools, older adults experience more trouble using them than younger people do.

According to a study by the Nielsen Norman Group, users aged >65 years had a success rate of just 53% when completing a series of assigned tasks (such as finding information and making a web-based purchase), compared to a group of younger users who had a success rate of 78%. In addition, the older group made an average of 3.7 errors on each task given, as opposed to the younger group's average of 0.6 errors [53]. Another issue is the decline in cognitive and motor function that comes with aging (eg, vision, hearing, short-term memory loss, and physical impairment), which makes it harder to adapt to a changing environment and assimilate new behavioral patterns [54].

The strong desire to interact directly and personally with the physician is another trait shared by older people. They typically prefer face-to-face interactions with health care providers, so telemedicine-based services delivered remotely are frequently not seen as relevant to them. In a study on older adults aged ≥60 years, Bujnowska-Fedak and Mastalerz-Migas [55] found that 61% of older adults stated a strong preference for direct contact with medical professionals as the main deterrent to contacting their family physician, specialist, or nurses via telephone or the web. Eliminating in-person care may give older persons the impression that they are engaging in less social interactions. Resistance to telemedicine in older population may be a result of their concern that the new technology will negatively impact their social and personal relationships [56].

The next barrier is money. Pensioners, typically those who are in need, worry about the high prices of buying computers or other electronics. Older persons are frequently reluctant to spend money on home health care monitoring systems, despite the health advantages and long-term cost reductions made available by telecare services [55]. In addition, for older persons, privacy and security are top personal concerns. They want more assurance that their private information is kept private from prying eyes. Better health care is not as important to them as feeling assured about the security of their medical information [56,57].

Accelerating Growth of Care Based On Telemedicine

Technology advancements have made it feasible to put into practice solutions that, up until recently, looked to be a long way off. Israel is regarded as a highly developed country with excellent infrastructure, a high degree of entrepreneurship and innovation, and widespread knowledge of telemedicine services. As part of the Digital Israel Project, the Ministry of Health declared that one of its objectives was to "bring about a leap in the health system that will enable it to become sustainable, advanced, innovative, renewed, and constantly improving, by optimally leveraging the information and communication technologies available to the entire Israeli population" [58]. Similar to other developed nations, Israel has seen a rise in telemedicine use because of the COVID-19 pandemic.

Telecare improves the quality of life of older citizens with chronic illnesses worldwide by providing them with new options for education, prevention, diagnosis, treatment, and rehabilitation. It equalizes possibilities for patients from urban and rural locations and lessens socioeconomic gaps in access to care. According to a prior study [45], 41% of older people had a favorable opinion of eHealth services and were willing to use them if and when given the chance. A considerable shift from passive monitoring to more active use of telecare technologies that enable and promote direct connection has occurred in well-developed countries in recent years. Patients now have more control over their own health and welfare because of the changing health care system [43]. They can make health-related decisions on their own and with knowledge of the repercussions, and they work as equal partners with their physicians [59,60].

Nevertheless, widespread acceptance by older persons themselves is a crucial component in the development of telecare systems for the older population [43,51]. Despite the growing popularity of computers and mobile devices among older people and improved computer literacy, many of them are still unaware of the opportunities that telemedicine presents. Training for the use of telecare appears to be quite vital, as does ongoing education of the older population in this area. The needs, abilities, and preferences of older people should now be taken into account while providing telemedicine-based care, with adjustments made over time as care requirements change. Older adults have a wide range of needs, which can alter with time. Therefore, it is essential to individualize and adapt telecare systems for a range of abilities of older people, addressing their changing care requirements in a flexible and adaptable manner, always considering their impaired motor, sensory, and cognitive function.

Before using telecare technologies, all older people must be familiar with their utilization and aware of their advantages. In addition, perceptions of older people and their caregivers about the usability of home telecare are a substantial predictor of compliance with telecare [51]. An equitable health system should understand that while many older persons are willing and able to learn how to use telemedicine, for some, such as those with dementia and social isolation, in-person visits are already challenging, and telemedicine may be impractical. Clinics and geriatric modes of treatment, such as home visits, are crucial for these individuals [59].

Telecare will soon become a crucial aspect of older people's lives, enabling them to function independently in a comfortable living environment, if technologies are developed that are familiar, usable, appealing, affordable, and fit into lives and plans of older people. Further research is required to accentuate the importance of offering the older population telehealth alternatives that are both easily accessible and easy to use.

Limitations

Despite the fact that this study included a large set of data from people belonging to Israel's largest health management organization (and one of the largest health care organizations in the world), it still represents trends in telehealth use among the older population in Israel and not necessarily in all parts of the world. Furthermore, there were several parameters that could have an additional impact on telehealth use (eg, level of education); however, we did not have access to these data.

Conclusions

It is generally acknowledged that telemedicine-based treatment for the older people has several advantages. However, telemedicine also has limitations and barriers, some of which are due to the older people themselves.

The key findings of our study demonstrate that, despite all the challenges and hurdles, the older population uses telehealth services when they need them. People use telehealth services for administrative purposes more frequently, but they also consult with their own physician via telephone and the web and sometimes even use after-hours virtual consultations. These services make it easier for individuals to get medical care without having to travel, wait, or risk infection. Older people can increase their consumption as necessary during times of pressing necessity, such as the COVID-19 pandemic, or if they are afflicted with a persistent illness.

The study also reveals that even after the COVID-19 pandemic, most uses remained higher than they were before, implying that this population can learn how to use digital health services effectively and that they should be given the opportunity to do so by creating suitable and straightforward telehealth solutions tailored for this population and enhancing their usability.

Acknowledgments

The authors would like to thank the Clalit Research Institute team for their invaluable assistance in data extraction.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files.

Authors' Contributions

MH was involved in the conceptualization of the study, methodology, investigation, data curation, analysis, and writing the paper. RS was involved in data curation, methodology, formal analysis, software, and supervision.

Abstract

Background: Older adults worldwide experienced heightened risks of depression, anxiety, loneliness, and poor mental well-being during the COVID-19 pandemic. During this period, digital technology emerged as a means to mitigate social isolation and enhance social connectedness among older adults. However, older adults' behaviors and attitudes toward the adoption and use of digital technology are heterogeneous and shaped by factors such as age, income, and education. Few empirical studies have examined how older adults experiencing social and economic disadvantages perceive the learning of digital tools.

Objective: This study aims to examine the motivations, experiences, and perceptions toward a community-based digital intervention among older adults residing in public rental flats in a low-income neighborhood. Specifically, we explored how their attitudes and behaviors toward learning the use of smartphones are shaped by their experiences related to age and socioeconomic challenges.

Methods: This study adopted a qualitative methodology. Between December 2020 and March 2021, we conducted semistructured in-depth interviews with 19 participants aged ≥60 years who had completed the community-based digital intervention. We asked participants questions about the challenges encountered amid the pandemic, their perceived benefits of and difficulties with smartphone use, and their experiences with participating in the intervention. All interviews were audio recorded and analyzed using a reflexive thematic approach.

Results: Although older learners stated varying levels of motivation to learn, most expressed ambivalence about the perceived utility and relevance of the smartphone to their current needs and priorities. While participants valued the social interaction with volunteers and the personalized learning model of the digital intervention, they also articulated barriers such as age-related cognitive and physical limitations and language and illiteracy that hindered their sustained use of these digital devices. Most importantly, the internalization of ageist stereotypes of being *less worthy* learners and the perception of smartphone use as being in the realm of the privileged *other* further reduced self-efficacy and interest in learning.

Conclusions: To improve learning and sustained use of smartphones for older adults with low income, it is essential to explore avenues that render digital tools pertinent to their daily lives, such as creating opportunities for social connections and relationship building. Future studies should investigate the relationships between older adults' social, economic, and health marginality and their ability to access digital technologies. We recommend that the design and implementation of digital interventions should prioritize catering to the needs and preferences of various segments of older adults, while working to bridge rather than perpetuate the digital divide.

KEYWORDS

digital divide; digital learning; smartphones; social gerontology; older adults; COVID-19 pandemic; technology adoption

Introduction

Globally, the COVID-19 pandemic has engendered unprecedented challenges for older adults. In addition to confronting the risks of infections and death [1], prolonged social distancing measures have worsened the physical and mental health as well as the quality of life in the older adult population. During this period, heightened loneliness, social isolation, and anxieties were attributed to reduced social engagement and support, mistreatment, and misinformation [2-4]. Loneliness is associated with higher risks of depression, functional and cognitive decline, and all-cause mortality and morbidity [5-7]. Older adults with lower socioeconomic status, preexisting comorbidities, and poorer access to health care were more likely to experience mental health–related problems [8,9]. Digital technology has surfaced as an essential way for older adults to cope with restrictions and mitigate loneliness by fostering social connections [10,11]. Studies have demonstrated the potential for technology to reduce perceived isolation via improved social support, connectedness, and engagement in activities [12,13] as well as promote a sense of autonomy and confidence [14]. Older adults who had more frequent digital contact, for example, through video calls, social media, or phone calls with friends and family, during the pandemic reported higher levels of satisfaction and well-being and a lower sense of social isolation [7,15,16]. Digital interventions have also been developed to enhance the psychosocial well-being of older adults. For example, a digital human facilitator was found to be feasible and acceptable in alleviating older adults' stress and loneliness [17], and a digitally guided group intervention increased their digital literacy and abilities to cope with distress [18].

However, a large proportion of older adults globally continue to have little or no access to digital technology [19,20]. With the accelerated digitization of basic services (eg, financial transactions, health, and communications), the growing digital divide may further worsen the inequities in health and exclude the already marginalized segments of the population. Inequalities in access to digital literacy exist not only based on age but also based on income, education, sex, disability status, and immigration status, which culminate in "distinct positionalities of privilege and disadvantage," shaping diverse attitudes and behaviors toward digital technology use [21-23]. Those with higher incomes across all age groups tend to adopt communication technologies earlier and more extensively than those with lower incomes [22]. In Singapore, older adults with poor health, with less education, and residing in low-income housing were found to experience greater difficulties with internet use [24].

The unequal access to digital technology and challenges associated with its adoption among older adults have been well established in the literature [25,26]. Studies have also reported factors, both at the individual and environmental level, that facilitate or hinder older adults' adoption of and continued engagement in digital technology [27]. While the factors influencing digital technology adoption among the older adult population have been well documented, there remains a gap in understanding the diverse attitudes, experiences, and perspectives among distinct subgroups of older adults [27]. In addition, much of the discourse and theoretical foundations regarding technology use was informed by conventional models of technology adoption (eg, Technology Acceptance Model and Unified Theory of Acceptance and Use of Technology) or behavioral health theories (eg, Theory of Planned Behavior and Social Cognitive Theory) [28]. While these models illuminate the influence of psychosocial and behavioral factors on technology adoption, they fail to account for the socioeconomic and environmental contexts that shape these attitudes and perceptions toward digital technology.

To fill this gap, this study aimed to explore the experience of and perceptions toward a community-based digital intervention among older adults living in low-income neighborhoods during the COVID-19 pandemic. Particularly, we sought to understand the motivations, perceived challenges regarding the adoption and continued use of smartphones, and benefits derived from the learning process, all in the context of social and economic vulnerabilities. The findings will inform how older adults who are considered vulnerable can most benefit from digital technology adoption and how program implementers can tailor the design of the interventions to older adults' needs to maximize their effect.

Methods

Overview

This qualitative study was part of a larger mixed methods study conducted to evaluate the impact of a community-based digital intervention, namely, Project Wire Up, on older adults' digital literacy and health-related outcomes in low-income neighborhoods in Singapore. This study used a generic qualitative methodology because the aim was to explore how older adults interpret and attribute meaning to the community-based digital intervention and smartphones [29]. Aligned with a constructivist epistemology, this methodology was selected to emphasize and foreground older adults' subjectivities and their experiences regarding the intervention.

Ethical Considerations

Ethics approval to conduct the study was obtained from the SingHealth Centralized Institutional Review Board (2020/2722). Ethical considerations were accounted for in the design and implementation of the study within the context of a marginalized older adult community. For example, as in-depth interviews with older adults regarding the challenges they face in their everyday lives may elicit sensitive or upsetting recalls, interviewers will provide options for receiving various forms of support when needed (eg, taking breaks, postponing the interview, and options for referral to mental health resources) and remind participants that responding to interview questions is voluntary. In addition, as participants are referred to the study upon completion of the digital intervention, they may feel obliged to enroll in the study. Thus, the study team will highlight that participation in the study is voluntary and will not influence their access to services or ability to participate in subsequent community interventions. Informed consent was obtained before the interviews.

Setting

Singapore is experiencing an accelerated rate of population aging [30]. By 2030, the country will have one of Asia's oldest populations, with one-fourth of the population aged >65 years. During the COVID-19 pandemic, heightened safety measures were implemented from April 2020 to June 2020 to curb widespread transmission. Nonessential services were stopped, and movement in public spaces was significantly curtailed. As most of the populace turned to digital means to maintain social connections and keep up to date with the news, a digital divide based on age became palpable [31]. Concerns that older adults would be *left behind* in the digital world became an impetus for a slew of government programs such as the Seniors Go Digital [32] to encourage smartphone adoption among this group [33,34]. Considering the heightened digital exclusion experienced by older adults with socioeconomic disadvantages, efforts were dedicated to enhancing access to digital literacy for this group of older adults [35].

Project Wire Up was established in July 2020 by TriGen, a voluntary organization, in partnership with Singapore General Hospital, Infocomm Media Development Authority, and older adult activity centers in Singapore to pilot a volunteer-led, one-on-one, home-based digital literacy program [35]. Those enrolled in Project Wire Up were eligible to purchase smartphones at subsidized rates and were matched to volunteers who provided one-to-one coaching regarding digital skills, including making video calls, connecting to Wi-Fi, performing web-based purchases, and using government services. An average of 6 sessions were conducted at participants' homes over 3 months and were personalized according to their interests and competencies. Upon the completion of the program, volunteers may connect older adults to formal and informal networks for social support [35]. The aim of the intervention was to close the digital gap and improve social connectivity among older adults with lower socioeconomic status living in public rental neighborhoods. Public rental housing units, a sensitive indicator of area-level socioeconomic status in Singapore, are heavily subsidized flats that cater to lower-income households. Individuals eligible for public rental housing have total household gross monthly incomes that do not exceed approximately US $1000 [36].

Older residents in public rental flats face higher risks of frequent hospital admission and readmission, higher use of hospital and emergency department services, and longer durations of hospital stay [37]. Living in rental flats has also been correlated with poorer physical and mental health, including poorer cognitive function and higher depression rates among older adults [38]. In addition to shouldering a higher disease burden, they are more likely to have limited social and financial support. As poorer digital literacy may negatively influence older adults' health via weaker social connections [39] and impact their ability to access health information and increasingly digitized modes of health care delivery [20], Project Wire Up's primary goal of enhancing social connectivity and digital literacy has the potential to improve older adults' well-being and mitigate health care use.

Recruitment and Data Collection

The study team worked closely with the implementation team to recruit eligible participants who met the inclusion criteria of being aged ≥60 years and successful completion of the program. Participants aged ≥60 years or who had not completed the intervention were excluded. A list of eligible participants was referred to the study team, who then contacted the participants to ask whether they were interested in participating in the study. A purposive sampling technique was used to obtain a diverse sample of participants, in terms of ethnicity, sex, and language spoken, to reflect the heterogeneous older adult population in Singapore. Between December 2020 and March 2021, the study team conducted semistructured interviews at various public rental housing estates. During the interview, participants were asked about their life histories, daily routines, challenges they faced during the lockdown, support received, meanings associated with smartphone use, and their experiences and challenges in participating in the program. Overall, 2 interviewers trained in qualitative research conducted the interviews, while observing the appropriate social distancing measures. Interviews usually lasted between 45 minutes and 1.5 hours and were conducted in English or local dialects (Mandarin, Cantonese, Hokkien, and Malay) and audio recorded.

Data Analysis

All interviews were transcribed and translated from local dialects to English. Then, the transcripts were coded using NVivo (version 12; Lumivero). Consistent with a generic qualitative methodology, a thematic analysis was conducted. An initial codebook was generated based on key sections of the interview guide. The interview guide drew on certain concepts from the existing literature, which posit that factors such as health, social network, and perceptions about technology influence how participants relate to and perceive smartphone use. These initial codes also included the challenges faced during the COVID-19 pandemic, as we anticipated that the pandemic may influence older adults' attitudes and behavior toward technology. Participants were also asked about their experiences with the program, including preprogram expectations, memorable moments, preferred mode of learning, postprogram smartphone use, and what they hoped to learn in future. These program-specific questions were intended to inform the design and implementation of future interventions.

Using this initial codebook, 2 coders coded 3 transcripts together through inductive and inductive coding methods to identify regularities in ideas and other emergent themes that may be relevant to the research problem. In this process, existing categories were expanded, and new categories were added to the codebook. Then, both coders coded the transcripts separately using the reviewed codebook. As both coders have each conducted several interviews with study participants, they had an in-depth understanding of and familiarity with the data and conducted regular discussions after coding 4 to 5 transcripts to resolve any discrepancies and discuss whether the key analytic categories that emerged were reflective of the meanings expressed by the participants. Analytic memos were also written alongside the coding process to reflect on any issues that arose during the coding process, emergent patterns, and thematic categories and subcategories [40]. Constant comparative analysis was performed throughout the process to compare the interview data to emerging categories and to determine the consistency in coding. Categories were created and refined when the data did not fit into categories. Then, the coders, together with members of the study team, discussed the key themes that were most salient in the interview data that shaped older adults' experiences with the intervention and smartphone use. This paper followed the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist to ensure comprehensive and transparent reporting of the results [41].

Results

Participant Characteristics

We conducted a total of 19 interviews over a period of 4 months. Data saturation was achieved at 15 interviews, and we conducted a few more interviews to ensure that new data did not disclose new insights. Of the 19 participants, 12 (63%) were female participants, 16 (84%) were Chinese, 13 (68%) were widowed or single, and 15 (79%) lived alone in 1-room rental flats. Most participants reported a relatively low educational attainment, where 32% (6/19) of the participants received no formal education, and 26% (5/19) received primary education. The participants' characteristics are presented in Table 1.

In this study, we identified three themes that reflect the perceived challenges and benefits related to learning the use of smartphones among older adults who live with low income: (1) age and social marginality, (2) technological design as a form of exclusion, and (3) digital learning process as a tool for mitigation of social isolation and marginality.

Table 1. Participants' characteristics (N=19).

Characteristics	Participants, n (%)
Age (years)	
60-69	5 (26)
70-79	7 (37)
≥80	7 (37)

Staying with helper	1 (5)
Employment status	
Working (full time)	2 (11)
Retired	13 (68)
Unemployed	4 (21)

Age and Social Marginality

Overview

Older adults' perceptions about smartphones and the digital intervention must be understood within the context of their experiences with aging and social precarities. Precarity refers to an existence characterized by insecurity, unpredictability, and vulnerability that could emerge at an intersection of social disadvantages that extend into later life [42]. This means that older adults' everyday experiences of aging must be understood and situated within the social structures that they are embedded in. In this study, most participants were in the middle-old category and experienced social and income-related vulnerabilities. Thus, our analysis demonstrated that the manner in which older adults relate to smartphone use and define their capacity as learners is inextricably connected to their age-related anxieties and perceived socioeconomic positioning.

Aging-Related Precarities and Internalized Ageism

The most cited barrier to learning was age-related cognitive and physical decline, including visual and hearing impairment, memory difficulties, and decreased agility in their fingers, which impeded the ability to use the smartphone and retain knowledge from each session. More than half of the participants felt embarrassed about not being able to remember what was taught. For example, some participants described the anxieties and feelings of helplessness related to a perceived "deterioration" in their minds that made it difficult to absorb and apply the information learnt—a problem they attributed to old age:

> *You are young, your minds are good, you can put many things inside but our mind is deteriorating, old already. [I] cannot see, cannot walk fast, this is natural for every person who gets old.* [Participant #3, female]

In addition to the challenges related to cognitive and physical constraints, participants also expressed negative aging self-perceptions throughout the interview. While these were not explicitly stated as barriers to smartphone learning, they reflect the attitudes toward learning or negative associations between learning and old age. For example, a participant expressed the futility and meaninglessness of learning during old age:

> *At first, I did not want to take [the phone], [but] the manager at the SAC said, "take it, learn slowly." I said I am already going to die, no point learning, so old already, no one will know what will happen tomorrow, just live one day at a time.* [Participant #6, female]

Our participants considered their unsuccessful attempts at mastering smartphone use as a sign of their inaptitude due to old age and the futility of the learning process. Participants had a strong tendency to individualize responsibility for the outcome of smartphone learning. Despite feeling uncertain about their ability to sustain smartphone use, participants chose not to seek help from volunteers after each visit due to their fear of "troubling" them and their reluctance to be seen as a "burden." For example, some participants assessed themselves as learners who were "not worthy" of the time and attention from the volunteers who have "better things to do":

> *I said as a volunteer, you need to work, if you come here it takes about 1 hour to teach us, we are wasting your time, how much can you teach us, after you leave, I cannot remember already, now we are old...I do not want to obstruct people's time...We do not want to trouble others.* [Participant #1, male]

Therefore, participants internalized ageist assumptions by viewing age-related limitations as "deficits" that prevent them from undertaking smartphone-related activities [43]. Such ageist self-judgments exacerbate their poor self-conception, low self-worth (ie, as learners with no scope for growth and whose needs should not be prioritized), and resistance toward learning.

Social Precarities and Self-Imposed Stigma

Participants' perceived lack of interest and confidence to learn smartphone use were also shaped by the awareness of their social positioning in relation to other older adults. Overall, one-third of the older adults emphasized that it was particularly difficult for them to learn to use the smartphone because of language barriers and illiteracy. For example, 1 participant was quick to distinguish himself from those who spoke English and were literate—characteristics that he felt predisposed them to increased competency and ability to acquire smartphone skills at a faster pace:

> *Those [literate] people know words, know English, know the language. It is different, teaching them is very fast. For us, we do not recognize words, you teach me 10 times but I cannot remember...Waste time, waste effort.* [Participant #1, male]

Most Chinese older adults residing in the neighborhood where the intervention was conducted are Mandarin-speaking or dialect-speaking individuals, making it challenging for them to navigate the smartphone. While volunteers helped these older adults change the default language setting to Mandarin, some participants were still not able to identify the characters due to their limited literacy. Participants viewed smartphone use as being in the realm of the privileged "other," which does not align with their identities as "low income" or "uneducated." For example, when asked how she feels about using the smartphone for purposes such as seeing the physician will change her life, 1 participant expressed that smartphones were not suitable for the "kind of people" living in her neighborhood:

> *Some of us are uneducated, if educated, they have means or help and the ability to have a higher [paying] job. They will not be living in this area, you must understand what kind of area people live and what kind of people are living inside here, it's not only when you think it's good you can see on TV it's good for old people.* [Participant #13, female]

By perceiving that smartphone use is not applicable to older adults living in a certain "kind of area," some participants "classified" themselves as failing to belong to the "in group" of digitally savvy older adults, thus reducing their self-esteem and motivation to learn.

Technological Design as a Form of Exclusion

Participants also expressed challenges related to smartphone technology, with its design primarily catering to the needs of a certain type of digitally literate individuals. Many participants described their interaction with the device as a stress-inducing process, pointing out that the sensitivity of the touch screen, small font sizes, multiple apps, and colorful esthetics made it confusing to navigate the interface. For example, 1 participant lamented that a combination of poor eyesight and stiff fingers resulted in her accidentally dialing the wrong numbers, incurring the wrath of family and friends:

> *The smartphone is very sensitive, my finger accidentally touches it, then the other person's phone will get it, so that is the trouble for [an] old lady...[my] eyesight is very poor, if our eyesight is*

> *poor and the writing is so small, how you expect us to see...This phone is sensitive. That's why I told you it's not suitable for us old people.* [Participant #13, female]

Thus, participants noted the incompatibility of smartphone's functions with the needs of older adults and suggested that smartphone use will be helpful for those in the young-old group but felt that learning at an older age may not be useful. The failure of some smartphone designs to consider older adults' age-related cognitive and physical limitations, needs, and preferences may also account for their sense of ambivalence toward smartphone use. For example, some participants expressed a disconnect between the prospects of learning a new, potentially disruptive technology and the fundamental priorities that they have at this point in their lives.

When asked what it means to be healthy, dominant themes expressed by participants included the ability to "walk," ability to eat as they desired, having a "clear" mind and good eyesight, absence of ailments and difficulties, and ability to "live day by day doing the things [they] enjoy." Therefore, the purportedly transformative potential of smartphones was incongruous with what participants valued or perceived as essential to their current life situation:

> *I want my life to be as simple as possible, do whatever I want to do...I just want to be happy, my mind has no space for other complicated things. At my age, I do not know when I am leaving this world, learn already also no point.* [Participant #8, female]
>
> *We do not use these phone applications, only the youngsters use, there is a camera, take whose picture? A lot of these games, play for what...? Young people like all these funny things, we old people only need big font, big screen, simple.* [Participant #3, female]

However, 11% (2/19) of the participants were motivated by the opportunity to learn new skills and expressed comfort and familiarity with navigating the smartphone. Their motivations were primarily shaped by active early-life work experience and the desire to keep in contact with closely connected family networks. Support from family members also facilitated their experience of uptake and sustained use. This aspect holds significance as it shows that despite cumulative disadvantages structured by lack of education, income, and employment opportunities, social support could influence their access, familiarity, and motivation to engage in digital learning.

Digital Learning Process as a Tool for Mitigation of Social Isolation and Marginality

While older adults in this study encountered challenges influenced by their experiences of aging, social precarities, and technological barriers, some participants expressed benefits related to the strengthening of relational ties with new friends or family members.

Many participants stated that their interactions with volunteers were one of the program's most memorable moments. They appreciated having "someone to talk to" and liked that the volunteers were friendly, helpful, and approachable and provided personalized attention to addressing their queries. Thus, participants enjoyed the social exchanges with the volunteers, particularly if they could "chat and get along very well":

> *I miss him [the volunteer], because when I sit here, I miss him sitting next to me, talking to me, teaching me what to do, [he] is a good person, really good, he's working, he said no problem auntie you can call me if you have any problems.* [Participant #15, female]

By learning how to make phone calls, send voice messages, and use mobile phone apps, participants mentioned improved social relationships, such as making new friends through the volunteers, and found it easier to communicate with others using the video call function:

> *It is more convenient to communicate with people, you can see them. Otherwise at that time, we did not know how to use the function, then it felt like we lost contact. You can only hear the voices but not see the people.* [Participant #12, male]

Thus, given that most older adults in this study lived alone, designing an intervention that not only emphasized acquiring smartphone skills but also concurrently nurtured social bonds and connections appeared to foster participants' initial acceptance and adoption of digital technology.

Discussion

Principal Findings

This study explored the perceptions and experience regarding a community-based digital intervention among older adults residing in a lower-income neighborhood. We sought to understand older adults' motivations for learning, challenges to uptake and sustained use, and benefits derived from the digital engagement processes in the context of age-related and social disadvantages.

We found that the meanings older adults associated with learning at old age shaped their motivation and confidence in learning. Participants cited cognitive and physical limitations such as visual or hearing impairment and memory difficulties and a perceived sense of futility and meaninglessness of learning at old age as factors that limited their capacity and interest in digital learning. Many older adults expressed embarrassment and frustration regarding not being able to retain or apply what was taught and viewed these challenges as a *natural* outcome of old age. These negative self-perceptions are emblematic of the internalization of ageist structures and stereotypes that associate "being old" with being not technologically savvy. These findings corroborate studies that have documented how older adults' identification with the negative connotations related to their age group may deter technology use [44,45]. These ageist stereotypes that depict older adults as "inflexible" or unable to "adapt to new ideas and to the use [of technology]" contribute to older adults' feelings of low self-efficacy and discomfort and beliefs that efforts to learn will be unproductive or embarrassing [46].

Our study also reveals that these age-based anxieties intersect with older adults' experiences of other forms of marginalization, including perceived stigma of being less educated and literate than other segments of the older adult population. The finding that older adults encounter language barriers aligns with those of a study in Singapore that described how the fear of information and communication technology among older adults in Singapore may be explained by their “limited command of English,” particularly among those with lower levels of education and socioeconomic status [26]. This study also found that older adults in this group expressed concerns related to the affordability of purchasing digital devices [26]. However, a novelty of our findings is that although the presence of subsidized smartphones facilitated smartphone uptake, older adults’ lingering ambivalence and aversion toward smartphone learning is also shaped by their consciousness and perception that smartphone use and technology adoption belongs to a privileged *other* from which they are excluded, and this influences their interest and motivation to learn. While the literature has recognized the importance of income and education in influencing older adults’ intention to use technology [28], our findings contribute to the existing literature by highlighting that older adults may internalize ageist attitudes and stigma resulting from their positionality within the social and economic structure. These self-perceptions hinder their desire to participate in and sustain smartphone learning. In addition, in the context of Singapore, public messages also showcase digital savviness and active social engagement as a marker of successful and healthy aging [33,47]. As studies have shown that engagement in digital practices corresponds to sociocultural conceptions of aging that is “active, engaged, independent [and] highly productive” [48], we posit that broader norms of successful aging may shape the identities, feelings of disempowerment, and negative self-perceptions of older adults with lower income and, in turn, affect their dispositions and perceptions toward smartphone learning.

In addition, our study demonstrates that older adults’ difficulties in navigating the smartphone’s user interface point to the absence of age-friendly features. These findings confirm those of earlier studies that suboptimal design features of digital devices, such as display screens that are challenging to navigate, small icons, and overall “low levels of graphic design adaptation” that fail to cater to the needs of older adults, may completely inhibit access [49]. However, our study adds to the literature by emphasizing older adults’ perceptions that the design and function of smartphones are incompatible with their existing priorities, needs, and visions of “healthy aging” and their feeling that it would be more relevant to the needs of young or middle-aged individuals or those who are digitally literate. While our study reiterates the need to examine the heterogeneity in technology use within the older adult population [50], we also emphasize that older adults’ perceived irrelevance and lack of usefulness of the smartphone in their everyday lives provoke a broader consideration of how existing digital tools and technologies often cater to the preferences and needs of a certain segment of the population, while excluding others.

Our study also highlighted that for older adults typically living alone in low-income neighborhoods, the community-based digital intervention had significant social meanings, creating new forms of social connection and relationships. In addition to improving digital literacy, most participants valued the interaction with the program volunteers. The importance of relationship building within the scope of digital learning is also underscored by the few participants who had demonstrated a strong motivation to learn. Participants in this group consistently practiced and used the smartphone to stay in contact with family and friends. This pattern is evident in studies that indicate the importance of familial and social support, particularly the efficacy of intergenerational approaches in the learning of digital skills, where older adults learn digital skills more readily from their grandchildren [50,51]. Overall, our findings reinforce how older adults’ aversion to digital technologies are shaped by factors such as age-related barriers and negative self-perceptions and a lack of user-friendly digital devices. However, our findings add to the existing literature by highlighting how individual-level factors are intertwined with and situated within the structural vulnerabilities that older adults confront such as age and income-related stigma and marginality. Thus, this study makes an important contribution to the existing theoretical models of technology use. Models such as the Senior Technology Acceptance Model have considered how technological use may differ in the context of older adults’ age-related physical, psychological, and social circumstances that predict their attitudes and behaviors toward digital technology [52]. The Senior Technology Acceptance Model explains that technology adoption is influenced by factors such as older adults’ self-reported health and cognitive ability, social relationships and life satisfaction, and levels of self-efficacy and anxiety toward gerontechnology [49,52]. However, our study’s findings supplement these frameworks by underscoring how the attitudes toward smartphone use among older adult populations that are considered vulnerable must be contextualized within intersecting age-related and income-related precarities that contribute to internalized ageist attitudes and social stigma among older learners, thereby shaping their self-perceptions, motivation, and identities. Existing models of technology use should consider the systemic ageism or exclusion that particular segments of older adults experience that may hinder technology adoption. The consideration of how older adults’ attitudes and behaviors toward digital technology are impacted by their experiences of other systemic disadvantages urges a shift from placing the onus of digital uptake on older adults toward bolstering the existing technological systems and social supports to improve digital connectedness.

Recommendations for Future Interventions

Based on our findings, 4 key strategies could be recommended to enhance the teaching methods and learning outcomes of older adults in low-income communities, as described in the following subsections.

Understanding the Compatibility of Digital Technology With Older Adults’ Lived Experiences

Implementers should consider whether the digital intervention and device are compatible with participants’ needs, preferences, and social circumstances. To comprehend the factors that influence participants’ motivations and attitudes toward learning a new technology, implementers could conduct a needs assessment to identify participants’ healthy aging goals, daily routines, support network, and interests to plan how the smartphone could be relevant to their priorities. Although the current intervention tailors the program according to participants' interests and abilities (where tier 1 involves learning "basic" phone functions such as video calls and tier 3 involves more "advanced" features such as web-based purchases or using government services), participants may not be able to derive meaning from learning these functions if they are not useful in their everyday lives. For example, if a participant wishes to increase their social interaction, the volunteer can teach them the video call function so that they can make a call to a family member or friend. Smartphone learning should not be seen as an end but as a means to fulfill objectives that are of importance to older adults.

In addition, smartphones may also not be perceived as a "resource" amidst financially precarious circumstances, where the urgent trade-offs in everyday priorities of living (eg, inability to pay for medical bills and uncertainties of welfare apps) mean that smartphone learning and its uncertain "rewards" cannot be prioritized alongside other competing demands on time and energy. Thus, volunteers and older adults should jointly examine ways in which they identify the perceived utility and relevance of the digital innovation in their current routines and life goals. Moreover, it is crucial to recognize that older adults do not necessarily share commonly held assumptions of smartphone as the indisputably "better," "more convenient," and "simpler" option; even if they do, they may also not perceive or understand these terms in the same ways. Thus, program implementers should consult older participants about what they value, the types of meanings they ascribe to the purported benefits of the smartphone, and the types of learning approaches that can best meet these needs. Expanding the discourses and meanings attributed to smartphones by different subgroups, particularly individuals considered marginalized, can promote intervention frameworks centered on equity and social justice, thus refuting "structures and systems designed by and for persons in more advantageous social positions" [21].

Strengths-Based Approach to Dismantle Ageist Stereotypes

To address older adults' negative self-perceptions about aging, digital interventions should take a directive approach to dismantle ageist stereotypes before cultivating more independent forms of learning [53]. Opportunities to contemplate age-related challenges should be built into the learning model, enabling older adults to confront their self-perceptions as being a "less worthy" or "incapable" learner. For example, techniques such as motivational interviewing can be adopted by volunteers to better understand older adults' motivations to learn or resist smartphone learning. Rather than using a deficits-based approach (eg, what older adults do not know), motivational interviewing [54] seeks to affirm participants' strengths, wisdom, and values and develops a plan toward change based on their own insights. This approach emphasizes the creation of a nonjudgmental, respectful, and compassionate space, where the older adults' choice to learn or not learn the use of smartphone is not frowned upon or stigmatized. When older adults feel more empowered to learn, they can begin to explore the possibilities of smartphone use and refute the previously held conceptions that technology use conflicts with their identities (ie, not for "someone like them"). At the same time, the encouragement of older adults to learn should not involve coercion or guilt-tripping those who choose not to participate. Efforts must be made to assure older adults that a lack of participation will not deprive them of any other community services or assistance, to reduce the likelihood of older adults participating out of fear or obligation. Moreover, the responsibility should not be completely placed on older adults to actively engage in and keep up with digital practices, where resistance to learning becomes stigmatized or viewed as a burden or sign of "backwardness;" the consequence would be a subversion of the "discourse of empowerment" that digital technology seeks to promote [48].

Strengthening Social Ties Through Technology

Our findings suggest that smartphones can be adopted to fulfill relational purposes. Incorporating the cultivation of relational ties, in the form of family members, peers, or volunteers within a digital learning model, can serve to be a "catalytic intermediary" to motivate the use of digital technology [26] and sustain older adults' interest in the program. In addition, digital technology can act as a medium through which older adults who live alone or lack a supportive social network can expand their social capital by "forming new social relationships or maintaining existing social ties" [26].

Digital technology can also serve as a medium through which older adults can acquire new skills or habits as part of a learning group. For example, a study has explored the application of gamification techniques to encourage older adults to improve digital skills through interactive games with a partner on a touch screen tablet. These games were designed to improve cognitive and motor skills and facilitate social interaction and were found to be effective in improving the acquisition of digital expertise [55]. Thus, intervention models that incorporate problem-solving activities and collaborative peer learning can create an interactive space that nurtures social connections and diminishes feelings of loneliness among isolated older adults in communities considered socially disadvantaged.

Ensuring Program Continuity

We found that the lack of opportunities for continued practice and application reduced older adults' motivation for sustained use of the smartphone following the intervention. Future interventions can provide options to participants based on their levels of interest, skills, and aptitude; this could include connecting older adults to guided learning groups to practice the skills taught or to specific interest groups (eg, playing mahjong on the web). In addition, volunteers can visit the older adults at a fixed time to resolve technical issues that they may have related to phone use.

Strengths and Limitations

While the literature has documented the challenges faced by older adults in the realm of digital learning, this is the first study that uses a qualitative approach to examine how older adults residing in low-income neighborhoods experience aging and the social and health-related challenges that facilitate or limit their self-efficacy and interest in digital devices. In a global context, there have also been other types of interventions that focus on improving older adults' digital literacy. For example, in North America, digital literacy training sessions have been conducted in public libraries and community organizations [45]; a 4-month program of weekly computer classes was organized for African American older adults with low income at an older adult community center to gain familiarity with assessing web-based information and privacy issues [56]; and a 4-week digital literacy program was conducted to equip older adults with knowledge about how to navigate their computer (eg, sending emails) during the COVID-19 pandemic [57]. However, to the best of our knowledge, it appears that no study specifically explored the impact of a home-based digital literacy intervention during the COVID-19 pandemic, particularly among older adults with lower income.

One limitation is that we were unable to analyze the data in terms of understanding how these experiences and perceptions regarding the program might have differed across different sociodemographic characteristics—sex, age profiles (young-old and old-old), and health conditions—which could have provided richer insights into the experiences of these subgroups. The distinct experiences of these subgroups and the types of responses needed to address the challenges they face also warrant further research [21]. While our study only considered the context of Singapore, we believe that these findings regarding the role of age and social and material precarities in shaping technological use and the suggested solutions to bridge the digital divide will be theoretically useful in understanding the experiences and perceptions of digital tools among marginalized populations in other contexts. Studies should be conducted to develop culturally sensitive approaches that can promote digital devices as a potential resource that is relevant to the needs of deprived communities, for example, in ways that can potentially improve the socioemotional and physical health outcomes of individuals or serve as a coping strategy in a precarious environment. Mixed methods studies using implementation science approaches [45] should also assess the maintenance of digital interventions in low-income communities, understand what is suitable for whom, and devise educational frameworks specific to the teaching of digital skills that can empower older learners.

Conclusions

The findings illuminate the need for community-based digital interventions to be designed with the particularities of the older adults' lived environment and experiences in mind and the sensitivity that these digital tools only occupy one facet of participants' lives, alongside other priorities and needs. Further studies are required to understand how these dimensions can be integrated into the intervention to enhance the smartphone's perceived relevance and utility, without being an unwelcome disruption. Measures aimed at promoting individual-level adoption of smartphones must also be addressed alongside approaches that tackle structural inequities, ageist structures, and stigma that disadvantages one group of older adults relative to others. Regarding those who choose not to participate in the "digital wave," the society must be willing to find and support alternative solutions to include these older adults in ways that promote social contact, autonomy, and socioemotional well-being—outcomes that technology purports to achieve—while not perpetuating their exclusion.

Acknowledgments

The authors express their gratitude to all participants who provided insights for the study as well as Sharon and Dhiya for their assistance with data collection and analysis.

Abstract

Background: Digital technology is a social determinant of health that affects older people's ability to engage in health maintenance and disease prevention activities; connect with family and friends; and, more generally, age in place. Unfortunately, disparities in technology adoption and use exist among older adults compared with other age groups and are even greater among low-income older adults.

Objective: In this study, we described the development and implementation of a digital literacy training program designed with the dual goals of training low-income older adults in the community and teaching students about aging using a community-engaged learning (CEL) approach.

Methods: The training program was embedded within a 10-week CEL course that paired undergraduates (N=27) with low-income older adults (n=18) for 8 weeks of digital literacy training. Older adults and students met weekly at the local senior center for the training. Students also met in the classroom weekly to learn about aging and how to use design thinking to train their older adult trainees. Both older adults and students completed pre- and posttraining surveys.

Results: Older adults demonstrated increased digital literacy skills and confidence in the use of digital technology. Loneliness did not change from pre to postassessment measurements; however, older adults showed improvements in their attitudes toward their own aging and expressed enthusiasm for the training program. Although students' fear of older adults did not change, their comfort in working with older adults increased. Importantly, older adults and students expressed positive feelings about the trainee-trainer relationship that they formed during the training program.

Conclusions: A CEL approach that brings together students and low-income older adults in the community has a strong potential to reduce the digital divide experienced by underserved older adults. Additional work is needed to explore the efficacy and scalability of this approach in terms of older adults' digital literacy as well as other potential benefits to both older and younger adults.

KEYWORDS

community-engaged learning; digital divide; underserved older adults; digital literacy training; intergenerational programs

Introduction

Background

Digital technology is a social determinant of health that plays a significant role in older adults' lives, including their ability to engage in health maintenance and prevention activities; connect with family and friends; and, more generally, age in place [1-3]. Recent evidence from the COVID-19 pandemic indicates that the digital divide contributed to health inequities among older individuals who were unable to benefit from technology to support health and well-being when in-person alternatives were unavailable or unsafe [4-7]. For example, without adequate online alternatives, older adults experienced greater health challenges and increased social isolation [8,9]. Conversely, older adults who had technology support during the pandemic fared better. For example, results from a qualitative study within a continuing care community indicated that technology mitigated social isolation and loneliness during the pandemic [10].

Disparities in technology adoption and use are particularly pronounced among older adults compared with other age groups [11-13] and are even greater among low-income older adults [3,14]. Some evidence suggests that internet use among low-income older adults may be as low as 17% [11] and that health-related technology use is significantly lower among racial and ethnic minority older adults as well as among low-income older adults [15]. Barriers that contribute to low rates of technology use among older adults include broadband availability, cost of broadband and devices, lack of awareness of potential technology benefits, low self-efficacy, and lack of training [16,17]. Some estimates indicate that only 25% of older residents in low-income housing have reliable internet access [18]. However, another study on low-income housing residents showed that although the housing communities in the study had access to broadband, few of the residents used the internet [19]. Thus, providing broadband and a digital device is insufficient. Digital literacy training is particularly important within this segment of the population to overcome barriers and promote sustained engagement [20].

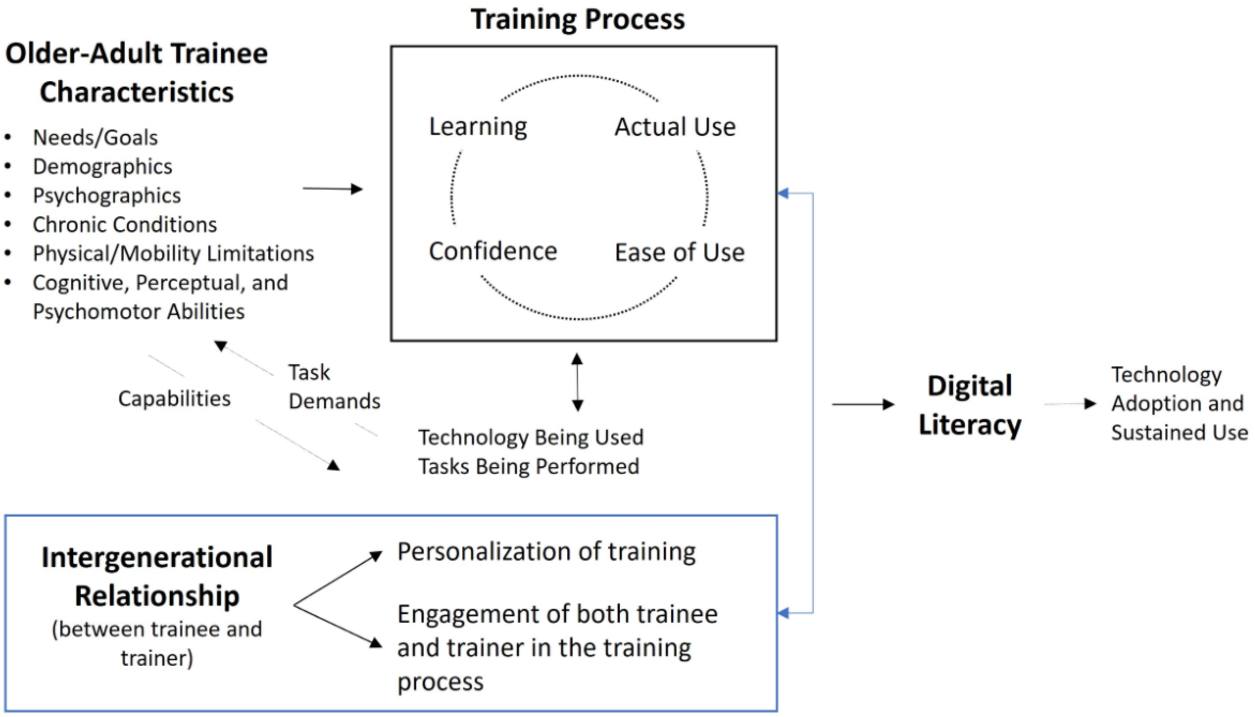
Digital Literacy Training

There have been numerous approaches used to teach older adults how to use technology [16,21-23]. Regardless of the approach, researchers tend to agree that hands-on training over multiple weeks and tailored training programs are particularly important to meet the needs of older adults [24]. Tailoring can be achieved in a variety of ways—either informally (eg, drop-in or as-needed help) or as part of an in-home or a classroom-style program in the community [25-29].

Two theoretical models of technology acceptance and use among older adults are particularly well-suited to promoting digital literacy in this population [16,24,30]. First, the Senior Technology Acceptance and Adoption Model (STAM) includes ease-of-learning and ease-of-using technology constructs and argues that these are significant drivers of actual use [31]. Second, the Center for Research and Education on Aging and Technology Enhancement (CREATE) model of technology use in later life focuses on older adults' characteristics, including demographics and psychographics (psychosocial background), cognitive, perceptual, and psychomotor abilities. The model also considers the relationship between older adults' capabilities and the demands of the technology task being performed (eg, more challenging tasks undertaken will require greater capabilities) [16,32]. Thus, the CREATE model informs training by highlighting the importance of the fit between trainee and training activities as well as the rate at which training proceeds.

Drawing on these 2 models, we developed a conceptual model of digital literacy training, which is shown below in Figure 1. First, our conceptual model incorporates the STAM's [31] close connection between ease of use on the one hand and actual use on the other. Last, the conceptual model places training at the center of adoption as being critical for low-income older adults who are far less likely to have prior experience with technology use and learning to use technology. The model provides a starting place for considering how training can be tailored to meet the needs of older adults with varying backgrounds and capabilities. Second, our model relies heavily on the CREATE model's [32] emphasis on older adults' characteristics (eg, demographics and cognitive and perceptual abilities) and the importance of the relationship between older adults' capabilities and the demands of the task being performed.

Figure 1. Conceptual model of digital literacy training.



Training programs targeting low-income older adults are far less common in the literature. Nevertheless, research suggests that factors that support older adults in general may be even more important for older adults from low-income backgrounds who may be reticent to seek training. Given the wide-ranging prior experience with technology and learning environments, a higher degree of tailoring and personalization may be critical to training those with lower-income and education backgrounds [20,24,33-35]. In addition to the insecurities surrounding the use of technology, low-income older adults may be more likely to have insecurities surrounding their ability to learn to use a computer, which in turn can impact enrollment into educational programs [33]. Low-income older adults may also lack awareness of the potential benefits of technology, which could also negatively impact motivation to learn to use technology and to persist in learning, especially when challenges arise [36,37]. For these reasons, programs that provide one-on-one training with highly individualized content and pacing may be a particularly important way to engage this population of older adults in training programs. Textbox 1 shows the training features, supported by the literature reviewed above, which may be particularly well-suited to low-income older adult populations.

Textbox 1. Evidence-based digital literacy training features proposed for low-income older adults.

Digital literacy training program features

- Hands-on (trainees use their device while being instructed)
- Tailored to the specific needs and goals of the trainee
- Personalized to optimize trainee engagement
- Delivered one-on-one (supports demonstration, practice, immediate feedback, and question and answer [Q&A] time)
- Trainee completes practices exercises in between meeting times; experience (successes and failures) is reviewed at subsequent meetings
- Same trainee-trainer pairs work together across training programs to foster trust and respect through relationship building

Intergenerational Approach to Digital Literacy Training

Another approach with the potential to engage and motivate older adults in digital literacy training, particularly older adults from underserved communities, is to provide opportunities for intergenerational relationships within the training process [38,39]. Intergenerational programs involve a younger generation (eg, college students) interacting with older adults who are typically from the same community. Opportunities in which different cohorts or age groups interact are becoming increasingly less frequent in society due to age segregation and changing family structures. In an age-segregated society, education, work, and leisure are apportioned to younger, middle, and older ages, respectively, restricting opportunities for older adults to spend time with younger individuals [40]. Intergenerational opportunities are further limited by changes in family structure, including fewer children and an increased likelihood of relocating to pursue a job or other opportunities [41]. Intergenerational programs often focus on fostering cooperation, interaction, and exchange between generations and can provide benefits, such as improved social connectedness and attitudes toward aging for both students and older adults [42-47].

Support for an intergenerational approach to digital literacy training comes from a study in which 38 pairs of high-school students and older adults met 2 or 3 times for 1.5 hours of training [21]. Although the study did not include digital literacy outcomes, results showed satisfaction for both the students and older adults. In another study, researchers explored 3 approaches to digital literacy training with students (undergraduate upperclassmen students in professional programs [eg, pharmacy]) and older adults [48]. With the first approach, students trained older adults in a 30- to 60-minute appointment at the senior center on an as-needed basis. The second approach matched students in a gerontology class with older adults from a local Osher Lifelong Learning Institute for a minimum of 6 hours of training at times and places determined by each trainer-trainee pair. The third approach consisted of as-needed, drop-in sessions held by students in 2- to 4-hour time blocks at the Osher Lifelong Learning Institute. Results showed that among older adult trainees who attended ≥3 sessions, trainees valued the intergenerational relationships developed over the training period as well as increased interest in working with technology. Moreover, younger adults showed improvement in attitudes toward aging, confidence in teaching older adults, and comfort working with older adults [48]. Similar to the matching program in Leedahl et al [48], Arthanat [49] paired undergraduate older adults in an occupational therapy degree program with older adults for 3 months of training (8 training sessions total) as part of a service learning project for an assistive technology course. Again, the training schedule was set by each pair. Before training, students attended a laboratory session on technology and aging and were encouraged to use Facebook as a forum to connect with other student trainers across the semester. Researchers reported increases in older adults' frequency of technology use for multiple purposes, including those related to health and hobbies, and self-reported independence in a range of digital activities, reflecting improved digital skills. In general, the data show that intergenerational programs can effectively engage older adults in digital literacy training.

Programs that bring together students and members of the community provide a critical opportunity for community-engaged learning (CEL). CEL incorporates activities typically associated with internships and service learning into formalized learning within courses that consider social needs and social changes in the community. It also emphasizes the significance of building relationships with individuals in the community to bring about social change [50]. Young adults are often at the forefront of social change, with a heightened interest in the broader world, where they see themselves in society and how they can make a difference [51]. Intergenerational CEL provides an opportunity for younger individuals to broaden their awareness of social needs by exposing them to issues related to digital exclusion among underserved older adults. Textbox 2 describes the intergenerational training features supported by the literature.

Textbox 2. Summary of intergenerational digital literacy training used in this study.

Intergenerational content and features

- A community-engaged learning framework was used that emphasizes providing students with the opportunities to develop academic skills, civic competencies, and ethical commitments while exploring community-based efforts to address social justice issues.
- The training program was integrated into a structured course with set weekly meeting times for (1) student classroom learning and (2) training older adults; set times remove weekly scheduling burden and uncertainty regarding the training schedule.
- Same trainer-trainee pairs worked together across the training program to enable the trainer to get to know the trainee to foster a trusting relationship that is conducive to frank and open discussion about training needs and pace.
- Weekly student classroom time used to teach students about aging (agism; technology as a structural determinant of health with cumulative disadvantage perspective; age-related changes in perceptual, cognitive, and motoric/physiological capabilities) and other factors that may impact older adults' acceptance, adoption, and sustained use of technology.
- Student classroom time was also used to teach students about design thinking and how to apply design thinking to designing personalized and tailored training for their older adult trainee.

Background Work

Before this study commenced, we explored the logistics of pairing students and older adults in the community within an existing course on aging and technology use. Students (n=30) were partnered with older adults (n=17) in small groups (typically, 3 students and 1 older adult) over 4 to 5 weeks. Students were responsible for contacting older adults by telephone (using a free app such as Google Meet) and scheduling weekly 30- to 45-minute meetings. Telephone discussions focused on older adults' current use of technology, attitudes toward technology, and what their preferences for training would be if they were to seek training. Students made notes each week to track what they learned about their partner's technology acceptance. At the end of the quarter, we asked both students and older adults to answer open-ended questions about the challenges and rewards of their student-partner interactions. Overall, we learned that both the students and older adults highly valued their time together, and their relationships grew as they got to know each other. However, scheduling weekly appointments took a substantial amount of time, due to difficulties in identifying time slots, cancelations, and rescheduling.

This Study

This study examined a digital literacy training program integrated within an intergenerational CEL course to explore a formalized pathway connecting undergraduate education and underserved older adults in the community. The digital literacy training program was embedded within a formalized course structure in which students received college credits as they learned about aging and social justice while working one-on-one with low-income older adults in the community. The training program, designed to work within a course structure rather than in parallel or as an add-on (eg, with a minimal connection between class time and training time), offered 3 additional benefits for student trainers and older adult trainees. First, a set time and place removed uncertainty in scheduling from week to week. Second, weekly contact between students and the instructor in the classroom provided time to teach students about aging, social justice, and digital literacy training. Third, weekly contact between students and older adults at the training location (ie, local senior center) allowed for meaningful relationship building. Fourth, the presence of the instructor at the training site supported the students and older adults by facilitating communication and troubleshooting should any problems arise. Overall, this provided students and older adults with formalized and consistent support and, potentially, higher-quality education for the students and training for older adults. Finally, we offered the CEL course as a first-year seminar (with no prerequisites) in an attempt to attract students early in their academic studies. Students from any majors (including “undeclared” majors) were able to review the list of first-year seminars and sign up for those they wished to take.

In pairing students with low-income older adults in the community over an 8-week period, we hypothesized that relationships would develop organically as the intergenerational pairs worked together. The CEL course included features to support the process and the course used “design thinking” to encourage students to consider the older adult holistically on how technology fits within this individual’s life. Design thinking is a human-centered approach that places the “user” at the core when solving “wicked” or ill-defined problems, such as how to design a digital literacy training program that is well-suited to the trainee [52,53]. The course also taught students about aging (eg, older adult characteristics shown in Figure 1), stereotypes and biases related to aging, and how to train older adults using a design thinking approach, which focuses on understanding the end user and defining the task at hand (ie, designing an effective training program for their trainee).

Methods

Participants

Undergraduate Students

There were no prerequisites and no restrictions on who could sign up for the course. Among the undergraduate students (N=26) in the course, 48% (n=13) were female individuals, and 77% (n=21) were underclassmen (ie, freshman or sophomore), and they represented a wide range of majors, including data science, mathematics, sociology, and animal biology.

Older Adults

Older adults (N=23) were recruited with the support of a local nonprofit organization as well as low-income housing organizations and the local senior center. Inclusion criteria consisted of older adults who were aged ≥60 years; were eligible for a federal or state safety-net program (eg, Meals on Wheels, senior low-income housing, Medi-Cal, Cal-Fresh [SNAP]); were residents in Yolo County; and had little-to-no prior experience with computers. Funds provided by the County helped pay for recruitment and enrollment support as well as new laptop computers (which the participants were allowed to keep) together with 2-year internet subscriptions for the low-income older adults in the training program. Screening resulted in 5 of 23 individuals being excluded (1 for not meeting the age criterion and 4 for not meeting the low-income criterion). The final sample of older adults (n=18) was predominantly female (n=17, 95%) and non-Hispanic White (n=10, 55%), with the remainder being Asian (n=4, 22%) and Hispanic White participants (n=4, 22%). Older adults’ age ranged from 61 to 87 (mean 72, SD 7.81) years and had a mean of 17.61 (SD 5.21) on the Lubben Social Network Scale, which assesses social networks for family and friends with possible a range of 6 to 36 and clinical cutoff of ≤12 [54].

Ethical Considerations

The study was deemed exempt by UC Davis’s institutional review board. Older adults were read an information script before the pretest, informing that they could quit anytime and that their individual-level data would be deidentified.

Measures

Undergraduate Student Pretest-Posttest Measures

Psychological Growth

The Psychological Growth scale (8 items) from the Attitudes to Aging Questionnaire [55] was used to assess students’ attitudes toward aging. The scale includes items, such as, “It is a privilege to grow old,” “As people get older they are better able to cope with life,” and “There are many pleasant things about growing older.” Responses are made on a 5-point Likert scale (1=strongly disagree; 5=strongly agree) and are summed, with higher scores reflecting more positive attitudes toward aging.

Fear of Old People

The Fear of Old People subscale of the Anxiety about Aging Scale [56] was used to assess students’ attitudes surrounding intergenerational relations. The subscale includes 5 items, such as “I enjoy being around old people” and “I like to go visit my older relatives,” with a 5-point Likert scale (1=strongly agree; 5=strongly disagree). Items were summed, with higher scores indicating more anxiety toward aging.

Working With Older Adults

We included 3 items to assess students’ attitudes toward working with older adults as they trained older adults [48]. The items were “I am comfortable working with older adults,” “I am confident in teaching older adults how to use technology,” and “I am likely to volunteer in the field of senior services,” with responses on a 5-point Likert scale (1=strongly disagree; 5=strongly agree).

Undergraduate Student Posttest-Only Measures

Rank Order

Students rank-ordered five aspects of the course from most important to least important: (1) learning about aging; (2) human-centered design and design thinking; (3) community engagement; (4) working with older adults; and (5) getting to know their trainee, specifically.

CEL Values

CEL addresses a specific community interest, problem, or public concern; includes working with and learning from a community partner; connects and integrates community-engaged experiences with educational content; and includes structured critical reflection. Students were given the following prompt: "Now that you've experienced CEL, we would like your perspective on its value. Please indicate how important the following CEL characteristics are to you," followed by 12 items, such as "It makes me a better student in the long run" and "I want to contribute to the good of our society," with responses on a scale of 1 to 3 (not very important to me, score=1; neutral, score=2; and very important to me, score=3).

Older Adult Pretest-Posttest Measures

Technology Skills

The Mobile Device Proficiency Questionnaire (MDPQ-16) was adapted to focus on "laptop" proficiency rather than mobile devices [57]. The questionnaire includes 8 scales, each assessing how easily the individual can perform digital tasks (n=18), such as navigating onscreen menus using the touchscreen, sending pictures by email, finding health information on the internet, and entering events and appointments into a calendar with responses of never tried (score=1), not at all easily (score=2), not very easily (score=3), somewhat easily (score=4), and very easily (score=5).

Loneliness

Loneliness was assessed using the 3-item Loneliness Scale [58], which asks how often individuals feel they lack companionship, are left out, and are isolated from others, on a scale ranging from hardly ever (score=1) to often (score=3). Scores are summed to create an overall assessment of loneliness. People who score 3 to 5 are considered "not lonely," whereas people who score 6 to 9 are considered "lonely."

Attitudes Toward Own Aging

Attitudes Toward Own Aging is a subscale of the Philadelphia Geriatric Center Morale Scale [59]. Respondents are asked to indicate whether they agree (score=1) or disagree (score=0), with 5 statements about aging such as "Things keep getting worse as I get older" (reverse scored) and "I have as much pep as I had last year."

Older Adults Posttest-Only Measures

Relationship Quality

On a scale of 1 to 5 (1=strongly disagree; 5=strongly agree), older adults were asked to rate the following: "To what extent do you agree with the following statements about working with the students?"; "I enjoyed working with the student(s)"; "I feel that I formed a close relationship with the student(s)"; and "I will miss interacting with the student(s) now that the project has ended."

Social Connectedness During Training

Older adults were asked how they feel about social connectedness using the following statement: "Did you feel more socially connected during the technology training program?" Responses were rated on a 3-point scale (1=no, 2=a little, and 3=a lot).

Self-Efficacy and Confidence

Three items on the extent to which participants agree with statements on computer skill improvement and confidence were as follows: "Your laptop skills have improved."; "You are more independent when using your laptop."; and "Your confidence in using laptop has improved." Responses were rated on a 5-point scale (1=strongly disagree to 5=strongly agree).

Overall Evaluation

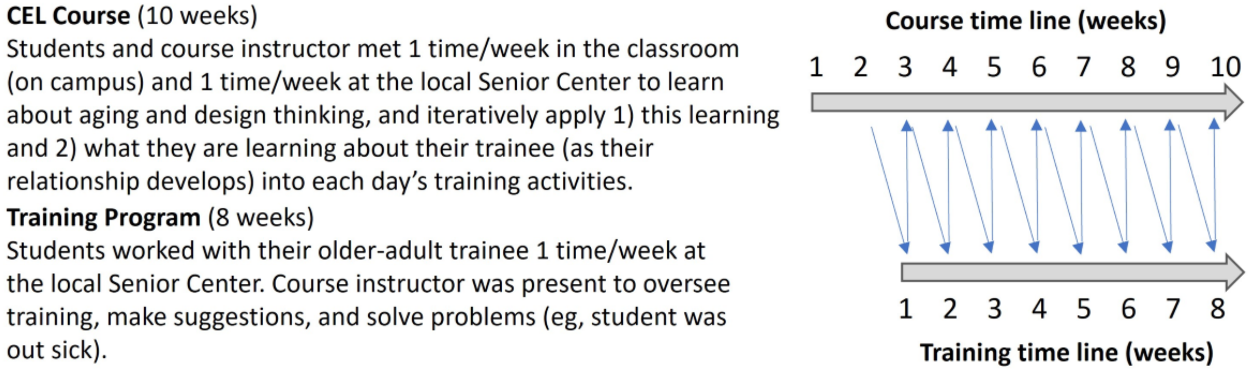
For overall evaluation, older adults were asked the following questions: "To what extent do you feel the training program was a positive experience" and "To what extent do you feel the training program was a valuable experience" with responses rated as 1=not positive or valuable to 5=very positive or valuable; "How likely would you be to recommend this technology training program to others?" with responses rated as 1=extremely unlikely to 7=extremely likely.

Procedure

Course

Undergraduate students enrolled in the CEL course in September 2022. In the first 2 weeks of the course, students (in groups of 1 or 2) were paired with an older adult so that each intergenerational group could begin to work together starting in week 3 of the course (which was week 1 of the training program) and continue to work together for the entire 8-week training program. Students met in the classroom on Tuesdays (50-min class) and in the senior center on Thursdays (50-min session), where older adults joined them for training. Figure 2 illustrates the back-and-forth nature of the education (CEL course) and training program and the overlap between the ten 50-minute classroom meetings and eight 50-minute training sessions at a nearby senior center where the training was conducted.

Figure 2. Illustration of how the digital literacy training was integrated into the community-engaged learning (CEL) course.



CEL Course (10 weeks)
Students and course instructor met 1 time/week in the classroom (on campus) and 1 time/week at the local Senior Center to learn about aging and design thinking, and iteratively apply 1) this learning and 2) what they are learning about their trainee (as their relationship develops) into each day's training activities.

Training Program (8 weeks)
Students worked with their older-adult trainee 1 time/week at the local Senior Center. Course instructor was present to oversee training, make suggestions, and solve problems (eg, student was out sick).

Each week, students submitted 2 assignments. First, they submitted their reflections on how the training process is going, observations about needs for subsequent training, and what they learned about their trainee as a person. The last part (what they learned about their trainee) formed the basis for our design thinking approach, which placed heavy emphasis on understanding older adults, including where and with whom they live, family members, motivations and needs for technology, and any other information that enabled the student to understand (get to know) the older adult trainee. Second, students submitted a training record that documented each task and their step-by-step instructions. The training records were combined to create a learner booklet for the trainee at the end of the training program.

Students completed the pretest during the second week of the quarter and the posttest during the week 9 of the quarter via Qualtrics (Qualtrics International Inc) online software. For older adults, a research assistant administered the pretest via telephone during weeks 1 and 2 of the training program and the posttest 1 to 2 weeks following the training.

Digital Literacy Training

A nonprofit community partner, Yolo Healthy Aging Alliance, provided trainees with (1) funds to purchase broadband internet for 2 years and (2) a Chromebook (a relatively inexpensive laptop costing about US $150 each, with a larger keyboard and screen than most tablets), which trainees used during training and were allowed to keep after the training. At the first session, older adults were introduced to their student trainers and were given their new laptops. Students then helped the older adults establish a user account and practice using the keyboard and touchpad to navigate to various places (note: due to an error, computer mice were not delivered until after the third week). Starting with a list of tasks that were commonly mentioned in the preliminary study and in the literature (eg, how to send and receive emails), students worked with their older adult trainees in the subsequent sessions to determine an appropriate pace and topics of importance to the trainee. See Multimedia Appendix 1 for the overview provided to students. After each session, students created step-by-step instructions for each task that they covered that day, including reminders and screenshots with arrows to direct attention. Students shared these instructions with trainees at the following session to obtain their feedback on clarity and granularity (level of detail) and adjusted the subsequent instructions as needed to maximize the older adults' learning. At the end of the training program, students presented these learner booklets to their trainees as a PDF document in hard copy and digital form (via email).

Results

Undergraduate Students

Pretest-Posttest Analyses

Table 1 shows the means for all the pretest-posttest measures. Students' scores on the Psychological Growth scale of the Attitude on Aging Questionnaire were summed to create a summary score for each time point. We found that scores did not significantly change from the beginning (mean 29.58, SD 3.11) to the end of the course (mean 29.19, SD 3.86; t_{25}<1, *P*=.46). Similarly, the sum of items on the Fear of Old People scale did not change significantly from the beginning (mean 10.19, SD 2.70) to the end of the course (mean 9.81, SD 2.95; t_{25}<1, *P*=.42). Student ratings of comfort working with older adults significantly improved from pretest (mean 4.00, SD 0.57) to posttest measurements (mean 4.27, SD 0.45; t_{25}=−3.04, *P*=.006). Neither confidence in teaching older adults how to use technology (t_{25}=1.31, *P*=.20) nor likelihood of volunteering in the field of senior services (t_{25}=1.22, *P*=.23) significantly changed.

Table 1. Pretest-posttest summary variables for students (N=26).

Pretest-posttest variables (range of possible scores)	Pretest measurements, mean (SD)	Posttest measurements, mean (SD)	*t* test (*df*=25)	*P* value
Psychological growth (8-40)	29.58 (3.11)	29.19 (3.86)	0.73	.46
Fear of old people (5-25)	10.19 (2.70)	9.81 (2.95)	0.82	.42
Comfort working with older adults (1-5)	4.00 (0.57)	4.57 (0.54)	−3.04	.006
Confidence in teaching older adults (1-5)	4.15 (0.54)	3.96 (0.72)	1.31	.20
Likelihood of volunteering in the field of senior services (1-5)	3.38 (0.98)	3.58 (0.95)	−1.22	.23

Posttest Analyses

The end-of-course rankings of course features showed that students preferred working with older adults in the community over other course features: working with their older adult trainees was ranked first by 46% (12/26) of students and ranked first or second by 70% (18/26) of students. Working with older adults in general or specifically with their trainees was ranked first by 77% (20/26) of students. Learning about aging ranked the lowest with 77% (20/26) of students placing it in the bottom 2 positions. CEL rankings dropped in the middle (12/26, 46%, in the third position), and human-centered design rankings were evenly distributed across the 5 positions. Last, endorsements of CEL statements showed that students particularly valued contributing to the good of society, with 88% (23/26) indicating that this is very important to them (highest endorsement). The following 3 statements received *very important* ratings from 84% (22/26) of the students: “It helps me build compassion for myself and other people,” “The skills and knowledge that I gain will help me in my career,” and “I build relationships with people who live and think differently than I do.” In total, 80% (21/26) rated “It makes me a better student in the long run” as being very important. The following 2 statements received the highest number of *not very important to me* endorsements: “I learn from agents of change in my community” and “I believe it’s important to live out my faith.” Table 2 shows the scores for each value.

Table 2. Student ratings of community-engaged learning (CEL) values: not very important to me (rating=1); neutral (rating=2); and very important to me (rating=3).

Statements	Scores, mean (SD); range
I want to contribute to the good of our society.	2.89 (0.31); 2-3
The skills and knowledge that I gain will help me in my career.	2.85 (0.36); 2-3
I build relationships with people who live and think differently than I do.	2.85 (0.36); 2-3
It makes me a better student in the long run.	2.81 (0.39); 2-3
It helps me build compassion for myself and other people.	2.81 (0.47); 1-3
I can learn more outside the classroom.	2.74 (0.44); 2-3
My assumptions and beliefs are challenged, and I get to challenge others.	2.67 (0.54); 1-3
It empowers me to be an agent of change.	2.63 (0.48); 2-3
I see my community in new ways.	2.56 (0.50); 2-3
It informs the way I engage with the world.	2.56 (0.57); 1-3
I learn from agents of change in my community.	2.52 (0.50); 2-3
I believe it’s important to live out my faith.	2.44 (0.63); 1-3

Older Adults

Pretest-Posttest Analyses

The means of the summary scores are presented in Table 3. Overall, digital proficiency was analyzed in 2 ways. First, the MDPQ-16 scores were summed across the 16 digital tasks to indicate changes in overall proficiency. We found that scores changed significantly from pretest (mean 33.72, SD 14.05) to posttest measurements (mean 54.89, SD 14.42; t_{17}=7.88, *P*<.001). Second, we assessed the changes in the range of activities performed by analyzing scores of 1 (never tried) on the MDPQ-16. Across all 6 activities, the number of “never tried” responses decreased from pretest (mean 9.61, SD 3.60) to posttest measurements (mean 3.83, SD 3.31), representing a significant change on a Wilcoxon signed-rank test of −3.73 (*P*<.001). Finally, we also examined the individual scales on the MDPQ-16 and found that all but basic skills (t_{17}=1.48, *P*=.16) increased from pretest to posttest measurements, with *P*<.01 for the remaining 5 scales. Figure 3 shows the scores for all 6 scales at both assessment times.

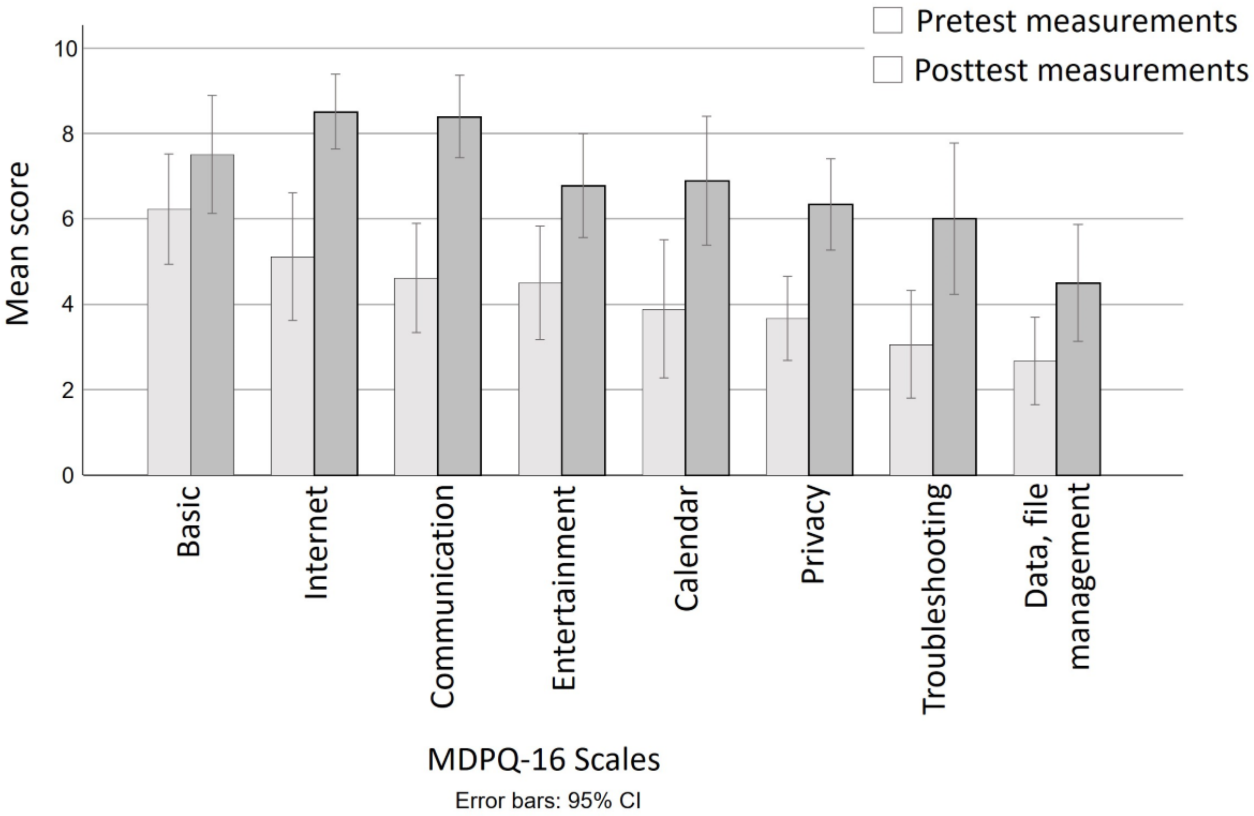
Table 3. Pretest-posttest summary variables for older adults (n=18).

Variables (range of possible scores)	Pretest measurements, mean (SD)	Posttest measurements, mean (SD)	Test statistic[a]	*P* value
MDPQ-16[b] total (16-80)	33.72 (14.05)	54.89 (14.42)	2.86	<.001
Never tried activities (0-16)	9.61 (3.60)	3.83 (3.31)	−3.73	<.001
Loneliness (3-9)	6.22 (2.58)	7.50 (2.77)	1.41	.18
Attitudes Toward Own Aging (0-5)	2.72 (1.74)	3.44 (1.50)	2.85	.01

[a] All tests are *t* test except "Never tried activities," which was tested using the Wilcoxon signed-rank test.

[b] MDPQ-16: Mobile Device Proficiency Questionnaire-16.

Figure 3. Technology proficiency at pretest and posttest by Mobile Device Proficiency Questionnaire (MDPQ-16) scale.



Loneliness scores were summed across the 3 items (possible scores of 3 to 9), with higher scores indicating greater loneliness. As shown in Table 3, loneliness scores did not change significantly from pretest (mean 6.22, SD 2.58) to posttest measurements (mean 7.50, SD 2.77; t_{17}=1.41, *P*=.18). Responses on the 5 Attitudes Toward Own Aging items were summed to create an overall score from 0 to 5, with higher scores reflecting more positive attitudes. We found significant improvements in attitudes toward aging from the pretest (mean 2.72, SD 1.74) to posttest measurements (mean 3.44, SD 1.50; t_{17}=2.85, *P*=.01).

Posttest Analyses

Relationship quality ratings were positive, with 94% (17/18) indicating that older adults strongly agreed (highest possible score) that they enjoyed working with their student trainer, 89% (16/18) strongly agreed that they formed a close relationship with their student trainer, and similarly 89% (16/18) strongly agreed that they would miss interacting with their student trainer after the project ended (Multimedia Appendix 2). More than three-quarters of older adults (16/18, 89%) responded that they felt "a lot" more socially connected during the technology training program, with the remainder (2/18, 11%) indicating that they felt "a little" more connected. Older adults' ratings of their computer abilities and confidence were also positive. Almost three-quarters of participants strongly agreed (highest endorsement) that their laptop skills had improved (13/18, 72%), that their confidence in using their laptop had improved (14/18, 78%), and that they were more independent when using their laptop (14/18, 78%). In terms of the overall evaluation of the training program, 100% (18/18) indicated their experience with the training program was very positive (highest endorsement) and 94% (17/18) indicated that the program was very valuable (highest endorsement). Finally, when asked how likely they would be to recommend the training program to others, 94% (17/18) responded extremely likely (highest endorsement) and 6% (1/18) responded very likely.

Discussion

Principal Findings

Multifactorial approaches are sorely needed to reduce the growing digital divide among low-income older adults [3,14,18]. The objective of the CEL study presented here was to address 1 component of the digital divide, digital literacy, using a potentially scalable approach. We sought to develop and implement a digital literacy training program using a CEL approach to bring together college students and low-income older adults in the community. There are several notable findings from this work.

First, we found significant improvements in digital literacy as assessed using the MDPQ-16, a measure of computer proficiency that is validated for older adults [57]. To our knowledge, proficiency has not been assessed in past work on training, regardless of whether the program used an intergenerational approach [23,48,49]. In addition to greater proficiency, we also found a significant increase in the breadth of technology use as reflected by a sharp decrease in the number of never-been-tried activities after training. This finding is consistent with intergenerational and nonintergenerational training studies, showing an increased frequency of technology use across multiple tasks [23,49]. However, another study using a similar approach (ie, the item, use of technology in many ways) showed no change following intergenerational training [48]. Overall, our findings add to a small but growing literature showing that intergenerational technology training programs can be an effective approach to improving digital literacy [25] and add to this literature by extending the findings to include digital literacy benefits for low-income older adults.

Second, we found significant improvements in older adults' confidence surrounding technology use, which is a critical component of technology acceptance and adoption [16]. This finding is consistent with past technology training studies showing improvements in older adults' confidence [23] and enjoyment of working with technology [48]. Because we included assessments of both confidence and skill, this study extends prior research by showing that both can improve when using an intergenerational approach to promoting digital inclusion.

Third, our results showed beneficial effects on how older adults think about their own aging. Although past work has shown that intergenerational contact can promote positive attitudes among younger individuals [46], we are unaware of prior studies that examined these attitudes among older adults. Past research has shown that older adults' positive attitudes toward their own aging protect against multiple diseases, including dementia [47,60]. Thus, policy makers interested in tackling the challenges of an aging population should consider investing in intergenerational programs to foster positive attitudes toward aging and enhance older adults' well-being.

Fourth, findings from this study did not show significant improvements in loneliness from pretest to posttest measurements. Although this was somewhat surprising, other training studies have also shown no effect of training on older adults' loneliness [23]. Indeed, a review of the literature on the effects of technology interventions, broadly defined, concluded that their impact on older adults' loneliness is ambiguous [61]. One reason for our findings could be that the pretest survey was administered at the start of the program when older adults had already met their trainers and worked within the same room as other trainers and trainees at the senior center. By contrast, shorter training programs (eg, 8 weeks compared with several months) tend to show null effects on loneliness [61]. Although ours was a group program (in which participants met in a setting with several other individuals), it remains unclear whether loneliness levels would have been impacted by the training program. Therefore, future research is needed to explore the effects of group training programs on loneliness in older adults.

Finally, older adults' end-of-program ratings suggest that the training program was a success. Self-reported improvements in digital literacy, program value, and program enjoyment were all high, and 94% (17/18) of older adults indicated that they were extremely likely to recommend the program to others. Enthusiasm for working with college student trainers has been reported in the past work [25,48]. High satisfaction with our digital literacy training programs may also be because the low-income older adults in our study (1) were able to keep the laptop and (2) received funds for a 2-year broadband subscription following the training (this support was for a federal low-income program called the Affordable Connectivity Program). This may also have helped to increase engagement and commitment to learning how to use the technology. Policy makers and community organizations interested in bridging the digital divide among low-income older populations should provide tangible support, such as digital devices and broadband connectivity to enhance program outcomes and promote continued digital engagement.

The significant improvements observed in older adults' digital proficiency, confidence in technology use, and attitudes toward aging underscore the potential of intergenerational approaches that bring together older adults and college students to promote digital inclusion and well-being among older adults. Programs that help to formalize opportunities for undergraduates to work with low-income older adults as part of their undergraduate education (rather than in addition to it) may be particularly impactful for both older and younger adults. In subsequent sections, we outline some of these benefits.

CEL Approach

Reduces Uncertainties Surrounding Logistics of Meeting Times and Place

The prescheduled meeting times and a meeting place at a local senior center provided structure, which reduced uncertainties for both students and older adults. Data from our preliminary study indicated that both students and older adults were frustrated and confused by scheduling constraints and last-minute changes.

Train the Trainer

Another advantage to this approach is the ability to focus on training the trainers, which in this study included students learning about design thinking and aging. The ongoing educational support to enable students to learn how to train older adults may be even more important when working with low-income older adults. Although other technology training programs have included educational support for students, they included only 1 session [48] or 1 session along with an optional social media forum for student trainers to support each other [49]. In this study, students' questions and observations about how to tailor the training to be more effective continued throughout the duration of the program.

Focus on Social Good

As with public psychology [62], CEL is concerned with social good and the welfare of others. This importance of social good is becoming increasingly acknowledged in other public and private institutions of higher education [63]. In this study, we found that the students were also concerned with social good. CEL ratings reflect students' interest in community, social welfare, and serving those in need. Developmentally, young adults tend to be concerned with the need for social change and identification of ways in which they can make a difference [51]. CEL with an intergenerational focus provides an opportunity for younger adults to express their concerns and broaden their awareness of social needs via exposure to underserved older adults. Furthermore, when CEL is embedded within the curriculum, students can more easily take advantage of opportunities to "give back" while also working toward their academic goals. This may be particularly important for underrepresented students who are often unable to do internships for a variety of reasons, including strict timelines for graduation, work obligations (sometimes several jobs), and family responsibilities.

Community and Campus Relationships

CEL relies heavily on close working ties with community members. In this study, the most important community members were the low-income older adults. Indeed, the relationship between the older adult trainees and the student trainers played a critical role in the success of the program. Community organizations also play a critical role and can help with recruiting older adults; donating space and associated services (eg, tables, chairs, parking, signage, and communication); and applying for funding to purchase laptops and broadband subscriptions. Finally, campus stakeholders also play a central role in the developing, testing, and scaling up of programs that focus on underserved older adults in the community. For example, campus leaders can express their enthusiasm for CEL courses, provide CEL experts to support instructors interested in designing courses, develop relationships with community stakeholders, and provide financial incentives (eg, to programs and departments) to incorporate these courses into existing degree requirements. The importance of campus and community partnerships cannot be underestimated [64]. Future work should therefore consider innovative ways to engage community organizations and campus leaders in efforts to build effective and sustainable intergenerational programs that improve low-income older adults' digital literacy.

Intergenerational Approach

This study used an intergenerational approach to serving low-income older adults. As suggested by the posttest scores, students valued getting to know their older adult trainees. Their experiences across the program led to greater confidence in working with older adults, as has been shown in past work [48]. In addition, consistent with past research, we did not find significant changes in fear of older adults (P=.42) [44,48]. Surprisingly, however, we did not find significant improvement in students' attitudes toward aging as has been reported in the past assessments [48]. A closer look at the prior study indicates that students in this study scored as high on the Psychological Growth scale at the pretest time point (mean 29.58, SD 3.11) as those in the study by Leedahl et al [48] at the posttest time point (mean 29.42, SD 3.19), suggesting that there was little room for improvement as a result of their interactions across the training program. In addition to whether changes in attitudes occur within an academic term, it is important to consider the possibility of longer-term effects of intergenerational programs, including CEL. In this study, the first-year seminar course had no prerequisites, potentially attracting those who would not otherwise consider working with older adults. Given an increasingly age-segregated society [40] and a severe shortage of individuals trained to work in fields related to aging [65], this approach may promote interest among students to work on solving some of the pressing issues in facing a world with an unprecedented number of older adults [66,67].

Limitations

There were several limitations of our study. First, because of our single-group design, we cannot know which components of the training program were responsible for the beneficial outcomes. For example, we cannot disentangle the effects of training from the effects of owning a new laptop or assume the intergenerational component is superior to other models of training (eg, the use of technology experts). Second, our pretest measures might have shown a stronger impact on the program had we administered them 1 or 2 weeks before the start of the training program. Because we assessed them in the first 2 weeks, it is possible that some outcomes, such as loneliness and basic technology skills, might have already improved. Third, as with some previous training studies [25,48], the sample size was small, which can limit the ability to detect smaller effects. The sample was also predominantly consisted of White and female individuals, limiting the generalizability of the findings. Our sample does not, for example, allow us to account for the potential role that sociocultural factors (eg, culture, country of origin, intersecting identities, situations, or the interplay between these factors) play in the augmentation of digital literacy in older adults. Importantly, however, participants in this study were from low-income households, which are significantly underrepresented in the literature. Finally, our study did not include a follow-up to examine the long-term impact of training on new technology adoption and sustained use of the laptops. It is also possible, for example, that greater digital literacy skills would lead to decreased loneliness over time as older adults begin to use technology for social interactions [68]. Additional work is needed to explore the longer-term impact and scalability of this approach to promoting digital literacy among low-income older adults and to examine other potential benefits to both older and younger adults.

Conclusions

Taken together, the current research contributes to a growing body of research on digital literacy training and provides a potential pathway to address the digital divide among underserved older adults [3,14,18]. Digital inclusion is central to older adults' ability to remain independent and live in their own homes as they age. Moreover, the intergenerational CEL approach used in this study promotes mutual respect across generations, breaks down harmful stereotypes, and helps to build a stronger community. Moving forward, continued research in this area is crucial for informing policy decisions that support digital inclusion for older adults and help to address broader challenges related to an aging global population, digital fairness, social justice, and the shared fate of humanity.

Abstract

Background: There is growing evidence that telemedicine can improve the access to and quality of health care for nursing home residents. However, it is still unclear how to best manage and guide the implementation process to ensure long-term adoption, especially in the context of a decline in telemedicine use after the COVID-19 crisis.

Objective: This study aims to identify and address major challenges for the implementation of televisits among residents in a nursing home, their caring nurses, and their treating general practitioners (GPs). It also evaluated the impact of televisits on the nurses' workload and their nursing practice.

Methods: A telemedical system with integrated medical devices was introduced in 2 nursing homes and their cooperating GP offices in rural Germany. The implementation process was closely monitored from the initial decision to introduce telemedicine in November 2019 to its long-term routine use until March 2023. Regular evaluation was based on a mixed methods approach combining rigorous qualitative approaches with quantitative measurements.

Results: In the first phase during the COVID-19 pandemic, both nursing homes achieved short-term adoption. In the postpandemic phase, an action-oriented approach made it possible to identify barriers and take control actions for long-term adoption. The implementation of asynchronous visits, strong leadership, and sustained training of the nurses were critical elements in achieving long-term implementation in 1 nursing home. The implementation led to enhanced clinical skills, higher professional recognition, and less psychological distress among the nursing staff. Televisits resulted in a modest increase in time demands for the nursing staff compared to organizing in-person home visits with the GPs.

Conclusions: Focusing on health care workflow and change management aspects depending on the individual setting is of utmost importance to achieve successful long-term implementation of telemedicine.

Introduction

Background

Population aging is an ongoing trend in industrialized countries and significantly impacts the health care sector [1-3]. Germany currently faces a steep increase in the number of older adult citizens and, concomitantly, in people needing care. Compared to the 2.63 million people needing care in 2013, this figure will increase by approximately 32% to estimated 3.48 million in 2030 [4]. As a consequence, more older adults will receive long-term care in nursing homes (NHs). To avoid future overcrowding of German hospitals and control overall health care costs, limiting hospital admissions (HAs) from NHs will be a major challenge. In fact, these HAs from NHs are frequently avoidable, with potentially avoidable HA cases from NHs accounting for €770 million (US $829 million) in avoidable health care costs in Germany each year [5].

Telemedicine is effective in reducing HAs from NHs and is an attractive modality of care, especially in the context of fewer home visits by general practitioners (GPs), a shortage of geriatricians, and difficulties in accessing health care in rural areas [6,7]. Both synchronous telemedicine, where a physician visits a patient in real time, and asynchronous telemedicine, where information on the patient is entered into a telemedical system and reviewed by a physician at a later time, can be implemented in NHs [8].

Another distinction of telemedical modalities is based on whether patients are accompanied by caregivers or not. Televisits are defined by the authors as videoconferencing among a remote physician, an NH resident, and an on-site caregiver (in this setting, a geriatric nurse) while having access to point-of-care (PoC) diagnostic devices that are integrated into the telemedical system. Televisits enable a structured physical examination and direct patient care, delegated by the remote physician and executed by the caregiver. This is not possible in video consultations, defined as simple videoconferencing between a physician and a patient. In the latter, the examination is limited without access to diagnostic devices, and direct patient care is not possible because there is no caregiver next to the patient.

Telemedicine is a safe modality of care and is noninferior in older adult patients presenting acute medical conditions in cases in which they are accompanied on-site by a nursing caregiver [9]. Several studies evaluating telemedicine for older adults have shown a reduced number of emergency department visits and HAs from NHs [10-22]. Despite these positive effects on the overall level of care and the widespread accessibility of telemedical tools, deployment in primary care and NHs is only progressing slowly.

Even though several implementation frameworks for telemedicine have been proposed in the literature [23,24], a lot of projects transferring telemedical or digital innovation into routine care fail due to poor consideration of change management (CM) aspects [25]. CM can be understood as an organized approach to drive organizational transformation from one current state to a new desired state. The concepts and various models commonly used for business transformation can be applied to health care, where new innovations are also constantly integrated [26-28]. While clinical research mainly focuses on creating evidence for better health-related outcomes, CM aims to ensure long-term adoption of change processes by promoting staff engagement and fostering a culture of continuous improvement. In fact, most of the clinical studies assessing the implementation of new technologies such as telemedicine focus on short-term adoption and technical issues but do not specifically address organizational, cultural, and educational challenges [29-31]. In contrast, the structured approach of CM involves methodically planning and monitoring the entire process to promptly identify and address challenges. This allows for the reduction in resistance to change, ensuring a smooth transition for health care providers and patients and, ultimately, enhancing the quality of care and organizational effectiveness. CM methods are action-oriented approaches focusing on managing specific change processes within one institution by directly addressing challenges. The field of implementation science (IS) must be distinguished from CM applied to health care. While IS also aims to understand implementation and the sustainability of implementation efforts, it takes a broader perspective. In fact, IS aims to create generalizable knowledge about effective implementation strategies of evidence-based health interventions by identifying facilitators and barriers across different contexts and health care settings [32].

Currently, many barriers to the implementation of telemedical tools are known, such as unstable internet connections and other technical issues, insufficient acceptance, privacy and security concerns, poor usability of the systems, a lack of patient support from health care professionals (HCPs), inadequate motivation and training, a shortage of staff, poor planning and engagement, and the fear of misdiagnosis or lack of trust in the technology [31,33-36]. However, implementation guidelines are still missing, and the best practice for implementing telemedicine for ensuring long-term adoption is still unknown. Moreover, there is a gap in research concerning the impact on nursing practice triggered by the organizational implementation of televisits.

Objectives

This study aimed to identify and address major challenges for long-term implementation of televisits as well as evaluating the impact of televisits on nurses' workload and their nursing practice.

Methods

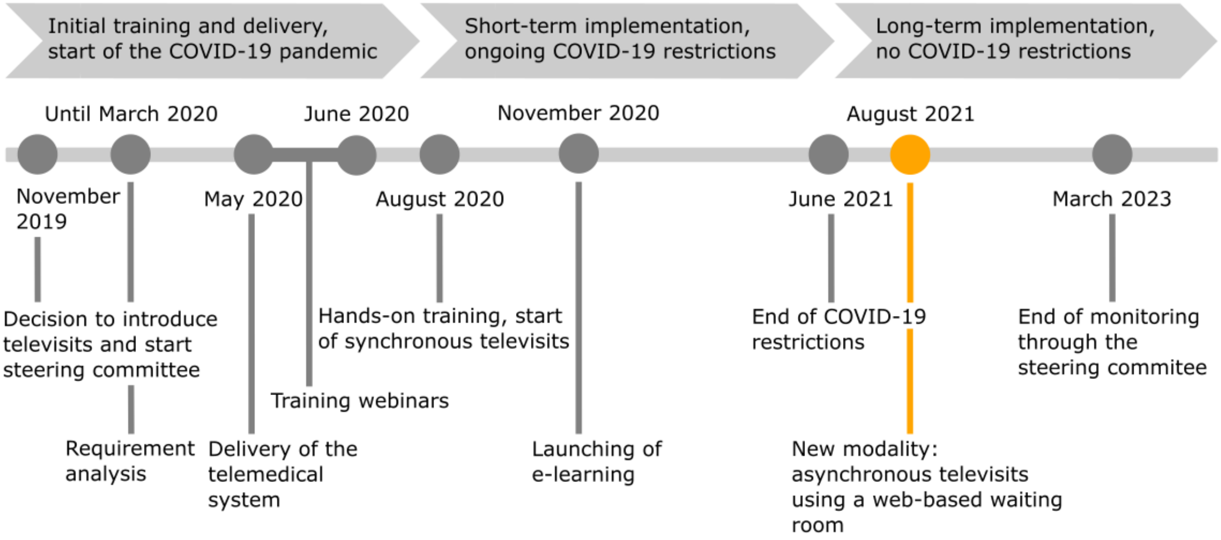
Setting

This study was conducted in 2 NHs located in 2 different rural areas of the federal state of North Rhine-Westphalia (Germany). Both NHs provide long-term stationary care for older adults, with an average resident age of >85 years. Although they are comparable in size (NH 1 provides care for 93 residents, and NH 2 provides care for 90 residents), they differed in the number of employees within the study period (NH 1 had 64 nurses and nursing assistants for a total of 39.6 full-time equivalents, and NH 2 had 37 nurses and nursing assistants for 32.5 full-time equivalents) and in the number of trainee nurses (14 in NH 1 and 69 in NH 2). There were more women (86% of the employees in NH 1 vs 70% in NH 2, trainees excluded) and older employees (mean age 47.8 years in NH 1 vs 33.3 years in NH 2, trainees excluded) in NH 1 than in NH 2. NH 1 was built in the 1970s and is administered by a foundation managing NH 1, a local ambulatory care service, and 1 facility for assisted living for older adults. NH 2 is run by a local nonprofit organization with a history of >150 years that provides stationary care in 3 NHs. The organization that runs NH 2 also offers care in all the other relevant fields of older adults' care (intensive care nursing, ambulatory care, assisted living communities, and palliative care). The regional district of NH 1 faces a steeper decline in the number of physicians than that of NH 2. This is reflected in the average travel time to the nearest GP practice, which was twice as long in the district of NH 1 as in the district of NH 2 (4.4 vs 2.0 minutes) in 2021 [37]. For the medical care of the residents, both NHs collaborate with a coordinating GP, who cares for approximately one-third to half of the total number of residents living in the NH. This is common in Germany, where the remaining residents are followed up on by other GPs located within the catchment area of the NHs. Only the corresponding GPs, and not the GPs of the other 2 NHs, participated in the implementation of televisits. However, an NH resident followed up on by a GP other than the corresponding one could still benefit from a televisit if the coordinating GP was covering for other GPs on holiday or sick leave.

Timeline

The timeline of the covered implementation process during this study is shown in Figure 1. The total follow-up period between November 2019 and the end of March 2023 can be divided into 3 phases. The first phase between November 2019 and mid-August 2020 consisted in planning the implementation process, supplying and setting up the telemedical system, and initial training of the HCPs. This was followed by 2 distinct implementation phases: a short-term implementation phase until June 2021, during which restrictions due to the COVID-19 pandemic were still in place, and a subsequent long-term implementation phase after the COVID-19 restrictions had been lifted.

Figure 1. Timeline of the implementation process.



From the very beginning, an interdisciplinary steering committee (see the *Evaluation: Steering Committee and Systematic Analysis of the First Implementation Phase* section) organized and supervised the entire change process. After a requirement analysis, the telemedical system was first delivered in May 2020. The initial training was delivered via web-based seminars as COVID-19 restrictions did not allow access to the NHs for external persons. A total of 5 webinars lasting approximately 1 hour each and held consecutively every week covered all the relevant aspects of televisits (the topics were *Introduction to telemedicine*, *Televisits*, *Televisits: the nurse's perspective*, *Televisits: the GP's perspective*, and *ECG, auscultation, and other diagnostic devices*). In parallel, the battery lifetime was enhanced, a bigger screen was installed, and the internet connection in the NHs was improved. In August 2020, hands-on training was organized for the entire staff in both NHs. After a short theoretical introduction summarizing the main learning points of the webinars, the participants were trained in televisits using simulated scenarios. Workflow organization was not part of the initial training. The nurse managers in the NHs received advanced training to become superusers, enabling them to feel comfortable in performing televisits, administering the users in the software, and guiding other nurses in their learning process. They later acted as contact persons for their colleagues regarding televisits. After the hands-on training sessions in August 2020, the NHs were asked to perform—whenever possible—weekly televisits with their coordinating GPs while still maintaining the weekly on-site home visits. No specific instructions or guidelines were provided regarding how the televisits should be incorporated into the existing workflows of the NHs. This provided the NHs with the flexibility to integrate televisits according to their specific requirements and organizational contexts.

To allow for continuous training, the webinar sessions, as well as additional step-by-step guides, were made available on an e-learning platform. The nurse managers continued weekly training of their colleagues and accompanied them in televisits when necessary. After a short familiarization period during which the nurse managers provided significant support, effective routine use was achieved between February 2021 and July 2021, covering the last COVID-19 lockdown in Germany from April 2021 to June 2021. When the COVID-19 restrictions ended, the first implementation phase was systematically analyzed within the steering committee. Challenges preventing further implementation were identified and addressed through specific control measures. This led to a new organization of televisits and marked the beginning of a second implementation phase beyond the constraints of the COVID-19 pandemic, referred to in this study as the long-term implementation phase.

The change process was monitored until the end of March 2023.

Telemedical System

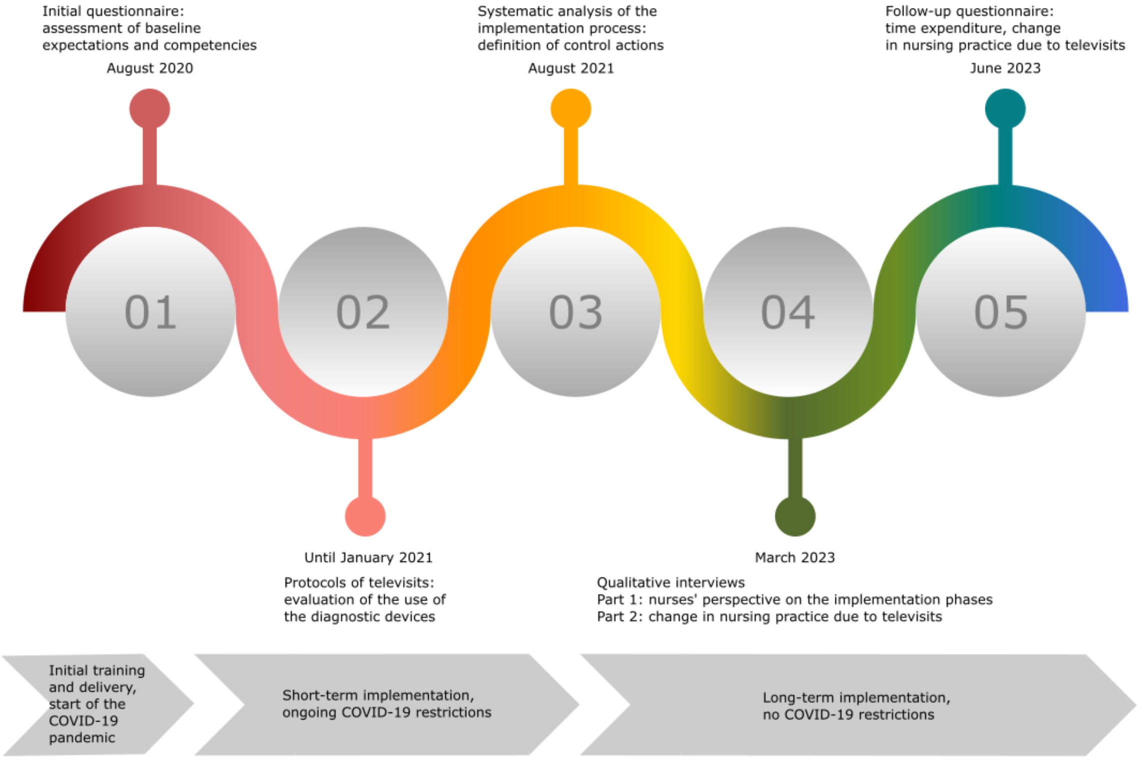
Televisits were performed using the so-called TeleDoc Mobile system (Docs in Clouds TeleCare GmbH), a market-available and mobile medical cart system for televisits with integrated medical diagnostic devices. The TeleDoc Mobile system was equipped with a blood pressure meter (BU 540 connect; medisana GmbH), a blood glucose meter (MediTouch 2; medisana GmbH), a 1-canal electrocardiogram (ECG; WIWE pocket ECG; myWIWE Diagnosztika Kft), and an electronic stethoscope (Littmann stethoscope model 3200; 3M). A conference camera offered a 10-time optical zoom in high definition (PTZ Pro 2; Logitech International S. A.). Screens on both sides of the system allowed for synchronous video communication among the GP, the nurse, and the resident. The software version of the TeleDoc Mobile system underwent multiple updates during the study period from version 1.0 in 2019 to version 3.6.2 in 2023. Feedback from HCPs was directly incorporated into these updates to meet their specific requirements. Previous work on the TeleDoc Mobile system had already demonstrated the technical feasibility of televisits and good acceptance by users [38].

Evaluation

Overview

A mixed methods approach was used for evaluation at different time points, as shown in Figure 2. A project diary in paper format containing a questionnaire and televisit documentation protocols (Multimedia Appendix 1) served to assess the nurses' baseline expectations and competencies and document the first televisits. This diary was distributed to all nurses in the NHs in May 2020, when the final telemedical system was delivered and the NHs were about to be trained and begin but had not yet done real televisits. The nursing staff were asked to fill in the questionnaire and document key elements of their first televisits, such as the date, the motive for consultation, and the number of PoC diagnostic devices used. The diaries were collected in January 2021. As already mentioned, the first implementation phase was observed and systematically analyzed within the steering committee in August 2021. At the conclusion of the study period in March 2023, qualitative interviews were conducted to retrospectively evaluate the nursing perspective regarding the implementation phases and the experienced change related to the implementation of televisits. The qualitative assessment of changes experienced in nursing practice was further quantitatively evaluated using a follow-up questionnaire in June 2023. The individual methods are described in detail in the following subsections.

Figure 2. Overview of the methods used for evaluation.



Questionnaire on Baseline Expectations and Competencies

The initial questionnaire (Multimedia Appendix 1) assessed nurses' self-reported competencies in the use of both medical devices and computer programs. A scale from 1 to 6 following the German school grading system was used (1=very good, 2=good, 3=satisfactory, 4=sufficient, 5=poor, and 6=deficient). Baseline expectations regarding the impact of implementing televisits on the residents' medical care and the nurses' time spent on televisits were assessed using preformulated multiple-choice questions. The nurses were also asked to rate, according to the German school grading system and before starting real televisits, their self-perceived level of knowledge of the medical devices as well as their level of understanding of the TeleDoc software. As the questionnaire was linked with the televisit documentation protocols, the questionnaire was not collected directly after the nurses had received training but only with the diaries in January 2021. In total, 20 diaries (n=12, 60% in NH 1 and n=8, 40% in NH 2) were handed back for analysis. After 1 diary was excluded because of missing data, 19 (n=11, 58% in NH 1 and n=8, 42% in NH 2) were used for analysis. Single missing data points were imputed with median imputation. Only the results regarding the self-reported competencies and the initial expectations are presented in the main text of this paper; however, the data for all questions can be found in Multimedia Appendix 2. Continuous variables were described as medians and IQRs and compared using the Mann-Whitney *U* test. Categorical data were described as numbers and percentages and compared using the Fisher exact test. All statistical tests were 2-sided with an α significance level of .05. They were applied in Python (version 3.9.7; Python Software Foundation) using the *scipy.stats* package.

Televisit Documentation Protocols

Televisit documentation protocols (Multimedia Appendix 1) were included in the second part of the project diaries. The nurses recorded in these protocols when a televisit took place and whether the televisit was preplanned or organized for an acute issue, such as an acute medical presentation by a resident. The nurses also documented the reason for the consultation and indicated whether they would have contacted the emergency service or the GP out-of-hours service or waited until the GP was available if they had not had access to televisits. In a second part, the nurses were asked to indicate which medical devices they used and rate how well they got along with these devices and the software. Data presentation and statistical analysis were conducted in the same manner as for the data of the initial questionnaire (continuous variables: medians, IQRs, and Mann-Whitney *U* test; categorical variables: numbers, percentages, and Fisher exact test; 2-sided statistical tests; α=.05; Python version 3.9.7). The protocols ended with questions regarding the interaction with the GPs and how the residents felt about the medical care during the televisits. They also contained some open-ended questions for providing personal detailed responses. These data are not presented in this paper but can also be found in Multimedia Appendix 2.

Steering Committee and Systematic Analysis of the First Implementation Phase

An interdisciplinary steering committee monitored the entire implementation process. It consisted of members from clinical and change research fields (n=3 physicians doing clinical research and n=2 researchers in CM), a health insurance representative (AOK Rheinland/Hamburg, Düsseldorf, Germany), NH and nurse managers of the participating NHs (n=3), and technical developers from the telemedical system manufacturer (n=2). All authors were part of the steering committee. The steering committee conducted the requirement analysis and organized and developed all forms of training and information material for the nursing staff, such as the hands-on training, the e-learning classes, standard operating procedures for specific presentations, and pocket cards for the use of the medical devices. As the nurses in the NHs reported directly to the senior nurses of their NHs, they were indirectly represented in this committee. Monthly meetings were held throughout the follow-up period to discuss the ongoing process and challenges encountered. If the challenges could not be resolved immediately, specific committee members were assigned to elaborate possible control measures and action plans, which were then presented and discussed in subsequent meetings. The challenges and the resulting actions are presented descriptively. The figures describing this process were created using Inkscape (version 1.3, Free Software Foundation, Inc) and based on free images from Freepik [39] designed by the authors Freepik, Slidesgo (Freepik Company SL), and stories.

Qualitative Interviews

The COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines were used to present the design and results of the qualitative interviews [40]. The COREQ checklist can be found in Multimedia Appendix 3 [40]. From March 2023 to June 2023, a semistructured interview study was conducted with nurses directly involved in the care of the residents (n=5 in NH 1 and n=3 in NH 2) and with senior nurses with additional administrative roles during the implementation of the televisits (n=1 in NH 1 and n=2 in NH 2). These senior nurses had all been part of the steering committee during the implementation process. The interview guide (Multimedia Appendix 4) was developed by TM, a physician and clinical researcher, and checked for consistency and missing questions by HG, a CM expert. The participants were selected through convenience sampling. The nurse managers proposed interview participation to all nurses who had performed televisits. The voluntary participants then received appointments for interviews via videoconferencing. The interviews took place in a dedicated room in the NHs where the nurses were alone and not interrupted during the interview. Before starting the interview, all interview partners were informed about the aim of the interview, which was to collect the individual perceptions and experiences related to the process of implementing televisits in their NH. All interviews were conducted by TM. While the senior nurses with additional administrative roles were known to TM before the interview, there was no previous relationship with the other interviewed nurses. The participants were also informed about TM's background and that this study on televisit implementation was part of his research for gaining his degree as Doctor of

Medicine. They were also informed about his role in the steering committee, where he provided scientific guidance and assistance. The participants received information and gave informed consent for the interviews.

Most of the interview sections were dedicated to evaluating expectations, experiences, and perspectives regarding televisits as well as assessing the impact of their implementation on the nursing practice. These inquiries were all presented as open-ended questions. Another part focused on the addressed challenges and control measures adopted throughout the implementation process. To facilitate focused and structured responses, the nurses were asked to comment freely on predefined statements regarding various aspects of the implementation process within the study period.

The interviews were conducted once without follow-up or subsequent interviews. All the interviews were held in German, visually recorded, transcribed, and analyzed using thematic analysis. No field notes were made during the interviews or when reviewing the interviews. The transcripts were not returned to the participants for comments. As most of the questions directly evoked specific aspects of the implementation process, such as the nurses' expectations for televisits (asked as follows: "What expectations did you have regarding telemedicine and televisits [note: before the implementation process]?"), the questions themselves predefined the main themes. The coding was done manually within different columns in Microsoft Excel (Microsoft Corp). The responses of the interview partners were divided into sections with different ideas, each collected in separate rows. In a second step, inductive coding was done by defining labels created based on the data. These were then regrouped into categories based on recurring patterns. The labels and the themes were translated into English. To present the data, the different categories under each main theme were condensed into key points or brief sentences.

Follow-Up Questionnaire

In June 2023, a follow-up questionnaire (Multimedia Appendix 5) was distributed via a web-based survey tool (UmfrageOnline; enuvo GmbH) to all the nursing staff in NH 1, in which long-term implementation of televisits had been achieved. For comparing pre- and postimplementation results, nurses were tasked with evaluating the time spent on televisits and the impact of implementing televisits on residents' medical care, mirroring the approach used in the initial questionnaire. In multiple-choice questions, the nurses also reported the impact on nursing practice. Several other aspects, such as the interaction with the GP, the usability of the telemedical system, and the potential of televisits with physicians from medical specialties other than family medicine, were assessed. Only the main results are presented in this paper.

Ethical Considerations

This study was approved by the ethics committee at the Faculty of Medicine of the Rheinisch-Westfälische Technische Hochschule Aachen (EK 23-178).

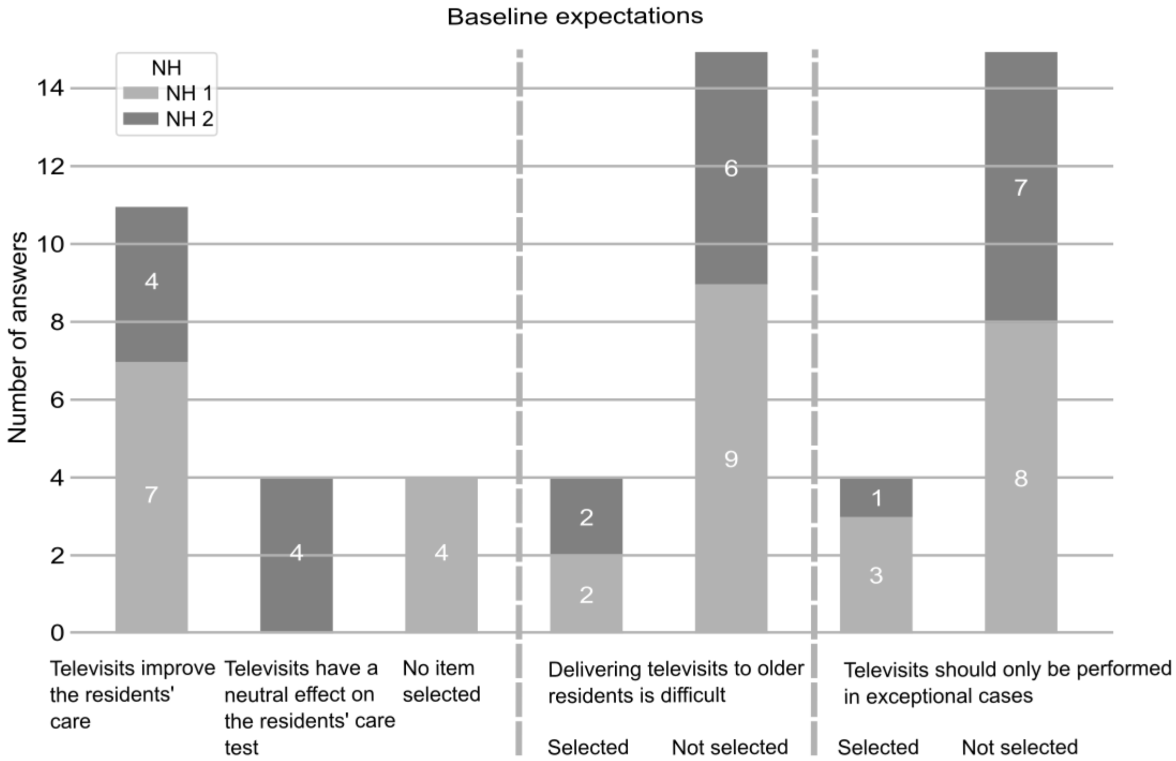
Results

Questionnaire on Baseline Expectations and Competencies

Before the implementation of televisits, nurses rated both their computer competencies and their clinical skills in taking vital parameters and examining a resident using medical diagnostic devices as good, with slightly better levels in NH 2 (computer competencies: median 2.0, IQR 2.0-3.0, and n=11 in NH 1 vs median 1.5, IQR 1.0-2.0, and n=8 in NH 2, *P*=.06; diagnostic devices: median 2.0, IQR 2.0-2.0, and n=11 in NH 1 vs median 1.5, IQR 1.0-2.0, and n=8 in NH 2, *P*=.10).

With regard to baseline expectations, slightly more than half (7/11, 64% of respondents in NH 1 and 4/8, 50% of respondents in NH 2; *P*=.66) of the nurses expected televisits to improve the residents' care, 4 nurses expected the positive and negative effects of televisits to be equal (0/11, 0% in NH 1 and 4/8, 50% in NH 2; *P*=.02), and 20% of the total nurses (4/11 in NH1 and 0/8, 0% in NH2, *P*=.1) agreed with neither of these 2 statements (Figure 3). In total, 4 nurses (3/11, 27% in NH 1 and 1/8, 13% in NH 2; *P*=.60) declared that televisits should only be performed in exceptional cases (see the raw data in Multimedia Appendix 2), 1 (25%) of whom expected that delivering televisits to older residents would be difficult and 2 (50%) of whom did not expect to see positive effects from televisits on the residents' care (Figure 3). The effect of implemented televisits on the nursing workload was estimated to be neutral by the vast majority in both NHs (9/11, 82% in NH 1 and 6/8, 75% in NH 2; *P*>.99) and to be time saving or time consuming by 3 (1/11, 9% in NH 1 and 2/8, 25% in NH 2) and 1 (1/11, 9% in NH 1 and 0/8, 0% in NH 2) respondents, respectively, with no significant differences between the NHs (*P*=.55 and *P*>.99, respectively).

Figure 3. Baseline expectations of the nurses as reported in the initial questionnaire; data presented for n=11 nurses in nursing home (NH) 1 and n=8 nurses in NH 2.



The initial training sessions on the diagnostic devices were rated as very good to good, and the software instructions were rated as good to satisfactory.

Televisit Documentation Protocols

A total of 30 televisits in NH 1 and 19 televisits in NH 2 performed between May 2020 and January 2021 were documented by 10 and 6 nurses, respectively, averaging 3.00 and 3.16 televisits per nurse, respectively. Of the total of 49 televisits, 36 (73%; 23/30, 77% in NH 1 and 13/19, 68% in NH 2; *P*=.53) were used for planned routine assessment. In 13 cases (7/30, 23% in NH 1 and 6/19, 32% in NH 2; *P*=.53), the televisits were scheduled at short notice for urgent assessments of residents who had acute medical presentations and issues. In NH 2, all the medical devices provided by the telemedical system were systematically used in every single televisit. In NH 1, the televisits included the use of 1 medical device in 50% (15/30) of cases. In 30% (9/30) of cases, the system was used for videoconferencing without further use of diagnostic devices. In total, 2 or 3 medical devices were only used in 13% (4/30) and 7% (2/30) of televisits, respectively. The blood pressure meter was the PoC device used most often for televisits (16 times), followed by the electronic stethoscope (8 times) and the 1-canal ECG (3 times; Table 1). During these first televisits, the nurses rated their competencies in handling the software and the medical devices as good (Table 2). In an open-ended question asking for possible improvements, they mentioned the need for further training in half (8/16, 50%) of the answers, followed by technological (6/16, 37%) and organizational (2/16, 13%; Multimedia Appendix 6) issues.

Table 1. Use of point-of-care (PoC) medical devices in nursing home (NH) 1 within the initial testing and familiarization period. Data presented for a subset of n=21 televisits where one or multiple PoC devices were used. In 9 additional televisits documented in NH 1, no PoC devices were used. The data for NH 2, where measurements were systematically taken using all the PoC devices in every televisit, are not presented (n=19).

Name or number of medical devices	Uses, n (%)
Medical device	
BP[a] meter	16 (53)
Blood glucose meter	2 (7)
1-canal ECG[b]	3 (10)
Electronic stethoscope	8 (27)
Number of devices	
No diagnostic devices	9 (30)
1 device	15 (50)
2 devices	4 (13)
3 devices	2 (7)

[a] BP: blood pressure.

[b] ECG: electrocardiogram.

Table 2. Self-reported competencies in handling the telemedical software and the point-of-care medical devices as assessed by the nurses themselves. *P* values are given for the Mann-Whitney U test comparing the results in nursing homes (NHs) 1 and 2. Scale from 1.0 to 6.0, with 1.0 corresponding to very good and 6.0 to deficient.

Point-of-care device and population	Number of ratings, n	Values, median (IQR)	*P* value
Camera			
NH 1	20	1.0 (1.0-2.0)	—[a]
NH 2	19	2.0 (2.0-2.0)	.02
Total	39	2.0 (1.0-2.0)	—
Blood pressure meter

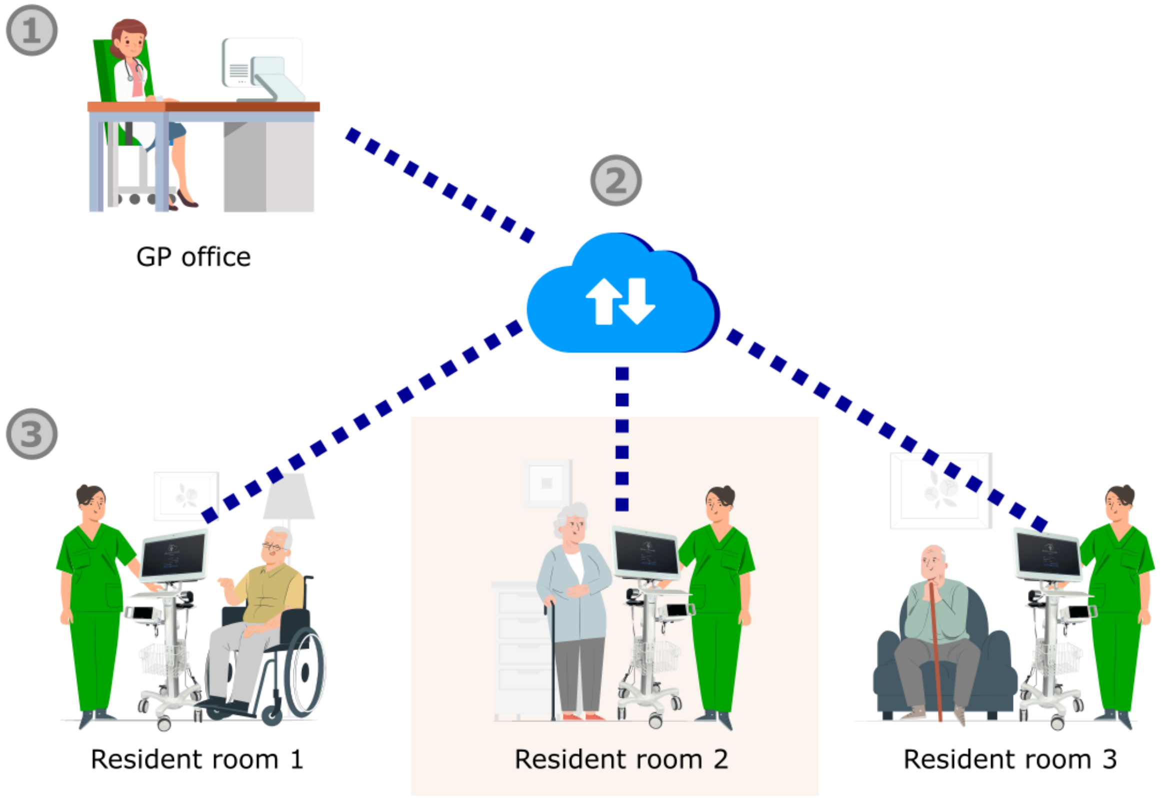
[b] ECG: electrocardiogram.

Systematic Analysis of the First Implementation Phase

Initial Organization of Televisits

In the first phase of implementation, televisits were organized in the same way as on-site home visits, where a physician sees several residents in an NH while moving between the different residents' rooms. The remote physician working in the GP office connected via the telemedical system to a nurse in the NH standing next to a resident to be consulted. The televisits had been synchronous at the beginning—thus, the GP in the office as well as the nurse and the resident in the NH both connected to the telemedical interface at the same time and no previous assessment of the resident such as taking of the vital parameters had been conducted beforehand. When the GP requested measurements, the nurses used the medical devices for taking vital signs during the ongoing televisits. Meanwhile, the physician connected to the telemedical system in the GP office via internet waited until completion before deciding which steps to take next. When one televisit had been completed, the nurse on-site moved the telemedical device (with the physician connected via internet) from one resident's room to another. During these transfer times, the GP also waited. We called this modality *synchronous televisits in the modality of web-based home visits* (Figure 4). During the first implementation period, the issues evoked by the NHs and addressed by the steering committee essentially concerned signal stability, specific software features, and the use of the medical devices. Issues on the side of the GP such as the billing of telemedical visits were also addressed. Televisits were performed regularly in both NHs until the easing of lockdown restrictions in Germany in June 2021.

Figure 4. Synchronous televisits in the modality of web-based home visits by a remote general practitioner (GP) in a GP office (1) connected via a telemedical system (2) with a nurse in the nursing home next to a resident (3).



Descriptive Presentation of Encountered Challenges and Adopted Control Measures

Health Care Context at the Time of the Systematic Analysis

When the German health care system and society were in transition between the pandemic and the postpandemic situation, the steering committee systematically analyzed in August 2021 the experiences of the first implementation phase. At that point, the last German COVID-19 restrictions were over, and normal home visits were possible again. Resistance to change was rising in the HCPs, who reported a lot of challenges and issues. Three main barriers to long-term adoption were identified: (1) conflicting workflows between the NHs and the GP offices, (2) the lack of time efficiency of the televisits, and (3) perceived uncertainty in using the technology among the nursing staff.

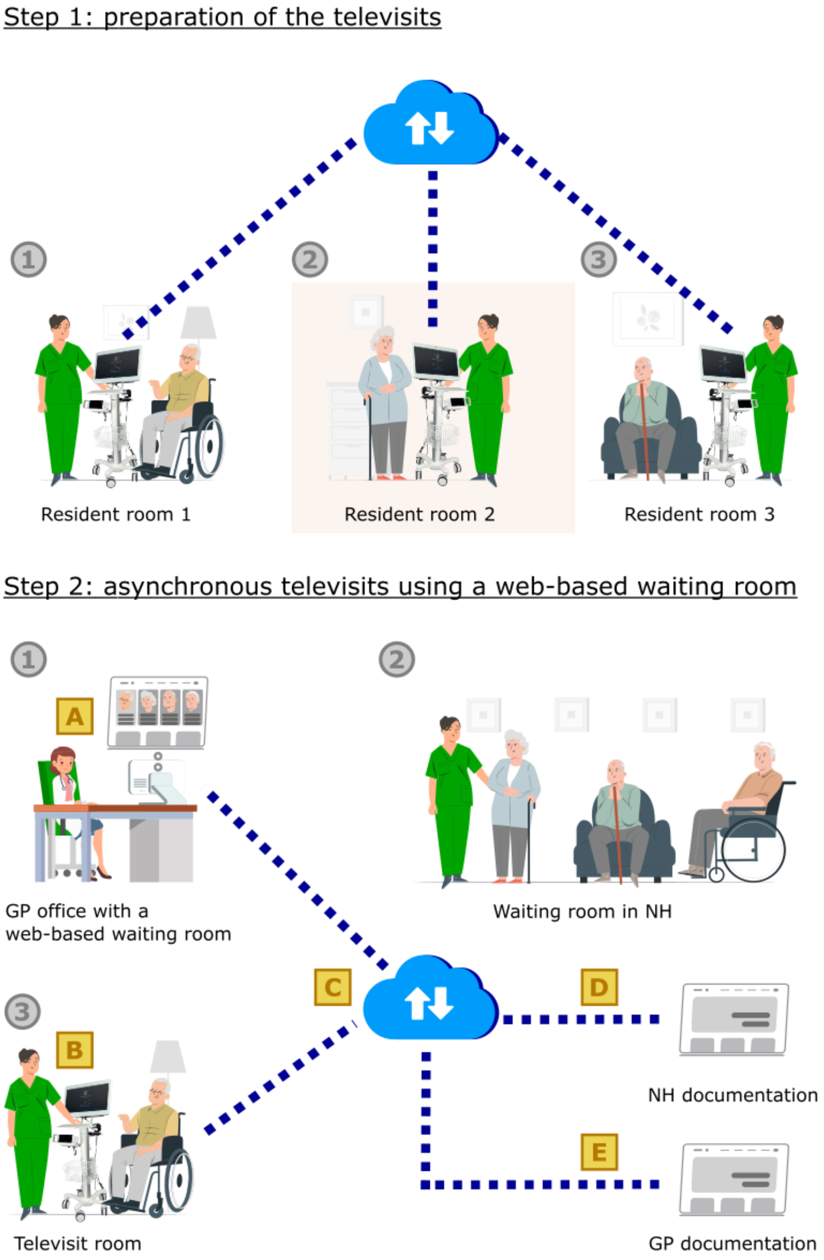
Conflicting Workflows

The daily routines and workflows were different in the NHs and in the GP offices. Finding suitable moments for televisits was difficult. For example, noon was a time when there were no consultations in the GP office, and thus, it was ideal for televisits from the GP's perspective. However, in the NHs, all the staff were busy serving and delivering lunch. Initially, televisits were scheduled at varying times every week, resulting not in the desired flexibility but in organizational stress and discomfort. This was addressed by agreeing on fixed weekly time slots for the routine televisits. With regard to unplanned televisits in the case of acute medical presentations, the workflows were also initially conflicting. The NHs did not bundle calls to the GP office. As a consequence, the workflow of the GP office was interrupted multiple times a day when 2 or more visits had to be planned. During the consultation hours in the GP office, phone calls were particularly disruptive because the GP was seeing other patients at that moment. To avoid disruption due to phone calls, the GP office and the NH grouped requests. Phone calls were completely abandoned except for extreme emergencies. The NH sent a fax containing a list with the residents proposed for consultations along with the reasons for consultation and some contextual information. On the basis of this information, the GP then responded with a fax indicating the vital parameters that should be assessed before the actual consultation (the organization of televisits was changed for an asynchronous modality with vital parameters being taken beforehand; see the following section).

Lack of Time Efficiency of the Televisits

The televisits, highly valued during the pandemic phase, were perceived as overly time consuming compared to normal home visits when the latter were regularly possible again. As mentioned previously, the workflows were interrupted during the transit times and when vital signs were taken. This was perceived by the GPs as a significant loss of time they could not spend with other patients in their offices. For the GPs, the time spent on televisits needed to be reduced so that the televisits were a real benefit to them compared to on-site home visits. As these challenges were mainly linked to the synchronous modality of televisits, the organization was completely changed for the modality of *asynchronous televisits using a web-based waiting room* (Figure 5). In this approach, the vital signs of the residents to be seen are taken beforehand by the nurses on-site. Then, with all diagnostic measures completed and documented, the televisits are performed at a scheduled time. The residents to be consulted physically wait in a waiting room in the NH. They also appear in a web-based waiting room in the GP's telemedical interface. The televisits take place in a dedicated room where the telemedical cart is used while stationary. Instead of moving the telemedical cart, the residents enter the televisit room one at a time as they would a consultation room in a GP office (Figure 5). This greatly improved the time efficiency of the televisits. To avoid losing time spent with doubled-up documentation, interfaces among the telemedical system, the GP, and the NH documentation systems were created. This made it possible to directly export the medical documentation from the TeleDoc software to the other programs.

Figure 5. Asynchronous televisits using a web-based waiting room. Step 1: taking of the vital parameters of the residents to be seen. Step 2: asynchronous televisits at a scheduled time using a web-based waiting room for the general practitioner (GP; 1), a physical waiting room in the nursing home (NH; 2), and a defined televisit room (3). The control actions were the creation of the web-based waiting room (A), training of the nursing staff (B), allowing for asynchronous documentation in the software (C), and interfaces to the existing programs (D and E).



Perceived Uncertainty in Using the Technology Among the Nursing Staff

Moreover, the nursing staff also requested more intense training. To this end, NH 1 and the cooperating GP office jointly hosted a medical student for 4 weeks, during which the student supported the training of the nursing staff. He trained nurses in the use of the PoC devices, helped prepare televisits, and accompanied them during these visits. During these 4 weeks, daily televisits were performed.

Finally, long-term implementation was reached in NH 1, with regular, most of the time weekly, televisits between the GP and

NH 1 from August 2021 until the end of follow-up in March 2023. A total of 163 televisits were performed during this period of 20 months. The televisits did not replace the preceding rhythm of on-site home visits but were performed in addition. In NH 2, further efforts to implement televisits after the COVID-19 period remained unsuccessful throughout the follow-up period.

Interview Findings

Selection and Characteristics of Interview Participants

In both NHs, it was planned that the first 5 nurses who volunteered would be included. In NH 2, many nurses considered their experience with telemedicine to be too little and too far away, so no one else wanted to participate after the first 3 nurses were recruited. As NH 2 did not achieve long-term implementation and had not regularly performed televisits since August 2021, additional interviews were unlikely to reveal new themes, insights, or perspectives. Thus, data saturation had already been reached after these 3 interviews. The interviewed nurses were predominantly male (5/8, 62%), with a median age of 26 years. The youngest and oldest participants were aged 26 and 63 years, respectively. The nurse managers were all male (3/3, 100%), with the youngest and oldest participants being aged 30 and 56 years, respectively. The interviews took, on average, 33 minutes for the nurses and 40 minutes for the nurse managers.

Interview Findings Concerning the Implementation Phases

In the follow-up interviews, the nurses and nurse managers stated that their main expectation before the implementation of televisits was to enhance residents' access to physicians, particularly beyond the regular GP consultation hours. The nurse managers further expected a decrease in psychological distress in their staff, along with enhanced legal protection through telemedical expertise during emergency situations with acute health-related deteriorations in their residents.

As regards the subsequent implementation, the interview findings are consistent with the analysis of the steering committee. Nurses in both NHs agreed that televisits were seen as useful during the COVID-19 pandemic and had offered manifest benefits for the residents. Televisits addressed the specific need for thorough medical assessment in the context of the then current contact restrictions. However, the benefits of the televisits seemed less identifiable for most of the nurses of both NHs after the end of the contact restrictions given that normal home visits were possible again and because the telemedical system did not provide the residents with better access to the health care system in terms of other medical specialties or access to physicians outside of the normal office hours. In total, 25% (2/8) of the nurses explicitly saw a benefit of televisits with the GP for residents with acute medical presentations outside the hours of the on-site home visits.

Nurses in NH 1, where long-term implementation was achieved, all agreed that "long-term benefits of televisits became apparent only after many repeated adjustments and training sessions." The nurses stated that the system became more user-friendly and easier to handle. Repeated use led to more routine use and more self-confidence in the televisits. For this, the repeated training and accompaniment in the televisits were very important for the nurses.

When asked about the factors that had contributed to the success of long-term implementation, the nurses underlined the adoption of asynchronous visits and the transformation of the workflows to a modality with a *web-based waiting room*. They also mentioned the crucial role of the nurse manager's and the GP's personal commitment in ensuring the long-term implementation of televisits. The fact that there was a clear benefit for the residents also added to the motivation.

Interview Findings Regarding the Change in Nursing Practice Due to Televisits

The 3 interviewed NH and nurse managers and 88% (7/8) of the interviewed nurses retrospectively evaluated the overall experience as positive. However, one nurse felt that the televisits were too impersonal and described difficulties in handling the telemedical system and in performing televisits for people with dementia. This nurse preferred in-person home visits.

The nurse managers stated that televisits reduced the psychological distress experienced by their nursing staff, improved the clinical skills of their employees, and led to greater employee satisfaction during the COVID-19 pandemic (in both NHs) and beyond (for NH 1 in achieving long-term implementation). The interviewed nurses mostly acknowledged the same effect on their clinical skills, but most denied psychological distress and insecurities in their work environment. While most of the nurses stated that asynchronous televisits compared to home visits translated to substantial time savings for the GP, the opinions varied regarding the effect on the nursing workload. Televisits were rather perceived as additional workload when performed for routine visits. In the case of unscheduled visits with GPs, some nurses praised the televisits as time saving, whereas other nurses considered telephone calls to be the faster solution. With regard to consultations outside GP hours, the nurses consistently declared that televisits would allow for a faster medical assessment and reduce nursing workload compared to calling the in-person out-of-hours GP service, for which a considerable waiting time is usual. On top of the organizational and technical challenges regarding the cooperation between the GP offices and the NHs, the nurses described personal challenges in adapting to change, using the technology, and developing effective skills for video communication. Some nurses saw positive effects of televisits on the nurses' self-image and with regard to legal certainty. Training in simulated televisits and support from nursing peers in a tandem approach were considered adequate to offer continuous training after the initial familiarization phase (Textbox 1).

Textbox 1. Summarized interview findings regarding relevant topics raised during the implementation process.

Psychological distress in situations with acute deterioration of a resident’s health status (need for prompt medical assessment)

- A total of 62% (5/8) of the nurses denied experiencing psychological distress in these situations.
- A total of 38% (3/8) of the nurses described psychological distress in these situations.
- Access to televisits can provide nurses with emotional security and reduce psychological stress.

Clinical skills of the nurses

- Most nurses saw improvements in their clinical skills, mainly due to more diagnostic equipment being available in the nursing home (NH), increased awareness of recognizing changes in residents’ conditions, and a more active participation in the residents’ medical care.
- Nurses reported higher confidence in the interactions with physicians since the implementation of televisits.

Nursing workload

- Asynchronous televisits saved time for the general practitioner (GP).
- Routine televisits seemed to be associated with a slight increase in workload.
- For unscheduled visits, some nurses considered the televisits to be time saving. However, for other nurses, telephone calls seemed to be faster.
- Televisits can be time saving for the nursing staff provided that a telemedical system is always available on standby (no loss of time due to booting), the nurses are experienced in televisits, and a physician is quickly available (direct medical assessment).
- A telemedical service with 24/7 access to a GP was seen as an advantage over the current out-of-hours GP service and would save time for the NHs (reduced waiting time—obsolete telephone waiting line and transfer time of the physician on duty).

Challenges in performing televisits at the beginning

- Technical challenges (software bugs, usability, and user experience aspects) and change management (for generating willingness in the nursing staff and the physicians) were seen as challenging at the beginning.
- Collaboration with the physicians, especially in scheduling televisits, and ensuring adequate staffing and support for the televisits were identified as the biggest organizational challenges.

Communication in a televisit between the nurse, the resident, and the physician

- It was completely unproblematic for one nurse and difficult and uncomfortable in all televisits for another.
- Most nurses reported challenges in this new setting at the beginning.
- Acoustic problems made televisits difficult for residents with hearing impairments, particularly those who partly relied on lipreading.
- By ensuring a calm and friendly environment and facilitating communication, televisits were possible for residents with dementia.
- Communication is likely to be easier with the next generations of residents in NHs who are already more familiar with modern communication technology.

Professional identity and self-image of the nurses

- Nurses understood televisits as a logical and upcoming innovation arriving in the nursing profession in the context of general progress in technology and digitalization.
- However, they did not think that televisits elevate the nursing profession.
- One nurse felt that his self-image in the interaction with the physician improved by experiencing close cooperation and teamwork in televisits.

Medico-legal aspects of the telemedical documentation

- Main advantage: written prescriptions and medication schedules established by the physician and serving as legal documents are available faster in the NHs.
- However, nurses did not consider the legal certainty that a televisit provides to be higher than that of telephone calls and their subsequent documentation.

Cooperation between GPs and NHs

- In both NHs, the cooperation with the physicians was perceived as already good or very good before the introduction of televisits.
- The implementation of televisits did not change the cooperation from the perspective of the nurses.

Training

- Training based on a tandem approach, where more experienced colleagues train less experienced colleagues in televisits, was considered useful. Training in simulated televisits with the opportunity to review the use of the technology hands-on meets the needs of the nurses. This also applied for training in the clinical aspects of resident care.

Follow-Up Questionnaire: Time Expenditure and Change in Nursing Practice Due to the Televisits

The follow-up questionnaire showed that most of the responding nurses performed televisits ≤5 times throughout the study period and only some nurses did so >10 times (>10 times: 4/19, 21%; 5-10 times: 4/19, 21%; 1-5 times: 11/19, 58%; median 1-5 times). Half (9/18, 50%) of the nurses agreed with the statement that televisits were associated with an additional burden related to uncertainty in using the new technology. The nurses rated the time expenditure for performing televisits significantly higher at the end of the follow-up than they did before starting the first televisits. At both timepoints, only very few nurses considered the televisits to be time saving for them (1/11, 9% before implementation, vs 3/18, 17% after implementation; *P*>.99). While the nurses did not expect the televisits to be time consuming in the initial assessment (1/11, 9%), the assessment was significantly different after the implementation process, where the vast majority of the nurses rated them as time consuming (12/18, 67%; *P*=.006). The relative percentage of nurses expecting a neutral effect on the nursing workload was accordingly lower after implementation (3/18, 16%) than before (9/11, 82%; *P*=.001). Compared to the assessment done before the intervention, the evaluation of the impact of televisits on the care of the residents remained unchanged, with half (10/19, 53%) of the nurses estimating a positive effect, one-third (6/19, 31%) estimating a neutral effect, only 1 person estimating a negative effect (1/19, 5%), and two persons with missing answers (2/19, 11%; *P*>.99 for the positive effect and *P*=.71 for the neutral effect when compared to the preimplementation assessment; see the *Evaluation of the Initial Testing and Familiarization Period Up Until January 2021* section). Most nurses fully or generally agreed that televisits were entirely suitable for assessing the residents and for initiating treatment decisions in the case of GP-related medical queries (full approval: 5/19, 26%; predominant approval: 11/19, 58%; mild disagreement: 2/19, 11%; full disagreement: n=0; 1/19, 5% missing answers). As in the interviews, the quantitative evaluation also showed further positive effects of the televisits in addition to improving the clinical and technological competencies of the nurses. These include a sense of empowered participation in the implementation process for about every fourth responding nurse (5/18, 28%), higher professional recognition from the GP and the residents for approximately every third responding nurse (each 7/18, 39%), and a decrease in psychological distress and greater legal certainty for more than half of the respondents (10/18, 56%; Multimedia Appendix 7).

Discussion

Principal Findings

Key Drivers for Successful Implementation

This study evaluated the implementation of televisits during the COVID-19 crisis in 2 NHs with a follow-up in the postpandemic setting. While both NHs achieved short-term implementation within the pandemic phase, only 1 NH attained long-term implementation. This was achieved in an action-based approach after control measures had been implemented following an analysis of the barriers to further implementation. Adapting the telemedical system and changing the workflows especially to asynchronous televisits with a web-based waiting room were key drivers for successful implementation.

There was no difference in the initial evaluation between the 2 NHs explaining why long-term implementation was only achieved in NH 1. It is noteworthy that, during the first implementation phase, NH 1 adopted a more pragmatic resident-centered approach using only the PoC devices required for the individual patients as shown in the documented televisits. In contrast, NH 2 systematically used all the devices for training purposes in their initial televisits. Moreover, there is a common perception that older nursing staff may possess lower levels of digital literacy, which in turn might render them more resistant to the adoption of new technologies. Interestingly, the staff in NH 1 was older than that in NH 2. Several factors may explain why, contrary to this perception, long-term implementation was achieved in NH 1 with the older nurses.

First, NH 2 simultaneously engaged in a second change process after the end of the COVID-19 pandemic when it changed its NH documentation software in November 2021. At this point, the nursing staff of NH 2 were extremely challenged by adapting to the new software. This competing project was more prioritized than continuing to implement televisits. Second, the interviews revealed that the nurses felt that the personal engagement of the nurse manager and the GP was very important for achieving long-term implementation. This barrier is consistent with findings in the literature indicating that gaining leadership and clarifying roles are important for driving implementation processes [32,34]. Competencies and criteria for leaders in implementing digital health care should be clearly defined in the future to enhance the implementation of telemedicine and digital health [41,42]. Third, NH 1 developed a specific training strategy with the medical student who helped train the nursing staff for 4 weeks. This also contributed greatly to the nurses' compliance and subsequent implementation.

Importance of Considering the User Perspective

The initial vision of how the televisits would be delivered differed significantly from how they were finally integrated by the HCPs to achieve long-term adoption. At the beginning of the transformation process, everybody involved (developers, GPs, nurse managers, and nurses) envisioned a modality that mirrored the workflow of a normal GP home visit (*synchronous televisits in the modality of web-based home visits*). However, another modality, that of “asynchronous televisits using a web-based waiting room,” proved to be more suitable and efficient for routine consultations. The conceptual shift from web-based home visits to the web-based waiting room led to profound organizational modifications and practice changes. Both the participating nurse managers and the developers of the telemedical system stated that they could not have anticipated the web-based waiting room modality before starting the implementation. This highlights the importance of considering the users’ perspective in all phases of development of eHealth solutions, including once a new system is made market available. This approach of broadly involving “a wide range of stakeholders in the entire development process, including especially end-users—patients and physicians” is referred to as “co-creation” [43]. In this study, the HCPs acted as cocreators for developing the asynchronous televisits using a web-based waiting room. They reported their in-use experience with the telemedical system to the steering committee, which triggered discussion on change within the committee. The telemedical system and the workflows were then adapted to allow for asynchronous televisits. This resulted in an improved telemedical system and, thus, a more valuable product. As it provides greater usability for the HCPs, their acceptance of the system and the implementation process increases. The CM approach in this study allowed for this interaction between end users and developers and additionally provided an organized platform for identifying ongoing challenges and steering the transformation process in the right direction. Imposing overly rigid application frameworks for new digital innovation in health care may be a major contributor to the failure of health innovations to be transferred into routine care.

Change in Nursing Practice Due to Televisits

In NH 1, the nurses were positive about the long-term implementation and acknowledged improvements in their clinical skills and technological competencies. In addition, the televisits improved their self-image and their recognition as nurses. These positive results were found in the interviews and confirmed in the follow-up questionnaire. When asked directly in the interviews, only a minority of the nurses reported experiencing physical distress when residents show acute medical presentations requiring prompt medical assessment. However, most agreed in the quantitative analysis that access to televisits was perceived as relieving and reducing emotional distress. The lack of consistency here is probably due to response bias, with nurses responding more honestly in an anonymous questionnaire than in a face-to-face interview.

Televisits were perceived as time saving for the GP but were associated with an additional technological burden and a slight increase in time spent by the nursing staff. The latter was not expected by the nurses when they were assessed before the implementation process. Interestingly, this observation is in line with those of other studies [44-46], which also show that televisits in NHs are associated with an increased workload for the nursing staff. Although most nurses in this study expected a neutral effect on workload rather than an increase, the staff in NH 1 adapted to televisits even though they increased their workload. This is a good indication that the other effects are seen as positive and valuable.

The taking of vital parameters using medical diagnostic devices or recording on an ECG are not among the normal tasks of a geriatric nurse in Germany. This means that there is unlikely to be an increase in the overall workload but rather a shift from GP activity to tasks performed by geriatric nurses. The GPs can use the time they save for other patients. This can be beneficial in the context of a shortage of GPs, especially in rural areas. Given the overall positive effects, health insurers and public health managers should consider providing financial support for the implementation of televisits in NHs. In particular, the initial setup and training should be financially supported to maintain high motivation for further implementation.

This work logically builds on and complements the group’s previous research, which demonstrated the technical feasibility and usefulness of integrating PoC diagnostic devices into video consultations for the assessment of older adult patients in NHs [38]. This study shows that there is no need to take all the vital parameters of the residents in every consultation. In more than three-quarters of the televisits (24/30, 80%), no or one single measurement was sufficient. Access to the right diagnostic device at the right time for the right resident with the right physician connected via telemedicine is essential for personalized care and to avoid unnecessary HAs. In line with the idea of effective workforce management, it does not make sense to ask nurses to take all the vital parameters but rather to decide in advance (ie, when planning the televisit) which vital parameters should be taken.

Limitations and Future Research

This study has certain limitations for the interpretation and generalizability of the results. The implementation of televisits in NHs was only evaluated in 2 NHs, and 1 failed to achieve long-term implementation. Therefore, generalization to other NHs may depend strongly on their individual organization and health care environment. However, this study shows that an action-based CM approach piloted by an interdisciplinary steering committee can allow for successful implementation. Future studies in the field of IS may add valuable insights to determine more objective criteria for the success of telemedical implementation efforts. Another major limitation is the relatively small number of televisits in the documentation protocols. However, this was sufficient to show that it is not useful to systematically take measurements using all diagnostic devices integrated into the system. This study was not designed to assess how the residents felt about being involved in promoting telecare. However, this is an important research question that should be evaluated in other studies. Furthermore, this study investigated the implementation of one technology—televisits—in NHs. Other digital technologies such as NH managing software, wearables, and home automation systems may also improve workforce management, enhance the quality of care, and provide a better living environment in NHs. As some authors believe that all these technologies are likely to be integrated into so-called “smart

NHs," possibly replacing conventional NHs in the decades to come [47-49], the implementation processes of these technologies should be specifically investigated as generalizability from this study is very limited.
