Abstract

Background: Sedentary behavior is highly prevalent among older adults, with adherence to exercise being a major challenge. Exercise offers substantial physical, psychological, and social benefits, but enjoyment is a key factor influencing adherence. Technology-based interventions have shown promise in enhancing motivation and participation, demonstrating higher adherence rates than conventional treatments, although challenges such as motivation loss and technological barriers persist. This review evaluates the effectiveness of active video game interventions on enjoyment and satisfaction in older adults.

Objective: This systematic review and meta-analysis aims to determine whether active video games are superior to other interventions in generating greater enjoyment or satisfaction in older adults.

Methods: PubMed, Cochrane, PEDro, SPORTDiscus, CINAHL, Web of Science, and Scopus databases were searched from inception to September 30, 2024, to identify randomized clinical trials or crossover studies. The primary outcome was enjoyment or satisfaction, assessed using various scales, including the Physical Activity Enjoyment Scale, Intrinsic Motivation Inventory, User Satisfaction Questionnaire, and Likert-type scoring scales. Secondary outcomes included adherence rates and adverse effects. Cochrane Risk of Bias 2 tool was used to evaluate the risk of bias.

Results: Five studies were included in the quantitative analysis. The results indicated a significant improvement in enjoyment or satisfaction compared to the control groups (standardized mean difference 0.34, 95% CI 0.05-0.64; P=.02; I^2=24%), although the effect size was small. Secondary outcomes could not be analyzed due to insufficient data in the selected studies.

Conclusions: Active video game interventions may improve enjoyment and satisfaction in older adults, but the evidence remains of low certainty.

gamification; exergaming; enjoyment; satisfaction; older adults

Introduction

The global population of older adults is projected to surpass 994 million by 2030, and this trend is expected to continue in the following years [1]. A major concern in aging is the reduced expectancy of healthy life years. The 3 aspects of healthy or successful aging are cognitive or mental well-being, social fulfillment, and physical health, with exercise being crucial for physical health [2]. However, older adults are among the most sedentary population groups, as sedentary behavior seems to increase with age, with older adults spending 62% to 86% of the day in sedentary behavior [3-5].

In 2018, the World Health Organization (WHO) launched an intervention plan aimed at reducing physical inactivity among adults and adolescents by 15% by 2030 [6]. This initiative enhances individual and community health by creating active societies, environments, people, and systems. The intervention emphasizes the importance of exercise or physical activity as a primary treatment approach, given its numerous benefits and low risks of side effects. Regular physical activity improves mortality rates, life expectancy, and physical and functional health outcomes [7-12].

There are discrepancies in the literature regarding the risks and benefits of sedentary behavior and physical activity on physical, psychological, and social outcomes [13,14]. Consequently,

sedentary lifestyles remain prevalent among older populations, as barriers or facilitators to physical activity adherence arise from intrapersonal factors (physical and mental health and individual preferences), interpersonal influences, as well as physical, structural, and organizational environments [15]. Numerous barriers and facilitators affect older adults' engagement and adherence to exercise, shaped by individual experiences and preferences. Researchers have suggested that fun should be incorporated into the FITT (Frequency, Intensity, Time, Type) prescription model [16], as enjoyment may be a critical factor in exercise adherence. Studies have shown that patients perceive exercise differently—some view it as a pleasant activity, while others regard it as an obligation like taking medicine [15,17]. Addressing this barrier through an immediate reward system like enhancing enjoyment could positively transform patients' exercise experiences and potentially improve adherence to physical activity interventions [18,19]. This can be explained through various theoretical frameworks such as operant conditioning theory, self-determination theory, or Ekkekakis model, which link enjoyment to perceived exertion [20,21]. Technology-based interventions, particularly those that integrate engaging and interactive elements, offer a promising solution to enhance motivation, make exercise more enjoyable, and encourage sustained participation among older adults [19].

Gamification, which applies video game design elements such as points, badges, leaderboards, and avatars in nongame contexts, has become an increasingly popular tool in recent years for enhancing adherence to various interventions. Gamification may positively influence user behavior and experience, although its effectiveness may vary depending on the intervention, as inconsistent results have been reported across different age groups [22,23]. Video games or technology-based interventions have demonstrated adherence rates as high as 91%, and in some cases, rates up to 1.38 times higher than conventional exercise treatments or no intervention, which could suggest that greater adherence to physical activity might lead to enhanced health benefits [19,24,25]. Adherence rates in exercise programs for older adults range from 65% to 86% but tend to decline in unsupervised training programs or when the duration exceeded 12 weeks, suggesting that factors such as supervision, program length, and the engaging nature of the intervention play a crucial role in maintaining adherence [19,24,26]. Despite these benefits, such interventions also present challenges, including loss of motivation or interest, space limitations, technological barriers, and feelings of embarrassment when using video games [24,27].

This systematic review aims to primarily evaluate the satisfaction and enjoyment experienced by older adults through active video games. The secondary objective was to determine their adherence to treatment and the possible side effects of the intervention. These metrics are essential for understanding intervention efficacy and long-term adherence.

Methods

Study Registration

The protocol for this systematic review and meta-analysis was registered in PROSPERO (CRD42024593212). This analysis was conducted following the recommendations of the Cochrane Collaboration and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines.

Search Strategy

A bibliographic search was completed between September 21 and 30, 2024, in the following health and sports science databases: PubMed, Cochrane, Web of Science, CINAHL, SPORTDiscus, PEDro, and Scopus. The search strategies used are available in Multimedia Appendix 1.

Inclusion and Exclusion Criteria

The inclusion criteria for this review were as follows: (1) randomized clinical or controlled trials and crossover studies; (2) patients older than 60 years; (3) exercise or physical activity intervention using gamification, including commercial apps, exergames, or serious games; (4) the comparison group had to perform some form of active exercise, follow their usual treatment, or do nothing; and (5) use of enjoyment or satisfaction scales.

Studies that met any of the following criteria were excluded: (1) case series, observational studies, and conference proceedings and (2) use of enjoyment or satisfaction scales in only one of the groups. No language exclusion criteria were applied.

Study Selection

Studies were selected based on a predefined PICOS (Population, Intervention, Comparison, Outcome) framework established at the outset of the review. The population included older adults, the intervention involved exercise delivered through video games, and the outcome focused on assessing the levels of enjoyment or satisfaction. After defining the search strategy, studies were entered into Rayyan (an app) [28] to exclude duplicate papers. Two researchers selected the studies according to the inclusion and exclusion criteria; in case of disagreement, a third researcher reviewed the study until a consensus was reached.

Data Extraction

First, 2 reviewers extracted informative data from the studies independently; in case of discrepancies, a third reviewer resolved this. The data to be extracted were first author and year, number of participants, design, groups, type of intervention in both groups, outcomes, number of sessions, session time, perceived effort, hardware and software used, and follow-up.

The second part consisted of extracting data values for the different outcomes—both primary and secondary. For the primary outcome of exercise enjoyment or satisfaction and for the secondary outcomes of adherence and adverse effects, mean and standard deviation values were extracted. When values were reported as change or as final values, the extraction of the final values for the analysis was determined as the preferred option.

If data were only available in graphs, the graph digitization software GraphGrabber version 2.0.2 [29] was used for extraction.

Risk of Bias

The methodological quality of the included studies was assessed by 2 independent reviewers (JBA and ITC) using the Cochrane Risk of Bias 2 tool, which evaluates the possible risk of bias in randomized trials for both parallel and crossover design studies [30]; in case of disagreement, the third reviewer broke the tie (HBA). This scale assesses bias based on 5 domains: process randomization, missing data on outcomes, outcome measurement, selection of reported outcomes, and deviations from intended interventions. An additional domain, bias arising from period and carryover effects, was assessed in crossover studies.

The GRADE (Grades of Recommendation Assessment Development and Evaluation) rating system was used to assess the quality of evidence. Publication bias was also assessed using the funnel plot and Egger test for publication asymmetry.

Main Outcomes

The primary outcome variable for this review was exercise enjoyment or satisfaction, which was assessed using the scales reported in the included studies. These scales were not predetermined but were identified during the review process based on the methodologies of the selected studies. Each scale was included because it was used by the respective studies to measure enjoyment or satisfaction, ensuring consistency with their reported outcomes. The following tools were identified.

1. Physical Activity Enjoyment Scale: This scale is a validated and reliable tool used to assess the level of enjoyment individuals experience during a physical activity. The studies reviewed utilized a modified 5-item version of the scale, with responses recorded on a Likert scale ranging from 1 to 7 [31].
2. Intrinsic Motivation Inventory: This is a multidimensional scale designed to assess intrinsic motivation, with various subscales, including interest or enjoyment [32]. Only the interest or enjoyment subscale was used as an outcome measure in the study reviewed.
3. User Satisfaction Questionnaire: This is a 15-item questionnaire divided into 2 parts, that is, the benefits and pitfalls of the intervention and self-perceived improvements in physical and cognitive outcomes.

Two studies [33,34] did not use specific enjoyment or satisfaction scales. Instead, the participants were directly asked about their levels of enjoyment or satisfaction, and their responses were measured using Likert-type scales.

Statistical Analysis

We assessed the overall effects of exercise through video games on enjoyment or satisfaction in older adults. As secondary outcomes, the effects of gamification compared to those of other interventions on adherence and adverse effects were analyzed. Subgroup analyses of the primary outcome (exercise enjoyment or satisfaction) were conducted to explore the key variables potentially influencing variations in enjoyment. These included session time (<10 min vs >10 min), target population (older adults without reported health conditions vs older adults with reported health conditions), immersion type (virtual reality vs augmented reality), type of control group (active vs passive), and the number of sessions (1 session vs >10 sessions).

The inverse variance method analyzed the primary variable (exercise enjoyment or satisfaction). Statistical heterogeneity was assessed using the chi-square test, and the I^2 value was calculated. Heterogeneity was established as low for I^2=25%, moderate for I^2=50%, and high for I^2=75%. The random effects analysis model was used when the heterogeneity was I^2≥50%, and the fixed effects analysis model was used when the heterogeneity was I^2<50%.

The standardized mean difference (SMD) was used for the overall effect on enjoyment or satisfaction, as different scales were implemented in the included studies. For all enjoyment or satisfaction scales, higher scores implied a better result on this outcome.

For all variables, a statistical significance level of P<.05 and 95% CIs were established. The effect size was determined as low when SMD was 0.2, moderate when SMD was 0.5, and high when SMD was 0.8, according to Cohen. Sensitivity analysis was performed individually per study to analyze their influence on the overall results and changes in heterogeneity according to study weight. RevMan software (version 5.4.1; The Cochrane Collaboration) was used for the quantitative analysis.

Deviations From the Protocol

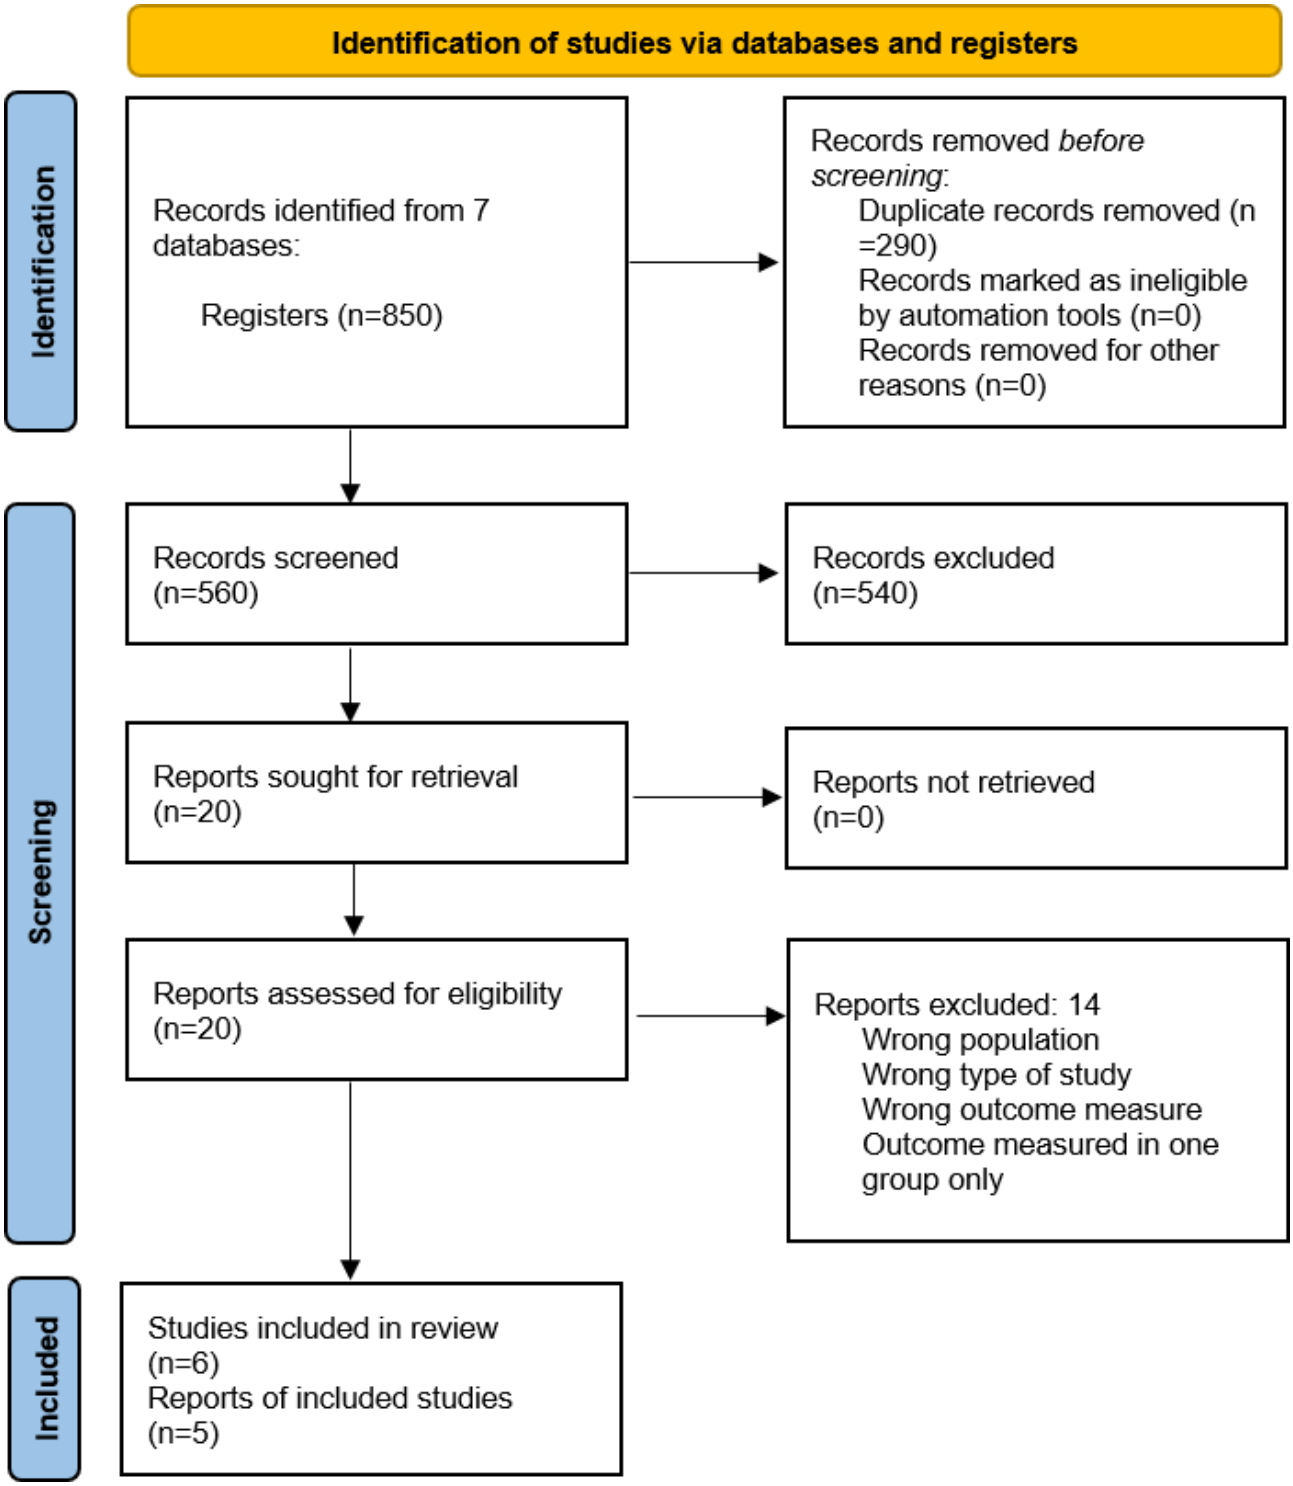
Some analyses foreseen in the protocol registered in PROSPERO could not be performed in this review. Secondary outcomes were foreseen to meta-analyze the adherence to exercise through video games and the adverse effects that these interventions could have; however, this analysis could not be performed, as adherence and the appearance of adverse effects were measured in only 1 [33] and 2 [33,34] studies, respectively.

Results

Study Selection

A total of 850 studies were retrieved from the search strategy. After the elimination of 290 duplicated papers, 560 papers were screened, of which 540 were excluded after reading the title and abstract. The remaining 20 studies were included for full-text reading, of which only 6 [33-38] were included in this systematic review, as represented in Figure 1. In the quantitative analysis, 5 studies [33,35-38] encompassing a total of 419 participants were included, with a mean age of 74.72 (SD 6.4) years; 215 participants played an active video game, while 204 participants received other interventions. Takei et al [34] were contacted to obtain the unavailable data in their published paper, but no response was received. This selection process underscores the robustness of the study inclusion.

Figure 1. Flow diagram in this review.



Characteristics of the Included Studies

This systematic review was performed on 6 studies: 2 randomized controlled trials and 4 crossover studies, involving 419 participants [33-38]. Among these, 3 studies focused on older adults without reported health conditions [35,36,38], 2 on older adults undergoing rehabilitation [33,34], and 1 specifically on older adults with Parkinson disease and mild cognitive impairment [37].

Most studies implemented active video game interventions that incorporated full-body movements, combining various therapeutic approaches such as strength training, balance exercises, flexibility routines, yoga, and jogging [33-36], while 2 studies focused on specific exercises for upper limbs and gait, respectively [37,38].

The comparison groups varied across studies. Dockx et al [37], Sayar et al [36], and Takei et al [34] compared the effects of active video games to those of another active intervention, while Kruse et al [38] and Oesch et al [33] compared the effects of video games to those of videos or exercise leaflets. Ferreira et al's [35] trial contrasted the effects of active video games with those of watching television. In terms of immersion, 5 studies

[33-37] employed augmented reality, while Kruse et al's [38] study used virtual reality.

Regarding session duration and frequency, training times typically ranged from 30 minutes to 1 hour, except for Kruse et al's [38] study, which had sessions lasting for 7-10 minutes. Four studies conducted only 1 session of the active video games [34-36,38], while Oesch et al [33] and Dockx et al [37] implemented interventions 2-3 times per week, with overall duration varying between 10 days and 6 weeks.

Two studies [34,36] included exercise intensity parameters measured using the Rate of Perceived Exertion scale, allowing participants to self-regulate the intensity of their interventions. In both cases, participants adjusted their exercise levels based on their own perceptions of effort. Oesch et al [33] mentioned that their exercise intervention was self-regulated, but they did not provide specific data on how this was measured or its effects.

Secondary outcomes such as adherence were investigated only by Oesch et al [33] who reported an overall adherence rate of 85% for both groups. However, the control group showed higher adherence, as the exergame group had more dropouts due to dissatisfaction with the intervention [33]. Regarding adverse effects, Oesch et al [33] and Takei et al [34] reported no adverse effects in their studies. The remaining studies [35-38] did not specify whether any adverse effects occurred. The general characteristics of the included studies and the intervention characteristics in the included studies are shown in Tables 1 and 2, respectively [33-38].

Table . General study characteristics.

Study ID	Study design	Participants (n)	Age (years), mean (SD)	Pathology	Intervention frequency	Time (min)
Dockx et al [37], 2017	RCT[a]	281 (114M[b], 167W[c])	73.75 (6.66)	Older adults without reported health conditions, older adults with mCI[d], older adults with Parkinson disease	3 days a week for 6 weeks	45

[g]RPE: Rate of Perceived Exertion.

Risk of Bias in the Included Studies

The agreement rate achieved between the two authors who completed the risk of bias assessment was 80%; in case of disagreement (20%), the third reviewer resolved it. The risk of bias in the 6 studies is represented in Figure 2 [33-38].

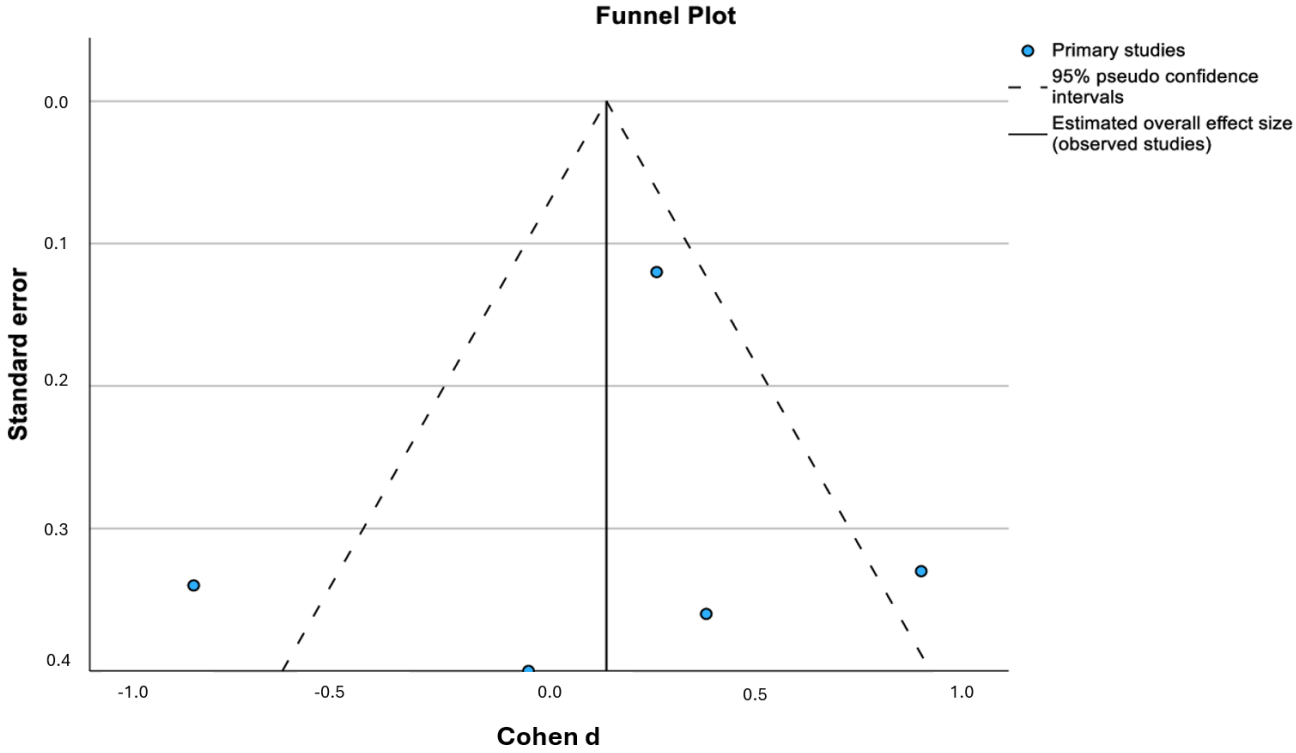
The Egger regression–based test was conducted to evaluate the presence of publication bias. The results indicated that the intercept was not significantly different from 0 (intercept=2.985; P=.83), suggesting no evidence of small-study effects.

The funnel plot (Figure 3) visually supports these findings, showing a relatively symmetric distribution of the effect sizes around the estimated overall effect size. The absence of asymmetry further suggests that publication bias is unlikely to have significantly influenced the results of this meta-analysis.

Based on these findings, there is no statistical evidence of publication bias in the included studies.

Figure 2. Risk of bias assessment. D1: randomization process. DS: bias arising from period and carryover effects. D2: deviation from intended interventions. D3: missing outcome data. D4: measurement of the outcome. D5: selection of the reported result.

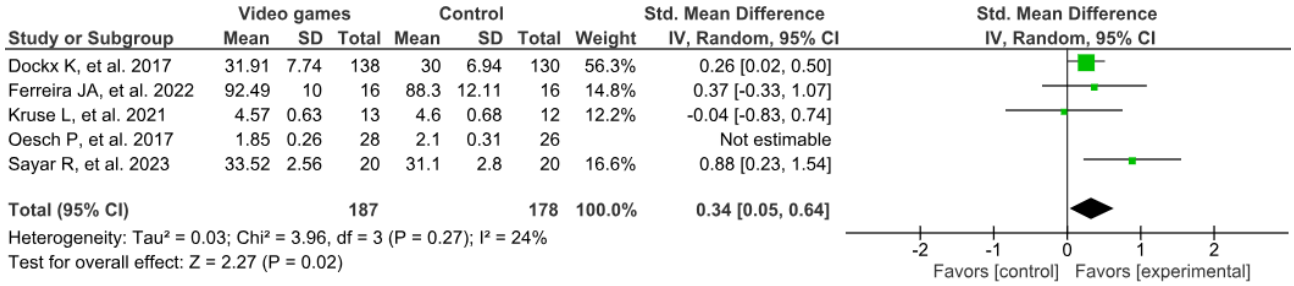
Figure 3. Funnel plot of the included studies.



Quantitative Analysis

The active video game group showed an improvement in the overall enjoyment or satisfaction compared to the control group after the intervention period, as shown in Figure 4 [33,35-38], which shows a small effect size and low heterogeneity (SMD 0.34, 95% CI 0.05-0.64; P=.02; I^2=24%). The certainty of the evidence for overall enjoyment in active video games versus that in control interventions was rated as low according to the GRADE approach. This was based on data from 4 randomized trials involving 187 participants in the intervention groups and 178 in the control groups. The SMD for enjoyment was 0.34 SD (95% CI 0.05-0.64) higher in the active video game group. The evidence was downgraded due to very serious risk of bias, while inconsistency, indirectness, and imprecision were not considered serious. No other concerns were identified (Multimedia Appendix 2).

Figure 4. Forest plot of the overall enjoyment.



For the quantitative analysis, the study by Oesch et al [33] was removed after the sensitivity analysis because it had a small sample size and a large effect size (SMD −0.86, 95% CI −1.42 to −0.3), which increased heterogeneity by 55% for a study weight of 20.6%. Its inclusion significantly affected the overall effect result (SMD 0.12, 95% CI −0.41 to 0.64; P=.67; I^2=79%), as shown in Multimedia Appendix 3.

The effect of active video games on exercise enjoyment or satisfaction by subgroups is shown in Table 3. No significant differences were found based on session time, target population, immersion type, number of sessions, or control group type. However, some subgroup comparisons were close to reaching statistical significance. Notably, when the effects of active video games were compared to those of an active intervention, enjoyment was higher with active video games, although this difference was not statistically significant (P=.08). Additionally, 2 other subgroup analyses approached significance: older adults without reported health conditions appeared to enjoy active video games more (P=.12), and fewer sessions seemed to result in greater enjoyment or satisfaction (P=.12).

Table . Subgroup analysis.

Subgroup	Studies (n)	Participants (n)	Random effect		Heterogeneity (%), I^2	Subgroup difference	
			SMD[a] (95%CI)	*P* value		Chi-square *(df)*	*P* value
Session time (min)						0.1 (1)	0.71
<10	1	25	−0.04 (-−0.83 to 0.74)	0.91	N/A[b]		
>10	4	394	0.15 (−0.48 to 0.78)	0.67	79		
Target population						1.3 (1)	0.25
Older adults without reported health condition-ss	3	97	0.44 (−0.09 to 0.96)	0.1	39		
Older adults with reported health conditions	2	322	−0.27 (−1.37 to 0.83)	0.63	92		
Immersion type						0.1 (1)	0.71
Virtual reality	1	25	−0.04 (−0.83 to 0.74)	0.91	N/A

Discussion

Principal Findings

This systematic review with meta-analysis evaluates the specific effectiveness of active video games on enjoyment and satisfaction experienced by older adults—outcomes that are crucial for adherence to physical activity programs. Our findings indicate that exercise delivered through active video games could provide greater enjoyment or satisfaction than control interventions.

Enjoyment is a key determinant in long-term adherence to physical activity, as it enhances engagement and sustainability. Consequently, incorporating enjoyable components such as active video games into exercise regimens aligns with proposals to include fun within the FITT principles for a more holistic exercise prescription [16]. Studies have shown that enjoyment could serve as either a barrier or a facilitator in the adherence to exercise routines [15,26]. Therefore, incorporating enjoyable elements such as active video games into exercise routines or treatments could potentially help individuals stay engaged in a physical activity, as the overall effect on enjoyment and satisfaction in this review suggests that active video games may offer a modest advantage over control interventions, potentially enhancing the appeal of exercise for older participants.

In this systematic review, we found that only Oesch et al [33] examined adherence to active video game interventions, and they reported that the control group showed higher adherence, while the experimental group showed a higher dropout rate due to participants disliking the treatment. These findings contrast with those of Valenzuela et al [24] who demonstrated increased adherence to technology-based interventions. This divergence may stem from differences in the intervention design, participant characteristics, or contextual factors, warranting further exploration. However, the results from Oesch et al's [33] study may align with general adherence trends for physical activity, where nonadherence rates range from 47% to 96% within the first year in healthy populations and from 50% to 70% in

patients undergoing physical therapy, while adherence rates in older adults range from 65% to 86% [26,39-41].

Among the reviewed studies, only Oesch et al [33] and Takei et al [34] reported adverse effects, with neither identifying any incidents during their interventions. Although these findings suggest that active video game interventions are generally safe, the absence of reporting in other studies limits definitive conclusions regarding their safety profiles [33,34]. However, most of the studies [35-38] included did not report the occurrence of adverse effects.

Subgroup analyses revealed no statistically significant differences between active video game interventions and control interventions; however, comparisons between the active video game intervention group and the control group approached significance (P=.08). This trend suggests a potential for differential effects that may become apparent with larger sample sizes or more targeted studies. Sayar et al [36] used a crossover design, allowing participants to experience both interventions and compare them directly in terms of enjoyment. This design made it possible to observe which intervention generated a greater sense of enjoyment among participants. In contrast, Dockx et al [37] compared the effects of the usual treadmill walking intervention with those of an intervention that had a screen simulating standard treadmill walking, and they suggested that the added visual and auditory distractions may have contributed to participants' preference for the screen-enhanced intervention, as participants may have perceived less exertion [42,43].

Other comparisons approaching significance (P=.12) were found in older adults without reported health conditions versus older adults with reported health conditions and in 1 session versus >10 sessions, with the same studies [33,35-38] included in each subgroup for the number of sessions. One possible explanation for greater enjoyment in fewer sessions is that repeated exposure to the same intervention might lead to decreased motivation, as older adults could lose interest in the video game or view the technology as more of a barrier than a facilitator [19,24]. Similarly, this may also explain why some older adults with health issues did not favor this type of treatment. A study [44] on older adults experiencing chronic low back pain indicated that continued engagement in physical activity was often due to the enjoyable experience of the exercise itself. In contrast, in Oesch et al's [33] study, older adults who did not find the activity enjoyable frequently might have perceived it as a barrier, which in some cases contributed to their decision to drop out of the study [33].

Limitations

This review has several limitations. The generalizability of our findings is limited by the small number of the included studies and their high risk of bias, primarily due to issues in randomization and blinding of participants and assessors. Although the statistical heterogeneity was low after removing one study [33] that significantly increased the variability, differences in the intervention types and outcome measurement methods still contribute to some methodological inconsistencies. Additionally, only 2 studies [34,36] reported on the exercise intensity—a factor known to influence enjoyment and satisfaction through established models [21,45,46]. Future research should explore how exercise enjoyment affects adherence in rehabilitation programs and examine whether perceived exertion influences enjoyment or satisfaction. Addressing these gaps could strengthen the evidence base. Other possible research directions include a systematic review on the role of active video games in adherence or a qualitative study exploring factors that influence older adults' adherence to exercise programs.

Clinical Implications

From a clinical perspective, this review does not establish a definitive advantage of active video games over traditional interventions. However, tailoring exercise programs to individual preferences and integrating enjoyable elements may optimize patient adherence and satisfaction, aligning with patient-centered care principles.

Conclusion

Active video games could help improve enjoyment or satisfaction in older adults, with a low certainty of evidence. In this systematic review, active video games did not show a superior effect to conventional treatment on adherence. Future research should explore optimizing gamification techniques to maximize adherence and satisfaction.

Abstract

Background: Exercise interventions can reverse frailty. However, their scalability and sustainability are limited by manpower, which is reducing due to population aging. GrandMove is a program that combines healthy and productive aging strategies to (1) train and employ robust older adults as exercise coaches and (2) improve fitness and motivate the adoption of an exercise habit in older adults with frailty and prefrailty.

Objective: The aim of this study is to examine the effectiveness of GrandMove in improving frailty, fitness, and quality of life in older adults with frailty and prefrailty.

Methods: This cluster randomized controlled trial recruited older adults with frailty and prefrailty (N=390) living in the community. The 18-month exercise program consisted of three 6-month phases of lifestyle education (E), resistance exercise (R), and aerobic exercise (A). Each group of participants was randomized into 3 intervention sequence arms: the E-R-A group, the A-R-E group, and the R-A-E group.

Results: At 6, 12, and 18 months, 346, 305, and 264 participants completed the frailty assessment, respectively. At 6 months, 100 of 346 participants (28.9%) were robust. A-R-E and R-A-E were no better than E-R-A as the active control in addressing frailty over the first 6 months (A-R-E: interaction coefficient 0.07, 95% CI −0.35 to 0.49, *P*=.68; R-A-E: interaction coefficient −0.02, 95% CI −0.42 to 0.38, *P*=.90). Compared to lifestyle education, resistance training and aerobic training over the first 6 months were associated with greater improvement in fitness measures of grip strength for the left hand (A-R-E: interaction coefficient 2.99, 95% CI 0.76 to 5.23, *P*=.009; R-A-E: interaction coefficient 2.21, 95% CI 0.63 to 4.36, *P*=.04) and right hand (A-R-E: interaction coefficient 3.75, 95% CI 1.54 to 5.97, *P*=.001; R-A-E: interaction coefficient 2.29, 95% CI 0.16 to 4.42, *P*=.04) and arm curl test (A-R-E: interaction coefficient 1.42, 95% CI 0.39 to 2.46, *P*=.007; R-A-E: interaction coefficient 1.11, 95% CI 0.12 to 2.11, *P*=.03). The sequence of exercise interventions (R-A-E vs A-R-E) did not make a difference in primary outcomes at 12 months, but the R-A-E group showed better quality of life (interaction coefficient 4.50, 95% CI 0.12 to 8.88, *P*=.008). Improved frailty outcomes were maintained by the end of the study, but the change in overall physical activity level was limited.

Conclusions: Combining healthy and productive aging strategies is a scalable and sustainable way to improve frailty, fitness, and quality of life in older adults with frailty and prefrailty. Different combinations of lifestyle education and physical interventions improved frailty.

Introduction

Frailty, a common condition that increases with age, is a dynamic clinical state that can improve or worsen over time [1,2]. About 1 in 10 older adults are frail and 46% are prefrail, a state with higher risk of progression to frailty [3]. Frailty is known to predict disability, mortality, risk of fractures, and many other adverse health outcomes [4]. To date, evidence for the management of frailty is the strongest with physical activity [5,6]. In older adults who are very frail, even small gains in strength can result in important functioning benefits and promote independence [5]. Evidence suggested superior outcomes with training carried out 3 or more times per week, for 30-45 minutes per session, and lasting at least 3-5 months [7]. Adherence to exercise training is good even in older adults with frailty, with few adverse events or safety concerns [5].

Practice guidelines widely recommend multicomponent exercise programs for the management of frailty [8]. Many programs concurrently prescribe multimodal exercise components, even though sequential prescription may promote adherence and minimize attrition [8,9]. The optimal sequence is yet to be investigated. Theoretically, strength and aerobic training contribute in different ways by slowing or compensating for muscle wasting and loss of endurance, as well as preventing other diseases and resisting the cascade of disability [10]. These exercise modalities impact on the older person's quality of life by affecting their ability to lift load (eg, arising from a chair) and endurance in performing activities of daily living (eg, walking), allowing them to take control and lead a purposeful life. These may have implications for the design of exercise training protocols for frailty intervention.

Past development of exercise programs put a greater emphasis on maximizing physical benefits, while less focus was put on the scalability and sustainability of the program. It is foreseeable that the health care manpower gap as a result of population aging is increasing [11] and heavy reliance on professionally led formal health care services for addressing frailty is unviable and unsustainable. Our team developed a multicomponent exercise program, namely the GrandMove program, which has a group of trained coaches in their 50s to 60s deliver the interventions. Delivery of exercise interventions by peer coaches rather than health professionals is a key to the long-term scalability and sustainability of such programs in the context of population aging. Our program incorporated both healthy and productive aging strategies. Although the program had clear goals of improving frailty, fitness, and quality of life in older adults with frailty and prefrailty, our peer coaches took on their own path to successful aging by adopting an active lifestyle and engaging in postretirement paid work. A detailed description of the program design is provided in the Methods and Multimedia Appendix 1.

In this study, three intervention sequences were designed to (1) examine the effectiveness of a 6-month aerobic or resistance training program compared with lifestyle education as the active control intervention at 6 months, (2) investigate any order effect in resistance and aerobic training in older adults with frailty and prefrailty at 12 months, and (3) evaluate exercise habit formation over 18 months.

Methods

Study Design and Participants

This is an 18-month, multicenter, cluster randomized controlled trial with 3 intervention arms. A cluster design was used because of the logistical issues associated with the implementation of the interventions. The study sites included 14 community service centers for older adults and 15 public rental estates in Hong Kong. The staff from the participating sites referred potential participants based on their age and frailty status at screening.

Ethical Considerations

Designated research assistants, who were not involved in the intervention, obtained written informed consent and conducted screening interviews with the participants. The study protocol was approved by the institutional ethics committee (reference number EA1511048). The study was registered with the HKU Clinical Trials Registry (reference number HKUCTR-1964). All data used in this study were deidentified before analysis. Participants did not receive any compensation for their involvement.

Participants

Target study participants were older adults living in the community who did not have any contradictions to participation in a moderate level of physical activity. Between February 2016 and May 2017, older adults were invited to take part in this study if they were aged 65 years or older and were screened as either prefrail (scores of 1‐2 on the FRAIL [Fatigue, Resistance, Ambulation, Illness, and Loss of weight] scale) or frail (scores of 3‐5 on the FRAIL scale) [2]. To ensure the safety of the participants, older adults were excluded from participating if they reported having specific conditions. Specific exclusion criteria are described in Multimedia Appendix 2.

The sample size was calculated based on an estimated 0.5-point improvement in the FRAIL score (SD 1) between an exercise condition versus lifestyle education, using a 2-sided test at 1% significance level with 80% power. Assuming a 20% dropout rate, the minimum sample size is 120 per arm. It was estimated that about 1 in 10 older adults was frail. To allow subgroup analysis by frailty status, the ratio of participants with prefrailty to those with frailty was set at about 6:4 (Multimedia Appendix 2).

Randomization and Masking

As shown in Multimedia Appendix 3, each group of participants was randomly assigned into one of three parallel arms with different intervention sequences: (1) lifestyle education – resistance training – aerobic training (E-R-A); (2) aerobic

training – resistance training – lifestyle education (A-R-E); and (3) resistance training – aerobic training – lifestyle education (R-A-E). Each intervention component lasted for 6 months, totaling up to 18 months. The sequence of the intervention components was designed to address the three research aims: (1) to evaluate the effectiveness of aerobic and resistance training at 6 months compared to lifestyle education, (2) to investigate the order effect of aerobic and resistance training at 12 months, and (3) to evaluate exercise habit formation over 18 months.

Randomization (1:1:1) was done by a research assistant using computer-generated random numbers stratified by frailty status. The person who was responsible for generating the random allocation sequence was not involved in any other parts of the research. Each group of consecutive participants was assigned to one of the 3 arms. Group allocation could not be masked for persons delivering or receiving the interventions. Our program exercise physiologists, who were responsible for developing the exercise protocols, training exercise coaches, and conducting the fitness tests with participants, were blind to the group assignment. Research assistants designated to assess outcomes were blind to group assignment and had no involvement in the delivery of interventions.

Intervention Program: GrandMove

The GrandMove program is a structured exercise training program that contains 2 protocols, one focusing on aerobic exercise and the other on resistance exercise. Two protocols for aerobic training and resistance training were designed by our program exercise physiologists with certified training in strength and conditioning and tailored for older adults with prefrailty and frailty in Hong Kong. Robust older people were trained as exercise coaches to deliver the exercise protocols. The design of the program was guided by social learning theory [12] and behavioral principles [13] (see Multimedia Appendix 1 for program characteristics). Both protocols were designed to be workable in a small home or group, using only small training implements such as rubber bands, towels, and water bottles for exercising. Each protocol had 5 levels, which indicate different levels of intensity. Based on the initial assessment, participants would start at a level that was realistic and attainable. A participant who reached a standard of fitness and strength in that level would continue with the next level.

The lifestyle education condition was comprised of 12 group sessions of health talks and 36 telehealth sessions. All health talks that covered different topics were delivered in a small group format by a retired nurse. Telehealth sessions involved a research assistant reviewing the health topics with participants and consolidating their understanding over the phone.

Each exercise intervention component lasted for 6 months (Multimedia Appendix 4). The 6-month schedule was designed to provide active coaching in the first 3 months, followed by monitoring and supervision (4th and 5th month), and self-sustained practice (6th month). Group sessions were provided in a small group format (8 - 10 older adults per group led by 2 coaches). Lifestyle education was designed to match the frequency of contacts with the exercise interventions.

Measures

The participants were assessed at baseline, 6 months, 12 months, and 18 months. Each assessment included a battery of self-report instruments administered through a structured interview and physical tests. Basic demographic characteristics were obtained, including age, gender, education level, marital status, and living arrangement.

Primary Outcomes

There were 3 primary outcomes. First, the frailty score was calculated using the 5-item FRAIL scale [2]. The items cover areas of fatigue, resistance, aerobic fitness, illnesses, and loss of weight. FRAIL scores are classified into three categories: robust (score of 0), prefrail (score of 1-2), and frail (score of 3-5). Second, physical performance was measured using the Short Physical Performance Battery (SPPB) [14]. The SPPB score ranges from 0 - 12, with a higher score indicating better performance. Third, quality of life was measured using the World Health Organization Quality of Life – Older adults module (WHOQoL-OLD) scale validated in a Chinese population [15]. The total score ranges from 0 - 100, with a higher score indicating better quality of life.

Secondary Outcomes

There were 3 fitness performance measures including isometric handgrip strength as measured by a digital hand dynamometer (Jamar Plus+), the 30-second arm curl test [16], and the 2-minute step test [17]. The hand grip strength of each hand was the average score of 3 trials. Higher fitness scores indicate better performance.

Other secondary outcomes included instrumental activities of daily living (IADL) as measured using the Lawton IADL scale (score range 0 - 100, with higher scores indicating a lower level of disability) [18], level of physical activity as measured using the Physical Activity Scale for the Elderly (PASE; higher scores indicate a higher level of physical activity) [19], sleep quality as measured using the Pittsburgh Sleep Quality Index (PSQI; higher scores indicate worse overall sleep quality) [20], social functioning as measured using the Lubben Social Network Scale (LSNS; higher scores indicate a greater level of social support) [21], and depressive symptoms as measured using the Patient Health Questionnaire-9 (PHQ-9; score range 0 - 27, with higher scores indicating greater symptom severity) [22].

Statistical Analysis

We conducted all analyses on an intention-to-treat basis. We generated descriptive statistics for baseline characteristics. The proportions of participants who achieved a robust or an improved frailty status (from frail to prefrail/robust or from prefrail to robust) at each follow-up were described. Within-group changes in proportions of robust or improved frailty outcome were tested using mixed effect logistic regression models.

The difference in outcome measures between intervention groups was estimated at each follow-up time point using repeated measures mixed effect linear regression models, adjusting for the fixed effects of gender and age at baseline. The main analysis using mixed models in the whole sample will

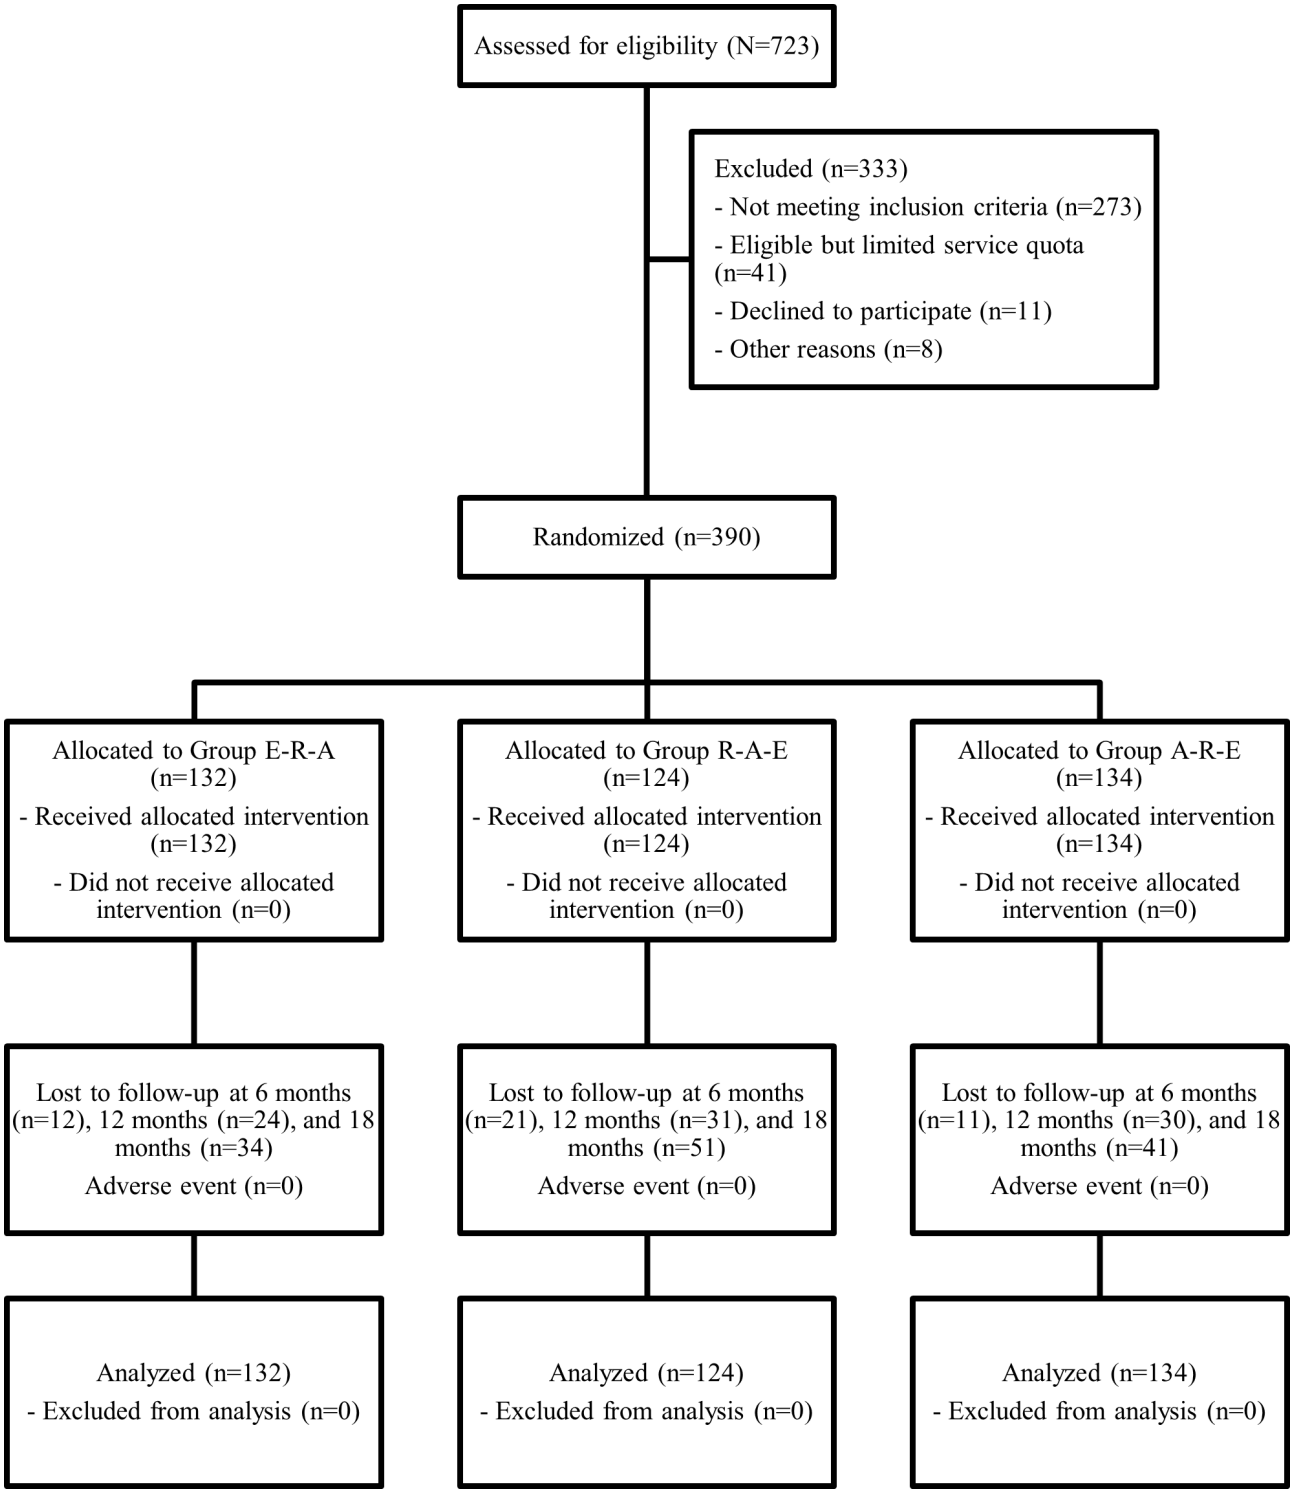
further adjust for other baseline covariates that were found to be significantly different between groups. To examine the effectiveness of 6-month aerobic or resistance training, outcomes in the A-R-E group and R-A-E group were compared to the E-R-A group. To investigate the order effect in aerobic and resistance training, we compared 12-month outcomes between the R-A-E group and the A-R-E group (reference group). To evaluate the maintenance of exercise effect and habit formation, we compared the outcomes including the level of physical activity between groups at 18 months. As intervention components were switched at the 6th and 12th month, time was treated as a categorical variable instead of continuous to account for the possible nonlinear relationship between time and outcome variables. Treatment effect referred to the coefficient of the intervention group × time interaction. Subgroup analyses by baseline frailty status and gender were individually made to delineate the differential treatment effects. Since 12 outcomes were examined in this study, we set the significance level at 1% and reported the 99% CIs for the primary outcomes to account for multiple comparison bias. The significance level for the secondary outcomes was set at 5%. All analyses were conducted using Stata/MP (version 17.0; StataCorp LLC).

Results

Sample Characteristics

In total, 723 potential participants were assessed for eligibility, of whom 390 (53.9%) were randomized (Figure 1). Of the 390 participants included in the study, 132 (33.8%) were assigned to the E-R-A group, 124 (31.8%) to A-R-E, and 134 (34.4%) to R-A-E.

Figure 1. Study flow chart. All participants were analyzed in repeated measures mixed-effect regression models.



Baseline characteristics for participants by intervention group are shown in Table 1. The average FRAIL score, SPPB score, and overall quality of life at baseline were 2.1 (SD 0.9), 7.8 (SD 2.8), and 91.6 (SD 13.1), respectively. Characteristics of participants in the 3 groups were similar, except for the quality of life ($F_{2,385}$=3.26, P=.04) and arm curl test scores ($F_{2,382}$=5.47, P=.005). As suggested by the mean PASE scores, all 3 groups were considered as having low activity levels in general [23]. No reports of adverse events that led to death, hospitalization, or medical attendance were received by the end of the program.

[i]LSNS: Lubben Social Network Scale.

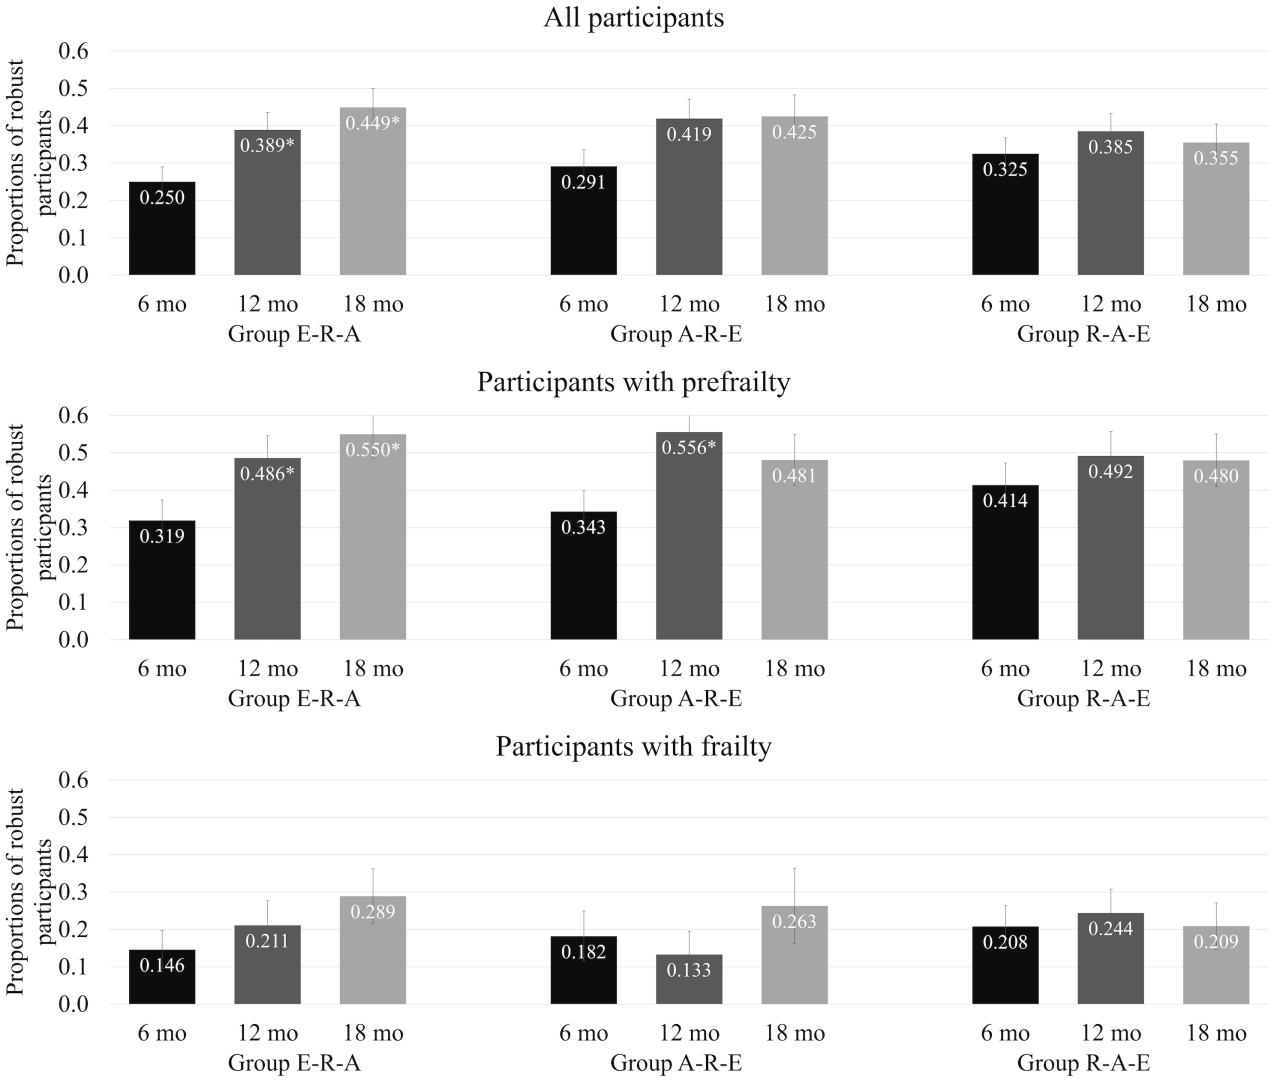
[j]PSQI: Pittsburgh Sleep Quality Index.

[k]PHQ-9: Patient Health Questionnaire-9.

Change in Frailty Status

We found a substantial overall improvement in frailty status (Figure 2 and Multimedia Appendices 5 and 6), both in terms of achieving a robust status and an improved status (from frail to prefrail/robust or from prefrail to robust).

Figure 2. Percentage of older participants obtaining robust status at the follow-up assessment time points. Absolute numbers are reported in Multimedia Appendix 5. The intervention only targeted older adults with frailty and prefrailty, and thus no robust participants were included at baseline. Asterisks (*) indicate a further significant increase (P<.05) in the proportion of robust status from 6 months. A: aerobic training; E: lifestyle education; R: resistance training.



In the prefrail sample, 35.8% (76/212) of all participants became robust after 6 months. The proportion of robust participants increased to 51.0% (98/192) at 12 months and remained stable (83/164, 50.6%) at 18 months. In the frail sample, 17.9% (24/134) of participants became robust at 6 months. The proportion increased to 20.4% (23/113) at 12 months and continually increased to 25% (25/100) at 18 months. In terms of within-group changes, participants from the E-R-A group and A-R-E group (prefrail sample only) continued to have a significant improvement in frailty beyond 6 months (Figure 2 and Multimedia Appendices 5 and 6). Although a smaller proportion of participants with frailty obtained a robust status within the first 6 months, the majority of them progressed to prefrailty.

Aerobic Versus Resistance Training: 6-Month Outcomes

As shown in Table 2, there was an overall improvement (having a significant time effect) in FRAIL score (coefficient −0.81, 95% CI −1.09 to –0.52; P<.001), IADL (coefficient 0.48, 95% CI 0.04 to 0.91; P=.03), PSQI (coefficient −0.74, 95% CI −1.34 to –0.14; P=.02), and PHQ-9 (coefficient −0.98, 95% CI −1.81 to −0.16; P=.02) in all groups over 6 months, suggesting that participants had improved frailty and functional and psychological outcomes.

[j]Measurements reporting 99% CI: 5-item FRAIL scale, SPPB, and WHOQoL-OLD. All other scales used 95% CI.

At 6 months, participants with resistance training (R-A-E group) compared with those with lifestyle education (E-R-A group) had greater improvement in quality of life (interaction coefficient 5.23, 99% CI 1.21 to 9.24; *P*<.001) but not in FRAIL

score and SPPB. Similar findings were observed in the prefrail subsample (Multimedia Appendix 7). Aerobic training (A-R-E group) was not different from lifestyle education in the primary outcomes.

For the secondary outcomes, both aerobic training (A-R-E group) and resistance training (R-A-E group) performed better in several fitness outcomes than the E-R-A group. The A-R-E group was associated with greater improvement in left hand grip strength (interaction coefficient 2.99, 95% CI 0.76 to 5.23; *P*=.009), right hand grip strength (interaction coefficient 3.75, 95% CI 1.54 to 5.97; *P*=.001), and the arm curl test (interaction coefficient 1.42, 95% CI 0.39 to 2.46; *P*=.007) than lifestyle education (E-R-A group). The R-A-E group was also associated with greater improvement in the 3 outcomes (Table 2). The A-R-E and R-A-E groups did not differ from the E-R-A group in all other nonfitness measures including the 2-minute step test, IADL, PASE, LSNS, and PSQI over 6 months. The R-A-E group had a significantly higher level of PHQ-9 scores (interaction coefficient 1.34, 95% CI 0.17 to 2.52; *P*=.02). Results of the subgroup analysis by frailty status were summarized in Multimedia Appendices 7 and 8, whereas results of the subgroup analysis by gender were summarized in Multimedia Appendices 9 and 10.

Aerobic and Resistance Training: The Order Effect (12-Month Outcomes)

To compare the order effect, we also compared the R-A-E group with the A-R-E group (reference group) on 12-month outcomes (Multimedia Appendix 11). The 2 groups did not differ in all outcomes except that the R-A-E group was associated with greater improvement in WHOQoL-OLD (interaction coefficient 4.50, 95% CI 0.12 to 8.88; *P*=.008). The result was similar when the analysis was applied in the prefrail subsample. Participants with frailty in the R-A-E group achieved significantly fewer steps in the 2-minute step test compared to their counterparts in the A-R-E group at 12 months (interaction coefficient −12.48, 95% CI −24.78 to −0.18; *P*=.047).

In sum, the findings suggested that the order of aerobic and resistance training did not have an impact on fitness outcome at 12 months, although some preliminary data suggested that undergoing resistance training before aerobic training might improve quality of life.

Maintenance of Exercise Effect and Habit Formation

The A-R-E and R-A-E groups did not receive a physical intervention between 12 and 18 months. If exercise effects were maintained, we expected to observe gains to be maintained by the end of the study. As shown in Table 2, the improvement in WHOQoL-OLD seemed to be maintained at 18 months in these 2 groups compared to the E-R-A group but the *P* value did not reach the .01 threshold (interaction coefficient 4.13, 95% CI −0.23 to 8.49; *P*=.02).

However, the gains in IADL appeared to reduce in the A-R-E (interaction coefficient −0.88, 95% CI −1.59 to −0.18; *P*=.013) and the R-A-E groups (interaction coefficient −1.22, 95% CI −1.89 to −0.56; *P*<.001) and also for PHQ-9 in the R-A-E group (interaction coefficient 2.14, 95% CI 0.87 to 3.41; *P*=.001).

Neither aerobic training nor resistance training improved PASE at 6 months compared to lifestyle education. We observed a significant time effect on PASE over 18 months in the whole sample (coefficient 10.99, 95% CI 2.06 to 19.90; *P*=.02) and in the frail subsample (coefficient 14.6, 95% CI 1.39 to 27.81; *P*=.03), indicating that combined exercise and lifestyle education, regardless of intervention sequence, might improve individuals' level of physical activity.

Discussion

Principal Findings

This study examined the effectiveness of both aerobic training and resistance training using a sequential cluster randomized controlled trial design, which enabled us to examine how these physical activity interventions and their sequence might influence frailty outcomes. Although lifestyle education was initially added as a comparator intervention, our findings have demonstrated that the 18-month intervention combining lifestyle education and physical interventions is a viable strategy to address frailty and is health-promoting. The frailty score improved across groups, providing further evidence that physical frailty is reversible. Our study also produced a few other key findings. Aerobic training or resistance training tended to improve fitness performance but was not superior to an intensive lifestyle education program in addressing frailty. It is possible that 6 months of resistance training followed by another 6 months of aerobic training might be better at improving quality of life. Although the overall improvement in frailty outcome was maintained over 18 months, IADL and PHQ-9 appeared to worsen over the post–physical intervention period. We observed a small increase in the level of physical activity over 18 months, but its relation to the formation of exercise habits and an active lifestyle is yet to be determined.

Despite physical activity intervention being the most widely studied and recommended approach for the management of frailty [24], we found that a single-mode exercise program (aerobic or resistance) for 6 months was no better than lifestyle education in addressing frailty. The findings coincided with a recent systematic review suggesting that physical activity intervention, when compared with an active control intervention, was not associated with a significant reduction in frailty [25]. We found that the administration of 2 physical interventions in sequence did not further improve frailty scores but participants were able to maintain the gain accrued over the first 6 months. The 3 study arms approximated a multifaceted intervention that incorporated physical, psychosocial, and educational components. There were a few multifaceted studies [26-28] but cross-study comparison was difficult due to their different designs and the lack of frailty as an outcome. The Hatoyama Cohort Study [27] found that resistance exercise in combination with nutritional education and psychosocial programs for 3 months successfully reduced the prevalence of frailty by 24%. Our study further added that the sequence of intervention components, if not delivered concurrently, might not make a significant difference. Nonetheless, older adults with frailty may find the program more acceptable if they have greater control over the sequence of interventions.

We added to the literature that psychosocial intervention might be complementary to physical activity intervention for the management of frailty. Following the lifestyle education program, the subsequent addition of physical intervention appeared to generate further gain. Participants from the E-R-A group were observed to have continued improvement in frailty outcomes after switching from lifestyle education to resistance training. There were only a few known studies to date exploring the effectiveness of psychosocial interventions on frailty. A Swedish study evaluated a 4-week senior group program similar to our lifestyle education program, which introduced and discussed various healthy lifestyle topics [29]. The senior group program had no impact on frailty outcomes, but it was reported to delay activities of daily living deterioration. Our lifestyle education program was more intensive in terms of frequency and duration than the senior group program. Further studies may explore whether shorter or longer combined interventions may make a difference in frailty outcomes.

Since frailty is suggested to result from cumulative declines in multiple physiologic systems [1], it is not surprising that interventions targeting different systems may yield similar positive results (ie, the equifinality principle). There might be common factors across the intervention approaches that mitigate frailty, such as social support from peers (exercise coaches and retired nurses). In our study, all 3 intervention components encouraged social engagement through the group sessions and peer coaching. Previous studies have suggested that social support might directly or indirectly contribute to higher levels of physical activity in older adults [30-32] and could therefore be health-promoting and lead to a healthier lifestyle. Further studies should include a comparison group without social influence and a measure of perceived social support to allow for an estimation of its impact on frailty and quality of life. Future studies may also include measures of other psychological mediators such as self-efficacy, enjoyment, and the use of behavioral and cognitive processes [33] for mediation analyses.

The subgroup analysis by frailty status showed that participants with frailty appeared to have a greater magnitude of reduction in FRAIL score, further demonstrating that frailty is a modifiable condition. The frail subgroup also had consistently reported increased social engagement and some reduction in depressive symptoms over 18 months. Some improvements in physical fitness were observed but may not have been sustained beyond the active intervention period. The results echoed our hypothesis that active physical or psychosocial interventions might enhance social support for older adults at high risk of vulnerability and social isolation [34]. Physical activity guidelines should recommend older adults with frailty to engage in moderate-intensity exercise regularly [35]. The design of physical activity interventions should incorporate social or group elements that enhance social learning and reinforcement. With a sample predominantly comprised of female older adults (~80%), the results for the female subsample were largely consistent with those in the full sample. There may be a lack of power to detect significant intervention effects in the male subsample. These results should be interpreted with caution.

We observed a significant increase in the level of physical activity over 18 months, probably due in part to the significant change within the frail subsample. No evidence showed that participants with prefrailty increased their level of physical activity after interventions. It might take as long as 18 months to observe an overall increase in the level of physical activity. The potential of exercise and lifestyle interventions to modify long-term exercise habits remains unclear. It is common to observe a relapse pattern in health behavior once an intervention has ended [36]. Program effectiveness and acceptability are equally important as pain and discomfort associated with physical activity could be an obstacle to engaging in further physical activity [37]. In addition, a physical intervention combined with smartphone-assisted e-reminders, an activity tracker, and e-coaching may help habit formation [38]. It is equally important to implement strategies to discourage unhealthy habits simultaneously. It is possible that our lifestyle education program helped increase participants' awareness about unhealthy habits and alternative healthy options in the environment. Further investigation to determine the optimal form of intervention(s) that best maintains exercise habit formation is warranted.

We consider the delivery of exercise interventions by peer coaches to be the key to long-term scalability and sustainability in the context of population aging. More research is needed to formally evaluate the sustainability and cost-effectiveness of the intervention model. Future research should consider the productive aging component for engaging retired older adults in productive activities, task shifting from health professionals to more available human resources (ie, peer coaches), and the implications of an increased number of robust older people in the community. Health care utilization associated with a positive change in frailty outcomes has not been explored, but it is worth further investigation.

Limitations

Due to the complexity of the study design, we lacked a care-as-usual comparator group. The active control group only abstained from physical intervention in the first 6 months. Therefore, we were unable to evaluate the effectiveness of physical activity interventions for 12 months compared with an active control intervention. Further multifaceted intervention studies may include both psychoeducational components in combination with physical interventions. An accelerometer-based measure of physical activity level may be better than a self-reported one in estimating the effect of a physical intervention on habit formation [39]. Similar to other physical intervention programs, the generalization of results might be limited by attrition bias and a predominantly female sample. This program was tested in a densely populated community. This setting may enhance the viability and cost-effectiveness of delivering both group and home sessions via peer coaches. Adaptations may be needed if the model is applied in other contexts, for example, in rural areas, which will require a separate evaluation of feasibility and effectiveness.

Conclusions

In contrast to most previous trials, we attempted to address frailty by examining physical interventions in comparison with a novel comparator, that is, lifestyle education. Both tested physical interventions and lifestyle education were effective in

improving frailty status. A simultaneous improvement in quality of life was observed. Participants with frailty appeared to benefit beyond a frailty outcome. Despite the positive findings, the impact of the interventions on exercise habit formation is yet to be investigated.

Acknowledgments

This work was supported by theSimon KY Lee Foundation, Hong Kong. The funding body had no role in the design, methods, subject recruitment, data collection, analysis, or preparation of the paper.

Authors' Contributions

All authors, led by GHYW and TYSL, developed the study concept and design. MT, TYSL, and GHYW were directly involved in activities related to the acquisition of data. JYMT, HL, and GHYW conducted data analysis, and all authors participated in the interpretation of the data. JYMT, HL, and GHYW drafted the manuscript. All authors critically revised the manuscript for important intellectual content.

Abstract

Background: Individuals with probable sarcopenia have shown excess mortality, yet no specific treatment regimen has been established. While lifestyle factors improve health and longevity in general populations, their role in probable patients with sarcopenia remains unclear due to differing lifestyle patterns. Clarifying this could inform strategies to address this unmet need.

Objective: We aim to quantify the impact of a healthy lifestyle on all-cause and cause-specific mortality in probable sarcopenic populations using a large-scale prospective cohort study.

Methods: Participants were selected from the UK Biobank, aged 40 - 69 years, during 2006 - 2010. Probable sarcopenia was identified according to EWGSOP2 (European Working Group on Sarcopenia in Older People 2) criteria, resulting in 20,654 participants being included in this study. Death dates and underlying causes were obtained from the National Health Service Information Center. Cox proportional hazard models and population-attributable risk were used to assess the associations between healthy lifestyle factors and premature mortality risk.

Results: A total of 20,654 individuals with probable sarcopenia were included in this study. The median age of the population was 62.0 (IQR 56.0-66.0) years, and 60.6% (n=12,528) were women. During a median follow-up duration of 11.5 (IQR 10.8-12.3) years, 2447 participants died. All healthy lifestyle factors, including nonsmoking (P<.001), moderate alcohol intake (P<.001), regular physical activity (P<.001), a healthy diet (P=.01), limited television-watching time (P<.001), adequate sleep duration (P=.001), and strong social connections (P<.001), were independently associated with lower mortality risk. To evaluate the cumulative associations between modifiable lifestyle factors and mortality outcomes (all-cause and cause-specific) among patients with probable sarcopenia, we developed a healthy lifestyle index. Participants were assigned one point per adherence to each optimal lifestyle factor. Compared with individuals with 0 - 2 healthy lifestyle scores, hazard ratios of all-cause mortality for those with 3 to 6 - 7 factors were 0.67 (95% CI 0.59 - 0.76), 0.51 (95% CI 0.45 - 0.57), 0.43 (95% CI 0.38 - 0.49), and 0.33 (95% CI 0.29 - 0.39), respectively (P for trend <.001). There was also a dose-response relationship between the number of healthy lifestyle factors and mortality from cancer, cardiovascular disease, respiratory disease, digestive disease, and other causes (all P for trend<.001). Population-attributable risk analysis indicated that 25.7% (95% CI 22% - 29%) of deaths were attributable to a poor lifestyle (scoring 0 - 5).

Conclusions: A healthy lifestyle is associated with a lower risk of all-cause mortality and mortality due to cancer, cardiovascular disease, respiratory disease, and digestive disease among individuals with probable sarcopenia. Adopting a healthy lifestyle (scoring 6‐7) could prevent 25.7% of deaths in this population.

KEYWORDS

healthy lifestyle; sarcopenia; mortality; cohort study; muscle strength

Introduction

Sarcopenia, a progressive and generalized skeletal muscle disorder, affects approximately 10%‐27% of people older than 60 years of age worldwide [1]. The sarcopenia diagnosis follows a three-stage hierarchy per the 2019 EWGSOP2 (European Working Group on Sarcopenia in Older People 2) guidelines: probable sarcopenia is defined by low muscle strength (primary criterion, measured via handgrip dynamometry); confirmed sarcopenia requires concurrent low muscle mass; and severe sarcopenia is diagnosed with additional functional limitation [2]. Even patients in the mildest stage, probable sarcopenia, exhibit a nearly 1.6 times higher risk of mortality compared to the general population [3-6]. Given the high prevalence and significant adverse consequences of sarcopenia, it is crucial to identify potentially modifiable factors to lower the premature mortality risk among this population.

The EWGSOP2 guideline underscores the critical role of lifestyle management in sarcopenia [7], given that physical activity and dietary interventions have been shown to retard sarcopenia progression and reduce mortality risk in this population [8]. However, current evidence is limited to a narrow range of lifestyle factors, notably neglecting other critical determinants, especially emerging ones such as sleep quality, sedentary behavior, and social engagement [9-11]. These lifestyle factors have already been proven to promote health in the general population by reducing inflammation and comorbid burdens [12-14], which are also relevant to sarcopenia [15]. However, whether and to what extent individuals with sarcopenia can benefit from such multidimensional lifestyle factors remains unclear due to their distinct behavioral patterns; for example, individuals with sarcopenia usually reduce their regular physical activity and tend to be more socially isolated [16,17]. Additionally, there is still a lack of evidence on the combined effects of lifestyle factors among individuals with sarcopenia, despite their strong interrelation [18]. Addressing this evidence gap is critical to inform evidence-based guidelines and population-level strategies for behavior change.

To bridge the knowledge gap, we analyzed data from the UK Biobank study to examine the relation of 7 healthy lifestyle factors, that is, no current smoking, moderate alcohol consumption, healthy diet pattern, regular physical activity, adequate sleep duration, short television watching time, and appropriate social connection to all-cause mortality. We also estimated the proportion of deaths that can be prevented theoretically by simultaneously adopting several healthy lifestyle factors among individuals with sarcopenia.

Methods

Study Population

The UK Biobank study is a population-based cohort that recruited more than 500,000 participants aged 40‐69 years during 2006‐2010 [19]. Participants provided detailed health-related data and lifestyle information, had physical measurements taken, and provided biological samples at 22 assessment centers across England, Scotland, and Wales [20].

Handgrip strength was measured using a Jamar J00105 hydraulic dynamometer by a trained nurse in a standardized clinical setting [3]. Participants were seated upright with forearms supported on armrests, and bilateral measurements were obtained via a single 3-second maximal voluntary contraction of each hand. The average of right- and left-hand measurements, expressed in kilograms, was used in this study. Sarcopenia was diagnosed according to the EWGSOP2 criteria [2]. Due to the scarcity of confirmed sarcopenia cases in the UK Biobank [21], participants with probable sarcopenia, defined as handgrip strength <27 kg among men and <16 kg among women, were finally included in this study.

Ethical Considerations

All participants provided written informed consent before the data collection. The study was approved by the National Information Governance Board for Health and Social Care and the National Health Service North West Multicenter Research Ethics Committee (16/NW/0274; ethics approval for UK Biobank studies). This study was conducted with permission (UKB application 77,646) from the UK Biobank. The UK Biobank has made necessary efforts to safeguard participant privacy and provided appropriate compensation to the participanting subjects; all patients'data have been anonymized and deidentified.

Assessment of Lifestyle Factors

The impact of seven modifiable healthy lifestyles was evaluated in the current analysis. These included four well-established factors (ie, smoking status, alcohol intake, physical activity, and diet) [22] and three emerging factors (television watching time, sleep duration, and social connection) [12,18,23]. All information on lifestyle factors was self-reported and assessed using a touchscreen questionnaire at baseline. Detailed definitions of each lifestyle factor are shown in Multimedia Appendix 1.

Each lifestyle variable was coded 0 or 1, with 1 indicating the adoption of a particularly healthy lifestyle factor based on the following criteria: no current smoking (never or previous smoker), moderate alcohol consumption (women ≤1 drink per

day, and men ≤2 drinks per day regularly), healthy diet pattern (≥5 recommended food component groups), regular physical activity (≥150 min per week of moderate activity, or ≥75 min per week of vigorous activity), adequate sleep duration (7 - 8 h per day) [24], short television watching time (<4 h per day) [25], and appropriate social connection (ie, moderately active and active social connection status) [26]. An overall healthy lifestyle score was constructed as the sum of the scores of 7 lifestyle factors, with a higher score indicating higher adoption of an overall healthy lifestyle. For the avoidance of extreme groups with limited cases, we collapsed scores of 0, 1, and 2 into one category and 6 and 7 into another category. The categorization choices are arbitrary but justifiable to avoid floor and ceiling effects.

Ascertainment of Outcomes

The outcome variables consisted of all-cause mortality and cause-specific mortality, that is, death from cancer, cardiovascular disease (CVD), respiratory disease, neurodegenerative disease, digestive disease, and other causes. Information about the death date and underlying cause was obtained from the National Health Service Information Center (for England and Wales) and the National Health Service Central Register Scotland (for Scotland). The cause of death was defined based on the International Classification of Diseases, 10th Revision code. Detailed information about the linkage procedure is web-accessible [27].

Assessment of Covariates

Covariates included age (years); sex (women or men); ethnicity (White, Black, Asian, Mixed or other); education (higher, ie, college or university degree or other professional qualification; upper secondary, ie, second or final stage of secondary education; lower secondary, ie, first stage of secondary education; vocational, ie, work-related practical qualifications; or other); social deprivation (Townsend deprivation index); and employment (currently employed or not).

Statistical Analysis

Baseline characteristics are presented as the mean (SD) if normally distributed or median (IQR) if nonnormally distributed for continuous variables and frequency (%) for categorical variables. The distribution of quantitative variables was evaluated using both graphical assessments (ie, histograms and Q-Q plots) and formal normality tests (ie, skewness and kurtosis metrics).

For each participant, we calculated person-years of follow-up from the date of recruitment (between 2006 and 2010) to the date of death or the end of follow-up (December 2020 for England and Wales and November 2020 for Scotland and elsewhere), whichever occurred first. Cox proportional hazard models were applied to examine the associations of each lifestyle factor and the overall lifestyle score with all-cause and cause-specific mortality risk. The results were reported as hazard ratios (HRs) with 95% CIs. We assigned a median value to each lifestyle score category to test the linear trend. Kaplan-Meier survival analysis and curve were also applied to reveal the association between lifestyle score and the cumulative incidence of death (Figure 1). We adjusted for age, sex, education, Townsend deprivation index, and employment to control potential confounders. Besides, lifestyle factors were mutually adjusted for when the relation of each lifestyle factor to all-cause mortality was examined. In addition, we performed sex-stratified analyses to evaluate the relation of healthy lifestyle scores to all-cause mortality in men and women. We took the same approach to examine the relation of healthy lifestyle scores to all-cause mortality. The proportional hazards assumption was tested using a Schoenfeld residuals plot. The population-attributable risk (PAR), an estimate of the proportion of all-cause deaths that would theoretically have been prevented if all individuals had a lifestyle score of at least 3, 4, 5, or >6, was calculated, with the 0 - 2 category as the reference group.

We conducted 2 sensitivity analyses to evaluate the robustness of our primary findings. First, we performed multiple imputations with chained equations with 5 datasets to deal with the missing values of exposure or covariates (Table S1 in Multimedia Appendix 1). Then, we excluded participants who died within 2 or 4 years of follow-up to reduce immortal bias (Table S2 in Multimedia Appendix 1).

P values were 2-sided with statistical significance set at less than .05. All analyses were performed using Stata SE (version 15; StataCorp).

Results

Population Characteristics

The baseline characteristics of 20,654 individuals with probable sarcopenia are shown in Table 1. The mean age of the population was 59.7 (SD 7.20) years, and 39.8% (n=8126) were men. The proportion of healthy lifestyle scores of 0‐2, 3, 4, 5, and 6‐7 was 9.7% (n=2015), 16.4% (n=3382), 25.7% (n=5316), 27.2% (n=5610), and 21% (n=4331), respectively. Participants with a lower lifestyle score (0‐2) were younger (mean 58.85, SD 7.15 vs 60.43, SD 7.11 y), less educated (20.8% (n=419) vs 51.5% (n=2232) with higher education level), less employed (19.1% (n=385) vs 42.3% (1833) employment rate), and more socioeconomically deprived (Townsend score: 1.27 vs −1.43), compared to high scorers (6-7). Conversely, higher lifestyle scorers (6-7) exhibited a lower prevalence of CVD [8.8% (n=383) vs 19.6% (n=394])], hypertension [33.7% (n=1460) vs 49.4% (n=996)], diabetes [7.5% (n=325) vs 15.4% (n=311)], hyperlipidemia [24.5% (n=1,061) vs 37.3% (n=752)], and depression [5.7% (n=245) vs 18.1% (n=364); Table 1].

Table . Baseline characteristics of participants with probable sarcopenia by lifestyle score category[a].

[a]Data are mean (SD) for continuous variables or n (%) for categorical variables.

Association of Individual Lifestyle Factors With the Risk of All-Cause Mortality

During 230,418 person-years of follow-up, 2447 participants died. As shown in Table 2, each lifestyle factor was significantly associated with all-cause mortality. Compared with no current smoking participants, the adjusted HR of mortality was 1.98 (95% CI 1.78 - 2.20) for those current smokers. Abstaining from smoking appears to be the most effective in reducing the risk of mortality. There was a U-shaped association between alcohol consumption and all-cause mortality, with moderate alcohol consumption (male ≤16 g per day; female ≤8 g per day regularly) being associated with lower mortality; other alcohol consumption levels (never or excessive) had a higher mortality risk (HR 1.28, 95% CI 1.17 - 1.39). Engaging in irregular physical activity and following an unhealthy diet pattern were associated with a higher mortality rate; the corresponding HRs were 1.36 (95% CI 1.25 - 1.47) and 1.11 (95% CI 1.02 - 1.20). Adoption of 3 emerging healthy lifestyle factors was also associated with lower mortality risk. Short (≤6 h per day) or long duration (≥9 h per day) of sleep versus adequate sleeping duration (7 - 8 h per day) was associated with a higher risk of mortality (HR 1.14, 95% CI 1.05 - 1.24), especially the long sleep duration group had a significantly higher mortality rate (HR 1.39, 95% CI 1.25 - 1.55; Table S3 in Multimedia Appendix 1). Participants with longer television-watching time (≥4 h per day) had higher mortality than those with short television-watching participants (HR 1.20, 95% CI 1.10 - 1.31), and those who had an isolated social connection could also significantly increase the risk of all-cause mortality (HR 1.22, 95% CI 1.09 - 1.35; Table 2). Besides, no apparent effect modification was observed by sex (Tables S4 and S5 in Multimedia Appendix 1).

[a]HR: hazard ratio.

[b]Low-risk lifestyle factors: no current smoking, moderate alcohol consumption (must be drinking but no more than 1 drink per day for women and 2 drinks per day for men on a relatively regular frequency, no drinking is risk factor), healthy diet (adequate intake of at least one-half of 10 recommended food groups), regular physical activity (150 min per week of moderate activity or 75 min per week of vigorous activity, or an equivalent combination), adequate sleep duration (7-8 h per day), short television watching time (<4 h per day), and appropriate social connection (not isolated).

[c]Adjustment for age (years), sex (women or men), ethnicity (White, Black, Asian, Mixed, or other), education (higher, ie, college or university degree or other professional qualification; upper secondary, ie, second or final stage of secondary education; lower secondary, ie, first stage of secondary education; vocational, ie, work-related practical qualifications; or other), Townsend deprivation index, and employment (currently employed or not). Lifestyle factors were mutually adjusted for analyses on the association of each individual lifestyle factor with all-cause mortality risk.

Association of Lifestyle Score With Risk of All-Cause Mortality

The healthy lifestyle score was inversely associated with all-cause mortality (Table 3). For each one-point increase, the HR of all-cause mortality risk was 0.78 (95% CI 0.76 - 0.81; *P* for trend <.001). Compared with those scoring 0 - 2, the multivariable-adjusted HRs of mortality for participants with healthy lifestyle scores of 3, 4, 5, and 6 - 7 were 0.67 (95% CI 0.59 - 0.76), 0.51 (95% CI 0.45 - 0.57), 0.43 (95% CI

0.38 - 0.49), and 0.33 (95% CI 0.29 - 0.39), respectively (*P* for trend <.001; Figure 2). The PAR for all-cause mortality increased as the healthy lifestyle score increased, from 3.1% for a score of ≥2% to 9.7%, 18.3%, 25.7%, and 34.6% for scores of ≥3, ≥4, ≥5, and ≥6, respectively (Table 4).

At least 5 vs <5	845	34.5	0.61 (0.56 - 0.66)	25.7 (22.0 - 29.0)
At least 6 vs <6	323	13.2	0.60 (0.53 - 0.68)	34.6 (27.9 - 40.5)

[a]Low-risk lifestyle factors: no current smoking, moderate alcohol consumption (no more than 1 drink per day for women and 2 drinks per day for men on a relatively regular frequency), healthy diet (adequate intake of at least one-half of 10 recommended food groups), regular physical activity (150 min per week of moderate activity or 75 min per week of vigorous activity, or an equivalent combination), adequate sleep duration (7-8 h per day), short television watching time (<4 h per day), and appropriate social connection (not isolated).

[b]Adjustment for age (years), sex (women or men), ethnicity (White, Black, Asian, Mixed, or other), education (higher, ie, college or university degree or other professional qualification; upper secondary, ie, second or final stage of secondary education; lower secondary, ie, first stage of secondary education; vocational, ie, work-related practical qualifications; or other), Townsend deprivation index, and employment (currently employed or not).

[c]PAR%: population attributable risk percent.

HRs and their 95% CIs were calculated in Cox proportional hazard models after adjusting for age (years), sex (women or men), ethnicity (White, Black, Asian, Mixed or other), education (higher, ie, college or university degree or other professional qualification; upper secondary, ie, second or final stage of secondary education; lower secondary, ie, first stage of secondary education; vocational, ie, work-related practical qualifications; or other), Townsend deprivation index, and employment (currently employed or not).

Association of Lifestyle Score With Risk of Cause-Specific Mortality

During the follow-up, 993 participants died from cancer, 533 participants died from CVD, 262 participants died from respiratory disease, 156 participants died from neurodegenerative disease, 143 participants died from digestive disease, and 360 participants died from other causes. There was a significantly inverse dose-response association between the health lifestyle score and the mortality from cancer, CVD, respiratory disease, digestive disease, and other causes (*P* for

trend <.001); however, no such pattern was observed for neurodegenerative disease (Table 3). Participants with higher overall lifestyle scores (6-7) had significantly lower mortality rates compared to those with scores of 0‐2. The multivariate-adjusted HRs of cause-specific mortality were 0.43 (95% CI 0.34‐0.55) for cancer, 0.39 (95% CI 0.28‐0.55) for CVD, 0.26 (95% CI 0.17‐0.41) for respiratory disease, 0.12 (95% CI 0.06‐0.27) for digestive disease, and 0.33 (95% CI 0.21‐0.51) for other causes.

Discussion

Statement of Principal Findings

In this cohort study conducted among individuals with probable sarcopenia, we found that adopting a healthy lifestyle was associated with significantly reduced all-cause mortality, notably deaths from cancer, CVD, respiratory disease, and digestive disease. We estimated that approximately 25.7% of deaths could be prevented if they could adopt six or more healthy lifestyle factors. These findings underscore the pivotal role of embracing a healthy lifestyle in alleviating mortality among individuals with probable sarcopenia.

Comparison With Previous Studies

Physical activity and nutritional interventions have already been recommended as primary strategies for managing sarcopenia, but previous evidence was inconclusive, with limitations such as small sample sizes and inconsistent adherence to interventions [28,29]. This study provides further evidence for the effectiveness of these two interventions among individuals with probable sarcopenia. Meanwhile, this study highlights divergent associations between lifestyle factors and mortality in probable sarcopenia populations versus the general population. Among individuals with probable sarcopenia, current smoking and excessive alcohol consumption exert the strongest mortality impacts (Table S3 in Multimedia Appendix 1). By contrast, in the general population, smoking cessation remains the most impactful lifestyle determinant on mortality [30], and Locquet et al [31] also discovered that smokers have a 2.36-fold higher likelihood of developing sarcopenia. Regular physical activity conferred the second-greatest survival benefit in the general population [30], which was consistent with prior reports by Li et al [32]; while dietary quality (HR 0.88, 95% CI 0.82‐0.94 in men; HR 0.97, 95% CI 0.90‐1.05 in women) and excessive alcohol intake (HR 0.95, 95% CI 0.89‐1.01 in men; HR 1.03, 95% CI 0.94‐1.12 in women) had weaker associations with mortality [30]. Notably, a meta-analysis also indicated that alcohol consumption is not associated with the presence of sarcopenia in the general population, with a pooled odds ratio of 0.964 [33]. Overall, these results indicate that it is meaningful to explore the impact of these healthy lifestyle factors on the mortality risk within the specific population of probable sarcopenia.

Three emerging healthy lifestyle factors also show a significant association with reduced risk of mortality. Social connection has garnered significant attention since the onset of the COVID-19 pandemic [34]. Previous studies have reported that individuals with sarcopenia are more prone to experiencing social isolation [17]. This study, for the first time, provides evidence for the beneficial effects of social connection on the probable sarcopenia population. Additionally, a recent meta-analysis showed that both short and long sleep durations are associated with an increased risk of all-cause mortality and cardiovascular events in the general population [35]. In this study, however, only long sleep duration was significantly associated with an increased mortality risk. There are two possible reasons: (1) individuals with probable sarcopenia who spend less time on sleep may allocate more time for physical activities, the interconnectedness among different lifestyle factors thereby potentially influencing the underlying association between lifestyle factors and mortality risk; and (2) sleep quality, such as chronotype, insomnia, snoring, and daytime sleepiness, can also affect the health outcomes [36].

To our knowledge, no study has examined the association between the combined healthy lifestyle score and mortality risk among individuals with sarcopenia. We have used Cox proportional hazard models and PAR to uncover whether and to what extent individuals with probable sarcopenia can benefit from a healthy lifestyle. These findings indicate that, beyond physical activity and diet, other healthy lifestyle factors also confer benefits to the probable sarcopenia population. This knowledge can contribute to the development of “core set outcomes” for lifestyle-based intervention trials in the field of sarcopenia. Additionally, a higher healthy lifestyle score is also associated with a reduced risk of mortality due to cancer, CVD, respiratory disease, and digestive disease, although not for neurodegenerative disease. Previous studies have demonstrated that adopting a healthy lifestyle can lower the risk of developing neurodegenerative diseases [37]. Nevertheless, since neurodegenerative diseases are typically not immediately life-threatening, their specific mortality risk might be attenuated.

Potential Mechanisms

Biological mechanisms linking various lifestyle factors to health outcomes have been postulated. Physical activity can impact systemic immune and metabolic response, stimulating adenosine monophosphate-activated protein kinase phosphorylation or other critical signaling pathways to promote multiple organ health and increase survival probability [38-40]. A balanced diet can provide sufficient protein, amino acids, and other essential nutrients [29]. Additionally, it can also help maintain intestinal microflora homeostasis and influence the aging gut, extending life span through metabolites produced by gut microbiota, such as short-chain fatty acids [41].

Cigarettes contain many toxic and carcinogenic components, which can impair mitochondrial function, increase oxidative stress [42], and cause epigenetic changes [43]. Therefore, avoiding tobacco exposure is an effective measure to lower disease and mortality risks. Individuals who frequently consume moderate amounts of alcohol show a lower mortality risk than those who drink alcohol rarely or excessively. A possible explanation for this phenomenon may lie in the fact that individuals who engage in regular moderate drinking tend to have better financial situations and social connections. Mechanistically, moderate alcohol consumption can lower the activity of a mental stress–related brain network [44] and reduce the risk of major cardiovascular events [45]. Besides, excessive

drinking leads to inflammation and immune-metabolic dysregulation, gut leak and dysbiosis, mitochondrial dysfunction, and epigenomic modifications [46-48]. These mechanisms synergistically interact to cause alcohol-mediated multiorgan injury and even death.

Sedentary behavior is directly associated with elevated levels of circulating inflammatory markers, such as interleukin-6 and C-reactive protein [49,50]. These markers have been proposed as senescent biomarkers due to their positive correlation with age and potential promotion of adverse health outcomes in older adults [51]. Growing evidence indicates that social connection influences various biological pathways, including blood pressure [52], oxidative stress [53], neuroendocrine dysregulation [54], chronic inflammation [55], and gut-microbiome interactions [56]. Similarly, social connections may indirectly influence health outcomes via stress perception and other behavioral factors, such as sleep quality and quantity, smoking, or even drug abuse [57,58]. These social stress-related behaviors are strongly associated with biological health.

Sarcopenia is associated with the aforementioned pathologic mechanisms that drive increased mortality risk and are influenced by lifestyle [59,60]. Individuals with sarcopenia often have multiple comorbidities (eg, diabetes, kidney disease, and chronic obstructive pulmonary disease) [61,62], and evidence indicates that healthy lifestyles significantly aid in managing these conditions [63,64], thereby reducing mortality risk.

Clinical and Research Implications

First, our findings provide incentive and support for the notion that lifestyle intervention strategies can have an impressive impact on mortality risk among individuals with probable sarcopenia, and this could help health professionals and policy makers to make preventive advice and policy recommendations for this population. Second, this study presented precise numerical values to which individuals with probable sarcopenia can benefit from a healthy lifestyle. Such knowledge might help motivate individuals with probable sarcopenia to change habits and adhere to a healthy lifestyle. Third, only 21% of the participants adhered to a healthy lifestyle (6‐7 healthy factors) in this study. In comparison, 51.9% adopted less than or equal to four healthy lifestyle factors, suggesting a large gap between current and ideal population lifestyles. Last but not least, this study found that certain lifestyle factors are more relevant than others; therefore, public health policies could focus on a few more potent risk factors (ie, smoking) rather than on costly strategies addressing multiple risk factors.

Strengths and Limitations

This study has several strengths. Foremost among these is the large sample size and comprehensive data resources, which encompassed detailed information on potential confounding variables. This robust dataset facilitated thorough analyses of mortality across various causes and allowed for stratification based on potential risk factors [22]. Additionally, this study pioneered the assessment of the combined impact of an overall healthy lifestyle on the probable sarcopenia population. This approach was particularly important due to the strong intercorrelations among various lifestyle factors [65]. Using an overall healthy lifestyle score enabled a comprehensive evaluation of the intricate relationships between lifestyle factors and mortality among individuals with probable sarcopenia.

However, several limitations should be acknowledged. First, the study's participant pool primarily consisted of Caucasians in the United Kingdom. Consequently, the generalizability of our findings to other ethnic groups may be limited. Second, due to the nature of the observational study, we cannot derive causality between lifestyle modification and mortality in this population, which warrants more well-conducted interventional studies to verify. Third, the temporal relationship between lifestyle factors and probable sarcopenia could not be clearly demarcated in this study. Thus, potential collider bias may arise when conditioning on probable sarcopenia status in analyses of lifestyle factors and mortality. This residual collider bias could attenuate associations toward the null [66], yet our identification of strong relationships strengthens confidence in these conclusions. Given this bias, estimating potentially preventable deaths via postprobable sarcopenia lifestyle changes would better clarify the importance of lifestyle management. However, UK Biobank's limited longitudinal data on postdiagnosis lifestyle modifications precluded formal analysis of how such changes affect mortality [19]. Fourth, further research can be conducted on confirmed patients with sarcopenia, although investigating lifestyles' impact on the risk of premature mortality among the probable sarcopenia population holds greater preventive implications. Fourth, measurement errors could occur in the self-reported lifestyle data. Fifth, those who died during the study period might have had serious diseases at baseline. Although the study excluded deaths within the first 2‐4 years of follow-up, the possibility of reverse causation and residual confounding remains. Finally, even though various covariates were adjusted for in our analyses, other confounders, such as BMI and comorbidities, may not have been included, which could result in residual confounding.

Conclusions

A healthy lifestyle was associated with a lower risk of all-cause mortality and mortality due to cancer, CVD, respiratory disease, and digestive disease among individuals with probable sarcopenia. A healthy lifestyle (scoring 6‐7) could prevent 25.7% of deaths in this population.

Abstract

Background: Walking is frequently recommended as a beneficial physical activity for older adults, as it can enhance both their physical and mental well-being and help prevent cognitive decline and dementia. While it is known that mobile health (mHealth) technology can help improve physical activity among older adults, there is limited research on its effectiveness for older individuals with cognitive impairment.

Objective: This study aimed to determine the effectiveness and feasibility of walking prescriptions using mHealth technology for older adults with cognitive impairment.

Methods: In total, 60 older adults (mean=76.1, SD 5.4) years; female, n=34) with mild cognitive impairment or mild dementia (n=28 and n=32, respectively; Mini-Mental State Examination [MMSE], mean=20.7, SD 4.0) who visited the memory clinic were enrolled. They were randomly assigned into three groups: (1) group A (n=20) was prescribed with a goal of daily steps based on their telemonitored activity using a smart band; (2) group B (n=19) only wore a smart band without a prescription; and (3) group C (n=21) took a monthly education to encourage their walking. All participants took monthly face-to-face sessions with a coach to check their performance and modify the goal of daily steps. Changes in daily steps (primary outcome), cognitive function, physical status, and depressive symptoms from baseline to post-intervention (12 weeks) and follow-up (24 weeks) were assessed by unblinded researchers. Linear mixed effect models with factors of group (reference: control), time (reference: baseline), and their interaction were used for data analysis. Post hoc analyses using paired *t* tests were also conducted.

Results: For group A, there was a significant group × time interaction effect on daily steps both at 12 and 24 weeks (β (SE)=2205.88 (672.34), *P*=.001; β (SE)=2194.63 (884.33), *P*=.015). Group B showed increased numbers of steps only at 12 weeks but not at 24 weeks. Group C showed a continuous decrease in daily steps during the study period. Regarding secondary outcomes, group C showed a significant decline in cognitive function measured by MMSE both at 12 and 24 weeks. However, groups A and B showed stationary MMSE scores during 24 weeks. The number of withdrawn participants did not differ among the 3 groups.

Conclusions: Our findings suggest that walking prescriptions using mHealth technology can effectively increase daily steps in older adults with cognitive impairment.

KEYWORDS

dementia; mild cognitive impairment; mobile health; physical activity; exercise

Introduction

Physical activity (PA) is protective against age-related cognitive decline and incidence of dementia in older adults [1,2]. It can reduce symptoms of depression and anxiety. It can also increase the psychological well-being of the aging population [3]. Even in older adults diagnosed with mild cognitive disorder (MCI) or dementia, moderate-to-vigorous intensity PA can effectively delay cognitive deterioration and prevent comorbid physical illnesses [4,5]. Therefore, clinical experts have advised older people to exercise regularly and continuously.

Unfortunately, the number of people doing exercise decreases as they get older due to their declined physical ability, lack of knowledge of age-appropriate exercise, false belief that exercise can cause injury, and psychosocial prejudice that older adults should behave carefully and calmly [6]. According to a national survey in Korea, only 37.6% of the population aged 65 years or older maintain PA at a recommended level of above moderate intensity for 150 minutes or more per week, and 46.3% do not exercise at all [7]. A US national survey has also found that only about 27% of individuals aged 65 years or older exercise for the recommended level for physical health [8]. According to a review paper summarizing studies from the United States, Europe, and Japan, 67% of older adults aged 60 years or older spend more than 8.5 hours sitting down [9].

It has been revealed that above moderate-intensity PA can protect or improve cognitive function, even in older adults with neurodegenerative brain diseases [10-13]. A recent study has analyzed the relationship between PA level, cognitive function, and brain pathology of older people using clinical data for 2 years before death and pathology data from brain autopsy and found that exercise and motor ability are associated with higher cognitive function independent of brain pathology, including Alzheimer's disease [14]. PA can have a counter-effect on degenerative brain diseases by improving brain plasticity and cognitive reserve. However, studies examining the effectiveness of PA programs for older adults with cognitive impairment have been mainly conducted on patients with advanced dementia in long-term care facilities due to limitations of clinic- or community-based programs. It is difficult to monitor PAs of older adults with cognitive impairment and lead them to plan and practice exercise continuously [11,13].

Recent advances in mobile health (mHealth) technology can be used to help individuals form exercise habits on their own or through expert assistance. Continuous monitoring and feedback of PA are possible because mHealth technology allows accurate activity measurements [15] and accumulation of activity information [16-18]. However, many studies on PA programs using mHealth technology have mainly been conducted on young people [19-22]. Although it has also been suggested that PA can be increased in the older population using mHealth technology [23], most studies have been conducted on older adults with physical diseases such as cardiovascular disease, diabetes, and obesity without cognitive dysfunction [23-25]. To the best of our knowledge, few studies have examined the effectiveness of PA programs using mHealth technology in older people with cognitive impairment.

Walking is the most commonly recommended PA. It is also suitable for older adults because it is easy to practice in daily life with few side effects. A relationship between maintaining recommended daily steps in older adults and low mortality has been reported [26]. While most previous studies have reported that moderate to vigorous PA is associated with improved cognitive function [10-13], a cohort study of 78,430 adults found that a higher number of steps (even if less than 10,000 steps per day) was associated with a lower risk of incident dementia [27]. Walking is not only directly influenced by physical functions such as aerobic capacity, balance ability, and limb strength but also by cognitive functions such as attention and executive function [28]. Regular walking can reflect an active lifestyle and self-directed health care. Mild cognitive impairment has been reported to be accompanied by a decrease in gait speed [29] and the decreased interest and motivation often seen in older adults with dementia leads to a decrease in PA [30]. Increasing steps in older adults with cognitive impairment may be a way to compensate for physical and mental frailty.

Clinical practice with prescribing and giving feedback to older patients to exercise at their physical level can lead them to set appropriate goals and practice PA [11,31-34]. While walking education alone has been reported to help increase step counts in older adults [32], it can be more helpful to directly prescribe a target step count based on assessing physical function for older patients with cognitive impairment. In addition, older patients with MCI or dementia may have difficulty remembering or reporting their daily steps; therefore, using mHealth technology to monitor daily step counts is useful to monitor their daily activity. However, simply monitoring daily activity can be insufficient to enhance daily steps; it requires setting appropriate goals, developing strategies to achieve them, evaluating outcomes, and refining the approach, which demands substantial cognitive resources. Consequently, human-led coaching, or personalized guidance, is essential for older adults with cognitive impairment [24]. In this study, mHealth technology is expected to function as a tool for clinicians to modify the daily activity of older patients with MCI or dementia. In other words, clinicians can improve their step counts more effectively if they use mHealth-based monitored data to make personalized prescriptions of steps.

Therefore, this study targeted older adults with cognitive impairment who visited a memory clinic to examine the effectiveness and feasibility of a program for changing daily steps by individualized walking prescription and monitoring using mHealth technology. A 3-arm design was used to compare the use of mHealth technology alone with the addition of human monitoring and feedback.

Methods

Participants

In total, 60 participants with mild cognitive impairment or mild dementia (clinical dementia rating [CDR] ≤1) were recruited from a memory clinic at a university hospital. A geriatric psychiatrist confirmed participants' cognitive diagnosis and evaluated their clinical status via CDR. Diagnoses of MCI and dementia were based on the comprehensive clinical assessments.

MCI was defined as individuals who met the core clinical criteria of MCI according to the recommendations of the National Institute on Aging and Alzheimer's Association guidelines [35]: (1) memory complaint corroborated by self, an informant, or clinician; (2) objective memory impairment for age, education, and gender; (3) largely intact functional activities; and (4) not demented. All MCI individuals had a global CDR score of 0.5. Participants diagnosed with mild dementia met the criteria for dementia in the Diagnostic and Statistical Manual of Mental Disorders 4th Edition (DSM-IV-TR [36]) and CDR score of 0.5 or 1.

Older patients performing no or low level of moderate PA (eg, fast walking for 30 min less than 3 times a week) were included, while those who had at least one of the following were excluded: (1) impossible to walk independently (cane users were not excluded); (2) diagnosed with an above-moderate degree of dementia (CDR ≥2); (3) having a physical illness that might affect their safety during the study period; (4) not being able to use a smart band by oneself or not having caregivers who could help them use it; and (5) participating in other exercise programs within the past year.

The sample size was based on a previous study reporting the effectiveness of the intervention using mHealth technology combined with SMS text messages to increase PA [20]. This study had a similar idea to ours, comparing 3 groups (mHealth-based monitoring with SMS text message vs mHealth-based monitoring without SMS text message vs control). The sample size was conservatively determined to yield a larger number of subjects after comparing 3 groups one by one. For achieving an 80% power ($1-\beta=.8$) at the 5% level of significance ($\alpha=.05$) with equal allocation, the sample sizes for intervention and active control are 10 and 10, respectively [37]. Then, we doubled the number of subjects to reflect the possibility of a small effect on steps from the intervention, given that the subjects in the reference study had twice as many baseline steps as our participants (9600 vs 4500 steps/day). The drop-out rate was assumed to be 40% since the participants of this study were older adults with cognitive impairment. Therefore, this resulted in 20 subjects in each arm, for a total of 60 subjects.

Ethical Considerations

This study was approved by the Institutional Review Board of Seoul National University Hospital (H-1708-118-879), and it was registered in a clinical trial registry (KCT0002610). All participants provided written informed consent. To protect privacy, the data used in this study were anonymized before analysis. Participants did not receive any compensation for their participation.

Study Design

Participants were randomly assigned into 2 intervention groups (group A, walking prescription and using a smart band; group B, only using a smart band) and a control group (group C) at a 1:1:1 ratio. For the randomization, an independent researcher who was not involved in patient evaluation or intervention created a random number table prior to registration of the subject. This study was not blinded even though 2 different researchers conducted baseline and follow-up assessments, respectively.

Intervention

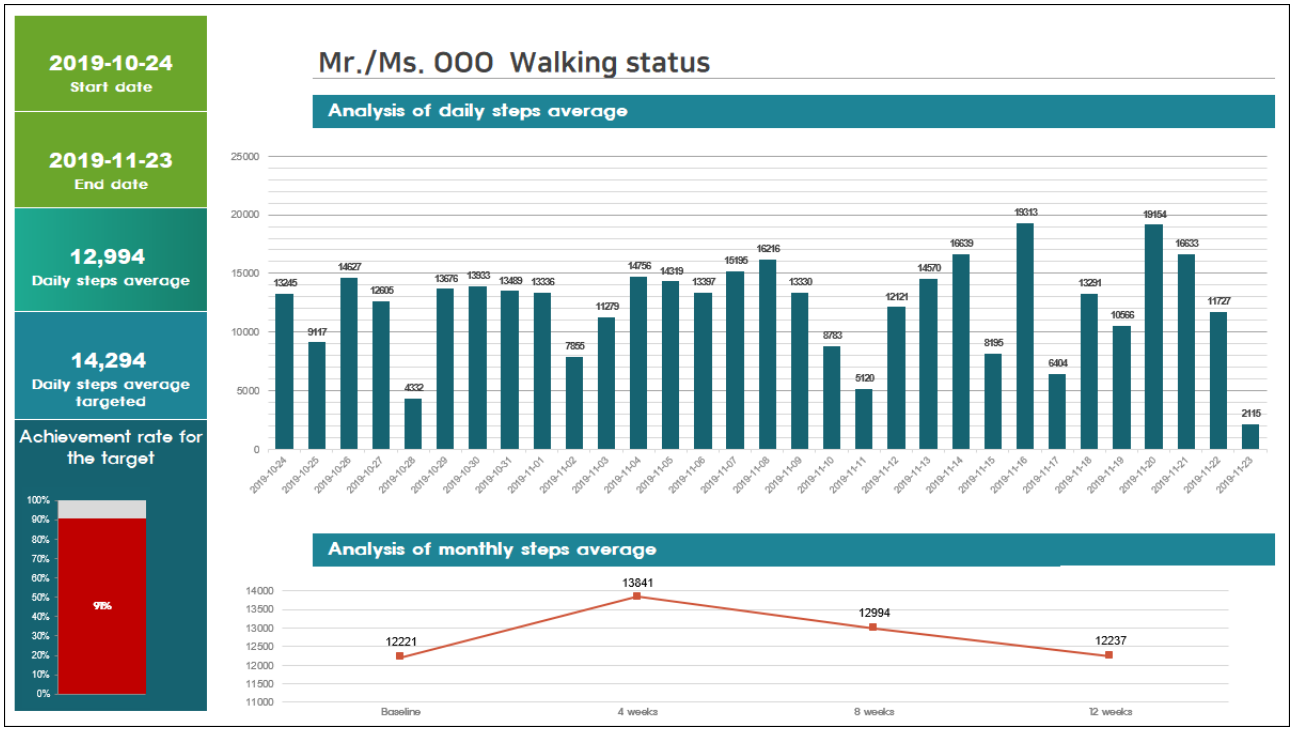
Our 12-week protocol of intervention was designed for use in a hospital setting. Physicians, nurses, psychologists, physical or occupational therapists, and any other trained paramedic professionals can use this program. In this study, a clinical psychologist and occupational therapist alternatively checked each participant's performance and compliance with the program and provided educational sessions. Both conducted study procedures uniformly according to the protocol, which included detailed methods of assessment, consultation, and feedback. Prior to the start of the study, a mock coaching session was conducted to validate the interventionists' adherence to the protocol and feedback skills with the supervision of a physician (a geriatric psychiatrist). Walking education was provided to all participants, including the control group, during the study period. It was conducted in monthly face-to-face sessions, which involved individual guidance for correct posture, appropriate intensity, and a favorable environment for walking.

Participants in group A wore a smart band and received a personal prescription of daily steps based on their usual walking for the first week. Daily steps were monitored and timely feedback for encouragement was given via telephone or SMS text message at least once a week. If steps were not recorded for 5 consecutive days, the researcher made an emergency call, as this was the deadline to recover data in the event that there was a connection issue between devices. Monthly face-to-face feedback sessions were adjusted depending on individuals' daily step goals based on their accumulated step data. The target number of steps gradually increased if participants achieved the goal in the previous month, up to the recommended steps by age based on the guidelines for walking in older adults [38]. Participants also discussed with a researcher about their walking tasks, such as when, where, and how much they were walking. A solution was found together in case they had problems in performing tasks. A graph sheet based on telemonitored data was used for these sessions (Figure 1). Even after the 12-week intervention, they were encouraged to wear a smart band and keep walking.

Group B participants were also instructed to wear a smart band. However, they were not given a walking prescription. They were also encouraged to keep wearing the band after the intervention period. The control group (group C) received monthly walking education only and was provided with the same protocol as the intervention groups. A smart band was applied only at baseline, 12 weeks, and 24 weeks for assessment. App screenshots can be found in Multimedia Appendices 1-3.

Subjects who withdrew consent to participate in this study, failed the baseline assessment, missed more than 2 face-to-face visits, or did not obtain activity data for more than 2 weeks were withdrawn early.

Figure 1. A monthly walking sheet for group A subjects.



Outcome Assessment and Measures

At baseline, information on demographics, anthropometrics, and histories of physical and mental illnesses was collected. Primary and secondary outcomes were assessed at baseline, postintervention (12 weeks), and follow-up (24 weeks).

Primary Outcome

A change in daily steps was the primary outcome of this study. Smart bands (HR LS405-B6 & HR2.5 Gold edition; Seven Elec Co., LTD) were used to measure subjects' daily steps. Participants downloaded a mobile application that was linked to the wearable device. They could check their accumulated data on steps, which was transmitted automatically to the database. Average daily steps in a week were calculated at baseline, 12 weeks, and 24 weeks.

Secondary Outcomes

Secondary outcomes included three domains: physical function, cognitive function, and depressive symptoms. The Short Physical Performance Battery (SPPB) was used to evaluate physical function [39,40]. Cognitive function was measured using the Mini-Mental State Examination in the Korean version of the CERAD assessment packet (MMSE-KC) [41,42]. The Korean version of the Geriatric Depression Scale [43-45] was used for evaluating depressive symptoms in older patients.

Statistical Analyses

Analysis of variance (ANOVA) and χ^2 tests were used for continuous and categorical variables, respectively, to compare baseline characteristics among groups. A modified intent-to-treat approach was used to examine effectiveness of the intervention. The analysis included all randomly assigned participants with at least 1 post-baseline observation. Linear mixed-effect models with factors of group (reference: control), time (reference: baseline), and their interaction were used to examine group differences in changes of primary and secondary outcomes from baseline to 12- and 24-week follow-ups. To analyze the primary outcome, age, sex, education, cognitive function, and depressive symptoms at baseline were included in the model as covariates. In addition, we conducted a 2-way mixed ANOVA, where missing data of drop-out subjects were conservatively input as "no change" by carrying forward previous assessment values. For post hoc analyses, time-related changes within each group were examined using paired 2-tailed *t* test (within-group analyses). Whether different patterns were observed by participants' cognitive status (MCI and mild dementia) was also tested. All statistical analyses were performed with SPSS software (version 23.0; SPSS Inc.).

Results

In total, 60 older patients diagnosed with MCI or mild dementia were enrolled in this trial and randomly allocated into three groups. Among them, 13 participants dropped out throughout the study period. They did not attend post-baseline assessments. The number of withdrawn participants did not differ among the three groups. Drop-outs were caused by refusals, poor device operation, or health problems. Figure 2 shows the overall study flow, allocation, drop-out, and reasons for withdrawal. As one participant dropped out from group B soon after allocation, a person on the waitlist was allocated to group C with an independent randomization procedure. No adverse events were reported during the study period.

Table 1 shows baseline characteristics of participants according to group allocation. Participants had a mean (SD) age of 76.07 (5.43) years and 11.38 (5.10) years of education. Of them, 34 (57%) were females. Among the three groups, there were no significant differences in demographics or baseline measures

such as daily steps, physical status, cognitive function, or depressive symptoms.

A linear mixed-effect model showed a significant group-by-time interaction for the primary outcome measure with adjustment of age, sex, cognitive function, physical status, and depression (Table 2).

Figure 2. Flowchart for enrollment, allocation, and participation.

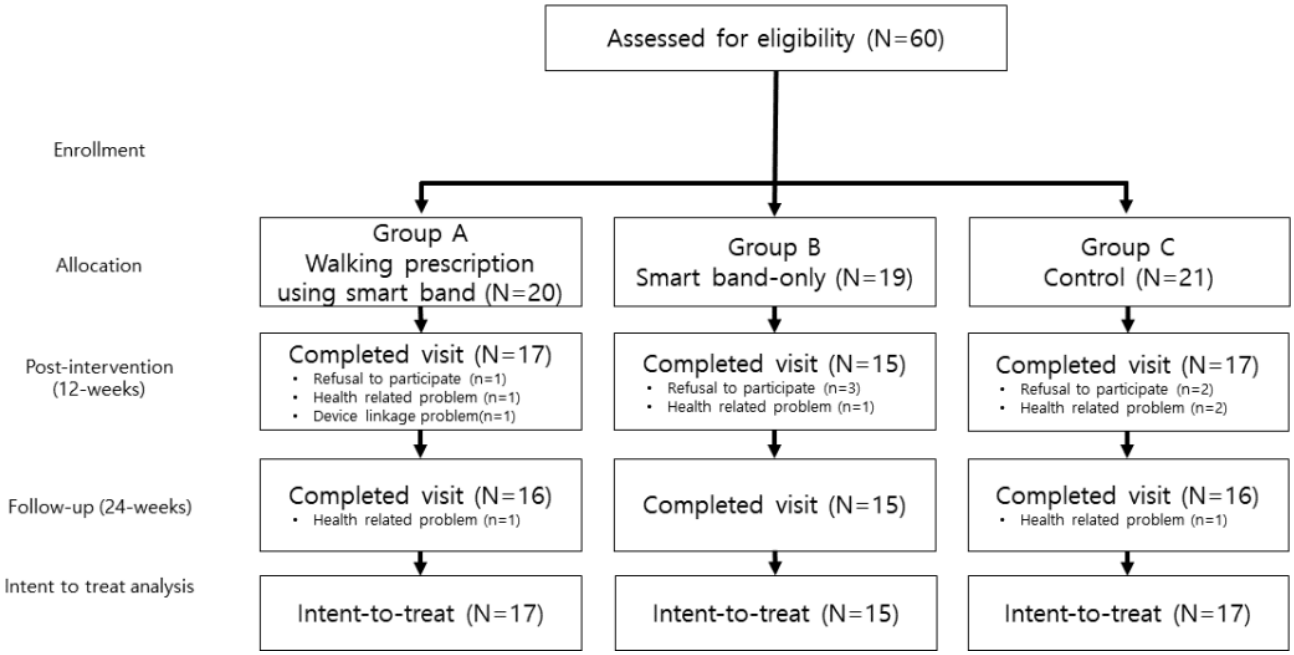


Table . Baseline characteristics of participants.

	Group A (n=20): walking prescription wearing smart band	Group B (n=19): wearing smart band only	Group C (n=21): control	*P* value

[f]Baseline as a reference time.

[g]$P<.001$.

[h]$P<.05$.

Daily step numbers were significantly increased in group A (walking prescription wearing a smart band) at 12 weeks and 24 weeks, whereas group B (wearing a smart band only) showed an improvement only at 12 weeks, with the increase not sustained till the follow-up. Meanwhile, a continuous decrease in daily steps was observed in group C (control) during the study period. Differences of changes in daily steps by groups were confirmed with a 2-way mixed ANOVA, in which missing data were conservatively substituted with “no change” by carrying forward values. Analyses were adjusted for baseline daily steps (Figure 3; $F(3.38, 2{,}146{,}208.77)=3.66$, $P=.01$).

Post hoc within-group analyses repeatedly showed a differential pattern of daily step changes according to intervention (Table 3). Step numbers in group A showed significant increases at 12 and 24 weeks. Although fewer steps were observed at follow-up compared to post-intervention timing, daily steps after 24 weeks were still more than those at the baseline. Participants in group B tended to walk more after wearing a smart band at 12 weeks than at baseline, whereas their daily steps decreased at 24 weeks below their baseline numbers of steps. Finally, group C participants showed a continuous decrease in daily steps over 6 months.

Figure 3. Daily steps by groups using 2-way mixed analysis of variance adjusted with baseline steps. Two-way mixed model analyses of covariance, in which missing data of follow-up were conservatively substituted by the value measured immediately before, included factors of group, time, and group × time interaction, and adjusted for individuals' daily steps at baseline. Significant group-by-time interaction was shown in daily steps (F(3.38, 2,146,208.77)=3.66, *P*=.01). The raw data on daily steps (mean (SD)) without adjustment of individuals' daily steps at baseline are as follows: group A: 4553.18 (3598.33) at baseline, 6119.12 (4218.33) at 12 weeks and 5235.76 (3626.98) at 24 weeks; group B: 4449.07 (1708.51) at baseline, 5524.33 (2870.45) at 12 weeks, and 3995.87 (1629.55) at 24 weeks; group C: 5218.12 (2512.09) at baseline, 4578.18 (2425.97) at 12 weeks, and 3707.59 (1799.96) at 24 weeks.

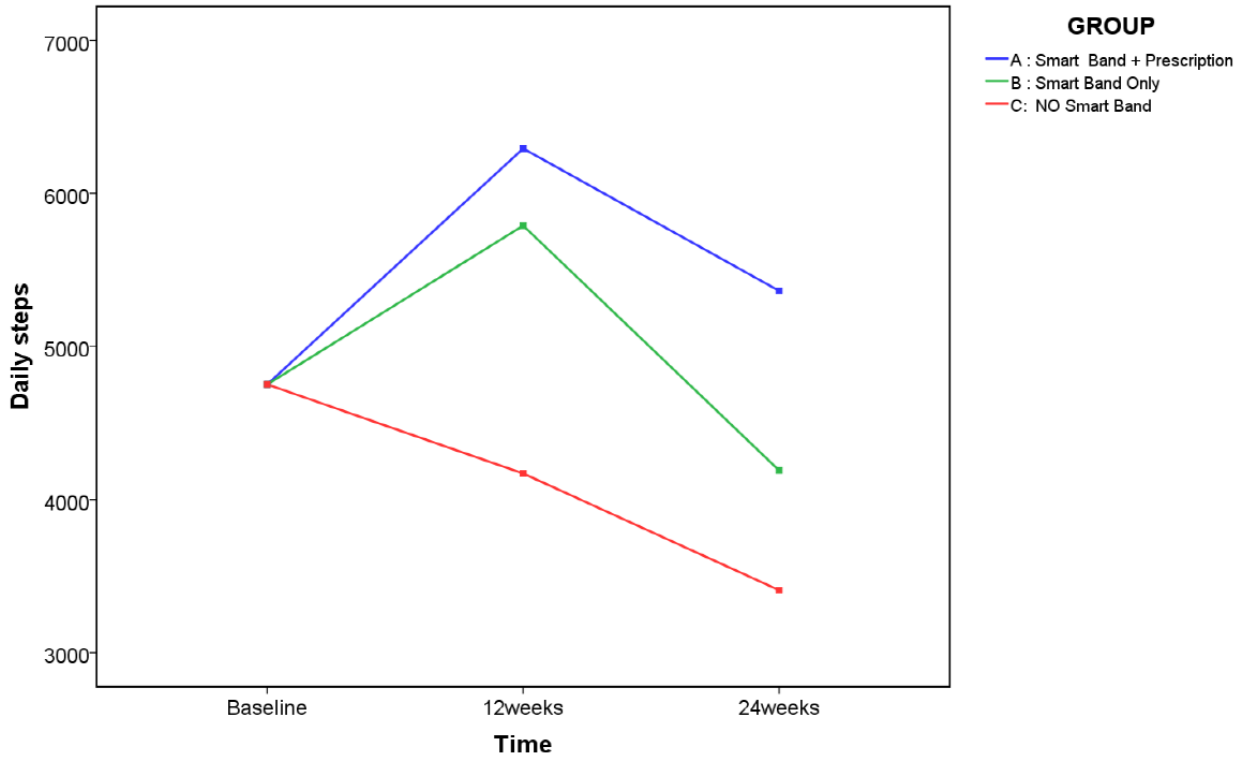

Table . Intra-group changes in daily steps and cognitive function from baseline to 12 weeks and 24 weeks follow-up.

	Group A (Smart band-based walking prescription, n=16)		Group B (Smart band only, n=15)		Group C (Control group, n=16)	
	Changes at 12 weeks Estimated mean difference (95% CI)[a]	Changes at 24 weeks Estimated mean difference (95% CI)[a]	Changes at 12 weeks Estimated mean difference (95% CI)[a]	Changes at 24 weeks Estimated mean difference (95% CI)[a]	Changes at 12 weeks Estimated mean difference (95% CI)[a]	Changes at 24 weeks Estimated mean difference (95% CI)[a]
Primary outcome						
Daily steps	1,549,000[a] (510.279 to 2587.721)	610.438 (−614.599 to 1835.474)	1075.267 (2400.059 to −249.525)	−453.200 (−1502.691 to 596.291)	−788.000 (−2089.440 to 513.444)	−1713.000[a] (−2761.966 to −664.034)
Secondary outcomes						
MMSE-KC[b]	−0.125 (−1.485 to 1.235)	−0.438 (−2.077 to 1.202)	0.600 (−1.136 to 2.336)	1.400 (−.627 to 3.427)	−1.875[a] (−2.991 to −.759)	−1.500[a] (−2.834 to 0.166)
GDS-K[c]	−.500 (−2.170 to 1.710)	−.750 (−2.841 to 1.341)	−.533 (−3.070 to 2.003)	1.667 (−1.123 to 4.457)	−.625 (−4.692 to 3.442)	−2.250 (−4.857 to 0.357)

[a]Significance at *P*<.008 with Bonferroni correction.

[b]MMSE-KC: Mini-Mental State Examination in the Korean version of the CERAD assessment packet.

[c]GDS-K: Geriatric Depression Scale-Korean.

Among secondary outcomes, cognitive function measured by MMSE-KC was changed differently by groups. A significant interaction between groups and time was shown in group B (Table 2). However, this result was not replicated in 2-way ANOVA in which missing data were conservatively substituted with their forward values ($F(4, 4.04)=1.73$, $P=.15$). In post hoc intra-group analyses, a significant decrease in MMSE-KC score was found in the control group at 12 weeks and 24 weeks. On the other hand, cognitive function in groups A and B was maintained at a level similar to the baseline (Table 3).

For depressive symptoms (Korean version of the Geriatric Depression Scale), a significant group-by-time interaction was revealed in group B at the follow-up point, although it was not confirmed in 2-way ANOVA ($F(4, 11.51)=1.62$, $P=.07$). In post hoc within-group analyses, a significant decrease in depressive symptoms was found in MCI individuals of group C at 24 weeks.

Discussion

Principal Findings and Comparison With Previous Works

This study examined the effectiveness and feasibility of mHealth-assisted walking prescriptions in older adults with cognitive impairment. It is the first study to demonstrate the effectiveness of a clinic-based PA program using mHealth technology, including people with dementia. Participants who were provided walking prescriptions and feedback based on data from smart bands (group A) showed increased steps in their daily lives both at postintervention (12 week) and follow-up (24 week) periods, whereas participants who were provided smart bands without personal prescriptions (group B) showed an increase in step numbers immediately after the intervention; however, such effect was not sustained at follow-up. Meanwhile, steps of the control group (group C) continued to decrease over the course of this study. As a secondary outcome measure, general cognitive function also showed a decreased pattern in the control group, while participants in groups A and B did not show decreased scores during 6 months, although they were diagnosed with MCI and mild dementia.

Previous studies have reported that walking can improve physical function, such as aerobic capacity [46], and reduce mortality in older adults with cognitive impairment [26]. However, a recent meta-analysis of randomized clinical trials reported that walking did not significantly improve cognitive function in older adults with MCI [46], whereas most previous studies demonstrated that moderate-to-vigorous PA improves cognitive function [10-13]. However, there are other benefits to maintaining adequate step counts for cognitively impaired older adults. Maintaining walking performance, such as pace, has been known to be associated with a lower risk of cognitive decline [47] and improved activities of daily living in older adults [48]. Regular walking can help maintain a robust rest-activity rhythm in cognitively impaired older adults who are vulnerable to circadian disruption, which is associated with the progression of dementia [49]. Since walking itself has cognitive components, including attention and executive function [28], it can stimulate cognitive function in MCI and dementia patients. Maintaining PA is challenging for older adults with cognitive impairment: guiding and monitoring high-intensity PA is nearly impossible in a memory clinic setting. Even though prescribing walking is not sufficient for direct effects on cognitive improvement, it can be a good alternative for maintaining PA for MCI and dementia patients.

A recent meta-analysis has demonstrated that mHealth intervention can increase PA, with such effects maintained for a long term [50]. However, most of the previous studies intervened with young adults. Older adults have many disadvantages when applying mHealth technology. They are less skilled at operating devices. They also have lower levels of digital literacy, making it difficult for them to adopt self-directed exercise programs using mHealth technology. Furthermore, it is almost impossible to have older adults with cognitive impairment, especially those diagnosed with dementia, stick with the exercise on their own. On the other hand, because they regularly visit clinics for treatment, it is easier for clinicians to implement programs in a direct manner. It is important to consider that older adults with cognitive impairment might have difficulty performing complex exercise tasks and accurately recalling their activities. Therefore, this study designed a program that could use mHealth technology to prescribe walking, a simple form of PA, and provide clinician-led monitoring and feedback.

To the best of our knowledge, only a few studies have tested the effectiveness of mHealth-assisted PA intervention in older adults with cognitive impairment. A previous study has confirmed the effects of a mHealth brisk walking intervention in increasing moderate-to-vigorous activity in older people with cognitive frailty [25]. Similar to our study, that study also prescribed and provided feedback on individualized goals. However, it primarily used automated monitoring and feedback generated by a smartphone application. Subjects in that study were recruited from the community. They had mild cognitive impairment with a baseline step count of >12,000 steps. Compared to subjects in our study, who were recruited from hospitals, including those with dementia and those who had a baseline step count of around 4000 steps, subjects in that study were cognitively and physically healthy. Therefore, a relatively self-directed intervention might show effectiveness. Group B subjects of our study were given a smart band and asked to perform self-directed walking. Similar to group A, group B also showed an increase in steps after 12 weeks. However, at the 24-week follow-up, steps tended to decrease back to baseline. That is, the effectiveness of mHealth-guided walking without constant monitoring and feedback was not sustained over a long term in older adults with cognitive impairment. As the previous study only tested the effect after 12 weeks, it was hard to know if the effect was sustained or not. However, the present study's results suggest that mHealth-supported PA is effective in increasing daily steps when it is accompanied by human-driven feedback, at least in older adults with dementia-level cognitive impairment.

Another previous study has also examined the feasibility and effectiveness of a memory clinic-based walking prescription for individuals with cognitive impairment [24]. In that study, participants did not show an increase in their step count after

applying the mHealth-supported walking prescription, similar to our approach. The main difference between that study and ours was the prescribing protocol. The previous study asked participants to double their steps in 6 weeks while our participants were asked to increase their steps by 500 biweekly. If such an increase was not achieved, they repeated the same goal. Our final steps were set at a realistic number based on age-appropriate guideline [38]. In addition, we checked participants' step counts daily and gave timely feedback at least once a week, whereas the previous study had a fixed biweekly feedback schedule. For older adults with cognitive impairment, the individualized coaching protocol might be more important than the use of mHealth technology itself (such as how to prescribe, monitor, and provide feedback on exercise). Realistic goals, frequent interventions, and flexible approaches might be essential to ensure the effectiveness of the mHealth walking program.

The study also suggests the potential for mHealth-supported walking prescriptions to help maintain cognitive function in older adults with cognitive impairment. Although this program did not improve participants' cognitive function, MMSE scores of intervention groups (groups A and B) were maintained during the study period, whereas the control group, MCI individuals in particular, showed a significant decrease in this global cognitive function score. A number of previous studies have reported that moderate-to-vigorous PA is an effective modality for maintaining cognitive function in patients with dementia and for improving cognitive plasticity in older adults with MCI [51-53]. Although the mHealth-assisted walking prescription in this study did not increase participants' cognitive scores, it has the possibility to prevent further deterioration of cognitive function in older adults diagnosed with MCI and early dementia, at least for some time. Given that subjects were already experiencing pathologic cognitive decline, a realistic goal of a clinic-based program might be to delay the rapid progression. At the same time, even though the sample size of this study was calculated to be more conservative than the previous study of similar design, it may have been insufficient to confirm the effectiveness on cognition. Future studies should include a larger number of subjects and different intensities of PA to test the program's effectiveness on cognitive function.

The mHealth-guided walking prescription in the present study was confirmed to be feasible to use in a clinic-based environment. There were no adverse events in our program. The number of withdrawn participants did not differ among the three study groups. Walking is the most accessible form of PA for older adults. It can be done anywhere and anytime. It is also easy to personalize and monitor individuals' goals [54]. Techniques we used in this program can be replaced by any application that includes an accelerator. This mHealth-supported walking may be one of the easiest and simplest ways to apply a PA program to older adults having a cognitive problem. Only one dropped out due to difficulty in using a mobile device, although all participants had cognitive impairment.

Strengths

We designed a 3-arm randomized controlled study. Therefore, we were able to analyze the effectiveness of the program from multiple perspectives: technology use alone versus technology use combined with personalized coaching. We also validated this mHealth-based program in a well-defined population with MCI and mild dementia through comprehensive clinical assessments. Lastly, our program and protocol were confirmed to be feasible in a clinical setting. Only 1 coaching person managed all three study groups' participants at a time. The coach monitored group A individuals' steps from the webpage, provided feedback via text or phone at least once a week, and conducted monthly in-person sessions with all participants. Training the coach on the structured protocol to deliver the program took about 4 hours, and the time required for the coach to manage the participants averaged 2-3 hours per day for 6 months. Assuming that there are 20-30 older adults with cognitive impairment over a 6-month period, the program could easily be replicated in other centers with 1 staff member.

Limitations

This study has several limitations. First, the numbers of participants were small. Although the effectiveness of the primary outcome (changes in step numbers) was confirmed, larger numbers of subjects and differentiated intensity of PA interventions might be needed to confirm the effect on cognitive function. Second, participants and researchers were not blinded to which group individuals were in. However, it was not possible to blind them as different protocols were applied by study groups. In addition, 2 different researchers conducted baseline and follow-up assessments, respectively. Third, the effectiveness of the program could have been different between individuals according to their baseline activity levels. Although we adjusted baseline steps in the analyses of group-level comparison, different effectiveness by individuals needs to be examined in the future. This approach will allow us to develop more personalized guides for PA in older adults regarding the intensity, duration, and interval of exercise. Fourth, the smart band used in this study had yet to be validated. Even though the accelerometer is a simple feature commonly found on smart bands, lack of validation is a limitation of this study. Fifth, apathy may affect motivation and adherence to a PA program. This study assessed depressive symptoms and found no difference in baseline depressive symptoms between participants who completed the program and those who dropped out. However, future research needs to measure apathy, which may directly affect motivation levels, and explore its impact on the effectiveness of the PA program. Lastly, impact of caregivers' support and assistance on the effectiveness of this program was not assessed. As some caregivers were essential in getting older adults to adhere to our program, it should be included as an important factor in future studies [55].

Conclusions

Our findings suggest that walking prescriptions using mHealth technology can effectively increase PAs and maintain cognitive health in older adults with cognitive impairment. It is also feasible to apply this mHealth-assisted program to older adults with MCI and mild dementia in the clinic setting. However, the effectiveness of our protocol needs to be confirmed with larger samples and more personalized methods in the future.

Abstract

Background: Physical inactivity, which increases the risk of chronic diseases in older adults, is prevalent among older adults in Hong Kong. To address this problem, the Hong Kong government has been proactively promoting active aging.

Objective: Following the World Health Organization's strategy to prevent chronic diseases in older adults and aligning with the global goal of active aging, this study evaluated the effects of a 16-week light volleyball (LVB) intervention program on the physical health of older adults in Hong Kong.

Methods: A total of 276 participants aged ≥60 years were recruited and randomly assigned to 1 of 3 groups: an LVB intervention group, a Taichi control group (ie, with light physical activity), and a control group. Tests on components of fitness were conducted before and after the intervention.

Results: Participants from the LVB intervention group exhibited significant improvements in lower body strength ($F_{2,272}$= 7.23, P=.001, η^2=.05), agility ($F_{2,272}$= 6.05, P=.003, η^2=.043), and dynamic balance ($F_{2,272}$= 9.41, P=.001, η^2=.065) when compared with those from the Taichi active control group and control group.

Conclusions: To promote active aging among older adults in Hong Kong, the findings of this preliminary study, along with forthcoming follow-up tests, will provide health specialists and practitioners with valuable insights regarding the health benefits of the LVB community program for older adults.

Introduction

Given the low birth rate and increasing life expectancy in Hong Kong, the trend toward an aging population is expected to persist in the coming decades in this region. The number of individuals aged ≥65 years is projected to rise substantially, reaching 1.89 million by 2019 and 30.5 million by 2069 [1]. This continual demographic shift highlights several societal challenges, including a decline in the working population and an increased burden on Hong Kong's social welfare and health care systems. With an expanding share of older adults in the population, public health expenditure in Hong Kong is forecasted to increase by 394%, from US $4.9 billion in 2004 to US $24.4 billion in 2033, accounting for 5.5% of Hong Kong's total GDP in 2033 [2]. The simultaneous decrease in the working population and increase in social welfare expenditures for the aging population are expected to create severe financial strain for the Hong Kong government in the coming decades.

Although the benefits of physical activity have been well-documented [3], approximately 40% of older adults aged 60 years or older in Hong Kong engage in insufficient physical activity [4]. More than 50% of older adults in Hong Kong have overweight or obesity [5], and 75% have one or more chronic illnesses [6]. Additionally, older adults in Hong Kong spend an average of 7.5 hours sitting and 6.7 hours lying down daily [7]. Spiteri et al [8] identified various barriers to physical activity for older adults, including perceptions of negative consequences (ie, pain, risk of injury, and fear of falling), and a lack of knowledge and skills. Similar barriers to physical activity have been reported among older adults in Hong Kong. To address

these challenges, promoting active aging through physical activity is essential [9]. The World Health Organization (WHO) [10] introduced the "Active Ageing: A Policy Framework," warning that failure to address the aging population crisis could lead to the collapse of health care and social welfare systems. The Hong Kong government interprets active aging as achieving full physical, social, and mental well-being [6]. Since 2001, it has developed a healthy aging report outlining strategies to promote active aging, including physical activity initiatives. For instance, the Hong Kong government installed 150 new fitness equipment sets for older adults across Hong Kong between 2017 and 2018 to encourage active aging [11].

Meta-analyses have demonstrated that physical activity interventions have a significant effect on improving balance, reducing falls [12], and enhancing physical function [13] in older adults. Both supervised resistance and aerobic physical activity interventions have demonstrated positive effects on physical function outcomes. Future research directions include (1) increasing the number of physical activity interventions conducted in Asia, (2) aligning intervention programs with the WHO's recommendation of 150 minutes of physical activity per week, (3) using more rigorous randomized controlled trial designs, and (4) implementing supervised physical activity interventions with larger sample sizes in Asia [14,15]. Recent reviews have emphasized the need to examine the effects of sports interventions on older adults' health, particularly among Chinese older adults. Wong et al [16] reviewed 371 studies from the past 15 years on the effects of physical activity on older adults' physical health, and they recommended exploring the health benefits of newly emerging sports, such as light volleyball, in future research [16,17]. Franco et al [17] qualitatively reviewed the literature on older adults' perceptions of physical activity participation, suggesting that older adults prefer physical activity programs that are (1) professionally instructed, (2) group-based and conducive for peer interaction, and (3) highly accessible, with affordability being a key factor influencing the willingness to participate [17]. Similar findings were reported by Van Dyck et al [18], who highlighted older adults' preferences for innovative physical activity activities, such as aqua fitness or light volleyball, over traditional options, such as walking and cycling, in intervention programs.

Light volleyball (LVB) is a newly adapted physical activity derived from traditional volleyball. Compared with traditional volleyball, LVB uses balls with a larger circumference (80 - 83 cm vs 65 - 67 cm) and lighter weight (150g vs 250g), allowing the balls to travel at a slower speed. These features make LVB more accessible, particularly for individuals with reduced physical capacity due to age-related decline (eg, older adults). Additionally, the LVB court is smaller (similar in size to a badminton court), and the net is set lower (1.8 m), further reducing the physical demands on participants. Studies from China have reported physical health benefits associated with regular LVB practice; however, most of these studies did not have standardized fitness measurements and control groups. In 2020, the first author and her team conducted a quasi-experimental intervention to examine the effects of LVB on the physical and psychological health attributes of 78 older adults aged ≥60 years. The results indicated significant improvements in physical (ie, lower and upper body muscle strength, agility, balance, and aerobic endurance) and psychological (ie, physical activity enjoyment) attributes among participants in the LVB group when compared with the control group [19]. Furthermore, improvements in upper body muscle strength, aerobic endurance, and physical activity enjoyment were significantly more pronounced in the LVB group than in the active control group, which participated in Rouliqiu. That study highlighted the effectiveness of LVB intervention programs in enhancing both physical and psychological health attributes in older adults. Despite these promising findings, that study had notable limitations. First, its sample size was small, with only 62 participants completing the screening tests, pre- and postintervention functional tests, and data analysis. Second, participants were not randomly assigned to groups, which could have introduced selection bias.

Building on the positive results of the LVB pilot study and the prioritization of resource allocation for promoting active aging in Hong Kong, the first author and her team secured Research Impact funding amounting to US $0.95 million for further research in this area. This funding supported an investigation into the effectiveness of an LVB intervention on the physical and psychological health attributes of older adults in Hong Kong using both quantitative and qualitative methods and examining a larger sample size of approximately 300 participants. In this study, we present the preliminary results of this LVB intervention in our quantitative arm using the results from the pretest and posttest. In the current study, Taichi was selected as the intervention for the active control group because both Taichi and LVB are whole-body exercises originating from China and suitable for older adults [20,21]. Compared with the team-based LVB, Taichi is an individual exercise, which may lead to differing effects on older adults' health and quality of life [22]. Prior research suggests that older adults with greater social support are more likely to continue exercising regularly [23,24]. Community-based group physical activity interventions with increased social support have also been associated with greater beneficial effects and program adherence. Additionally, Taichi is a popular activity among Chinese older adults [25]. With LVB gaining traction in Hong Kong, Taichi serves as a relevant comparison, providing valuable insights into physical activity promotion among Hong Kong's older adult population. This study aimed to assess the effects of a 16-week LVB intervention compared with Taichi and a control group on two key outcomes in Chinese older adults aged ≥65 years: (1) functional fitness and (2) balance. The hypothesis was that both LVB and Taichi would result in significant and comparable improvements in these physical health attributes relative to the control group.

Methods

Study Design

A randomized controlled trial design was used to assess the effects of the LVB intervention on participants' physical health outcomes. Following the CONSORT (Consolidated Standards of Reporting Trials) guidelines (Checklist 1) [26], detailed information about the intervention can be found in our

previously published study protocol (trial registration number ChiCTR1900026657) [19]. The LVB group was compared against an active control group (ie, Taichi) and a control group. Participants were randomly assigned into LVB group, Taichi group, and control group in 1:1:1 ratio.

Study Intervention

The intervention program was conducted from mid-2021 to early-2023, with data collection performed at pretest (immediately before the intervention) and posttest (immediately after the intervention). The preliminary results presented here are based on pretest and posttest data only. Participants in the LVB and Taichi groups attended a 16-week training program consisting of two 90-minute sessions per week following the pretest. This intervention duration aligns with the guidelines of the Centers for Medicare and Medicaid Services of the US Department of Health and Human Services, which suggest that the health benefits of physical activity for older adults can be observed within 1 to 3 months after the start of a program [27]. In contrast, the control group was instructed to continue their usual daily activities while participating in monthly social gatherings (eg, health workshops) to control for psychosocial effects.

Participants

Participants were eligible for recruitment if they (1) were aged ≥60 years, (2) lived independently, (3) had no cognitive impairment, (4) had not participated in physical activity programs for 2 consecutive years prior to the program, and (5) had passing scores on the Abbreviated Mental Test (AMT) and Timed-up-and-go (TUG) test [28,29]. Specifically, individuals had to obtain a score of at least 6 out of 10 on the AMT to demonstrate sufficient cognitive capability and complete the TUG test within 20 seconds. Participants were ineligible for recruitment if they had steady hypertension (≥160/90 mmHg), arthritis, or neurological disorders.

Recruitment and Procedures

Participants were recruited through informational sessions conducted by the research team and advertisements placed in local neighborhood elderly centers. All participants were informed about the confidentiality of their personal data collected for the study and were assured they could withdraw from the program at any time. The research team sought consent from each participant before collecting data and proceeded immediately to conduct the AMT and TUG test to screen unqualified participants. After participants passed the screening tests, they completed the following steps: (1) questionnaires, (2) sociodemographic questions, (c) measurements of weight and body fat percentage using the Tanita machine (TBF-410GS), and (d) a functional fitness test based on the work of Leung et al [19,20]. After the pretest, an independent researcher used a computer-generated random number system to assign participants to the intervention conditions. Data collection and entry personnel were blinded to the group assignments of participants. The intervention program commenced the following week in sports complexes at community centers or community halls in Hong Kong and lasted for 16 weeks (approximately 3.5 months). The research team arranged the posttest for participants within 7 days after they completed the intervention program. All participants received a supermarket cash voucher worth US$ 12.84 as an incentive for their participation.

Ethical Considerations

The study was reviewed and approved by the Education University of Hong Kong's Research Ethics Committee (approval number E2022-2023-0013).

Measures

Functional Fitness

The research team used the Senior Fitness Test Manual to assess the physical attributes of older adults [30]. The test comprises 6 items: the chair stand test (lower body strength), arm curl test (upper body strength), chair sit-and-reach test (lower body flexibility), back-scratch test (upper body flexibility), 8-foot up-and-go test (agility and balance), and 2-minute step test (aerobic endurance). These have been demonstrated to be reliable, with intraclass correlation coefficients ranging between .80 and .98 in participant trials. Their validity has been supported through content, criterion-related analyses, and construct validation, including comparisons of senior fitness test scores with other established measures, such as treadmill VO2 testing [31]. Higher scores in the chair stand test (repetitions), arm curl test (repetitions), chair sit-and-reach test (cm), back-scratch test (cm), and 2-minute step test (repetitions) indicate higher levels of lower and upper body strength, flexibility, and aerobic endurance; the converse is the case for the 8-foot up-and-go test (seconds). For the flexibility assessments, negative scores reflect an inability to reach the toes during the chair sit-and-reach test or to make hand contact in the back-scratch test.

Balance Test

The Balance System SD (BBS-SD, 950 - 441 model) was used to measure the dynamic balance of older adults in the current study. Participants were asked to stand upright at the center of the platform while observing a screen situated 30 cm (approximately 11.1 in) in front of them. They completed three 20-second trials with 10-second breaks in between. The results of 3 trials were collected, and the mean values were recorded by the research team. The findings of previous studies support the reliability and validity of this balance test [32,33]. The measurement index and overall stability index generated by the Biodex balance system were included in the current study. These indices measured the participants' dynamic balance, specifically assessing their balance fluctuations across multiple axes. Higher values indicated greater deviations and poorer balance control.

Data Analysis

Data were analyzed using SPSS 27.0 software (IBM Corp). Descriptive statistics, specifically mean and SD values for continuous variables and frequencies and percentages for categorical variables, were used to describe the data. Preliminary checks were conducted to ensure that the assumptions of normality and homogeneity of variance were met. One-way ANOVA was performed to evaluate baseline differences between the groups. To examine the effect of the 16-week intervention program on physical attributes, a series of analysis of covariance tests were conducted, comparing the 3 groups

(LVB, Taichi, and control groups) at 2 time points (pre- and posttest). Body mass was used as a covariate because of its correlation with the outcome measures [34]. Partial eta squared (η^2), *P* values, and contrast *t*-statistics were calculated. Planned contrasts were used to analyze the differences between the LVB and control groups, and between the LVB and Taichi groups. Cohen *d* was calculated as a measure of effect size, with thresholds of 0.1 for a small effect, 0.3 for a medium effect, and 0.5 for a large effect [35]. Statistical significance was set at $P<.05$.

Results

Overview

Figure 1 presents the recruitment process for the current study. At the start of the intervention, 334 older adults from 7 elderly centers were enrolled in the program and completed the pretest. With simple randomization, there were 122 older adults in LVB group, 113 in Taichi group, and 99 in control group. A total of 3 participants (2 from the LVB group and 1 from the Taichi group) withdrew from the program because of personal reasons, and 7 others (2 from the LVB group, 1 from the Taichi group, and 3 from the control group) withdrew without providing any reason. Among the remaining 318 participants, 42 did not complete the posttest for various personal reasons (eg, illness, Lunar New Year gatherings, and concerns about social distancing during the late COVID-19 pandemic). This sample size met our calculated sample size for this intervention (with effect size of 0.5 [Cohen *d*]) in order to achieve a power of 80% at a significance level of 5% [19]. The retention rate was 82.6%, slightly higher than the expected 80%. Ultimately, 276 participants (LVB group, n=100; Taichi group, n=86; control group, n=90) who completed both the pre- and posttest were included in the final data analysis.

Table 1 presents the sociodemographic characteristics of the participants. Approximately 56% (156/276) of the participants were aged ≤70 years, and only 8% (22/276) were aged ≥80 years. The majority of the participants were female (229/276, 83%) and retired (217/276, 78.6%). Approximately 57.3% (158/276) had attained secondary education or higher. Approximately half (161/276, 58.3%) reported their financial status as average. The average BMI was 24 (SD 3.6) kg/m^2. The groups did not significantly differ with each other at the pretest with respect to all variables ($P>.05$).

[c]CG: control group.

Improvement in Physical Fitness

Table 2 presents the mean and SD values of physical measures for the groups at pre- and posttest, along with the results of analysis of covariance with repeated measures, with BMI controlled for. After the intervention, the LVB group achieved statistically significant improvements in lower limb muscular endurance (chair stand test, $F_{2,272}$= 7.2, P=.001, η^2=.05), agility (up-and-go test, $F_{2,272}$= 6.1, P=.003, η^2=.04), and dynamic balance (Biodex balance test, $F_{2,272}$= 9.4, P=.001, η^2=.07) compared with the other groups.

Pairwise comparisons revealed that both the LVB and Taichi groups exhibited significantly improved adjusted performance in lower limb muscular endurance (chair stand test, LVB group, mean 17.6, SD 5.0; Taichi group, mean 15.3, SD 4.9, P=.001), agility (up-and-go test, LVB group, mean 5.6, SD 1.3; Taichi group, mean 6.2, P=.001), and dynamic balance (Biodex balance test, LVB group, mean 0.5, SD 0.5; Taichi group, mean 0.7, SD 0.6, P=.001) compared with the control group (chair stand test, mean 15.3, SD 4.9; up-and-go test, mean 6.1, SD 1.2; Biodex balance test, mean 0.7, SD 0.5). Notably, the LVB group performed significantly better on all three measures (chair stand test, up-and-go test, and Biodex balance test) at posttest compared with the Taichi group. No significant group

differences were identified for the arm curl test ($F_{2,270}$=2.8, P=.1, partial η^2=.02), chair sit-and-reach test ($F_{2,270}$=0.06, P=.5, partial η^2=.005), and back scratch test ($F_{2,270}$=1.3, P=.3, partial η^2=.01), and 2-min step test ($F_{2,270}$=1.1, P=.3, partial η^2=.008).

Table . Mean and SD values for measures in groups at pre- and posttest.

Measures	LVB[a] (n=100), mean (SD)		TC[b] (n=86), mean (SD)		CG[c] (n=90), mean (SD)		*F* test (*df*)	Mean difference (95% CI)

Discussion

Principal Findings

Given the continued aging of the population in Hong Kong and the limitations of our previous LVB pilot study, the current study aimed to investigate the effect of a 16-week LVB intervention program on physical health outcomes among older adults. Compared with the pilot study, the current study used an randomized controlled trial design and recruited 5.45 times more participants. The results indicated that the LVB intervention had a greater effect on improving lower body strength, agility, and dynamic balance in older adults when compared with both the Taichi intervention and the control group. Although significant improvements in lower body strength, agility, and dynamic balance were identified in the LVB intervention group, no significant changes in aerobic endurance and upper body strength were identified.

Improvement in Physical Health

The current study hypothesized that the LVB intervention would lead to greater improvements in lower body strength, agility, and dynamic balance relative to the control. This expectation is supported by our pilot study in 2018, which revealed significant improvements in these physical attributes for the LVB intervention group when compared with the control group [20].

We also hypothesized that the LVB intervention would improve lower body strength, agility, and dynamic balance relative to Taichi. First, LVB shares several similarities with traditional volleyball, such as involving a considerable amount of lower body movement, which helps enhance lower body strength [36]. Second, LVB was expected to result in more significant improvements in agility and dynamic balance compared with Taichi. This is because LVB requires players to use open skills, enabling them to react and adapt to dynamic, constantly changing environments. In contrast, Taichi primarily involves closed skills, which do not require such adaptive responses to environmental changes [37]. Although there may be differences, Sheppard and Young [38] defined agility as the ability to change speed or direction in response to a stimulus, such as an environmental change. A recent systematic review comparing the effects of open-skill physical activity and closed-skill physical activity on cognitive function reported that open-skill physical activity was more effective in enhancing cognitive

function than closed-skill exercises were [39]. Furthermore, Young et al [40] suggested that agility is strongly linked to cognitive functions such as decision-making ability and perception.

Additionally, a strong correlation has been observed between lower body strength and the ability to change direction (change-of-direction ability) [41]. Recent research has demonstrated a significant correlation between relative and absolute strength and agility, including change-of-direction ability and linear speed [42]. In the current study, we also identified a correlation between lower body strength and agility. These were the 2 physical attributes for which more pronounced improvements were identified in the LVB intervention group than in the Taichi group. In addition to lower body strength, balance plays a crucial role in maintaining good posture during acceleration, deceleration, and sudden changes in location or direction. Balance training has been found to be beneficial in improving the agility of volleyball players [43].

Although the participants in the LVB group exhibited greater improvements in lower body strength, agility, and dynamic balance, an unexpected finding was the minimal differences in upper body strength and aerobic endurance, 2 physical attributes that were initially hypothesized to exhibit significant improvement in the LVB group compared with the Taichi group. For upper body strength, LVB involves more frequent and vigorous arm and shoulder movements relative to Taichi, such as spiking and blocking, which were expected to result in greater upper body strength improvements compared with Taichi [44]. Similarly, the higher energy demand in volleyball was assumed to lead to greater improvements in aerobic endurance in the LVB group compared with Taichi [45]. However, despite these expectations, no significant differences in improvements were observed between the LVB and Taichi groups for these two physical attributes. Nonetheless, both the LVB and Taichi programs were demonstrated to improve upper body strength and aerobic endurance in older adults, although LVB did not significantly outperform Taichi as was hypothesized. Previous studies have indicated that both LVB and Taichi can be beneficial for improving upper body muscle strength in older adults [19,44]. Regarding aerobic capacity, although we assumed that volleyball would require higher aerobic endurance,Taichi's breathing techniques were found to be beneficial for improving aerobic capacity in older adults, providing benefits similar to those achieved through LVB [46].

Limitations

Although this study addressed the limitations of the previous pilot study, it still has several limitations of its own. First, these are only preliminary findings, and the scheduled follow-up evaluation in 6 or 12 months will help determine whether these advantages are seen or sustained over the longer term after the intervention. Second, the gender representation was disproportionate; the number of female participants was higher because recruitment was conducted through local elderly centers. These centers in Hong Kong have predominantly female memberships, with older women showing a greater tendency to participate in activities [47,48]. This imbalance in gender representation limits the generalizability of the findings. Furthermore, the study was conducted during the COVID-19 pandemic and the proposed intervention period was postponed from 2020 - 2022 to 2021 - 2023, which may have introduced variables that are not typically present in nonpandemic conditions. These factors could have affected the results of the interventions.

Conclusions

The current study examined the effects of a 16-week LVB intervention program on the physical health of older adults in Hong Kong. The results indicated that the participants in the LVB group experienced significant improvements in lower body strength, agility, and dynamic balance compared with both the Taichi active control group and the control group. This study builds on the previous pilot by adopting an randomized controlled trial design, incorporating dynamic balance as a fitness component, increasing the sample size, and collecting data from 7 local elderly centers instead of just one.

Future studies should address the following: first, studies should aim for more balanced gender representation and include follow-up tests to monitor the long-term maintenance of physical improvements. Numerous studies have highlighted the positive effects of physical activity on aspects such as cognition and psychology in older adults, whereas the current study focused solely on physical attributes. Future research could explore the effects of LVB on cognitive and psychological outcomes to provide a more comprehensive understanding of its benefits. Furthermore, future studies should consider qualitative approaches to understand participants' experiences and assess how LVB intervention influences various health dimensions. Given the potential limitations due to the COVID-19 pandemic, future studies may benefit from replication under more stable conditions, free from social distancing policies, to determine whether similar results can be observed. In conclusion, this large-scale study provides strong evidence supporting the physical health benefits of LVB for older adults. The results from our future qualitative studies and follow-up measures will further inform researchers and practitioners about the acceptability and appropriateness of LVB interventions for older adults.

Abstract

Background: Mobile apps and peer support are known to effectively promote physical activity in older adults, which, in turn, improves physical function. Previously, we investigated the feasibility and impact of using digital peer-supported apps (DPSAs) to increase physical activity among older adults over a 3-month period. However, the long-term feasibility and impact on sustainable behavior change remain unknown.

Objective: This study aims to evaluate the 12-month feasibility of the DPSA and to obtain preliminary estimates of its effects on physical activity and physical function among older Japanese adults.

Methods: This nonrandomized controlled trial recruited older adults aged 65 years or older from 2 physical activity programs. Participants chose either the intervention (app program + exercise instruction) group or the control (exercise instruction only) group. Only those participants who had completed the 3-month intervention and wished to continue in the 12-month follow-up intervention study were included. DPSA feasibility was assessed using retention and adherence rates. Physical activity was assessed using accelerometers, capturing daily step count, light-intensity activity, moderate to vigorous intensity activity, and sedentary behavior. Physical function was evaluated using grip strength and the 30-second chair stand test (CS-30). Accelerometer measurements were collected every 3 months over 12 months (5 time points, including baseline), whereas physical function was measured at baseline, 3 months, and 12 months.

Results: The follow-up study included 44 of 66 participants from the 3-month intervention study, with 26 participants in the intervention group and 18 participants in the control group. The 12-month retention rate for participants in the DPSA intervention group was 73% (19/26), whereas the retention rate among all 41 participants, including those who chose not to participate in the follow-up study, was 46% (19/41). The adherence rate was 85.9%. The average number of steps per day (95% CI) in the intervention group changed before and after DPSA use (P=.048). We observed an increase of 1736 (β=1736, 95% CI 232-3241) steps per day compared with baseline. No significant change was observed in the control group. There were significant within-group differences in CS-30 scores for both intervention (P<.001) and control (P=.03) groups over the 12-month period. Specifically, there was a significant change in CS-30 scores (95% CI) between the baseline and 12-month assessments for the intervention (β=6.5, 95% CI 3.8-9.1; P<.001) and control (β=3.8, 95% CI 0.6-7.1; P=.02) groups.

Conclusions: Participants with long-term DPSA use observed increases in average daily steps and CS-30 scores before and after DPSA use, although only a limited number of older adults had long-term access to the DPSA. Identifying ways to expand long-term DPSA use among older adults is necessary. Additionally, randomized controlled trials should be conducted to determine the long-term effects of DPSAs on physical activity and function in older adults.

Introduction

Background

The world's population is aging at an unprecedented rate [1]. The number of adults older than 65 years has tripled over the past 50 years, and by 2050, older adults are expected to account for a quarter of the global population [2-4]. Japan has a high proportion of older adults: 29.1% of the total population was aged 65 years or older in 2023 [5]. Healthy aging is a global health care challenge as population aging accelerates [6]. Regular physical activity aids in reducing the risk of noncommunicable diseases [7] and is associated with improved physical health [8] and increased life expectancy [9]. However, despite decades of public health interventions, the global physical activity level has remained stable or even declined, making it an important health policy challenge [10]. Given the world's aging population and the health benefits of physical activity, it is critical to promote regular physical activity among older adults. The Japanese guidelines for physical activity [11] recommend a minimum of 15 metabolic equivalent (MET) hours per week of physical activity with an intensity of at least 3 METs in older adults. Physical activity of 15 MET hours per week can be converted into steps, which is more than 6000 steps per day [11]. However, few older adults meet this recommendation: among men, 45% of those aged 65 - 74 years, 32% of those aged 75 - 84 years, and 11% of those aged 85 years or older meet this recommendation, and among women, 38% of those aged 65 - 74 years, 22% of those aged 75-84 years, and 5% of those aged 85 years or older meet this recommendation [11]. Regular physical activity improves physical function in older adults [12]. Declining physical function is linked with the loss of mobility and activities of daily life, which are core dimensions of physical disabilities [13,14], and thus, both physical activity and physical function need to be improved.

Recently, mobile apps have been successfully used to increase physical activity levels [15,16]. eHealth, or electronic health, encompasses health care services supported by information and communication technology, including computers, mobile phones, and satellite communications, for health services and information. Moreover, mHealth, or mobile health, refers to the use of smart or portable devices for providing health services and information [17]. These interventions for older adults have been shown to be effective in increasing the time spent in physical activity, energy expenditure in physical activity, and steps walked [18,19]. In a review comparing mHealth with face-to-face interventions, interventions that included mHealth were shown to have increased steps and total physical activity, but there was no observed difference in physical function [20].

In the systematic review by Duan et al [21], eHealth interventions for physical activity have shown that theory-based interventions are more effective than non–theory-based interventions. The transtheoretical model and social cognitive theory were the top 2 most frequently supporting theories, and the studies included in this systematic review with the largest effect sizes were based on these 2 theories [22]. The social cognitive theory proposed by Bandura [23] stipulates that behavior is learned by observing and imitating others. This process is called observational learning or modeling and has been extensively studied in the context of motor skill development and education [24-26]. Self-efficacy, an important aspect of social cognitive theory [23], is an crucial determinant of exercise persistence and outcomes; interventions based on self-efficacy can promote exercise participation [27].

The effectiveness of peer support interventions for physical activity is often explained by social cognitive theory [28]. Webel et al [29] defined peer support as "a method of teaching or facilitating health promotion that makes use of people sharing specific health messages with members of their own community." Our previous study using a digital peer-supported app (DPSA) framed by the social cognitive theory showed that the feasibility of the DPSA was adequate and that the number of daily steps and the level of moderate to vigorous intensity physical activity (MVPA) increased in older participants [30]. There are 2 main types of peer support [31]: the first includes methods related to education and information, such as peer tutoring and mentoring; the second is the emotional support provided by peers. Our research is based on peer support interventions that provide emotional support. Peer support is provided by comparable peers and promotes physical activity in ways that cannot be done by professionals or family members; Burton et al [32] reported that peer support increased adherence to an exercise program; Ginis et al [28] reported that peer support was as effective as professional intervention. Peer support may be cost-effective when considering the expense of paying professionals [33]. Peer support through the DPSA includes social support, which contributes to the success of eHealth and mHealth interventions for increasing physical activity among older adults [34]. In addition, DPSA interventions do not require in-person gatherings, thus reducing constraints owing to scheduling issues, meeting locations, and costs (eg, transportation) [35]. Thus, the DPSA may be effective in promoting physical activity among older adults. However, our previous study was a short-term intervention of 3 months, and the long-term feasibility and impact for sustainable behavior change remains unknown.

Three of 4 review studies concluded that mHealth or eHealth interventions are effective over short term (1 - 6 months) in promoting physical activity in adults aged 50 years or older [34]. All 3 reviews incorporated randomized controlled trials (RCTs) comparing interventions that were not eHealth or mHealth (eg, paper-based intervention, professional face-to-face intervention, and group face-to-face intervention), or no intervention. Despite the demonstrated long-term health benefits of physical activity [36], long-term empirical evidence of

mHealth and eHealth, beyond 6 - 12 months, remains scarce [37-39]. Furthermore, no study has continued the app intervention for 12 months and collected device-based physical activity measures in community-dwelling older adults older than 65 years [40]. Physical activity interventions for older adults often face challenges regarding long-term participation owing to age-related health decline, low self-efficacy, and poor geographic access to physical activity spaces [41,42]. There is a need to test the long-term effectiveness of the DPSA in promoting physical activity among older adults. However, before testing the long-term effectiveness of the DPSA on a large scale, a reasonable first step is to examine the feasibility and preliminary changes in physical activity, physical function, and self-efficacy in community settings. We hypothesized that 1 year of DPSA use would increase physical activity owing to increased self-efficacy for exercise. We also expect that the increase in physical activity will be accompanied by an increase in physical function.

Objectives

This study was a 12-month longitudinal study of participants in a 3-month DPSA intervention study who volunteered to participate in a follow-up study. The objectives of this study were twofold: (1) to evaluate the feasibility (retention and adherence rates) of using the DPSA to promote physical activity in older adults over a 12-month period, and (2) to measure preliminary estimates of the effects of physical activity, physical function, and self-efficacy for exercise through the use of the DPSA.

Methods

Study Design

This study is a nonrandomized controlled trial of 2 groups conducted over 12 months and is a follow-up study of a 3-month intervention trial [30]. This study was conducted in Fujisawa City, Kanagawa, Japan. Fujisawa City is in the southeastern part of Kanagawa and is an urban area close to Tokyo. As of April 2023, the city had a population of 445,291; of those, 24.5% (109,005) were aged 65 years or older. The percentage of older adults in the total population is increasing year by year [43]. This study was conducted as a collaboration between local governments, mobile app development companies, and universities. Industry-government-academia collaboration is important to further scientific research that is relevant to real-world community issues [44,45].

Ethical Considerations

This study was approved by the research ethics committee of Sports Medicine Research Center at Keio University (approval no. 2022 - 07). Informed consent for the follow-up study was obtained from all participants in the 3-month intervention study. The data obtained were anonymized. The study protocol was registered in the University Hospital Medical Information Network (UMIN000050618).

Participants

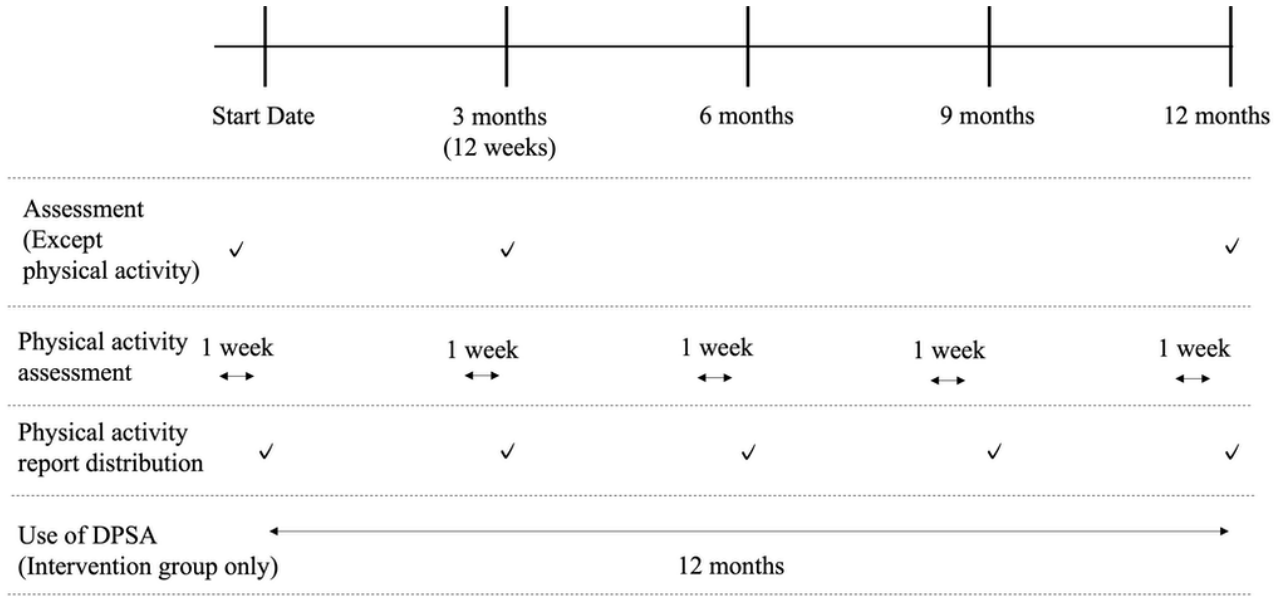
The study included Fujisawa City residents aged 65 years or older. In Japan, older adults are generally defined as persons aged 65 years or older [40]. We recruited participants for two 3-month programs designed to increase physical activity [30]. Participants from 2 different areas within the municipality of Fujisawa City were recruited through flyers, local newsletters, and calls to related organizations. Participants chose either intervention (app program and exercise instruction) or control (exercise instruction only) group. The 3-month intervention study [30] included 74 participants (intervention group: 41, control group: 33). The follow-up study was introduced to 66 participants who completed the 3-month intervention. Participants (n=8) who did not provide their informed consent were excluded from the follow-up study. The eligibility criteria were adults aged 65 years or older who could walk independently and perform daily activities without being advised by a physician to refrain from physical activity (self-reported criterion). Prospective participants were screened using a personal health status questionnaire based on the Physical Activity Readiness Questionnaire [46-48] to ascertain any potential health problems with study participation. Because the purpose of this study was to assess feasibility and obtain preliminary estimates, sample size was not calculated; the number of participants was limited because the study was conducted in collaboration with the local government.

Intervention

Program

Regardless of program selection, all participants underwent face-to-face exercise instruction, program introduction, and baseline assessment by a physical therapist or health fitness instructor. Exercise instructions focused on aerobic, stretching, muscle strengthening, and balance exercises based on the original “Fujisawa + 10 exercise” program [49,50]. The timeline of the study procedure is shown in Figure 1. Both intervention and control groups were instructed to increase their daily physical activities. The participants completed surveys and physical function measurements at baseline (start date), 3 months, and 12 months postintervention. Additionally, physical activity levels were measured every 3 months, 5 times in total, using triaxial accelerometers. Individualized physical activity reports were generated from the collected data and provided as feedback to the participants. The intervention group began using the app 1 week after the baseline outcome assessment.

Figure 1. Timeline of 12-month intervention procedure. DPSA: digital peer-supported app.



Digital Peer-Supported App

This study used Minchalle, a commercially available DPSA [51]. This mobile app was developed in June 2015 by A10 Lab Inc, with an initial release in November 2015. Figure 2 shows a sample app screen. The DPSA creates a group chat for up to 5 people with a common goal, and participants anonymously interact with each other in the group. The common goal of the intervention group was to increase their physical activity by walking and exercising. Once a day, participants posted their step counts, photographs, and comments in a group chat box. The main functions of the DPSA used in this study were as follows: (1) posting photographs, step counts, and comments about the day, (2) reaction buttons from group members (Figure 2), (3) setting step count goals on a group basis, and (4) providing feedback on the group's total daily step count. Step counts were measured using a smartphone, and the DPSA reported the number of steps taken on that day at the time of posting. The participants were asked to carry smartphones throughout the day while they were awake. Participants had the option to post comments or photographs multiple times a day and engage with other members. The mobile app was provided to the participants free of charge. Details of the DPSA's functionality are summarized in Multimedia Appendix 1.

Figure 2. Examples of mobile app screens. (**A**) A group is selected. (**B**) Photographs, step count, and comments are posted on the group. A photograph taken that day is posted and comments are added on the day's events. (**C**) Contents of the posts are displayed in the group. The total number of steps for the group is displayed. (**D**) Responses to posts by group members.

Characteristics of Research Participants

In addition to general characteristics, such as age and sex, the survey enquired about smartphone ownership, frequency of app use (except DPSA), and exercise habits. Body weight (kg) was measured using a digital scale, and height (m) was measured with a stadiometer after removing shoes. BMI was calculated as body weight divided by the square of height. Exercise habits

were considered as "those who exercised at least twice a week for 30 minutes or longer each time for at least 1 year" [52].

The frequency of neighborhood interaction was assessed by asking the participants how many times they interact with people in the neighborhood within 1 week. Group exercise participation was defined as study participants who participate in a group of 3 or more people who meet voluntarily to exercise.

DPSA Feasibility

DPSA feasibility was assessed based on retention and adherence rates during the year of program implementation. The retention rate indicates how many of the participants continued to use the DPSA for 12 months. The adherence rate indicates how often participants used the DPSA during the intervention period. The DPSA used in this study excludes a person from a group if they have not posted a set of step counts, photographs, or comments for 15 consecutive days. Dropouts were defined as those excluded from the group during the 12 months of DPSA use by researchers. Retention rates were calculated using a population of 26 participants in the intervention group and a population of all 41 participants who decided not to participate in the follow-up study. The retention rate was considered good if it was ≥70% (≥29 retention out of 41) based on previous studies by Farrance et al [53] and Picorelli et al [54]. The adherence rate was calculated by dividing the number of sets of step counts, photographs, and comments posted during the intervention period by the duration of the intervention. Adherence was calculated as the percentage of both participants, including dropouts and not including dropouts. Considering that the adherence rate for participants in the 3-month program was 87.7% [30], an adherence rate of ≥80% was considered good. The adherence rates were also calculated by group (7 groups: A-G). The number of all chat posts per person by group was calculated to assess the degree to which the group was used. The observed negative physical conditions during the intervention were ascertained by interviewing participants 12 months later. The app developers and the municipality were available to support the participants for any privacy breaches and technical issues.

Outcome Measure

To assess physical activity, participants were asked to wear a triaxial accelerometer [55] (Active Style Pro HJA-750C activity meter; Omron Healthcare) at the waist level for 7 consecutive days for a total of 5 times every 3 months starting before the intervention. This accelerometer provides a relatively accurate measure of physical activity in healthy older adults [56]. Participants were instructed not to remove the device unless required for certain tasks, such as changing clothes and bathing. At the end of the measurement, all the data collected were transferred from the accelerometer to a personal computer. Following the suggested method [57] for estimating physical activity, an individual was required to record ≥10 hours of activity per day for 3 days to be included in the subsequent analyses. The data were collected in 60-second epochs for data analysis and used to estimate the intensity of the activity (METs). Outcome measurements of physical activity included the mean daily step count and time spent in sedentary behavior (SB: ≤1.5 METs), light-intensity physical activity (LPA: 1.6 - 2.9 METs), and MVPA (≥3 METs) per day. The number of steps reported to the group chat in the DPSA was measured by the smartphone but was not used as an outcome.

Physical function was assessed using grip strength and the 30-second chair stand test (CS-30). The grip strength was measured using a digital dynamometer (Grip D; TKK 5401; Takei Scientific Instruments). This digital dynamometer was reliable and was validated relative to the Jamar dynamometer, which is the most frequently cited instrument for assessing grip strength in adults aged older than 60 years [58]. Measurements were taken in the standing position with the elbow joint in extension and the wrist joint in midextension. The left and right hands were measured once, and the highest value was used for data analysis. For the CS-30 test [59], seated participants were instructed to stand up from the chair with their arms crossed at the chest level as many times as possible in 30 seconds. The CS-30 has been reported to be quite reliable and valid as an indicator of lower-limb function in older adults [59].

Self-efficacy for exercise consisted of 4 questions on self-confidence in exercising under the following conditions [60]: physical fatigue, mental stress, lack of time, and bad weather. In response to the question, "Do you have the confidence to exercise regularly under the following conditions?" participants were asked to select 1 of 5 answers ranging from "No, I don't have any confidence at all (1 point)" to "Yes, I am quite confident (5 points)." The total score ranged from 4 to 20.

Statistical Analysis

This study used intention-to-treat analysis. Participant characteristics between groups were compared using independent sample *t*, chi-square, and Mann-Whitney *U* tests. Fixed-effects models were used because of the intensive repeated-measures design [61]. The advantage of this method is that it can handle nested observations, unbalanced numbers of observations, and missing values [62]. Although it would have been desirable to use a model that included random effects in this study, sample size limitations impeded the convergence of the mixed-effects model, and thus, we applied a model with fixed effects only. Yet, the fixed-effects model is still capable of capturing changes in the repeated measures in the outcomes. On a related note, linear mixed-effects models can be used with small sample sizes [63,64]. Between-group differences (intervention vs control) were analyzed using fixed-effects models adjusted for baseline age, sex, and app usage frequency (at baseline). The interaction between the groups and the time of the intervention was then analyzed.

Subsequently, the effects of the intervention for each group were analyzed using linear mixed-effects models, and significant differences compared with preintervention were evaluated using the Bonferroni method (accelerometer data were adjusted for wear time). Dependent variables, such as daily step count, SB, LPA, MVPA, grip strength, CS-30, and self-efficacy for exercise, were analyzed in separate models. Although the daily step count distribution did not precisely follow the normal distribution, the consistent results were obtained when applying a square root transformation, and, therefore, the results without the square root transformation are presented for interpretation.

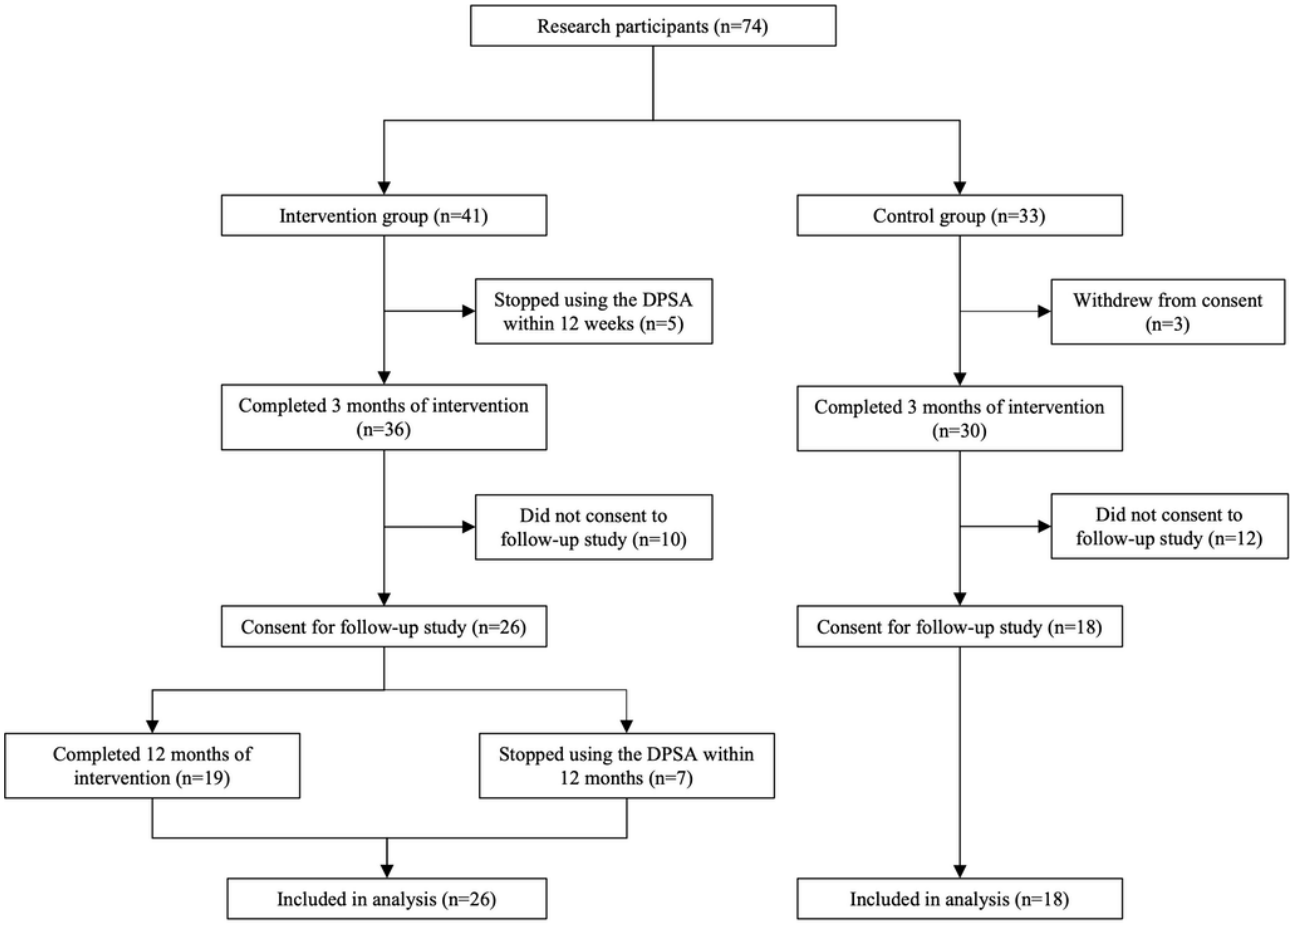
Data were analyzed using IBM SPSS Statistics 29 (IBM). The statistical significance level was set to 5%.

Results

Participants

The follow-up study included 44 of 66 participants from the 3-month intervention study. Of these, 26 were in the intervention group and 18 in the control group (Figure 3). The intervention group consisted of 7 groups of 3-4 people.

Figure 3. Flow diagram of participant enrollment and follow-up. DPSA: digital peer-supported app.



Participant Characteristics

Table 1 shows the baseline participant characteristics. The mean age (SD) of the participants in the intervention group was 75.1 (5.1) years, with 13/26 men (50%). In the control group, the mean age was 77.4 (SD 5.3) years, with 6/18 men (33%). Although the participants were relatively older (average age of 76.0 years), both groups consisted of active older adults who had regular exercise habits, engaged in active interactions with their neighbors, and had no health problems that would interfere with study participation. No statistically significant differences were observed in the baseline demographic characteristics between the intervention and control groups. Although statistically significant differences were not observed arguably owing to the small sample sizes, the intervention group had larger proportions of smartphone ownership and app use frequency.

Table . Participant characteristics.

Characteristics	Total sample (n=44)	Intervention group (n=26)	Control group (n=18)	*P* value

[a]Analysis was conducted using the independent samples *t* test (2-tailed).

[b]Analysis was conducted using the chi-squared test.

[c]Exercise habit was defined as exercising at least twice a week for ≥30 minutes each time for ≥1 year.

[d]Analysis was conducted using the Mann-Whitney *U* tests.

[e]LPA: light-intensity physical activity.

[f]MVPA: moderate to vigorous intensity physical activity.

[g]SB: sedentary behavior.

[h]CS-30: 30-second chair stand test.

Feasibility: Retention Rate, Number of Posts, and Negative Impact

The retention rate among the 26 participants in the intervention group was 96% (25/26) in the 6th month, 92% (24/26) in the 9th month, and 73% (19/26) in the 12th month. The retention rate, based on 41 participants, all of whom did not participate in the follow-up survey, was 61% (25/41) in the 6th month, 59% (24/41) in the 9th month, and 46% (19/41) in the 12th month; thus, this retention rate was <70% at the beginning of the follow-up study. The reasons for dropping out of DPSA were “contracted COVID-19 and stopped submitting” (n=1), “unknown cause” (n=2), and “after discussion in a group chat, everyone stopped using DPSA” (n=4).

The adherence rate and number of total posts per day among members of the intervention group are summarized in Table 2. The adherence for the DPSA was 85.9%. The total number of chats per person averaged 2.55 (SD 1.28) per day. Excluding dropouts, the adherence rate was 92.3%, with a total of 2.88 (SD 1.24) posts per day per person. Adherence rates were good among participants in the follow-up study. One group had all members drop out; all members of the group were male. Three cases of mild physical discomfort that did not interfere with daily life were reported, with 2 participants reporting knee pain and 1 reporting foot pain.

Table . Digital peer-supported app adherence rate and number of total posts per day among members of the intervention group.

	All participants (n=26)		Excluding dropout (n=19)	
Group	Adherence rate, n (%)	Total posts/person /day, mean (SD)	Adherence rate, n (%)	Total posts/person /day, mean (SD)
All	26 (85.9)	2.55 (1.28)	19 (92.3)	2.88 (1.24)
A	4 (86.3)	1.40 (0.33)	4 (86.3)	1.40 (0.33)
B	4 (95.4)	2.61 (0.77)	3 (99.1)	2.63 (0.94)
C	4 (75.0)	1.17 (0.41)	All dropouts	All dropouts
D	4 (98.6)	2.24 (0.58)	4 (98.6)	2.24 (0.58)
E	3 (84.7)	4.17 (0.22)	3 (84.7)	4.17 (0.22)
F	4 (85.4)	3.28 (0.63)	4 (85.4)	3.28 (0.63)
G	3 (75.9)	3.66 (2.10)	2 (99.6)	4.74 (1.38)

No privacy breaches were associated with app usage. There were 2 inquiries from participants, including account transfer after a smartphone model change (about 30 minutes) and uninstallation of the DPSA (about 20 minutes).

Changes in Physical Activity and Function and Self-Efficacy for Exercise

Table 3 shows the analysis results. In the group comparison of the linear mixed-effects model analyses of physical activity and function and self-efficacy for exercise, no differences were observed. However, a significant change was observed in step count over time only in the intervention group (P=.048), wherein we observed an increase of 1736 (β=1736, 95% CI 232-3241) steps per day compared with baseline. LPA and SB showed differences in the control group, but no significant difference was noted at any time point compared with baseline. Regarding the CS-30, there was a significant within-group difference in the increase in CS-30 scores for the intervention (P<.001) and control (P=.03) groups over the 12-month period. Additionally, the change in CS-30 scores between the baseline and 12-month assessments was 6.5 (β=6.5, 95% CI 3.8-9.1) times in the intervention group (P<.001) and 3.8 (β=3.8, 95% CI 0.6-7.1) times in the control group (P=.02). Regarding the self-efficacy for exercise, a significant change over time was observed only in the intervention group (P=.03), wherein an increase of 1.6 (β=1.6, 95% CI 0.2-3.1) points was observed after 12 months compared with baseline (P=.03).

Table . Included outcome measures at baseline and 3, 6, and 12 months with within-group and between-group comparisons (26 participants in the intervention group and 18 participants in the control group).

Outcome measures	Intervention			Control			Group × time[a]
	Comparison with baseline		Within-group changes	Comparison with baseline		Within-group changes	
	β (95% CI)	*P* value	*P* value	β (95% CI)	*P* value	*P* value	*P* value
Steps per day[b]			.048			.08	.25
Baseline	Reference

[a]Analyses were adjusted for age, sex, and frequency of app use (baseline).

[b]Triaxial accelerometer data were adjusted for wear time.

[c]LPA: light-intensity physical activity.

[d]MVPA: moderate to vigorous intensity physical activity.

[e]SB: sedentary behavior.

[f]CS-30: 30-second chair stand test.

Discussion

Principal Results

This study aimed to confirm the feasibility of a 12-month intervention using the DPSA to improve physical activity among older adults and to obtain preliminary estimates of its effects on physical activity, physical function, and self-efficacy for exercise. The retention rate in the intervention group (n=26) over the 12-month period was 73% (19/26). Considering the 41 participants who did not express interest in the follow-up surveys as the denominators, the retention rate was 46% (19/41). The adherence rate was 87.7%. This study obtained preliminary estimates of the effects of DPSA use on physical activity, physical function, and self-efficacy for exercise.

Comparison With Previous Studies

This is a rare study that examined the 12-month long-term feasibility and changes of an app intervention aimed at promoting physical activity in older adults. The 26 participants in the intervention group who used the DPSA had a 12-month retention rate of 73%. Including participants who did not indicate a desire for a follow-up survey, the 12-month retention rate was 46%. A previous study that used a smartphone app and smart band for weight loss, physical activity, and caloric intake in an overweight and obese population aged between 20 and 65 years for 12 months reported a 12-month retention rate of 68.4% (227/332) [65]. Moreover, a previous study of adults aged 30 - 60 years on physical activity and weight loss in Japan using a smartphone app focused on steps reported a 12-month retention rate of 95% (52/55) [66]. Compared with that reported by these previous studies, the 12-month retention rate was lower. The low retention rate might have been because the study included older adults who were less familiar with the app than younger adults [67], and daily posting may have been stressful for participants with the limited app experience. Only about half of the older adults were capable of long-term retention in the DPSA. One of the 7 groups had all its members drop out; this group was unique in that all members were males. Groups comprising a mix of male and female members may last longer. Group chat members with fewer posts, indicating lower engagement, tended to drop out. The following strategies can be adopted to prevent dropouts: providing opportunities for interactions among group members, encouraging people to make supportive posts to each other, and providing canned messages, such as greeting and appreciation messages, to allow group chat members communicate with each other through simple operations. Only 3 negative physical effects were reported; however, they were all minor and did not cause privacy issues.

In this study, significant changes in the number of steps taken and the self-efficacy for exercise score (Table 3) were observed

within the intervention group, but there was no significant difference between groups. Self-efficacy is an important aspect of social cognitive theory [23]. As hypothesized, peer support based on social cognitive theory improves self-efficacy for exercise, resulting in increased steps. In the intervention group, an increase of more than 1000 average daily steps was observed. Increasing the number of steps taken daily by ≥1000 reduces the risk of various diseases and mortality [68,69] . A systematic review of 17 prospective studies by Hall et al [68] showed that each 1000-step increase in the daily step count decreases the risk of death and heart disease, with a 6% - 36% decrease in all-cause mortality risk and a 5% - 21% decrease in heart disease risk. Furthermore, an increase of 1000 steps per day decreases a woman's risk of diabetes by 6% and an increase of 2000 steps per day decreases the risk of diabetes by 12% [69]. Although there was an increase in MVPA in the 3-month intervention, there were no significant differences within groups in this study. However, MVPA increased by 10 (95% CI −3 to 22) minutes per day at 12 months compared with baseline. This result may be an effect of the small sample size. Peer support can build trust and provide social support through interpersonal communication [70]. In peer-based intervention strategies aimed at promoting physical activity among older adults, social support is considered a key factor in facilitating behavior change [71]. In this study, social support through peer support may have influenced physical activity levels. However, the evaluation of social support provided by the DPSA was lacking and should be addressed in future research.

In this study, CS-30 scores changed from baseline to 12 months for both intervention and control groups (Table 3), but no significant differences were observed between groups. In the intervention group, long-term continuation of the DPSA may have increased self-efficacy for exercise and the number of steps taken, leading to improved lower limb function. The DPSA may be effective as a means to improve lower limb function. This is a meaningful result because improving lower limb function may lead to the prevention of falls [72,73], sarcopenia [9,74,75], frailty [74,76], and dementia [34,72,77], and may also lead to reductions in health care costs associated with these conditions [78]. The control group also improved lower extremity function with an increase in CS-30 scores. Older adults in the control group did not use the DPSA. They attended exercise instruction and continued regular physical activity monitoring with an accelerometer. The improvement in lower limb function may have been due to voluntary physical activity or strength training that could not be adequately measured with an activity meter. The DPSA is not for everyone, as it requires possession of a smartphone and an understanding of its usage. It may be important to select a menu of interventions that is tailored to the characteristics of the participants.

Limitations

This study has the following 4 limitations. First, the study design was less capable of demonstrating the effects of the DPSA, compared with an RCT. Participants were nonrandomly assigned to the intervention and control groups and free to choose the group in which they would participate. Older adults who did not own a smartphone were unable to participate in the intervention group, and those unfamiliar with the app's operation were less likely to join. Given that this was a non-RCT, fully accounting for possible confounding bias was challenging, making it difficult to accurately estimate the intervention's effect by comparing the 2 groups. Additionally, follow-up participation was voluntary. The use of the DPSA is applicable to only eligible older Fujisawa City residents who own smartphones and are interested in mobile apps.

Second, the sample size was small. The follow-up participation rate was 63% (26/41) in the intervention group and 55% (18/33) in the control group. This low participation rate reduces the study's validity and may have impacted the feasibility and estimates of the effects on physical activity, physical function, and self-efficacy for exercise. The small sample size might have resulted in insufficient statistical power to detect differences between groups, and the model parameter estimation might have been unstable. Furthermore, the small sample size did not allow the convergence of the mixed-effects model. The older adults in this study took more steps per day and were originally sufficiently physically active compared with the general healthy older adult population [79]. The mean baseline score for adults in Japan aged 60 years or older for CS-30 score was 17.3 times [80]. At baseline, the intervention group averaged 20.4 times and the control group averaged 19.6 times. The study participants originally had the adequate level of lower extremity function. Future studies may benefit an aging society by targeting many older adults who are less physically active and have poor lower extremity function.

Third, given that this study included only those who participated in the follow-up, survival bias may have been present. In the intervention group, participants who did not complete the follow-up study were older and engaged in less physical activity at baseline than those who did. Therefore, the feasibility findings and estimates of changes in physical activity, physical function, and self-efficacy for exercise may be overestimated.

Fourth, the generalizability of this study is limited owing to potential selection bias. Participants in the intervention group were not only motivated to increase physical activity but also familiar with using the app. The DPSA was not adaptable to all participants, as it required a certain level of information technology literacy and cognitive function. Social, cultural, and economic factors (eg, older age, privacy concerns, and low income) may influence preference and feasibility with smartphone apps [81-83]. Therefore, the use of DPSA may not be widely accepted.

Conclusions

This study assessed the 12-month feasibility of using the DPSA and measured preliminary estimates of its effects on physical activity, physical function, and self-efficacy for exercise. The 12-month retention rate for participants in the DPSA intervention group was 73% (19/26), and that for 41 participants including those who decided not to participate in the follow-up study was 46% (19/41). The DPSA adherence rate was 85.9%. Only a limited number of older adults had long-term access to the DPSA. Preliminary estimates suggest that DPSA use may improve step count, lower extremity function, and self-efficacy for exercise. However, various biases were introduced, preventing the demonstration of clear intervention effects. There

is a need to identify ways in which more older adults can use DPSAs for extended periods of time; RCTs should be conducted to ascertain the long-term effects of DPSAs on physical activity and function in older adults.

Acknowledgments

This study was supported by a Doctoral Student Grant-in-Aid Program from the Ushioda Memorial Fund. The Fujisawa City government, A10 Lab Inc., and Keio University independently funded their respective parts of the research. The authors thank the staff of the Elderly Support Division of the Fujisawa City government (Shinichi Sakae, Mayumi Taguchi, Mari Sakata, and Shizuka Kobayashi) for recruiting participants and managing the project, Ken Takahashi of the Fujisawa City Health and Medical Foundation for his cooperation as a health fitness instructor, and Oguma laboratory staff for their help in collecting the data.

Authors' Contributions

KT, YO, SY, and MS were responsible for designing this study. KT, YO, SY, MS, MN, ND, AH, and TM were responsible for the data collection. KT and YO were responsible for analyzing and interpreting the data. All authors have edited, reviewed, and approved the final manuscript.

Conflicts of Interest

SY and MS were employees of A10 Lab Inc at the time of the research.

Abstract

Background: Sexual response problems among older adults are not an inevitable consequence of aging but rather a response to sexual health. However, there is a lack of recent and multicenter data on this issue in China.

Objective: This study aims to assess the prevalence of sexual response problems and their correlates among older adults.

Methods: A multicenter cross-sectional study on sexual well-being was conducted among individuals aged more than 50 years in China between June 2020 and December 2022. Data on sociodemographics, physical health, psychological health, and sexual response problems were collected through face-to-face interviews. We included sexually active older adults who reported either vaginal, oral, or anal sex in the past 12 months for this study. Sexual response problems included a lack of interest or enjoyment in sex; feeling anxious, having pain, or no excitement during sex; no desire or orgasms; and the lack of lubrication in sex. The stepwise logistic regression models were used to examine the correlates of sexual response problems.

Results: A total of 1317 sexually active older adults (842 men, 475 women) were included. Older women reported a higher prevalence of sexual response problems than older men (52.0% [247/475] vs 43.1% [363/842]). Common factors associated with at least one of the sexual response problems included living in rural areas (men: adjusted odds ratio [aOR]=0.31, 95% CI 0.22 - 0.43; women: aOR=0.29, 95% CI 0.19 - 0.43) and abnormal BMI (aOR=men: 1.52, 95% CI1.11 - 2.07; women: aOR=2.19, 95% CI 1.47 - 3.28). Among older men, sleep quality (aOR=1.87, 95% CI 1.30 - 2.68), emotional connection with sex partners during sexual intercourse (aOR=0.69, 95% CI 0.50 - 0.96), frequently experienced fatigue (aOR=2.47, 95% CI 1.59 - 3.90), anxiety (aOR=4.26, 95% CI 1.12 - 21.27), and seeking professional help for sex life (aOR=1.58, 95% CI 1.14 - 2.21) were associated with sexual response problems. Among older women, sexual response problems were associated with a lack of physical exercise (aOR=1.69, 95% CI 1.13 - 2.54), poor sex-partner relationships (aOR=1.70, 95% CI 1.12 - 2.60), and depressive symptoms (aOR=3.18, 95% CI 1.18 - 10.24).

Conclusions: Sexual response problems are common among older adults. These problems were associated with adverse physical health, mental health, and poor sex-partner relationships. These findings highlight the importance for health care providers to take into account the physical and psychological health of older adults, as well as the quality of their relationships with sexual partners when diagnosing and addressing sexual response problems.

Introduction

Sexual response problems are characterized by diminished or absent sexual interest and disruptions in the physiological or psychosocial patterns associated with the sexual response cycle. These disruptions include a lack of interest, enjoyment, desire, orgasms, and lubrication in sex [1]. Sexual response problems have a profound impact on various aspects of life for older adults, affecting their quality of life, interpersonal relationships, dissatisfaction in marriage [2,3], work efficiency [4], self-esteem [5], and physical and mental health [2,3,6].

Recent studies have shown a high prevalence of sexual problems in both older men and older women. For instance, in Europe, a majority of men (73.7% - 79.8%) and women (23.5% - 50.2%) reported experiencing at least one sexual problem, with the most prevalent sexual problems being orgasmic difficulties and reaching orgasm more quickly than desired and failure to reach orgasm or taking too long to climax [7,8]. An early national survey in urban China indicated that 21% of men and 35% of women aged 20 - 64 years had at least one persistent sexual dysfunction, with lack of sex interest, erectile difficulties (men), and inability to reach orgasm being the most common problems [9]. There are substantial variations in the prevalence of sexual response problems across different global regions, with noticeable differences between men and women. As extensively demonstrated by a significant number of epidemiological studies worldwide, there are substantial differences in the prevalence of sexual response problems among men and women. A few researchers have suggested that the prevalence of sexual response problems was higher in men compared to women [10,11]. Conversely, more studies have reported a higher prevalence among females [12-15]. It is necessary to elucidate the specific causes of these differences and inform gender-specific prevention and intervention strategies.

Sociodemographic, psychological, sex partner relationships, chronic disease, and physical health were found to be important determinants of sexual response problems among older adults. The prevalence of sexual problems tends to increase with age [16], and there are notable differences between men and women in terms of prevalence and types of sexual response problems [17]. Psychosocial factors such as anxiety, depression, stress, and the quality of marital relationships play significant roles in sexual response problems [16,18,19]. Intimate partner violence is associated with a higher likelihood of experiencing sexual problems [20]. In addition, chronic diseases like cancer [17], diabetes [21], and coronary heart disease [22] are linked to an increased risk of sexual dysfunction. Moreover, sexual response problems in one partner may influence the sexual function of the other partner [23].

Despite extensive studies on sexual problems, most of the existing literature was from developed countries or early studies, and there is a lack of nationally representative, large sample and recent data on the prevalence and correlates of sexual response problems among older adults in China. Given China's rapidly aging population [24,25], the sexual health of older adults is a growing concern. A comprehensive understanding of older adults' sexual response problems may enhance sex education, research, policy, and clinical care for this growing population. This multicentre cross-sectional study, using data from the Sexual Well-being (SWELL) study in China, aims to fill the research gap by examining the prevalence of sexual response problems and their correlates among older adults. These epidemiological data are essential for andrologists, gynecologists, urologists, venereologists, and other health care providers involved in treating and caring for older adults. They may help them counsel their patients on the potential adverse effects of different treatment modalities. Moreover, the findings are expected to contribute valuable insights for developing targeted interventions to enhance sexual relationships, improve quality of life, and address the sexual health challenges faced by aging populations in China.

Methods

Study Participants and Procedures

Our study was based on the SWELL study, a multicenter cross-sectional survey conducted between June 2020 and December 2022. The survey spanned four different regions in China, including Shanghai (Eastern China), Jinan (Eastern China), Chongqing (Western China), Guangzhou (Southern China), and Tianjin (Northern China). Participants were recruited using a multistage sampling design, and more detailed sampling procedures are provided in our previous protocol [26]. We collected data on demographic characteristics, physical health characteristics, mental health characteristics, sex partner relationship characteristics, and sexual behavior characteristics through face-to-face interviews. All participants provide formal informed consent to participate in the study.

Participants were enlisted from subdistricts within each chosen city. Eligibility criteria for participants in this study included: (1) aged 50 years and older; (2) only heterosexual orientation; (3) having engaged in heterosexual activities (including oral or vaginal intercourse) in the preceding year; (4) being able to comprehend the survey instrument of the SWELL Study.

Ethical Consideration

The SWELL study was approved by the School of Public Health (Shenzhen), Sun Yat-sen University Research Ethics Committee (approval number SYSU-PHS [2019] 006) and was performed following the Helsinki Declaration. Written consent was obtained from all participants, who were informed of their right to withdraw from the study at any time. Participant information and responses remained confidential, with anonymized data stored in password-protected folders accessible exclusively to the research team and supervisors.

Study Variables

Sexual Response Problems (Outcomes Variables)

Respondents were asked to report if they had experienced any of the following sexual response problems for three months in the preceding year: (1) lacked desire for sex, (2) lacked enjoyment in sex, (3) anxiety during sex, (4) discomfort or pain in sex, (5) no sexual arousal or excitement during sex, (6) lack of or delayed orgasm despite arousal, and (7) reaching orgasm faster than you would like, (8) lubrication difficulties (women only) or erectile function difficulties (men only). These items captured the major sexual response problem domains in the classification of sexual dysfunction in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition [27]. The reliability of sexual response problems in this study was 0.75.

Sociodemographic Characteristics

Age, gender (men and women), living area (rural or urban), monthly income (Chinese Yuan [CNY]), and years of education (<6 years: primary and lower; 7 - 12 years: senior or high school; >12 years: college and above) were included in demographic characteristics. Age was categorized into 3 age groups (50 - 59 years, 60 - 69 years, and older than 70 years). Monthly income (CNY) was categorized into 2 groups (≥5000 CNY [US $700] and <5000 CNY [US $700]).

Lifestyle Characteristics

Physical Exercise

Physical exercise was assessed with 5 items that inquired about the frequency of participation (6 times a week, 3 - 5 times a week, 1 - 2 times a week, no more than once a week, hardly ever, or never). The participants who reported engaging in physical exercise more than 1 - 2 times a week were categorized as often engaging in physical exercise. The remaining responses were categorized as not often exercised [28].

Seeking Professional Help for Sex Life

Participants were asked whether they had sought help or advice about their sex life from a range of sources in the past year. These sources included 4 informal sources (family member or friend, information and support sites on the internet) and 6 professional sources (general practitioner or family doctor, sexual health clinic, genitourinary clinic, sexually transmitted infection clinic, or relationship counselor); more than one answer was allowed. If a participant responds that they have previously sought help for sex life from 6 professional sources, this is defined as “seeking professional help for sex life.”

Physical Health Characteristics

Frequently Experiencing Fatigue

As for frequently experiencing fatigue, the participants were asked about their fatigue levels using a question: “Do you frequently experience fatigue?” with response options of “Yes” or “No.”

Chronic Disease

Chronic disease is defined as one or more diseases that last for 3 months or more including cardiovascular diseases (including myocardial infarction, coronary heart disease, angina, other forms of heart disease, and hypertension), arthritis, diabetes, or hyperglycemia, cerebral hemorrhage or stroke, chronic lung disease (excluding asthma), Parkinson disease, epilepsy, hyperlipidemia, gout or hyperuric acid, chronic gastroenteritis and chronic pain. A separate section was directed at women participants, whether they have a history of one of the following, including bladder surgery, genital or gynecologic surgery, cesarean section, abdominal surgery, and hip pelvic fractures or hip replacement.

Body Mass Index and Sleep Quality

In the SWELL Study, BMI is considered abnormal when lower than 18.5 or higher than 25.

Sleep quality was evaluated using the validated single-item sleep quality scale (SQS), which ranges from 1 to 10 and has been proven to be divided into 2 categories for analysis: those indicating poor sleep quality (scores 1 - 6) and those indicating good sleep quality (scores 7 - 10) [29]. The SQS had an acceptable internal consistency (Cronbach α=0.85).

Mental Health Characteristics

Depressive Symptoms

Depressive symptoms were measured by the 9-item Patient Health Questionnaire (PHQ-9), which has been validated and proven [29,30]. The scale’s total score ranges from 0 to 27, with scores≥10 representing clinically significant depressive symptoms. This study defined a score greater than or equal to 10 as depressive symptoms.

Anxiety Symptoms

The anxiety symptoms were measured on the generalized anxiety disorder-7 (GAD-7) scale with 7-item. Mild or normal anxiety was defined as a GAD-7 score <10, while moderate-to-vigorous anxiety was defined as a GAD-7 score ≥10 [29]. In this study, a score greater or equal to 10 was defined as with anxiety symptoms.

Sexual Relationship Characteristics

Emotional Connection With a Sexual Partner During Sex

The participants were asked, “How often would you say you feel emotionally close to your partner when you have sex together? (options: always, most of the time, sometimes, not very often, hardly ever).” The participants who selected the options of “always” and “most of the time” were defined as having a “good emotional connection with a sexual partner

during sex;" otherwise, they were defined as having a "poor emotional connection with a sexual partner during sex."

Relationship With Sex Partners

Regarding relationships with sex partners, the participants were asked, "How do you evaluate the relationship with your recent sex partner? Please assign a rating to the quality of your partnership with them." The rating scale ranges from 1 to 7, with 1 indicating "very good" and 7 representing "very poor." We categorized the responses into 2 categories for analysis: good relationship with a sex partner (scores 1 - 4) and poor relationship with a sex partner (scores 5 - 7).

Sexual Satisfaction

Sexual satisfaction was measured on a 5-point Likert scale, with responses ranging from 1 to 5 (strongly agree, agree, medium, disagree, and strongly disagree). In this study, we reclassified scores of 1 - 3 as sexual satisfaction and scores of 4 - 5 as sexual dissatisfaction [30].

Statistical Analyses

Descriptive analyses were conducted to characterize the study sample, including presenting percentages, means, and SD. The χ^2 test was used to compare the proportions of characteristics between the sex groups.

For the multivariable logistic regression analysis, collinearity diagnostics were initially performed for all potential variables (Multimedia Appendices 1 and 2). Subsequently, multivariate logistic regression analysis was carried out for noncollinear variables. The multivariable logistic regression models selected variables using a stepwise method based on the Akaike Information Criterion (AIC). The stepwise regression method combines forward selection and backward elimination approaches, adding and removing predictors in the model-building process. This approach effectively minimizes the inclusion of covariates, thereby enhancing the robustness of the analysis. Finally, the model with the minimum AIC was adopted (men: 1005.929; women: 582.316). Adjusted odds ratios (aORs) and their corresponding 95% CIs were estimated.

All statistical analyses were performed using R software version 4.2.3 (R Project). The Stats package (version 4.2.2) was used to build the stepwise multivariable logistic regression models. In addition, the figures were generated using the ggplot2 package (version 3.4.3) and forestmodel package (version 0.6.2) from CRAN.

Results

Demographic and Health Characteristics of the Participants

As shown in Table 1, 1317 older adults were included in this analysis. The average age was 64 years (SD 8.4 years, ranging from 50 to 86 years). Over half of the participants resided in rural areas (men: 53.1% [447/842], women: 50.9% [242/475]), and the majority reported 7 - 12 years of education (junior or senior high school; men: 70.0% [589/842], women: 59.6% [283/475]). In addition, a significant proportion of participants reported infrequent engagement in physical exercise (men: 54.8% [461/842], women: 48.2% [229/475]). Regarding physical health, more than half of the participants did not frequently experience fatigue (men: 85% [716/842], women: 74.9% [356/475]) and did not have chronic diseases (men: 55.2% [465/842], women: 62.9% [299/475]). Regarding sexual relationship characteristics, the majority of male participants reported sexual satisfaction (479/842, 56.9%) and a good relationship with their sex partner (615/842, 73.0%). In comparison, women reported slightly lower rates of sexual satisfaction (228/475, 48.0%) and a good relationship with their sex partner (306/475, 64.4%). Furthermore, less than 5.1% (24/475) of both men and women reported symptoms of anxiety and depression.

Table . Demographic, lifestyle, health, and sexual relationship characteristics among older adults aged more than 50 years in China (stratified by sex).

[a]N/A: not applicable

[b]Sexual response problems include lacked interest in having sex, lacked enjoyment in sex, feeling anxiety during sex, feeling physical pain as a result of sex, feeling no excitement or arousal during sex, difficulty in reaching climax, reaching climax more quickly than desired, trouble getting or keeping an erection(men) or uncomfortable dry vagina(women).

Prevalence of Sexual Response Problems

The prevalence of at least one sexual response problem (including or excluding lack of interest in sex) is shown in Figure 1 and Table 2. In total, 610 out of 1317 participants had sexual response problems, with an overall prevalence of sexual response problems of 46.3% (610/1317). There was a significant difference in the prevalence of the reported at least one sexual response problem between women and men, with being significantly higher in women than in men (52.0% [247/475] vs 43.1% [363/842], χ^2_1=9.6, *P*=.002). The prevalence of at least one sexual response problem increased with age among men (The Cochran-Armitage Trend Test, Z=−2.476, *P* for trend=.01). However, this trend was only observed in the age group between the older than 70 years age group and the other 2 age groups among men. There was no significant difference in the prevalence of sexual response problems between the 60 - 69 years age group and the 50 - 59 age group among women.

Figure 1. Prevalence of sexual response problems among older adults aged 50+ years**.** (**A**) At least one of sexual response problems among men and women; (**B**) At least one of sexual response problems excluding lack of interest in sex among men and women.

Correlates of Sexual Response Problems

The results of multivariable logistic regression analysis stratified by sex, which was presented in Figure 2, revealed several significant associations with reporting at least one sexual response problem.

Figure 2. Correlates of sexual response problems among older adults aged 50+ years**.** (**A**) Correlates of sexual response problems among men aged 50+ years; the multivariable logistic regression analysis was adjusted by living area, age, educational level, feeling of fatigue, body mass index, sleeping quality, seeking professional help for sex life, emotional connection with sexual partner during sex, anxiety, depressive symptoms. (**B**) Correlates of sexual response problems among women aged 50+ years; the logistic regression model was adjusted by age, living area, physical exercise, body-mass index, sleeping quality, sexual relationship with partner, emotional connection with sexual partner during sex, depressive symptoms. SRP: Sexual Response Problem; aOR: adjusted odds ratio; CI: confidence interval.

For older men, residing in rural areas (aOR 0.31, 95% CI 0.22 - 0.43) and maintaining an emotional connection with a sex partner during sexual intercourse (aOR 0.69, 95% CI 0.50 - 0.96) were associated with a reduced likelihood of reporting sexual response problems. In contrast, being 70 years or older (aOR 1.72, 95% CI 1.05 - 2.81), frequently experiencing fatigue (aOR 2.47, 95% CI 1.59 - 3.90), and poor sleeping quality (aOR 1.87, 95% CI 1.30 - 2.68) were associated with higher odds of reporting sexual response problems. In addition, moderate to severe anxiety symptoms (aOR 4.26, 95% CI 1.12 - 21.27), abnormal BMI (aOR 1.52, 95% CI 1.11 - 2.07), and seeking professional help for sex issues (aOR 1.58, 95% CI 1.14 - 2.21) were positively associated with reporting sexual response problems among older men.

Older women residing in rural areas (aOR 0.29, 95% CI 0.19 - 0.43) were less likely to report sexual response problems. Conversely, factors such as infrequent engagement in physical exercise (aOR 1.69, 95% CI 1.13 - 2.54), depressive symptoms (aOR 3.18, 95% CI 1.18 - 10.24), having an abnormal BMI (aOR 2.19, 95% CI 1.47 - 3.28), and being in a poor sex partner relationship (aOR 1.70, 95% CI 1.12 - 2.60) were associated with higher odds of reporting sexual response problems.

Discussion

Principal Results

Our study demonstrated a high prevalence of sexual response problems among older adults, with variations noted between men and women. In older men, sexual response problems correlate with advancing age. Our findings also linked sexual response problems with adverse physical health outcomes such as frequent experiencing fatigue, poor sleep quality, and abnormal BMI. In addition, we observed strong associations between sexual response problems and mental health issues, including anxiety and depressive symptoms. Moreover, poor sex partner relationships, sexual dissatisfaction, and lack of emotional connection during sex were also associated with sexual response problems. These findings significantly contribute to the existing literature, underscoring the importance of addressing sexual response problems within the domain of sexual health and enhancing our understanding of these issues among older adults.

Comparison With Previous Work

In this study, women reported a higher prevalence of sexual response problems compared to men, consistent with findings from other countries [12-14]. This discrepancy may be due to several factors, including physiological alterations, psychological elements, and sociocultural dynamics. With advancing age, women experience a significant decline in estrogen levels, especially after menopause [31]. Furthermore, older women are subject to various age-related psychological changes, such as concerns about body image, fears about aging, and self-consciousness about their sexual lives, which may lead to decreased sexual desire or arousal issues. In Chinese culture, the sexual lives of older adults are frequently neglected or deemed inappropriate, which may influence the perceptions and expectations of sex among older women, making them feel ashamed or uncomfortable in their sexual lives. This sex difference highlights the need for targeted interventions for women's sexual health. These interventions should address the multifaceted nature of sexual health in older women, combining physiological, psychological, and sociocultural interventions.

In this study, adverse physical health, such as abnormal BMI, frequent fatigue, and poor sleep quality, played a crucial role in sexual response problems. These findings were identified by evidence from high-income countries, which linked poor physical health to sexual response problems [32-34]. Obesity, characterized by an abnormal BMI, detrimentally impacts the reproductive system and sexual function [35-37]. Both men and women affected by obesity face a heightened risk of fertility challenges and sexual dysfunction [38]. Weight loss can reduce fatty tissue and diminish aromatase activity, leading to a relative increase in testosterone levels [39], which enhances sexual function in men. Besides, weight loss tends to improve sexual functioning for women and men [40]. Obesity significantly affects the hypothalamic-pituitary-gonadal axis in men, leading to diminished libido and erectile dysfunction [41]. The previous review highlighted that excess body weight negatively affected hormones contributing to sexual behavior, noting that adipose tissue facilitates the conversion of androgens to estrogens, further impacting sexual function [42]. Given the inverse association between body mass and sexual response problems, it is recommended that clinicians, both in general practice and in weight loss programs, should more fully address sexual response problems.

Poor sleep quality was associated with sexual response problems in previous studies [43,44], which was also demonstrated by this study. Poor sleep is closely linked to sexual dysfunction due to several physiological and psychological factors. Inadequate sleep can disrupt hormone production, notably reducing testosterone levels, which are essential for sexual desire and performance. Studies have shown that sleep deprivation can decrease testosterone production, leading to impaired sexual activity [45]. In addition, sleep disorders often contribute to stress, anxiety, and depression, all of which can diminish libido and sexual satisfaction [46]. Furthermore, chronic stress and anxiety can lead to sleep problems, which in turn may cause erectile dysfunction [47]. Sleep is fundamental to health, and its bidirectional relationship with sexual response difficulties necessitates that clinicians conduct thorough assessments to identify underlying causes of poor sleep, encourage patient-partner communication to alleviate psychological burdens, promote regular physical activity to enhance sleep quality, and recommend professional sleep therapy to improve physiological function when necessary.

Our study showed that lack of physical exercise was correlated with the occurrence of sex response problems among older women. Regular physical activity is a healthy practice that can mitigate the risk of sexual response problems [36,48]. These associations between sexual response problems and physical health underscore the importance of prioritizing sexual function within sexual health. Physical exercise and high-quality sleep are recommended, along with other lifestyle guidance, to improve sexual functioning in both men and women and to improve health across a range of domains.

Psychosocial factors, including symptoms of anxiety and depression, exhibited the strongest association with sexual response problems, as evidenced by findings from the Global Study of Sexual Attitudes and Behaviours (GSSAB) [49]. Other studies also linked the associations between mental health and sexual response problems, which highlighted that men with anxiety disorders are at a higher risk of developing erectile dysfunction [50,51]. Moreover, the physiological responses triggered by heightened anxiety levels may contribute to disruptions in sexual function [52]. This finding will capture the attention of practitioners exploring the causes and treatment of sexual problems in patients. In clinical practice, there should be heightened efforts to address sexual problems within integrated services of mental health and sexual health counseling, as well as in primary and secondary care.

Our findings underscored the importance of sex-partner relationships in the context of sexual response problems. Specifically, men who maintained an emotional connection with their sex partners during sex were less likely to report sex response problems, while women experiencing poor relationships with sex partners were more likely to encounter sexual response problems in older women. This underscores the role of brief emotional interactions during sexual activity in men's adaptation to sexual response problems. In contrast, long-term sexual relationships appear to be more influential in women's adjustment to sexual response problems. Existing studies have consistently underscored the significance of partner relationships for sexual response problems in women [53], emphasizing the impact of daily intimacies in relationships [9]. In contrast, emotional intimacy is presumed to play a significant role in maintaining sexual desire and partnered sexual activity for men [54,55]. In addition, emotional connection with a partner may foster open communication, trust, and mutual understanding, all essential to a satisfying sexual relationship. The variation in sexual response problems concerning sex partner relationships among older men and women underscores the importance of physicians considering sex differences when diagnosing and treating patients with sexual response problems. In future studies, the sex partner should be included and involved in the evaluation and management to achieve a better intimate relationship in an established couple and avoid sexual response problems.

Limitations

Our study has several limitations that should be considered. First, as a cross-sectional study, it cannot establish temporal order and causal direction. Second, the reliance on self-reporting in the questionnaires, especially for sensitive issues, introduced the possibility of recall biases. Third, the sexual response problems were reported by the participants experiencing them, and the differences in the sensitivity and understanding of the same sexual problem may exist among participants, potentially influenced by factors such as education, age, or living area. Finally, some analyses were based on small cell sizes, particularly for variables like anxiety and depressive symptoms, which may result in unstable estimates.

Conclusion

This study showed a substantial prevalence of sexual response problems among older adults, with women experiencing these problems more often than men. The study identified adverse physical health, poor mental health, and poor relationships with sex partners as factors contributing to increased sexual response problems among older adults. To address these concerns, health care professionals can implement interventions for older adults experiencing sexual response problems, such as enhancing physical health, supporting mental health, improving intimate relationships, and providing educational and cognitive-behavioral interventions. These insights drawn from the latest and representative SWELL study data enhance our understanding of sexual response problems among older adults and have the potential to promote overall health and well-being among the aging population in China.

Acknowledgments

We thank the investigation staff, all participants, and Ms Bowen Liang for her outstanding contribution to this study. This study was supported by the Natural Science Foundation of China International/Regional Research Collaboration Project (grant number 72061137001), and the Natural Science Foundation of China Excellent Young Scientists Fund (grant number 82022064). All funding parties had no role in the study design or data explanation.

Data Availability

The data collected in this study will not be publicly available. However, upon reasonable request, the corresponding author can be contacted for de-identified data.

Authors' Contributions

HZ conceived and designed the study in consultation with BL, CX, BW, XL, and XP. BW, XP, YW, HL, YL, XS, LO, GW, MY, JL, and XM contributed to data collection. BL, CX, BW, XM, WT, and JT contributed to data analysis and presentation. BL, CX, BW, XP, and XL drafted the manuscript, with all authors critically reviewing the paper. All authors approved the final report. BL, YC, and HZ contributed equally as co-corresponding authors.

Conflicts of Interest

None declared.

Abstract

Background: Older adults face several barriers to exercise participation, including transportation, lack of access, and poor weather conditions. Such barriers may influence whether older adults meet the Canadian 24-Hour Movement Guidelines. Recently, older adults have adopted technology for health care and are increasingly using digital health technologies to improve their access to care. Therefore, technology may be a valuable tool to reduce barriers to exercise and increase exercise participation rates within this population.

Objective: This study aimed to explore older adults' perceptions and experiences of exercise, in general, and specifically related to our synchronous online exercise program for community-dwelling older adults.

Methods: A total of 3 registered kinesiologists and 1 physiotherapist with experience working with older adults delivered an 8-week, thrice-weekly synchronous online group-based exercise program for older adults in 3 cohorts. The program focused on strength, balance, and aerobic activity. Following the program, a qualitative study with interpretive descriptive design was conducted to explore participants' perceptions and experiences. Participants were invited to take part in a 30-minute, one-on-one semistructured interview via Zoom with a research team member. Interview data were thematically analyzed to identify common themes.

Results: A total of 22 older adults (16 women, 6 men; mean age 70, SD 4 years) participated in interviews. Three themes were identified as follows: (1) health, exercise, and aging beliefs; (2) the pandemic interruption and impacts; and (3) synchronous online exercise programs attenuate barriers to exercise. Participants discussed their exercise beliefs and behaviors and their desire to safely and correctly participate in exercise. Older adults found that their physical activity was curtailed, routines disrupted, and access to in-person exercise programs revoked due to the pandemic. However, many suggested that our synchronous online exercise program was motivational and attenuated commonly reported environmental barriers to participation, such as transportation concerns (eg, time spent traveling, driving, and parking), accessibility and convenience by participating at a location of their choice, and removing travel-related concerns during poor weather conditions.

Conclusions: Given these reported experiences, we posit that synchronous online exercise programs may help motivate and maintain adherence to exercise programs for older adults. These findings may be leveraged to improve health outcomes in community-dwelling older adults.

Introduction

Physical activity (PA) guidelines are not met by ≈85% of older adults in Canada [1,2]. The Canadian Society for Exercise Physiology recommends that older adults participate in 150 minutes of moderate-to-vigorous PA and 2 bouts of strengthening exercise each week [3], similar to the World Health Organization guidelines [4]. If PA guidelines are not met, older adults are at greater risk of adverse health outcomes, including falls, cardiovascular disease, mobility limitations, hospitalization, and mortality [4].

Older adults commonly report barriers to participating in PA and exercise. A systematic review by Spiteri et al [5] determined that environmental factors, resources, lack of assistance in managing change, and social influences are among the common barriers to PA participation for older adults aged 65 - 70 years. Baeret et al [6] reported similar barriers in their systematic review of 44 journal papers describing motivators and barriers to PA in older adults. Common environmental barriers for older adults include transportation, geographic accessibility, affordability, and weather [5-7]. Transportation barriers can be attributed to a lack of transportation to facilities, challenges navigating parking, and poor reliability of affordable transportation [5,6]. Lack of access to exercise facilities, the cost of exercise programming, and distance to programs contribute to environmental barriers [5,6]. Lastly, poor weather conditions reduce the likelihood of adults participating in recreational activities or attending recreation centers [7]. Among Canadians, 64% are less active in the winter compared with the summer [8]. Developing exercise programs to mitigate common environmental barriers may aid in improving older adults' abilities to participate in exercise and meet PA guidelines.

Recently, older adults have adopted technology for health care to improve access to care [9,10]. Technology may, therefore, be a valuable mode of delivery to reduce barriers to exercise and increase participation rates within this population [11]. Current evidence suggests that online exercise programs improve physical function and cognition in older adults, although these programs are exclusively asynchronous, web-based, or interactive exercise-based video games [12]. Older adults have reported not enjoying asynchronous exercise programs as they lack social connectivity, accountability, and adherence, making it difficult to stay motivated [12,13]. Recently, there has been a greater uptake of asynchronous and synchronous programming due to the COVID-19 pandemic [14-16]. A scoping review by Dagenais et al [16] described the nature and extent of the existing literature on online exercise programming among older adults and found 17 studies using asynchronous (9/17, 53%), synchronous (5/17, 29%), or both asynchronous and synchronous programming (3/17, 18%). For older adults, group-based synchronous programs have demonstrated improvements in muscle strength, balance, physical function, aerobic capacity, and quality of life [14]. Therefore, gaining insights into older adults' perceptions and experiences with synchronous programming is important.

We developed and delivered a synchronous online exercise program to help older adults engage in exercise while in-person programming was temporarily suspended [17]. The synchronous program was designed and delivered by registered kinesiologists and physiotherapists. The main aim of the parent trial was to investigate the preliminary effectiveness and feasibility of the synchronous online exercise program through a mixed method pilot randomized controlled trial (RCT) [17]. The aim of this paper was to explore older adult participants' perceptions and experiences of exercise, in general, and of our synchronous online community exercise program.

Methods

Design

This qualitative study was part of an 8-week community-based, pilot RCT [17]. An interpretive descriptive design explored community-dwelling older adults' experiences and perceptions of exercise, in general, and of the synchronous online exercise program [18]. Interpretive description offers a flexible approach to analyzing qualitative data within medical education research, as it can explore individuals' experiences while producing practical clinical outcomes [19]. The pilot RCT compared community-dwelling older adults aged 65 to 80 years participating in a synchronous online exercise program (ACTIVE) delivered on Zoom with a waitlist control group (CON). A total of 3 registered kinesiologists and 1 physiotherapist with experience working with older adults conducted the intervention online in 3 cohorts at the Physical Activity Centre of Excellence at McMaster University in Ontario, Canada. The intervention and all data collection, including the qualitative interviews, were conducted remotely via Zoom. Zoom meets McMaster University's privacy legislation. The study duration was from January 2021 to May 2022. The study was reported in accordance with the consolidated criteria for reporting qualitative research [20]. For the purpose of this paper, the qualitative findings alone will be reported.

Ethical Considerations

This study was approved by the Hamilton Integrated Research Ethics Board (#11429) and registered at ClinicalTrials.gov (NCT04627493). Participants were informed of the study content and procedures both verbally and in writing. Informed written and oral consent was obtained from all participants. All participants had the right to withdraw from the study at any time without any adverse consequences. All data were anonymized. Participants did not receive compensation for their participation.

Participants

ACTIVE and CON group participants enrolled in our 8-week synchronous online program were invited via email to participate in an individual qualitative interview after completing the exercise program. The eligibility criteria for the full trial have been previously reported [17]. Briefly, they were healthy older community-dwelling women and men between the ages of 65 and 80 years, had access to the internet via a personal smartphone, tablet, or computer, and participated in ≤150 minutes of moderate to vigorous PA per week. To be eligible for the qualitative portion of the study, participants must have

remained enrolled in the study and needed to participate in the online exercise program. Interested participants were contacted within 2 weeks of the end of the synchronous online exercise program to schedule an interview time. With a purposeful subsample of interested participants from the pilot RCT, we aimed to conduct between 20 and 24 interviews, as data saturation typically occurs within this range [21].

Intervention

The 8-week intervention consisted of thrice-weekly 60-minute synchronous online exercise classes (totaling 24) delivered online via Zoom by health professionals (ie, registered kinesiologists and physiotherapists). Briefly, the group-based classes began with a 5-minute warm-up, 50 minutes of progressive strength (25 min), aerobic (20 min), and balance training (5 min), and a 5-minute cool-down [17]. The physiotherapist (n=1) and registered kinesiologists (n=3) were trained to work with older adults and adjusted exercise intensity weekly to meet participants' abilities. The instructors and research team members supervised and moderated each class to ensure participant safety and assist with technological difficulties. All interactions between participants and the research team were conducted remotely via Zoom; no pre-established relationships existed prior to the study.

Qualitative Data Collection

Semistructured, open-ended one-on-one interviews were conducted via Zoom by a study investigator (GC, female, PhD Candidate) with experience in qualitative research [22]. A qualitative interview guide (Multimedia Appendix 1) was developed with a qualitative methodology expert (MG) to generate discussion around participants' experiences and perceptions of exercise, in general, and with our synchronous online exercise program [22]. Questions were not provided to participants before the interview. However, participants were aware of the interviewer's personal goals (ie, PhD research) for conducting the research. Transcripts were transcribed verbatim from Zoom audio recordings, checked for accuracy, and not returned to participants.

Data Analysis

The interviews were thematically analyzed using the computer software Dedoose (version 9.0.17; SocioCultural Research Consultants, LLC) [23]. Two authors, GC and KSN, independently coded the first 2 transcripts and discussed initial patterns and themes to inform the preliminary coding book [24], which was shared and refined with input from the qualitative expert. The coding book was used to review subsequent transcripts and iteratively revised to reflect new concepts. Themes and subthemes were inductively developed and refined with the research team. At least 2 interviewers (GC, KSN, and MG) discussed any disagreements in transcription or content to reach a consensus [23,25].

Results

Participants' Characteristics

Of the 32 who participated in the pilot RCT, which determined the preliminary effectiveness of the synchronous online exercise program [17], 22 older women and men participated in semistructured interviews. Ten participants declined or did not respond to the invitation to participate in this study. Table 1 presents the descriptive characteristics of the sample. There were no major differences between groups for any variable. The majority of participants were women (25/32, 78%) and had completed postsecondary education (29/32, 91%). All interviews were approximately 30 minutes in duration by design.

Table . Descriptive characteristics for the ACTIVE, control group (CON), and no-interview participants (N=32).

	ACTIVE[a] (n=13)	CON[b] (n=9)	No interview (n=10)

[a]ACTIVE: exercise group.

[b]CON: waitlist control group.

Qualitative Findings

Overview

Our thematic analysis identified 3 main themes with respect to participants' perceptions of exercise in general and with the synchronous online exercise program: health, exercise, and aging beliefs; the pandemic interruption and impacts; and synchronous online exercise programs attenuate barriers to exercise (Textbox 1). Participants described various subthemes within these 3 main themes, including their exercise beliefs and behaviors and their desire to safely and correctly participate in exercise as an older adult. They also reflected upon the impact of the pandemic on their PA, routine, and lack of access to exercise programs. Participants discussed how the online synchronous format contributed to their motivation to exercise, reduced concerns about transportation, enabled participation from their desired training location, and allowed them to avoid poor weather conditions. Our findings provide greater insight into older adults' perceptions and experiences of exercise, in general, through the themes of health, exercise, and aging beliefs and the impact of the pandemic on older adults' PA. We also provide insight into the delivery of synchronous online community exercise programs and how common barriers to exercise may be attenuated.

Textbox 1. Qualitative themes and subthemes.

Health, exercise, and aging beliefs

- Exercise beliefs and behaviors.
- Desire to safely and correctly participate in exercise as an older adult.

The pandemic interruption and impacts

- Physical activity curtailed.
- Routines disrupted.
- Access to exercise programs revoked.

Synchronous online exercise programs attenuate barriers to exercise

- Synchronous programming is motivating.
- Removed concerns about transportation.
- Ease of participation from desired training location.
- Removed poor weather condition concerns.

Health, Exercise, and Aging Beliefs

Participants believed in the benefits of exercise and sought ways to become more physically active. Many had participated in PA throughout their lives, and they valued the importance of the health benefits of exercise. Three participants described their beliefs about the benefits of exercise and its importance to health and longevity.

> *Yeah, it's like exercise should be long-term or lifetime commitment… it can really benefit you through your own lifetime.* [CON1]
>
> *I have the attitude exercise is important for everybody, but it's especially important as we get older.* [CON2]
>
> *I need physical exercise. My body feels better.* [CON3]

Two participants discussed the reasons for seeking out opportunities to increase their PA.

> *If I joined the program at least it would give me a reason to get up and get started in exercise.* [ACTIVE4]
>
> *Since I've retired, I'm trying to find some kind of routine that would keep me active, and [help with] losing weight and trying to get healthy for longevity.* [ACTIVE5]

Participants expressed concern about their declining fitness levels. Three participants described their desire to continue participating in meaningful activities and believed that becoming more active would help them maintain or improve their health.

> *I was getting too unfit basically… If I think in terms of basic fitness, it would be functional fitness. Can I bend down to get something on the bottom shelf? Can I reach the top shelf? Can I get in and out of a bathtub?… Activities of daily living, but all of them, like the reaching bending stretching [exercise would help with this].* [CON6]
>
> *Because I want to be active in my older age. I don't want to be, you know, stuck in a chair and very limited in what I can do. I still want to travel… You know I want to be mobile.* [ACTIVE7]
>
> *What does motivate me is as I'm aging, I want to get healthier… I want to maybe see my grandkids get married, you know, things like that, so as I age, I get more motivation.* [ACTIVE8]

One participant described their motivation to become more physically active for health and vanity.

> *It's for health, and to be honest with you, it partly is vanity, too.* [CON2]

The participants in our study had prior beliefs regarding exercise and believed in the long-term benefits of exercise. Their motivation stemmed from their desire to improve their health and continue to participate in activities that are meaningful to them. While participants expressed a desire to be active, many disclosed that they lacked knowledge of how to exercise. One participant described that as an older woman, strength training is not an easily accessible exercise modality. Aerobic is traditionally the commonly prescribed type of exercise, but older adults, including women, are interested in learning about strength training.

> *I think as an older person and a woman, I'm less likely to do [strength training] on my own. I can go out and walk and do aerobic stuff, but it's the resistance work that I would be interested in.* [ACTIVE5]

Three participants described concerns over incorrect form, potentially leading to injury. Older adults discuss a lack of confidence, fear of injury, and desire for more supervision when exercising.

> *I think as we get older, certainly doing it the proper way even becomes more important than when you were young.* [ACTIVE9]

> *It's not like I didn't want to try and join some of those [traditional] gyms sometimes, but I didn't feel as confident about it because of some of the medical part [injuries].* [CON3]

> *But there's not a lot of supervision happening there [traditional gyms]… the opportunity to do things incorrectly kind of opens you for doing something wrong and hurting yourself.* [ACTIVE7]

Participants in this study desired to become more physically active and believed in the benefits of exercise. Their motivations for exercising varied from wanting to continue with their activities of daily living to longevity and vanity. However, our participants suggested that traditional gym settings do not offer adequate supervision for older adults as they learn to participate in exercise safely.

The Pandemic Interruption and Impacts

The COVID-19 pandemic interrupted participants' daily routines and limited access to PA during this study. The first cohort of participants began the study during the second wave (Beta variant) of the COVID-19 pandemic and completed the study during the third wave (Gamma variant). The second cohort of participants began the study during the third wave of the COVID-19 pandemic and completed the study as the fourth wave (Delta variant) began. The third cohort of the study started and completed the study during the fifth wave (Omicron variant) of the COVID-19 pandemic. Participants voiced several concerns about their own inactivity levels and how these were affected by COVID-19. For example, 3 participants spoke of the secondary consequences of the pandemic resulting in unhealthy habits.

> *I had joined the gym, and then COVID happened. So, then I've put on another 30 pounds, so now I'm 70 pounds over my optimum weight…. I don't want to risk it right now because of the COVID stuff. Yeah, and I'm not doing massages and not doing physiotherapy, so you know that's kind of hindered things too.* [ACTIVE10]

> *I got out first thing in the morning; it was a part of a routine during the pandemic. I lost all of that; consequently, I put on weight… when the pandemic hit, I literally turned into a couch potato.* [CON2]

> *I was really surprised at how de-conditioned I became over the course of the pandemic; I mean, it wasn't great before, but it became a lot worse during the pandemic.* [ACTIVE11]

The pandemic's secondary consequences left participants more sedentary during this period and disrupted their routines. For example, 2 participants described the challenge to keep track of weekdays.

> *COVID really slowed us down, and I didn't know what day of the week it was.* [CON1]

> *Well, yeah, until the program that you gave us, I was getting lost on what day of the week it was. At least I knew when it was Monday, Wednesday, Friday.* [ACTIVE10]

In addition to disruptions to participants' daily routines, the pandemic revoked access to exercise programs. The public health-mandated lockdowns resulted in canceled in-person exercise programs, further limiting access to PA and exercise. Prior to the pandemic, participants had been engaging in exercise programs and were members of local gyms. COVID-19 interrupted their participation in programming, and many found it difficult to motivate themselves to exercise.

> *… once COVID hit, other classes [exercise programs] closed, it was very difficult… it's almost impossible to continue [exercising]. And I'm not very good at self-motivating.* [CON1]

> *Okay, I go to the gym quite often, like maybe four times or five times a week and, of course, the gyms are closed [COVID], and I found it hard to get motivated to do stuff on my own.* [ACTIVE4]

> *I just started at the Mac gym in the Senior's Program in February, so I was just sort of getting into the three-times-a-week schedule when, of course, we stopped in March because of the pandemic.* [ACTIVE11]

The pandemic interrupted many participants' routines, including canceled exercise programs and memberships and curtailing PA.

Synchronous Online Exercise Programs Attenuate Barriers to Exercise

Participants reported that our synchronous online exercise program removed several common environmental barriers to exercise and motivated them to become more physically active. For example, one participant discussed enjoying exercising from home while still connecting to people in real time.

> *The fact that we got to do it at home… that was cool. I think, maybe something like that would probably motivate me again that there's interaction, it's real people, and it's done in real-time… I actually liked having it [online].* [ACTIVE8]

Another participant spoke about how synchronous programming, in general, allows them to continue to exercise when they are not comfortable attending in-person programming.

> *Yeah, if you have sniffles, you might still want to do the exercises, but you don't want to spread the disease…* [ACTIVE10]

A third participant described how our synchronous online exercise program was advantageous compared with in-person programming.

> *So, it's just me moving around in the room, not, you know, bumping into other people like in a small gym… We're always overheated. Here I have a fan blowing on me, and I don't have somebody complaining that wind is blowing on them because they don't like wind.* [ACTIVE10]

Our synchronous online exercise program motivated participants to exercise as it allows individuals to remain connected with others while participating safely and easily from their own homes. Participants described enjoying the ease of participating

in our program from home since it removed their concerns about transportation and reduced time spent traveling to and from the exercise program, which allowed more time to engage in other activities. Participants discussed their concerns about driving, traffic, and parking when attending in-person exercise programs at the university or recreational facilities. For example, one participant referred to the difficulty of driving and finding their way around campus.

> *… I didn't like driving to McMaster, and then you have to figure out where you're going… that was just a part that I don't care about… So, I like local these days, and the fact that I could do that on Zoom is great. I think it's the best thing ever.* [CON12]

Another participant spoke about not having to drive (or otherwise find their way) to the session and how it streamlined their exercise experience.

> *No, that was actually really, really good. So, because it's COVID, you don't have to worry about being in contact. But yes, I don't like the concept of having to drive somewhere to exercise. It just defeats the whole purpose… I liked that.* [ACTIVE5]

A third participant discussed the inefficiency of driving to the gym.

> *I always used to say if people just walk to the gym or bike to the gym they wouldn't even have to go in the gym. So yes, you've cut out that timepiece of having to go somewhere to do something.* [ACTIVE7]

Our online exercise program eliminated transportation concerns and was described as motivational as it allowed individuals to participate from their desired training location, including their homes and while on holiday. For example, one participant described the ease of connecting to our program while away from home.

> *I was out of town, okay? I ended up at my nephew's place, and he works the night shift. So, I didn't want to disturb him inside, so I went outside, and they had a nice strong Wi-Fi connection, and it worked out really good.* [CON1]

Another participant enjoyed the flexibility of our program, allowing them to maintain their routine while away from home.

> *We'll sign up for that. We can do it at the lake as well… With this type of activity, you can do it in your living room, you can do it out on the deck, and you can do it wherever you want. I think it's great that there's more flexibility, that you can take the program to where you are, rather than you go[ing] there.* [ACTIVE9]

Two participants discussed how offering the exercise program through a synchronous videoconference platform enabled participation due to the ease of access.

> *It [Zoom] made me kind of want to go on… how can you argue about getting up five minutes before it starts? And, yeah, it's really, it's fantastic.* [ACTIVE13]

> *Having it be virtual means that you don't have to worry about traffic and parking and driving.* [CON6]

The synchronous program allowed flexibility in how and where participants engaged with our program, easing participants' concerns about traveling in poor weather conditions. Older adults described their fears and worries about navigating poor weather conditions (eg, extreme heat, rain, snow, and ice) on foot or by car to attend exercise programs or to be physically active. One participant described enjoying not needing to leave the house during the winter months to exercise.

> *Yeah, absolutely. In the winter, too, you didn't have to, you know, shiver and so on.* [CON14]

Two participants spoke of the inconvenience of navigating the weather conditions when exercising.

> *To go warm up my car, put my boots on, then go to the gym, take my boots off... It just doesn't make sense to me.* [ACTIVE8]

> *It was helpful that I didn't have to go running and try to park somewhere and find something [parking] and go through a snowbank.* [CON3]

Another participant discussed barriers when leaving the house when weather conditions are poor and how exercising from home helped to ensure they could still exercise.

> *… if it's like a torrential rain or snowstorm or ice, I don't go out on ice. Yeah, you know, then you would do it from home.* [6ACTIVE10]

Participants described poor weather conditions as negatively impacting their PA levels. Overall, they enjoyed the ease of the videoconference platform and participating in a synchronous online exercise program.

Discussion

Principal Findings

This study provides novel insights into synchronous online exercise programs for older adults. Specifically, participants identified themes including health, exercise, and aging beliefs; the pandemic interruption and impacts; and synchronous online exercise programs attenuating barriers to exercise. Our findings suggested that participants in this study believed in the benefits of exercise and wanted to learn how to exercise safely. The pandemic curtailed their PA, disrupted their routines, and revoked access to exercise programs, leaving them seeking new approaches to exercise. We found that our synchronous online exercise program was motivational and may reduce commonly reported environmental barriers, including removing concerns about transportation (eg, time spent traveling, driving, and parking), improving access through ease of participation from desired training locations, and removing poor weather condition concerns. Therefore, participants expressed a preference for synchronous online delivery of exercise programs, which may be a valuable option for motivating older adults to become physically active while reducing common environmental barriers.

Our findings suggested that participants believed in the health benefits of exercise. Participants described motivation to

exercise due to their desire to be healthy, mobile, and participate in meaningful activities as they aged. Notably, the majority of participants in our study were previously active and had prior experience with exercise, which may influence their perceptions and experiences with exercise. Our findings are similar to findings from a qualitative study by Harrison et al [26] focused on understanding the barriers and motivators of 58 older adults (49/58, 84% females; 60‐85 years) residing in an urban community in Washington, DC, which suggested that the main benefits and reasons for exercising are prolonged life, more energy, and a stronger body. Other participants in our study reported their appearance as a motivator for exercise. While participants in our study discussed their motivations for exercising, they lacked confidence in their abilities to exercise safely, feared injury, and desired supervision. Participants described how traditional gyms lack adequate supervision and support for older adults learning how to exercise. Access to exercise programs specific to older adults is critical to help motivate individuals to exercise and maintain PA levels [5,6].

Our study was conducted during the COVID-19 pandemic, which has been shown to limit walking, biking, PA, and mobility while increasing sedentary behavior across all age groups [27]. As a result, participants discussed the interruption of the pandemic to their lives and its impact in our interviews. While some evidence suggests that older adults became more active in the pandemic [28], this was not the case for our participants, who reported experiencing changes to their PA levels and daily routines and found it difficult to motivate themselves to be physically active independently. Similarly, in a 2021 qualitative study by Petersen et al [29], 12 healthy Canadian adults (6/12, 50% females; 20‐70 years), participants described disruptions to their daily routines and changes in PA as a result of the pandemic. Our study builds upon these findings by providing insight into how the closure of gyms and canceled exercise programs impacted participants in our study, as many were active members before the pandemic. Limited access to exercise programs may lead to difficulty for older adults in motivating themselves to be physically active.

Social connectivity is a key motivator for older adults to maintain adherence to exercise programs [6,30]. Our findings suggest that synchronous online exercise programs are motivational for older adults as they can connect in real time with instructors and other participants, which is unique to synchronous programming compared with asynchronous programs as older adults identify the lack of real-time objective feedback [31]. However, some older adults in our study had previously noted that socializing may not be important when exercising, and they prefer to focus on exercising alone [17]. The synchronous program made our participants feel comfortable exercising when they could not attend in-person programs, and it was advantageous compared with in-person exercise as they did not need to share their space. Synchronous programs may be a useful exercise approach as many older adults are shifting towards more digital connections with family and friends beyond the pandemic, as seen in a sedentary behavior reduction intervention with older adults [32]. However, this may not be a generalizable finding, particularly for older adults in Canada with lower socioeconomic status and lower educational attainment, as there may be barriers to technological access and literacy [33,34]. Careful consideration is needed to develop accessible future interventions and programs when leveraging technology to deliver synchronous PA and exercise programs more broadly. Future work should consider using in-person recruitment to ensure greater diversity in studies [35].

In addition to technology barriers, other commonly cited barriers to participation in PA and exercise included environmental factors, access to resources, assistance in managing change, and social influences for older community-dwelling adults [5,6]. Our findings reflect the environmental barriers reported in the literature, including transportation, access to exercise facilities, and poor weather conditions. Participants in our study expressed concerns about driving and parking at fitness centers, but these transportation concerns were alleviated through our online exercise program, which enabled participants to focus on exercising. Participants described how the “Internet” was a good way to “deal” with transportation concerns, as many described the extra mental load of in-person programming. Previous research has highlighted the importance of transportation assistance in promoting the uptake of programs and maintenance of PA for community-dwelling older adults who are socially disadvantaged or experience disability [36-38]. Reducing transportation concerns may improve the accessibility of exercise programs and the ability for older adults to participate from their desired training location [38].

Barriers to exercise accessibility due to lack of time (family and work) and lack of facilities are other commonly reported environmental barriers [5,6]. In focus groups with recently retired older adults, they described feeling like they are relied upon by children, grandchildren, parents, and friends, making it difficult to prioritize structured PA [39]. For some, online programs provide convenience in terms of not needing transportation, allowing older adults to spend more time on other priorities [40]. Our participants commented on the ease of getting up 5 minutes before class and our program’s convenience. The frequency of our program, 3 times per week, was also feasible for older adults [17]. Our synchronous online exercise program improved participants’ access to exercise specific for older adults and allowed the flexibility of attending class from home while still remaining socially connected. It additionally created a psychologically safe place for participants compared with traditional gyms, which are dominated by younger adults and lack supervised training specifically for older adults. Creating convenient, safe, and synchronous programs is important for ongoing adherence [39].

Poor weather conditions (eg, winter, rain, extreme heat) in Canada are another environmental barrier that contributes to increased sedentary time [41]. Our findings suggest that ice, snow, rain, and extreme heat discourage exercise, particularly since most older adults must travel to a facility to participate in an exercise program. Participants suggested that online delivery may effectively reduce this environmental barrier as participants do not need to be concerned with “cleaning their cars off” or “walking on ice” to attend a training facility to exercise. In older Canadians, there is a decrease in PA levels during precipitation [42] and winter months [8]. Synchronous delivery of exercise may be a feasible approach to deliver programs broadly,

particularly to populations who may not access in-person programs easily. Future work should explore hybrid exercise programming models, including in-person and synchronous delivery.

Strengths and Limitations

Our study suggests that synchronous exercise programs are motivational for older adults as they can connect in real-time with instructors while eliminating common environmental barriers to in-person exercise programming. Interpretive design allowed us to address a complex experiential question while producing a practical outcome [19]. A potential limitation of this study is the limited diversity among our sample. Our study population was predominately Caucasian, with high education attainment, women between 65 and 80, and motivated to exercise. Thus, the findings do not represent the perceptions and experiences of structurally marginalized populations, those experiencing lower socioeconomic status, men, older than 80 years, and those with low levels of education attainment or motivation to support behavioral change. We did not include nonparticipants in the program (n=1) in the interviews. Including nonparticipants may have allowed us to elucidate further barriers and health inequities for those unable to complete the program. Although the study lead provided technological support and assistance through Zoom or a phone call, including turning on cameras, muting and unmuting, and connecting speakers, all participants had good technology literacy and digital access. Future studies should consider including individuals in different populations with varying degrees of technological literacy. Additionally, conducting the synchronous online exercise program outside of the COVID-19 context would provide valuable insight into the long-term feasibility of this program. Trustworthiness may not have been achieved as the transcripts and codes were not checked and confirmed by the participants in this study [25]; however, triangulation across analysts strengthened this aspect of rigor.

Conclusion

The delivery of exercise programs using synchronous online classes may help older adults meet PA guidelines. Older adults report experiencing environmental barriers, including transportation, lack of access, and poor weather conditions when exercising. Our findings suggest that synchronous online exercise programs may serve as an approach to mitigate these environmental barriers and motivate older adults while keeping them socially connected. Considerations for designing exercise programs for older adults include delivery of the program by exercise and health professionals, synchronous programming to maintain social connectivity, and reducing environmental barriers such as transportation and weather concerns. Community programs may consider implementing synchronous online exercise programs as part of their recreational programming for older adults to increase engagement and reduce accessibility barriers. Future work should focus on leveraging synchronous exercise programs in community programs to engage older adults in PA and exercise and explore hybrid (synchronous and in-person) options.

Acknowledgments

We would like to acknowledge and thank the Physical Activity Centre of Excellence (PACE) registered kinesiologists and physiotherapists for their assistance in designing and delivering our online exercise program.

Abstract

Background: Telomere length (TL) is a marker of cellular health and aging. Physical exercise has been associated with longer telomeres and, therefore, healthier aging. However, results supporting such effects vary across studies. Our aim was to synthesize existing evidence on the effect of different modalities and durations of physical exercise on TL.

Objective: The aim of this study was to explore the needs and expectations of individuals with physical disabilities and their interventionists for the use of a virtual reality physical activity platform in a community organization.

Methods: We performed an umbrella review and meta-analysis. Data sources included PubMed, Embase, Web of Science, Cochrane Library, and Scopus. We selected systematic reviews and meta-analyses of randomized and nonrandomized controlled clinical trials evaluating the effect of physical exercise on TL.

Results: Our literature search retrieved 12 eligible systematic reviews, 5 of which included meta-analyses. We identified 22 distinct primary studies to estimate the overall effect size of physical exercise on TL. The overall effect size was 0.28 (95% CI 0.118-0.439), with a heterogeneity test value Q of 43.08 (P=.003) and I^2 coefficient of 51%. The number of weeks of intervention explained part of this heterogeneity (Q_B=8.25; P=.004), with higher effect sizes found in studies with an intervention of less than 30 weeks. Exercise modality explained additional heterogeneity within this subgroup (Q_B=10.28, P=.02). The effect sizes were small for aerobic exercise and endurance training, and moderate for high-intensity interval training.

Conclusions: Our umbrella review and meta-analysis detected a small-moderate positive effect of physical exercise on TL, which seems to be influenced by the duration and type of physical exercise. High quality studies looking into the impact of standardized, evidence-based physical exercise programs on TL are still warranted.

KEYWORDS

aging; chromosome; exercise; meta-analysis; telomere; telomerase; genes; genome; DNA

Introduction

Life expectancy has increased worldwide over the last century. The United Nations World Population Prospects [1] estimates that the world's population aged 65 years or older will rise by 16% in 2050, doubling the number of children younger than 5 years. This prospect will lead to a significant increase in age-related illnesses, such as cancer, dementia, or cardiovascular diseases [2], and is prompting research into the primary

mechanisms of aging and, subsequently, strategies to promote a healthy late-life.

López-Otín et al [3] have recently postulated 12 basic biological mechanisms of aging: epigenetic alterations, loss of proteostasis, disabled macroautophagy, deregulated nutrient-sensing, mitochondrial dysfunction, cellular senescence, stem cell exhaustion, altered intercellular communication, chronic inflammation, dysbiosis, genomic instability, and telomere attrition. Indeed, one of the main theories that has attempted to explain aging relates to telomere length (TL) and the role of telomerase, an enzyme responsible for maintaining and elongating telomeres. Telomeres are essential nucleoprotein structures located at the termini of eukaryotic chromosomes that play pivotal roles in safeguarding genomic integrity and regulating processes such as tumor suppression and aging [4]. Typically composed of a repetitive guanine-rich sequence extending from the chromosome end in the 5’ to 3’ orientation, paired with a complementary cytidine-rich strand [5], telomeres exhibit variations in sequence among species, yet share a common repetitive pattern across organisms. Measuring around 15 kilobases at birth in human somatic cells, telomeres undergo gradual attrition, with approximately 25 to 200 bases lost from their ends during each cell division in the absence of telomerase [6]. Upon reaching a critical length, telomeres signal cell cycle arrest, leading to cellular senescence and eventual demise [7]. Telomeres serve to shield chromosome ends from degradation and fusion, thereby upholding genomic stability [8,9].

There are different demographic factors that influence TL, such as genetics that may explain the high heritability of TL [10,11]; sex, with longer telomeres found in adult females [12]; or ethnicity, with the White community usually having longer telomeres than Black or Hispanic communities [13]. Also, stress levels have been associated with shorter TL, which may be due to oxidative stress and reduced telomerase enzyme activity [14,15]. Obesity [16], alcohol consumption [17], and smoking [16,18] are also factors that negatively influence TL.

Notably, longer telomeres have been found in people who exercise regularly [19] or with higher levels of daily physical activity [20,21]. Indeed, one of the most studied interventions regarding TL is physical exercise. Recent systematic reviews and meta-analyses [22-26] have investigated the effect of physical exercise on the TL of clinical and nonclinical samples, showing some positive, but still inconclusive, results. Aerobic exercise, such as running or swimming, has been consistently associated with longer telomeres. Denham et al [27] conducted a study that found individuals who regularly engage in aerobic exercise show greater telomerase activity, the enzyme that helps maintain TL, compared with those who lead a sedentary lifestyle. In addition, Ludlow et al [28] demonstrated that resistance training, which includes exercises like weight lifting, may also have beneficial effects on TL, possibly through mechanisms involving the reduction of oxidative stress and inflammation. In addition, more recent research has indicated that high-intensity training, such as high-intensity interval training (HIIT), may be more effective in preserving TL compared with low- to moderate-intensity exercises [29]. This type of exercise can induce more robust adaptive responses at the cellular level, including increased expression of genes related to longevity and telomere protection [3].

The aim of this umbrella review was to synthesize existing evidence on the effect of different modalities and durations of physical exercise on TL to inform the implementation of evidence-based physical exercise programs or recommendations to add healthier years into longer lives.

Methods

Overview

This umbrella review was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [30], and it is registered in the International Prospective Register of Systematic Reviews (PROSPERO; registration number CRD42024500736).

Inclusion Criteria

The inclusion criteria and description of studies in this review followed the PICOS (Population, Intervention, Control, Outcomes, and Study design) framework for reviews [31].

Study Design

We selected systematic reviews, with or without meta-analyses, of randomized and nonrandomized controlled clinical trials, excluding nonexperimental designs, such as observational studies. No restrictions were applied on the basis of any particular language, following current international recommendations [32].

Population

Study participants were people with or without a clinical condition. The systematic reviews had to explicitly state that they included humans in their analyses. Therefore, studies involving experimental animals, such as rodents, were excluded.

Intervention and Control

We selected all systematic reviews and meta-analyses comparing the effects of physical exercise versus other intervention, or none, on TL. In addition, we further divided the results according to different types of physical exercise. If any reviews included primary studies combining different types of exercise, they were classified as “combined.”

Outcome Measure

The outcome measure was TL-related calculations.

Search Strategy

We performed a literature search for scientific articles published until January 19, 2024, using the following databases: PubMed (Medline), PEDro, Embase, Web of Science, and Cochrane Library. Multimedia Appendix 1 provides the search strategies, tailored for each database. A total of 2 independent reviewers (JLS-G and JLS-R) conducted the search using the same methodology. Any discrepancies during this process were resolved through consensus including a third reviewer (VN-L). In addition, we manually examined the reference sections of the original studies, and, if needed, contacted the authors for additional information.

Selection Criteria and Data Extraction

A total of 2 independent reviewers (JLS-G and JLS-R) initiated a screening process to evaluate relevance of the systematic reviews and meta-analyses. The initial screening was based on the title, abstract, and keywords for each review. When there was no consensus, or if the abstracts provided insufficient information, the full text was examined. During the second screening phase, the full text was evaluated to confirm inclusion criteria. Data presented in the results section were extracted using a protocol to ensure retrieval of the most relevant information for each study. The sample sizes, type of exercise, duration, means, and SDs of the telomere size data were extracted for each of the studies included in this review. During the analysis, we checked whether the results were repeated in different reviews or meta-analyses; if the effect sizes coincided, only one of the effect sizes was chosen; if the effect sizes did not match, the primary study was selected.

Methodological Quality Assessment

A total of 2 independent reviewers (JLSG and VNL) evaluated the methodological quality of the systematic reviews and meta-analyses, using the modified quality assessment scale for systematic reviews (AMSTAR-2 [A Measurement Tool to Assess Systematic Reviews]). AMSTAR-2 [33] is a questionnaire comprised of 16 domains, with simple categorical options: "yes," when the result is positive; "no," when the standard is not met or there is not enough information to answer it; and "partial yes," when there was partial adherence to the standard. In addition, we calculated the kappa coefficient (κ) and percentage (%) agreement scores to assess reliability before reaching consensus. Interrater reliability was estimated using κ, where κ>0.7 indicates a high level of agreement between reviewers, κ of 0.5 - 0.7 indicates a moderate level of agreement, and κ<0.5 suggests a low level of agreement [34].

Risk of Bias Assessment

We evaluated the risk of bias using the Risk Of Bias in Systematic reviews (ROBIS) assessment, which includes three domains: (1) relevance of assessment (optional); (2) identification of concerns with the review process through 4 domains related to study eligibility criteria, identification and selection of studies, data collection and study appraisal, and synthesis and findings; and (3) judgment on the risk of bias. The ROBIS tool includes signaling questions to assess specific domains and to guide the judgment of the systematic review's risk of bias, with responses categorized as "yes," "probably yes," "probably no," "no," or "no information." The risk of bias is then categorized as "low," "high," or "unclear" [35].

A total of 2 independent reviewers (JLS-G and JLS-R) assessed the risk of bias in the selected studies. In addition, we computed the kappa coefficient (κ) and percentage (%) agreement scores to evaluate reliability before reaching consensus.

Grading of Evidence

The Physical Activity Guidelines Advisory Committee Grading Criteria (PAGAC) were used to evaluate grading of evidence. The criteria used for assessing the quality of evidence included (1) applicability of the study sample, exposures, and outcomes to the research question; (2) generalizability to the population of interest; (3) risk of bias/study limitations; (4) quantity and consistency of findings across studies; and (5) magnitude and precision of the effect. Based on this information, final evidence grades and conclusion statements for each research question were formulated [36].

Overlap of Primary Studies

The overlap analysis of primary studies among the systematic reviews was performed with the Graphical Representation of Overlap for OVErviews (GROOVE) tool [37]. Using a matrix of evidence, GROOVE establishes the number of primary studies and systematic reviews, the absolute number of overlapped and nonoverlapped primary studies, and an overall corrected covered area (CCA) assessment. GROOVE also offers a detailed CCA assessment for each possible pair of systematic reviews (or "nodes"), with a graphical and easy-to-read representation of these results. In addition, it provides an optional function that incorporates the structural missingness within the matrix.

Data Synthesis and Analysis

Given the high variability of designs, patients and endpoints across studies, results were integrated following a random effects model. The Hedges unbiased standardized mean difference was used to determine effect sizes. Heterogeneity was measured using Q-tests, I^2 coefficients, and prediction intervals [38]. Metaregression and metapartition [39] were used to explain heterogeneity. These techniques involve partitioning sum of squares of the homogeneity test into 2 components, Q_B and Q_W, to account for quantitative or qualitative variables. If the Q_E value was large and statistically significant compared with the value of Q_W, it was considered that this variable explained part of the heterogeneity found in the integration of results across studies. If the variable was qualitative, subgroups of studies, which differed in the effect size and also showed less heterogeneity, were created. The procedure was repeated for subgroups that still presented large heterogeneity for other variables. Publication bias was assessed using the contour-enhanced funnel plot, Egger test, Doi plot, and LFK index procedures. 95% CIs were calculated for effect sizes. The significance level was set at 5%. The analyses were carried out with the *meta* v7.0, *metafor* v4.6 and *metasens* 1.5 - 2 libraries of the R statistics software (version 4.4.0; R Foundation for Statistical Computing).

Ethical Considerations

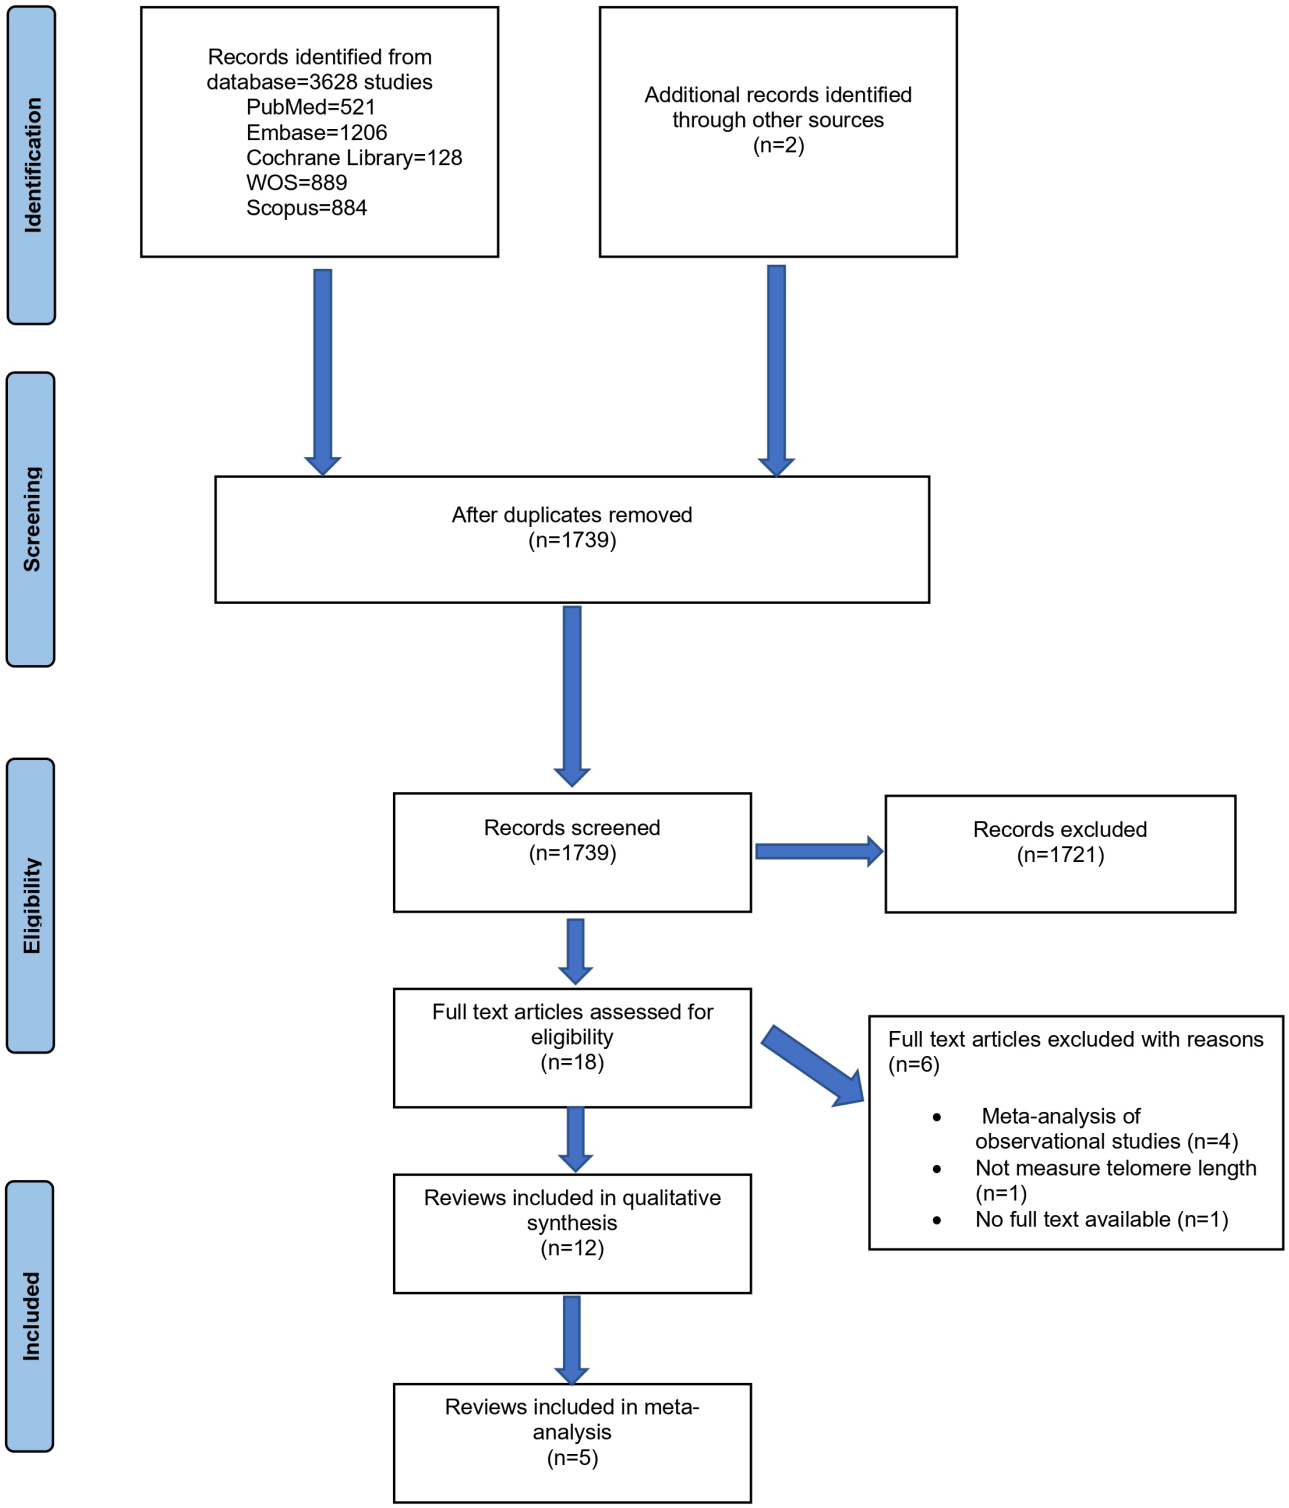
As this is an umbrella review, it is not necessary to have the approval of the ethics committee.

Results

Study Selection

The initial literature search revealed 3628 records. In addition, 2 more were retrieved manually from the references. A total of 12 systematic reviews were eligible for qualitative synthesis, and 5 of them allowed a meta-analysis. Figure 1 shows the study screening strategy.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.



Characteristics of the Systematic Reviews

Table 1 lists the characteristics of the systematic reviews and meta-analyses (type of study, design, sample, intervention, lab technique to measure TL, risk of bias, evaluation of quality, and conclusions).

Table . Characteristics of the systematic reviews.

Study	Type of study	Study design, n		RCCTs[a] or CCTs[b] with physical exercise intervention					Risk of bias	Evaluation of quality	Conclusions
		Interventional	Observational	Sample		Intervention		Lab technique for TL[c]			
				n	Condition (number of studies, n)	Type (n)	Duration: weeks (n)				
Song et al [26]	Systematic review and meta-analysis	7 (RCCTs)	0	939	Healthy (3), breast cancer (2), polycystic ovary syndrome (1), and obese (1)	Aerobic exercise (4) and endurance training (3)	48 (2), 24 (3), and 16 (2)	qPCR[d]	Yes	No	The type and duration of exercise for positive improvement in TL is aerobic exercise for more than 6 months.
Buttet et al [22]	Systematic review and meta-analysis	13 (RCCTs) and 3 (CCTs)	5	908	Healthy (5), obese (1), and myocardial infarction (1)	Endurance training (7), strength (1), and HIIT[e] (1)	48 (2), 32 (1), and 24 (4)	qPCR	No	No	A lifestyle intervention with physical activity + diet can increase TL, independently of population characteristics or baseline TL.
Sánchez-González et al [19]	Systematic review and meta-analysis	8 (RCCTs) and 1 (CT)	0	1320	Healthy (9)	Endurance training (4), aerobic exercise (4), HIIT (3), and aerobic + endurance (1)	8 (1), 16 (1), 24 (4), and 52 (3)	qPCR	Yes	Yes	The findings suggest that HIIT seems to have a positive effect on TL compared with other types of exercise such as endurance training or aerobic exercise in healthy population.

AMSTAR-2 Appraisal

The overall confidence ranged from critically low to moderate quality scores. A total of 2 studies (16.6%) obtained an overall confidence of moderate, and 10 studies (83.4%) had critically low quality (Multimedia Appendix 2). The items with the highest scores were “did the review authors use a comprehensive literature search strategy?”, “did the review authors describe the included studies in adequate detail?”, “did the review authors provide a satisfactory explanation for, and discussion of, any heterogeneity observed in the results of the review?”, and “did the review authors report any potential sources of conflict of interest, including any funding they received for conducting the review?” The lowest scoring items were “did the review authors account for risk of bias in individual studies when interpreting/discussing the results of the review?”, “did the review authors report on the sources of funding for the studies included in the review?”, and “if meta-analysis was performed, did the review authors assess the potential impact of risk of bias in individual studies on the results of the meta-analysis or other evidence synthesis?” The interrater reliability of the methodological quality assessment was high (κ≥0.8).

ROBIS Assessment

Multimedia Appendix 3 summarizes the risk of bias using ROBIS. 40% (5/12) of the studies had a low risk of bias, 20% (2/12) had an unclear risk of bias, and 40% (5/12) had a low risk of bias. The domains related to “data collection” and “synthesis and findings” had the highest risk of bias. On the other hand, the domain related to “eligibility criteria” had the lowest risk of bias. The interrater reliability of the risk of bias was high (k>0.8).

PAGAC Grades of Evidence

The grades of evidence were classified as not assignable, limited, moderate, or strong according to the PAGAC. The level of evidence was limited to moderate among the studies. Most reviews evaluated a heterogeneous population of individuals, which limited the applicability and generalizability of the results. The domain “quantity and consistency” was affected because

some studies had inconsistency in the direction of or the effect size itself (Multimedia Appendix 4).

GROOVE Analysis

A total of 39 primary studies were identified across all systematic reviews and meta-analyses, 24 of which were distinct studies. The overall overlap in the matrix of evidence was moderate (CCA=32.5%) and it remained moderate (CCA=15.63%) after adjusting for the chronological structural missingness. Multimedia Appendix 5 shows a graphical representation of the GROOVE results.

Telomere Length

The number of studies in the systemic reviews that were finally integrated in the quantitative (meta-analytic analysis) was 22. The estimated effect size was 0.28 (95% CI 0.118-0.439), with a heterogeneity test value (Q) of 43.08 (P=.003). The I^2 coefficient was 51% and the prediction interval was −0.26 to 0.81. The number of weeks of intervention explained part of this heterogeneity (Q_B=7.54; P=.006). This factor explained 20% of the overall heterogeneity. Figure 2 shows that studies where the number of weeks of intervention was greater than 30 had smaller effect sizes. In fact, if the intervention time was categorized into <30 and ≥30 weeks, Q_B was 11.64 (P<.001).

Figure 2. Scatterplot of primary studies including effect size and number of weeks of intervention.

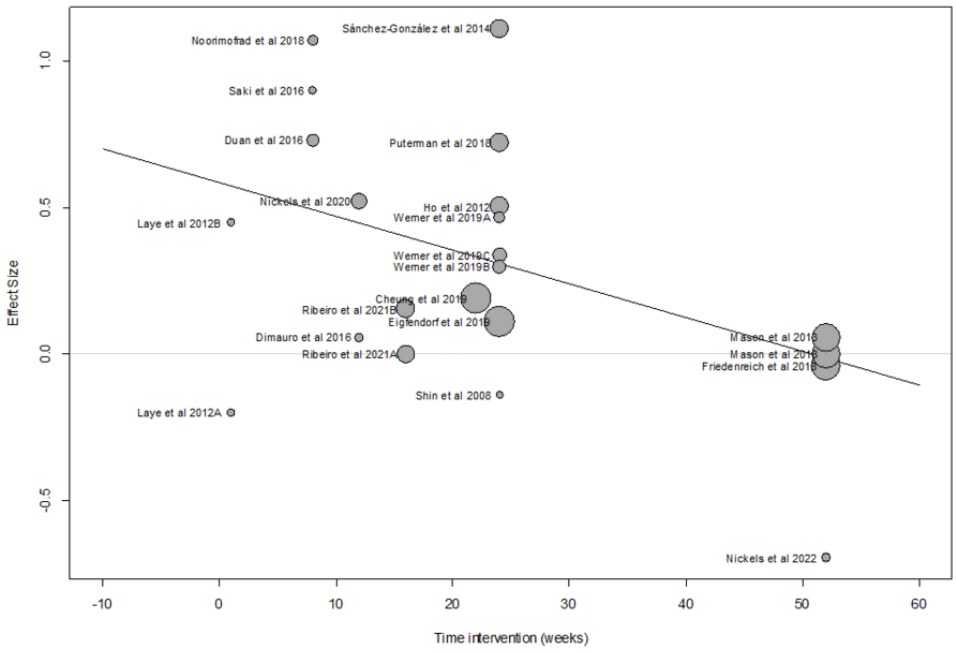

Figure 3A shows that the effect size was 0.39 for studies with an intervention length of less than 30 weeks, and −0.01 for those with interventions longer than 30 weeks. There was no significant difference in the average number of weekly sessions between these two groups (3.3 vs 3 sessions, respectively). Interestingly, the first group presented a statistically significant heterogeneity (I^2=41%), whilst the second, despite having a large range of outcomes, did not. Since heterogeneity was high in the group of studies with shorter interventions (<30 wk), it was analyzed with respect to other variables. The factor that better explained this heterogeneity was the type of physical exercise defined by the 4 categories (subgroups) as shown in Figure 3 (Q_B=11.15, P=.01). One subgroup was comprised of just 1 study that included a combination of aerobic exercise with endurance training and achieved a large effect size. The other 3 subgroups did not have a statistically significant heterogeneity between them, although the subgroup of studies defined by an intervention based on HIIT, which alternates short periods of intense anaerobic exercise with brief recovery periods, had a marked I^2 value (49%). The HIIT subgroup only included 3 studies, one of which had a very high effect size compared to the other two. When we compared the effect sizes of the 3 types of noncombined physical exercises, the value was small for aerobic exercise and endurance training, and moderate for HIIT.

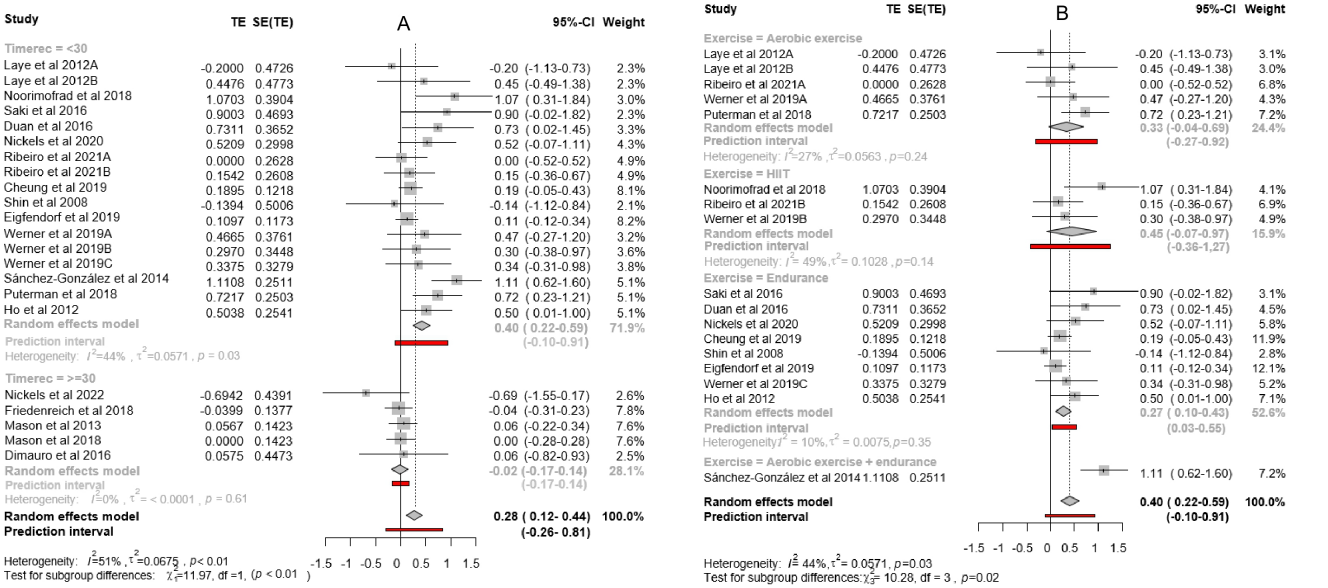
Figure 3. (A) Forest plot of subgroups of primary studies defined by length of intervention. (B) Forest plot of subgroups of primary studies defined by type of exercise. TE: treatment effect.



The contour-enhanced funnel plot (Multimedia Appendix 6) did not identify publication bias. Many of the effect sizes were not significant, and at the top of the funnel, there was some asymmetry, which could be due to the heterogeneity of results. The nonpresence of publication bias was confirmed with the Egger method (*P*=.10). The Doi plot and LFK index also found a weak asymmetry (Multimedia Appendix 7).

Discussion

Principal Findings

This umbrella review studied the effects of physical exercise on TL. The estimated overall effect size indicated a small-moderate positive impact of exercise on TL. However, we found some discrepancies in the results across studies that may be explained by several methodological and contextual reasons, including different methodologies for measuring TL, such as quantitative polymerase chain reaction and terminal restriction fragment assays, that can contribute to inconsistencies in TL calculations. In this regard, Smith et al [47] pointed out that intraindividual TL can vary significantly depending on the lab technique used to measure it. Differences in study populations could also be a factor responsible for disparities in results. Demographic factors, such as age, sex, ethnicity, and health status, can influence the relationship between exercise and TL. For instance, LaRocca et al [48] and Puterman et al [21] suggest that the benefits of exercise on TL may be more pronounced in older adults and in those with higher stress levels. In addition, the duration and intensity of the intervention could be another confounding factor. Our findings suggest that interventions longer than 30 weeks tend to show a lesser positive impact on TL. This could be due to a ceiling effect where additional benefits of exercise do not translate into further increase of TL. This is consistent with Werner et al [29], who observed that the beneficial effects of exercise on TL are more evident in the early phases of physical exercise programs.

The high heterogeneity in study designs, including interventions, participant adherence, and control measures, could have also contributed to different outcomes. In fact, Denham et al [23] and Puterman et al [21] have already highlighted the importance of these methodological issues when interpreting TL results. Studies such as Cherkas et al [20] had found that vigorous aerobic physical activity was associated with longer telomeres in adults, which is in line with our finding of a positive effect of aerobic exercise, especially when combined with endurance training, on TL. However, a systematic review by Du et al [49] did not identify a significant association between aerobic exercise and TL in younger populations, suggesting that age may be an important moderating factor. Denham et al [23] found mixed results related to endurance physical training. Our review also found significant variation in the effects of noncombined endurance training, which suggests that factors such as the intensity and duration of this type of physical exercise may influence the magnitude of the effect on TL. Finally, HIIT had previously shown a significant positive effect on TL [29]. Our review results are consistent with this; nonetheless, the low number of HIIT studies and variety of designs limit generalizability.

Biological Understanding of the Effect of Exercise on TL

Reduction of Oxidative Stress and Inflammation

Oxidative stress and chronic inflammation are 2 major factors contributing to telomere erosion [50,51]. Studies have shown that regular exercise can mitigate these factors [52-54]. Acute and chronic physical activity have different effects on oxidative stress. While acute exercise triggers the production of reactive oxygen and nitrogen species, leading to oxidative stress, regular exercise training enhances the body's endogenous antioxidant system, offering protection against the harmful effects of oxidative damage [55]. This antioxidant effect protects cells from oxidative damage, which in turn preserves the integrity of telomeres. In addition, exercise reduces the levels of inflammatory markers such as C-reactive protein and tumor necrosis factor-alpha, which can protect telomeres from inflammation-induced damage [56].

Increase in Telomerase Activity

Telomerase is a crucial enzyme for maintaining TL, as it adds repetitive sequences to the end of chromosomes. Research suggests that exercise can increase telomerase activity. Ornish et al [57] demonstrated that an intensive lifestyle change program, which included regular exercise, significantly increased telomerase activity in men with prostate cancer. This finding suggests that exercise can directly influence telomere biology by activating telomerase, which helps maintain TL and protects cells from premature aging. In addition, a systematic review with meta-analysis published by Denham et al [23] concludes that regular exercise may attenuate telomere attrition through a telomerase-dependent mechanism and ultimately prolong lifespan and longevity. Furthermore, Ludlow et al [28] found that moderate physical activity levels are associated with increased telomerase activity in leukocytes, indicating that regular exercise not only improves overall health, but also acts at a molecular level to protect cells from premature aging. These studies highlight the importance of exercise continuity and intensity in maximizing the benefits related to telomerase activity and cellular longevity.

Improvement of Cardiovascular Capacity and Metabolic Health

Improved cardiovascular capacity and metabolic health are also associated with longer telomeres. Puterman et al [21] found that better aerobic capacity and higher insulin sensitivity are associated with longer telomeres. These cardiovascular and metabolic benefits reduce oxidative stress and inflammation, creating a healthier cellular environment that protects TL. Regular exercise enhances cardiovascular system efficiency, increases blood circulation, and facilitates the delivery of oxygen and nutrients to cells, which can contribute to the preservation of telomeres.

Strengths and Limitations

We present a comprehensive analysis of systematic reviews and meta-analyses of the effect of physical exercise on TL, providing a broad and robust synthesis of the available evidence. The methodology used to assess the quality of studies and the application of standardized tools for evaluating the risk of bias and heterogeneity strengthens the validity of our results. However, our work has some limitations. The methodological quality of the reviews included in this analysis varies, with many of them classified as critically low. Also, the heterogeneity in study designs, samples, and interventions makes difficult to generalize the results, even after the use of a random effects model to integrate outcomes. Furthermore, some meta-analyses reported results only using postintervention measures, whilst others used postintervention differences adjusted for preintervention measures; this may lead to variations in effect sizes.

Clinical Implications

The implementation of exercise programs into clinical practice could be an effective strategy to limit telomere shortening, promoting healthy aging and reducing the incidence of age-related diseases. HIIT and the combination of aerobic exercise with endurance training may be promising interventions in this regard but still require to be further tested in high-quality studies. In addition, physical exercise should be tailored to each individual's physical capability and health condition to maximize cellular health benefits. Implementing physical exercise programs will also require ongoing health education and monitoring to ensure adherence to and adjustment of interventions based on observed outcomes. Future studies should investigate sex and ethnic TL differences in response to various types of physical exercise. This could help personalize recommendations and optimize benefits on cellular health and aging.

Conclusions

Our umbrella review and meta-analysis identified a small-moderate positive effect of physical exercise on TL, which seems to be influenced by the duration and type of physical exercise. In health care systems, the implementation of evidence-based physical exercise, training programs, and/or recommendations tailored to each individual might be a valuable preventive strategy for a healthy aging. More studies, with larger sample sizes, testing the impact of standardized, evidence-based physical exercise interventions on TL are warranted.

Disclaimer

The lead author affirms that the manuscript is an honest, accurate, and transparent account of the study being reported; that no important aspects of the study have been omitted; and that any discrepancies from the study as planned (and, if relevant, registered) have been explained. Dissemination to participants and related patients and public communities: After publication, the findings of this review will be disseminated to appropriate audiences, such as academia, clinicians, policy makers, and the general public, through various channels including blogs, press releases, and social media.

Data Availability

The data sets generated during and/or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

JLS-G, JLS-R, RG-S, JP, and JM-V contributed to the design of this review. JLS-G, VN-L, JP, and JM-V conducted study selection, data extraction and analysis, and wrote the first draft of this manuscript. RJ-V provided a detailed review of the statistical

analysis. All authors reviewed and approved the final version of the manuscript. The corresponding author, JP, confirms that all listed authors meet authorship criteria and that no others meeting these criteria have been omitted.

Abstract

Background: Advancements in mobile technology have paved the way for innovative interventions aimed at promoting physical activity (PA).

Objective: The main objective of this feasibility study was to assess the feasibility, usability, and acceptability of the More In Action (MIA) app, designed to promote PA among older adults. MIA offers 7 features: personalized tips, PA literacy, guided peer workouts, a community calendar, a personal activity diary, a progression monitor, and a chatbot.

Methods: Our study used a mixed methods approach to evaluate the MIA app's acceptability, feasibility, and usability. First, a *think-aloud* method was used to provide immediate feedback during initial app use. Participants then integrated the app into their daily activities for 5 weeks. Behavioral patterns such as user session duration, feature use frequency, and navigation paths were analyzed, focusing on engagement metrics and user interactions. User satisfaction was assessed using the System Usability Scale, Net Promoter Score, and Customer Satisfaction Score. Qualitative data from focus groups conducted after the 5-week intervention helped gather insights into user experiences. Participants were recruited using a combination of web-based and offline strategies, including social media outreach, newspaper advertisements, and presentations at older adult organizations and local community services. Our target group consisted of native Dutch-speaking older adults aged >65 years who were not affected by severe illnesses. Initial assessments and focus groups were conducted in person, whereas the intervention itself was web based.

Results: The study involved 30 participants with an average age of 70.3 (SD 4.8) years, of whom 57% (17/30) were female. The app received positive ratings, with a System Usability Scale score of 77.4 and a Customer Satisfaction Score of 86.6%. Analysis showed general satisfaction with the app's workout videos, which were used in 585 sessions with a median duration of 14 (IQR 0-34) minutes per day. The Net Promoter Score was 33.34, indicating a good level of customer loyalty. Qualitative feedback highlighted the need for improvements in navigation, content relevance, and social engagement features, with suggestions for better calendar visibility, workout customization, and enhanced social features. Overall, the app demonstrated high usability and satisfaction, with near-daily engagement from participants.

Conclusions: The MIA app shows significant potential for promoting PA among older adults, evidenced by its high usability and satisfaction scores. Participants engaged with the app nearly daily, particularly appreciating the workout videos and educational content. Future enhancements should focus on better calendar visibility, workout customization, and integrating social networking features to foster community and support. In addition, incorporating wearable device integration and predictive analytics could

provide real-time health data, optimizing activity recommendations and health monitoring. These enhancements will ensure that the app remains user-friendly, relevant, and sustainable, promoting sustained PA and healthy behaviors among older adults.

Trial Registration: ClinicalTrials.gov NCT05650515; https://clinicaltrials.gov/study/NCT05650515

Introduction

Background

Ensuring the well-being of the global aging population is a pressing concern, particularly as the World Health Organization predicts a significant rise in the number of individuals aged >65 years by 2050 [1]. To confront this impending public health challenge, the promotion of regular physical activity (PA) is paramount [2].

Research has consistently demonstrated the multifaceted advantages of regular PA on physical, cognitive, and mental health even in advanced age. In recognition of these benefits, the World Health Organization advocates for specific PA guidelines for individuals aged ≥65 years [3,4]. These guidelines encompass moderate-intensity aerobic activities, muscle-strengthening exercises, and balance training. However, despite the wealth of evidence supporting these recommendations, a substantial proportion of older adults worldwide fail to meet the prescribed PA levels [5,6]. Hence, adherence to recommended guidelines remains a challenging issue [7].

Addressing the gap in PA participation among older adults necessitates the implementation of innovative and sustainable interventions. Mobile technology has opened up avenues for innovative approaches to foster PA and cultivate healthier lifestyles even among older adults [8,9]. Mobile health (mHealth) apps have emerged as promising and cost-effective health intervention tools, especially in promoting PA. These apps harness technology to offer personalized guidance and track and encourage PA [10]. Capitalizing on the widespread use of smartphones and tablets, these apps possess the potential to revolutionize how we address and promote PA among aging populations [11]. They offer convenient access to PA advice and support, deliver an enjoyable user experience, and furnish feedback on progress over time [12-14].

Despite these positive trends, adoption of these technologies in real-life conditions is still relatively limited. Several challenges and hurdles must be overcome before such interventions can be successfully and sustainably implemented in the field. The challenge is not solely in developing mHealth apps but also in maintaining long-term engagement and motivation among older adults. In addition, studies often report high attrition rates and small intervention effects [14-16]. These problems must be addressed to use the full potential of mHealth interventions. First, high attrition is likely due to the intervention not matching the users' needs, goals, and expectations [17,18]. This may be avoided by involving potential users during the entire cycle of intervention development [19-22]. Second, research has revealed that theory-based interventions are more effective at modifying health behaviors than traditional interventions [23,24]. Thus, interventions should be grounded within and informed by theoretical models.

Objectives

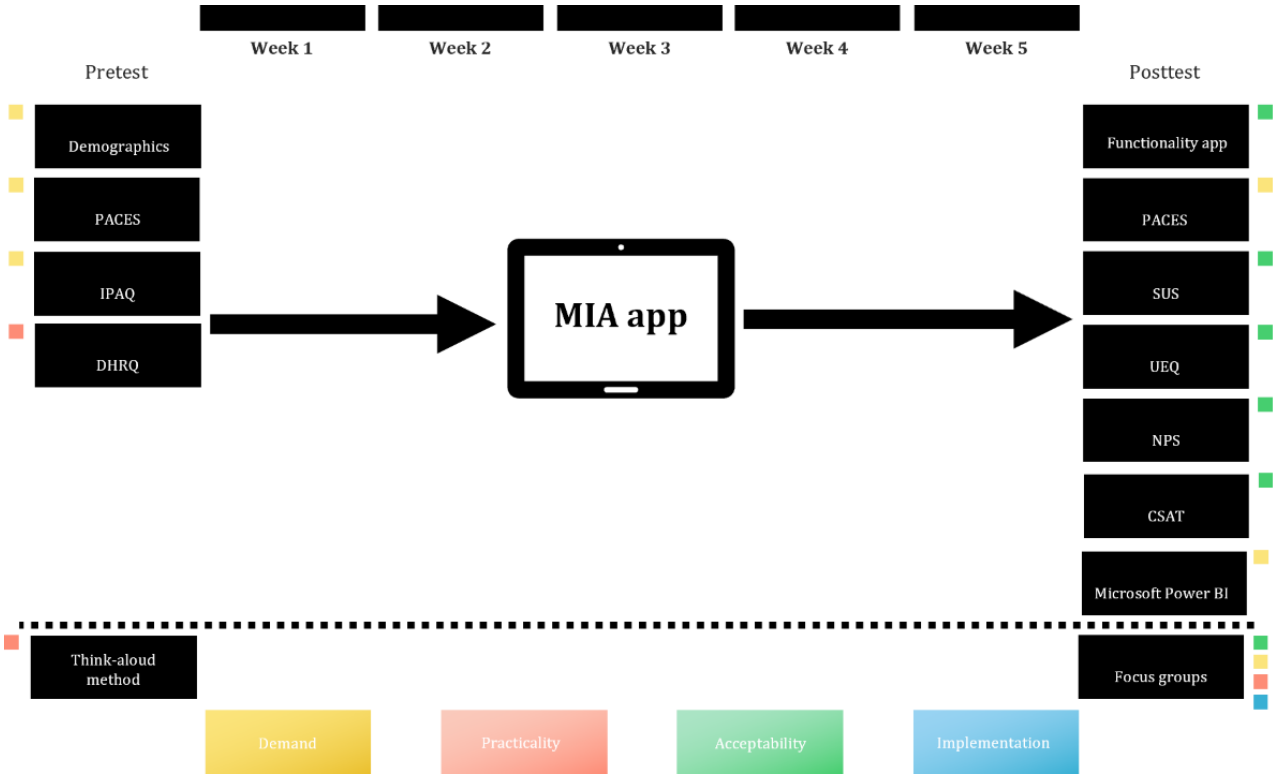
In response to these challenges, a collaborative cocreation process led to the development and refinement of an mHealth app named More In Action (MIA) [19]. The app's content and design were crafted through cocreative workshops and based on the theoretical framework of the Behavior Change Wheel (BCW) [23]. Despite the active involvement of end users from the outset of development and throughout the iterative process, as well as preliminary results indicating high levels of enjoyment and ease of use of the app [19], the long-term retention rate and motivation levels of the participants remain unknown. Therefore, the primary objective of this study was to thoroughly explore the acceptability, feasibility, and usability of the MIA app in promoting PA and encouraging sustained, active, and healthy behaviors among its users.

Methods

Study Design

We used a comprehensive mixed methods approach to assess the MIA app's acceptability, feasibility, and usability, as shown in Figure 1.

Figure 1. Study design. The colors represent the different evaluation focuses: yellow for demand (interest and need), orange for practicality (feasibility), green for acceptability (user satisfaction and acceptance), and blue for implementation (integration into the study). CSAT: Customer Satisfaction Score; DHRQ: Digital Health Readiness Questionnaire; IPAQ: International Physical Activity Questionnaire; MIA: More In Action; NPS: Net Promoter Score; PACES: Physical Activity Enjoyment Scale; SUS: System Usability Scale; UEQ: User Experience Questionnaire.



Our methodology adhered to the recommended framework for feasibility studies by Bowen et al [25]. This framework allowed us to explore critical aspects of the MIA app, such as *acceptability*, *demand*, *practicality*, and *implementation*. These interrelated concepts were systematically integrated into our study design and procedures, as detailed in Table 1.

Acceptability was defined as the perceived suitability of the app and is directly tied to user satisfaction and their intent to continue using the app, as shown in Table 1. Feasibility, on the other hand, addresses the ease of implementing the app among older adults [26], focusing on demand and implementation and examining whether it can be effectively implemented and sustained in users' daily routines. In Table 1, feasibility is broken down into 2 distinct areas. The first is demand, which addresses whether older adults are willing to adopt and regularly use the app. This area evaluates actual use, intention to use, and perceived demand. The second is practicality, which assesses how easily the MIA app can be integrated into the users' daily lives. This area was explored through the *think-aloud* method, focus groups, and questionnaires. Practicality measures the ease of integrating the app into daily routines, user willingness to pay, and any perceived positive or negative effects. Usability, a key aspect of our investigation, was defined as the ease of use and suitability of the system or product for a specific user group performing designated tasks in a particular environment, including practicality. In this context, *ease of use* directly impacted user performance and satisfaction, whereas *acceptability* determined the likelihood of the product being embraced and used [27]. In Table 1, usability directly impacts acceptability (satisfaction and intent to continue using the app) and feasibility (ease of integration and ability to perform the required intervention activities).

Table 1. Key areas of focus for the More In Action (MIA) feasibility study based on the framework by Bowen et al [25].

Area of focus and research question	Method	Outcome	Measures
Usability			
Acceptability			
To what extent is the MIA app as a means to promote PA[a] acceptable among community-dwelling adults aged ≥65 years?	• Questionnaire • Focus group	• Satisfaction • Intent to continue use	SUS[b], CSAT[c], NPS[d], and Likert-scale questions on how the app fits into the end users' daily-life activities
Feasibility			
Demand			
What is the level of adoption of the MIA app among community-dwelling older adults? What factors influence the intention to use and engage with the app?	• Questionnaire • Microsoft Power BI (Microsoft Corp) analytics • Plausible Analytics	• Actual use • Intention to use • Perceived demand	Questions regarding the influence of the app on modulating PA behavior (eg, PACES[e] and IPAQ[f]) and analytics to compare the frequency of use and patterns of use across the participants
Practicality			
To what extent can the MIA app be integrated into the daily lives of older adults aged ≥65 years residing within the community?	• Think-aloud method • Questionnaire • Focus group	• Positive or negative effects • Ability of participants to execute intervention activities • Willingness to pay	First impressions, Likert scale, and in-depth questions regarding integrating the app into their daily lives (eg, DHRQ[g])
Implementation			
How can the MIA app be optimally implemented to facilitate sustained engagement in PA among community-dwelling older adults?	• Focus group	• Amount and type of resources needed to implement • Factors affecting implementation	In-depth questions on how the MIA app can be deployed in the community context

[a]PA: physical activity.

[b]SUS: System Usability Scale.

[c]CSAT: Customer Satisfaction Score.

[d]NPS: Net Promoter Score.

[e]PACES: Physical Activity Enjoyment Scale.

[f]IPAQ: International Physical Activity Questionnaire.

[g]DHRQ: Digital Health Readiness Questionnaire.

Ethical Considerations

This study was registered at Clinical Trials.gov (NCT05650515) and was approved by the ethical committee of Hasselt University (B1152023000011). All participants provided informed consent. To ensure privacy, the data used in this study were deidentified before analysis. Participants did not receive any compensation for their involvement.

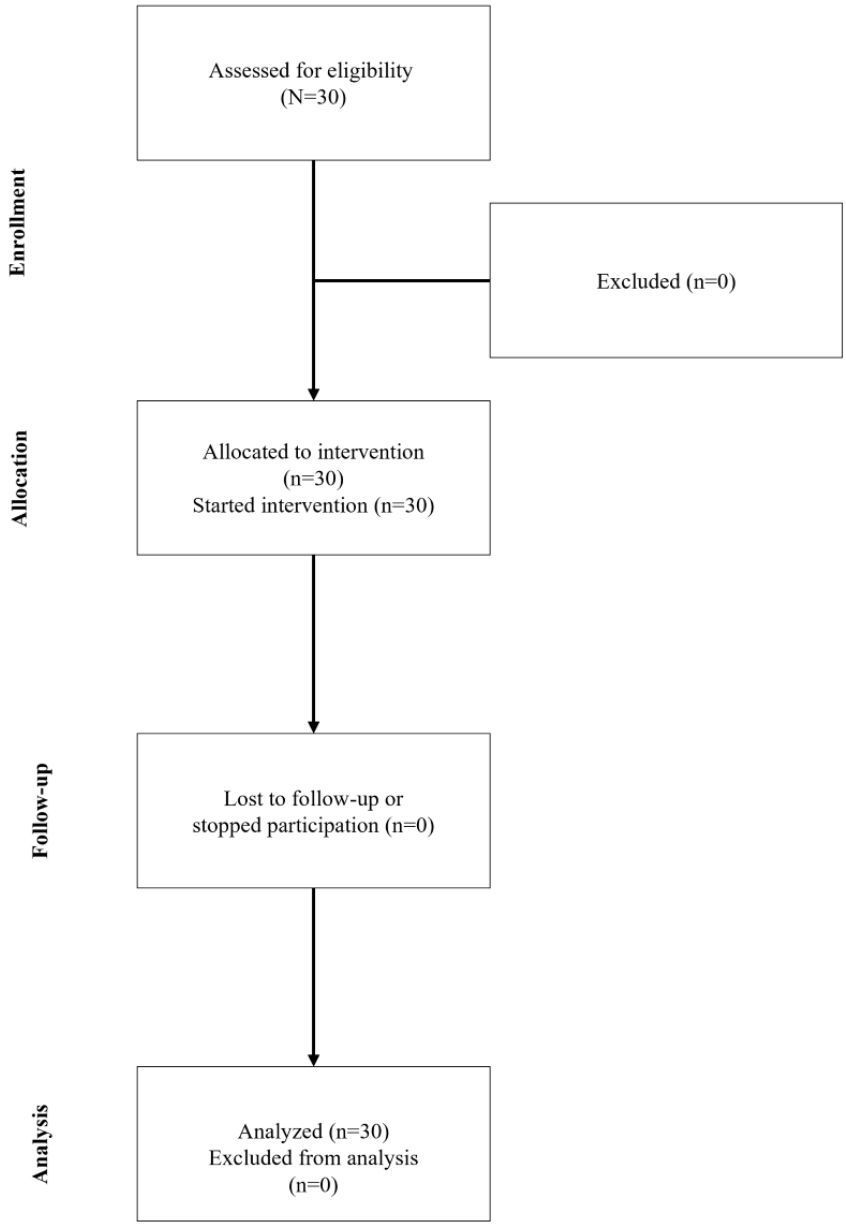
Participants

Older adults without severe illness were invited to participate in this study. They were recruited via social media outreach, newspaper advertisements, and pitches at several older adult organizations and through the local community services during the recruitment period from August 2023 to September 2023.

The inclusion criteria for participants encompassed that they had to be aged ≥65 years, competent to provide informed consent (Multimedia Appendix 1), able to actively participate in the study, community dwelling (living either independently at home or in a serviced apartment), without any severe illnesses, and native Dutch speakers. The exclusion criteria were the presence of current neurological, cardiovascular, respiratory, severe metabolic, or cognitive disorders. Participants were not excluded based on digital literacy, ensuring a diverse range of digital competence levels. The complete list of exclusion criteria is presented in Multimedia Appendix 2.

Figure 2 provides a CONSORT (Consolidated Standards of Reporting Trials) flowchart for this single-arm feasibility study. The methodology and results were reported following the CONSORT 2010 checklist [28].

Figure 2. Modified CONSORT (Consolidated Standards of Reporting Trials) flow diagram for a single-arm feasibility study of the 5-week More In Action intervention.



Intervention

General Description

The mHealth app MIA represents an innovative approach to promoting PA and fostering a lifestyle centered on health and activity among older adults. Developed through a collaborative cocreation process, MIA has been refined over several iterations to meet the specific needs and preferences of its target user group [19]. MIA is optimized for both smartphone and tablet use, thereby ensuring accessibility and user engagement across a broad spectrum of mobile devices.

The app's design and content draw upon insights gained from cocreative workshops and are firmly grounded in the intervention functions of the BCW theoretical framework [29] as well as principles from self-identification theory [30,31] as key elements to motivating individuals toward healthier behaviors. Textbox 1 presents a comprehensive summary of the behavior change techniques incorporated into MIA.

Textbox 1. Overview of behavior change techniques implemented in the More In Action (MIA) app.

Behavior Change Wheel (BCW) [32]

- The BCW framework is centered on 3 core components: capability, opportunity, and motivation (Capability, Opportunity, and Motivation–Behavior system), which can drive behavior change. The MIA app enhances users' *capability* through educational content and reminders, increases *opportunity* through social features such as the community calendar, and boosts *motivation* by offering personalized goals and feedback.

Self-determination theory (SDT) [33]

- SDT emphasizes 3 fundamental psychological needs—autonomy, competence, and relatedness—as essential for motivation toward healthy behavior changes:
- *Autonomy*: the MIA app can provide users with the ability to customize their exercise routines, choose their goals, and select the types of physical activity (PA) they prefer. The workouts are composed personally based on the tailored personal goals users enter after registering.
- *Competence*: to enhance users' feelings of competence, the MIA app incorporates a system of progressive challenges and feedback. The app tracks users' progress in real time, offering progress bars or celebratory messages for achieving milestones (eg, achieving the World Health Organization guideline for PA). In addition, educational content on the benefits of regular PA and other health benefits helps users feel more skilled and capable.
- *Relatedness*: the MIA app fosters a sense of relatedness by integrating a community calendar that allows users to connect with others.

Self-identification theory (SIT) [31]

- Implementing SIT within the MIA app involved creating features that allow older adults to integrate PA into their self-concept, making it a core part of their identity. Users start by *selecting goals* that resonate with their personal aspirations and lifestyle. These goals can range from improving health, gaining strength, and enhancing mobility to participating in community activities or playing with grandchildren. They choose freely. The key is for users to choose goals that reflect their values and how they perceive themselves.

Unique Attributes of MIA

The MIA app exhibits several unique attributes within the scope of gerontechnology that set it apart from other existing mHealth technologies. To compare MIA with existing solutions, we conducted a review to map the currently available mHealth technologies for promoting PA in older adults.

All technologies were scored according to 11 key components previously identified [19,20,34]. These findings are detailed in Table 2.

[a]This design prioritizes the end user's needs, preferences, and limitations throughout the development process.

[b]These are systematic strategies derived from behavioral science theories to influence and sustain behavior modification.

[c]Personalized interventions involve tailoring health-related strategies and communications to individual users based on specific data gathered about their behaviors, preferences, and environmental contexts.

[d]Refers to the dynamic capability of the app to engage users through direct and responsive interactions.

[e]Integrates physical activity into routine daily tasks to reduce perceived barriers and enhance the practicality of exercises.

[f]This component involves the app's capability to synchronize with wearable technology to gather continuous physiological data, which can be used for monitoring health conditions in real time.

[g]Encourages the formation of supportive social networks within the app, enhancing user engagement through community building.

[h]Delivers evidence-based health information and instructional content to improve knowledge and skills related to physical activity.

[i]Uses motivational elements such as web-based badges, achievement unlocking, and progress tracking to enhance motivation and encourage continual app engagement.

[j]Accessibility ensures that products and services are usable by people with various abilities, whereas inclusivity focuses on creating environments that accommodate and welcome diverse individuals across all backgrounds and needs.

[k]An older adult–specific feature is a design element in a product or service, particularly mobile apps, that addresses the physical, cognitive, and social needs of older adults, such as mobility, sensory impairments, chronic conditions, and isolation, to enhance usability, safety, and autonomy.

[l]Presence of component.

[m]PACE: Physical Activity Cardiorespiratory Exercise.

[n]MIA: More In Action.

Features

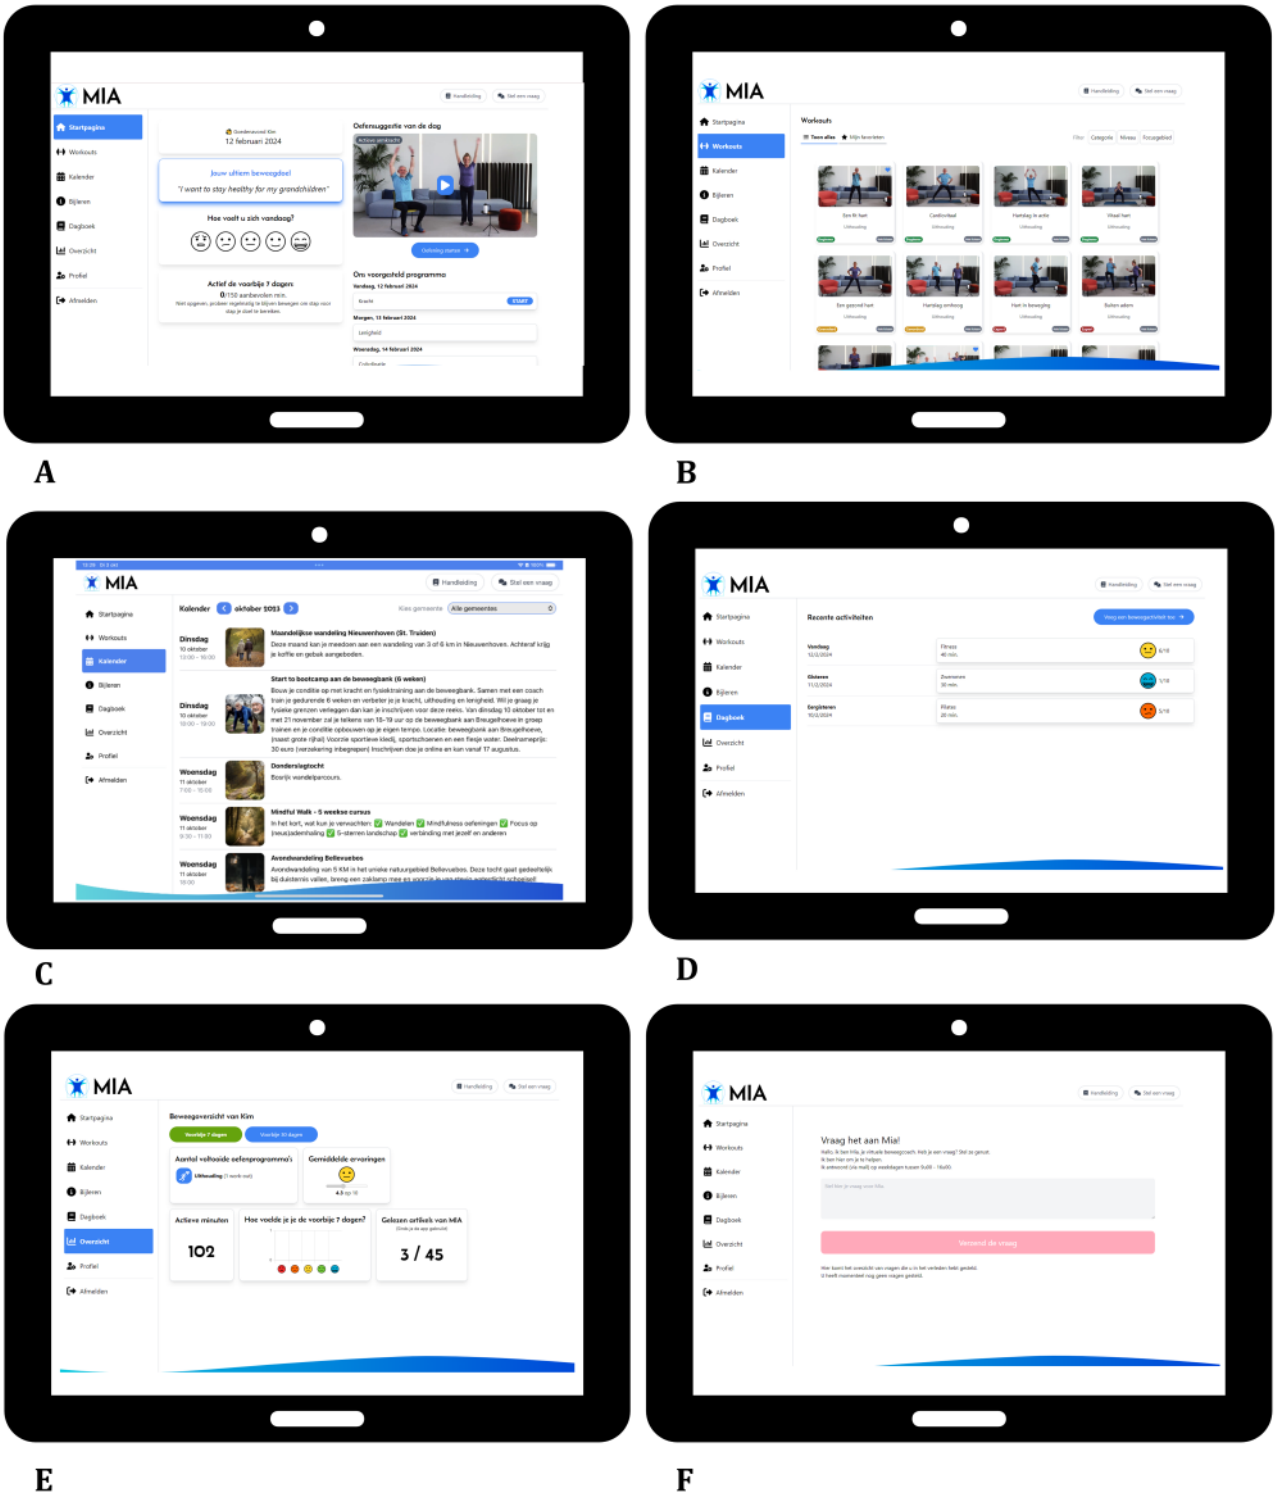
MIA incorporates 7 major features: tailor-made tips, literacy initiatives to enhance awareness about PA and a healthy lifestyle, guided exercise workouts with peers, a community calendar fostering social connections, a personal diary for manual uploads of non–app-based PAs, a progression monitor, and a chatbot named MIA. The chatbot serves as a platform where users can pose questions and receive insights, motivation, and support in return. The current chatbot function is managed manually, with researchers on the development team directly addressing user inquiries. This approach allows for personalized responses and ensures that user concerns are addressed with accuracy and expertise but also for the collection of data that will be used later on to develop an artificial intelligence (AI)–driven chatbot. This AI chatbot would maintain human oversight to ensure the accuracy and relevance of the responses, particularly for complex queries. The app also includes 195 guided workout videos, each featuring 30-second exercise bursts followed by breaks. These exercises cover strength, endurance, coordination, and balance and are demonstrated by peers. Workouts are tailored to 3 skill levels—beginner, advanced, and expert—and range from 10 to 20 minutes. MIA continuously adapts workouts based on user experiences; for example, if an exercise is too challenging, the algorithm adjusts future sessions to ensure that they remain enjoyable and achievable.

User Onboarding and Interaction

Upon initiating MIA, users undergo a preliminary assessment through a questionnaire that informs the customization of their exercise regimen. This personalization is central to MIA's approach, tailoring the app experience to individual needs and preferences.

As shown in Figure 3, the home page presents a personalized PA agenda that adapts daily based on user feedback to align with their physical and mental health status. This adaptive feature is critical for tailoring the experience to the user's day-to-day condition, emphasizing the interconnection between mental well-being and PA.

Figure 3. Screenshots of the More In Action interface: (A) home page displaying a physical activity (PA) agenda, suggested workout videos, and daily tips designed to engage users with personalized fitness guidance; (B) library of workout videos with filters for exercise type, fitness level, and target body areas supporting a tailored workout experience; (C) a community calendar for local PA events; (D) manual logging of nonapp PAs; (E) PA progress monitor; and (F) a web-based coach. MIA: More In Action.



Throughout the intervention period, participants were not required to use the app daily. Instead, following the principles of behavior change techniques, autonomy was emphasized, allowing users to set personalized goals and choose their own frequency of app engagement. This flexibility enabled participants to engage with the app at their preferred rate, from as little as once a week to daily over the course of the 5-week intervention.

Outcome Measures

Quantitative Measures

At Baseline

Demographics and PA levels were first assessed during the baseline measurement. The International Physical Activity Questionnaire–Short Form (IPAQ-SF) [54], the Physical Activity Enjoyment Scale (PACES) [55], and the Digital Health Readiness Questionnaire (DHRQ) [56] were used to measure digital health readiness via a web-based questionnaire using Qualtrics (Qualtrics International Inc). The IPAQ-SF showed moderate validity with accelerometry but had wide limits of agreement, indicating caution for longitudinal use [57,58]. Both the PACES [55,59] and DHRQ [56] demonstrated strong internal consistency and reliability, making them suitable for assessing enjoyment of PA and digital health readiness, respectively.

The 5-Week Postintervention Assessment

To evaluate user satisfaction and experience, 3 established instruments were used: the System Usability Scale (SUS) [60], Net Promoter Score (NPS) [61], and Customer Satisfaction Score (CSAT) [62]. The SUS provides a standardized assessment of usability through 10 items with response options ranging from *Strongly agree* to *Strongly disagree*. Scores of >68 indicate above-average usability. The SUS has demonstrated high internal consistency (Cronbach α=0.74) and test-retest reliability (Pearson correlation coefficient=0.75), supporting its use in evaluating digital health interventions [63]. The NPS measures user loyalty by asking participants to rate their likelihood of recommending the app on a scale from 0 to 10. This metric is calculated by asking older adults the following: *On a scale from 0 to 10, how likely are you to recommend MIA-app to a friend or peer?* Respondents are classified into 3 categories: promoters (those who provide a score of 9-10), passives (those who provide a score of 7-8), and detractors (those who provide a score of 0-6). The NPS, derived by subtracting the percentage of detractors from that of promoters, offers a straightforward approach to understanding user loyalty and referral potential [62].

The CSAT quantifies user satisfaction using a 10-point scale, capturing immediate feedback on the app experience. App-specific concerns (user-friendliness, layout, and utility) were also evaluated across multiple categories, with ratings ranging from 1 to 5 (1-2 indicating dissatisfaction, 3 indicating neutrality, and 4-5 indicating satisfaction).

Microsoft Power BI (Microsoft Corp) was used to analyze participant behavior during app use to provide insights into app use analytics and user engagement patterns [64]. Data on metrics such as workout frequency, session duration, and instances of premature workout termination were collected using integrated tracking tools such as Plausible Analytics. These data were imported into Microsoft Power BI for further analysis. Web-based dashboards and visualizations, including bar charts, were created to represent key engagement metrics and user navigation patterns.

Qualitative Measures

At Baseline

A *concurrent think-aloud* approach allowed participants to voice their thoughts and actions while using the app throughout installation and use [65,66]. Usability and enhancement suggestions were supplied to the researchers in real time [67-69]. Multimedia Appendix 3 details the think-aloud protocol, with an average procedure time of 20 (SD 6.2) minutes. These sessions were conducted in our laboratory at PXL University of Applied Sciences and Arts.

The 5-Week Postintervention Assessment

Qualitative data from focus groups were also collected to better understand app users' experiences. Following the 5-week trial of the app, the participants were invited to take part in focus groups in our laboratory at PXL University of Applied Sciences and Arts, each consisting of 6 older adults. Each focus group session lasted 2 hours and aimed to explore participants' perceptions of the app along with their reflections and suggestions for improvement. The sessions covered all app features. The focus groups were facilitated by experienced researchers (JR and KD) who are specialized in qualitative research. Multimedia Appendix 4 contains the interview guide.

Data Analysis

Quantitative Analysis

The quantitative analysis used mostly descriptive statistics to examine the data. Frequency distributions were also used to observe the occurrence of data values or categories, offering a detailed view of data distribution across outcomes. In addition, Microsoft Power BI analytics played a crucial role in visualizing and interpreting the data. Microsoft Power BI allowed for dynamic dashboards and visualizations, making it easier to explore trends, patterns, and relationships within the data. By integrating various data sources, it enabled the creation of charts, graphs, and tables that provided real-time insights into participant behavior and app use.

Qualitative Analysis

The think-aloud method and focus groups were audio recorded with participants' consent for the qualitative component. The transcriptions of the focus groups were carried out verbatim, followed by a rigorous content analysis using the NVivo software (QSR International) [70]. Themes were systematically coded based on the guidelines by Braun and Clarke [71]. The coding process was independently carried out by 2 experienced researchers (KD and JR), ensuring reliability and reducing the potential for bias in theme interpretation.

Integration of Qualitative and Quantitative Results

The Nonadoption, Abandonment, Scale-up, Spread, and Sustainability (NASSS) framework was used to integrate both the qualitative and quantitative results of the study, providing a structured analysis of the potential for sustainable implementation of the MIA app [72]. Recognized for its utility in evaluating complex technological health interventions, the NASSS framework allows for a systematic examination of key factors influencing the deployment and long-term sustainability

of digital health technologies. The analysis encompassed the framework's 7 domains: the condition being addressed (physical inactivity among older adults), the technological characteristics of the MIA app (including usability and technical robustness), the value proposition (perceived benefits to end users and stakeholders), the adopter system (end users and supporters), the organizational context (integration within health care systems), the wider sociopolitical environment (regulatory and cultural considerations), and the processes of embedding and adapting the technology over time.

Results

Demographic Characteristics

A total of 30 participants (mean age 70.3, SD 4.8 y; n=17, 57% female) were included in this study. Participants had different educational backgrounds; the largest proportion (15/30, 50%) had completed higher education. Their level of digital literacy was commendable, displaying a mean score of 59.6 (SD 8.8) out of 75 on the DHRQ. Notably, 80% (24/30) of the participants acknowledged the affirmative impact of digitalization on health, whereas 73% (22/30) actively engaged with social media, among whom 36% (8/22) used it daily, 23% (5/22) used it often, 23% (5/22) used it occasionally, and 14% (3/22) used it rarely. Furthermore, 67% (20/30) of the participants sought health-related information on the web, whereas all 30 participants reported internet use, with 27 (90%) of them accessing it daily, and 17 (57%) owned a smartwatch. When it came to monitoring PA through their smartphones' health apps, 73% (22/30) of the participants checked their step count daily, 13% (4/30) did so frequently, 3% (1/30) did so occasionally, 3% (1/30) did so rarely, and 10% (3/30) never did. Regarding health-related app use, 17% (5/30) of the participants actively used this type of apps.

The IPAQ-SF revealed variability in PA levels among individuals. The median activity levels indicated moderate engagement in walking (1386, IQR 284.8-2178 metabolic equivalent of task min/wk) and lighter involvement in vigorous activities (median 0, IQR 0-1830), suggesting a skew toward lower-intensity exercises. Moreover, it was found that 10% (3/30) of the participants were classified as inactive, 40% (12/30) fell into the category of minimal activity, and a significant 50% (15/30) were categorized as vigorously active. High SDs across all categories underscored a wide range of PA levels, from minimal to extremely active, reflecting the diverse nature of physical engagement in this sample.

The PACES results revealed that participants, on average, reported a moderate to high level of enjoyment during PA, with a mean score of 107 [55]. Considering that the PACES scale ranges from 18 to 126, where higher values signify greater enjoyment, the mean score of 107 suggests that participants' enjoyment levels were significantly skewed toward the upper end of the scale. This positioning implies a generally positive perception of PA among the participants. The complete sociodemographic characteristics of the participants are presented in Table 3.

Table 3. Participant characteristics (N=30).

Variable	Values
Age (y), mean (SD)	70.3 (4.8)

[b]IPAQ-SF: International Physical Activity Questionnaire–Short Form.

Quantitative Analysis

Acceptability

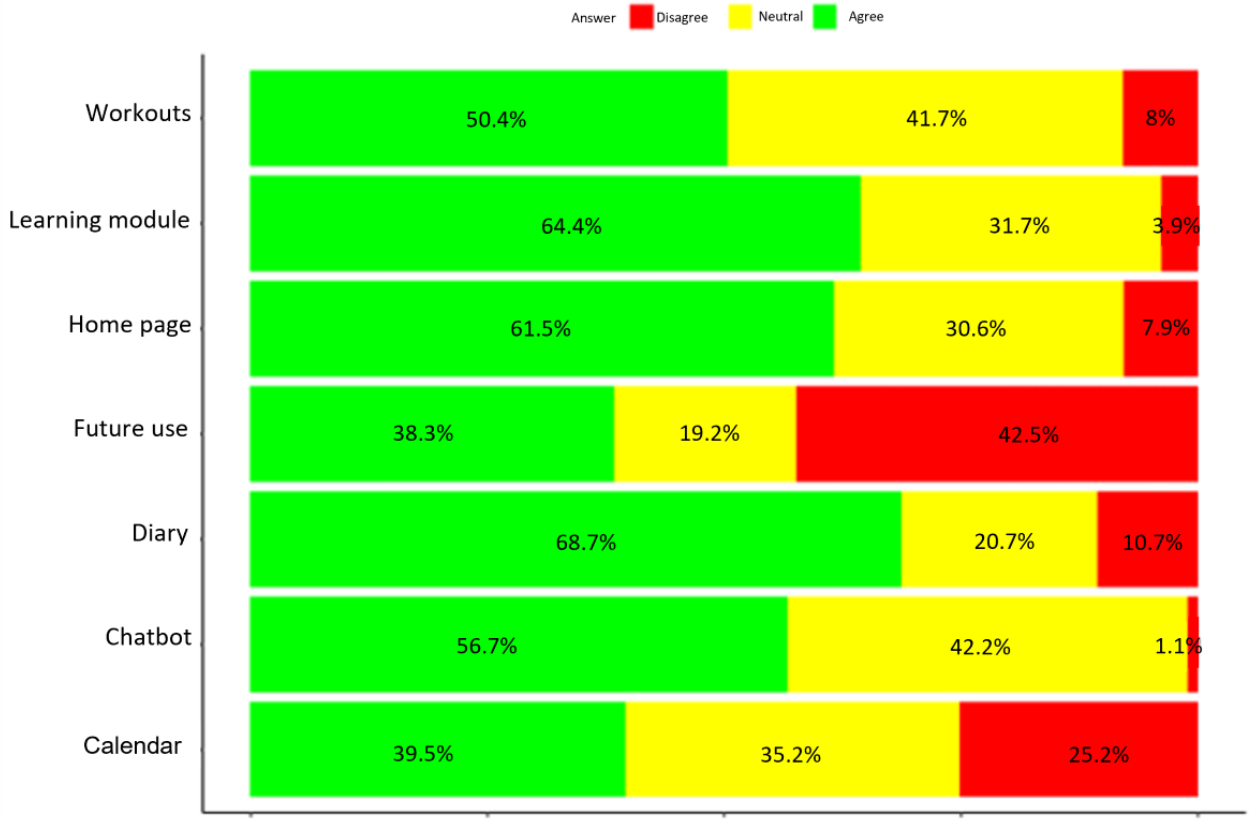
First, the general acceptability was accessed using the 3 main indicators, as shown in Figure 4.

Figure 4. Results of the System Usability Scale, Customer Satisfaction Score, and Net Promoter Score (NPS). MIA: More In Action.

According to the SUS, the mHealth app was considered *acceptably good*, with a mean score of 77.4 (SD 14.3). The results of the CSAT revealed that 47% (14/30) of the participants indicated that they were *very satisfied*, whereas 40% (12/30) reported being *satisfied*. Another 10% (3/30) had a neutral response, and only 3% (1/30) were *dissatisfied*. None of the participants provided a *very dissatisfied* score. This distribution led to a CSAT score of 86.6%, indicating a high satisfaction level among older adults using the MIA app. The NPS was used to assess customer satisfaction with and loyalty and enthusiasm toward the app. A total of 50% (15/30) of the participants were *promoters*, indicating that they would recommend the MIA app to peers and family. In addition, 33% (10/30) were *passives*, reflecting moderate satisfaction without strong advocacy, whereas 17% (5/30) were *detractors*, indicating that they were unlikely to recommend the app. The resulting NPS is calculated by subtracting the percentage of detractors from the percentage of promoters, yielding a total NPS of 33.34.

Furthermore, the specific acceptability of the different features was assessed. The quantitative results also guided the qualitative part of the study, where focus groups were conducted to dive deeper into participants' reflections and gather additional insights. The aggregated results are presented in Figure 5. The complete results per category are presented in Multimedia Appendix 5.

Figure 5. User satisfaction and engagement—categorized ratings of app features and interface (1-2: dissatisfaction [red]; 3: neutrality [yellow]; 4-5: satisfaction [green]).



User Behavioral Patterns

To track user navigation and behavior within the app, Microsoft Power BI analytics were collected on the following features: workout videos, learning modules, community calendar, manual diary, progression monitor, and chatbot. Visual representations of the Microsoft Power BI analytics are available in Multimedia Appendix 6.

Workout Videos

A total of 585 workout videos were analyzed, highlighting general satisfaction with a median satisfaction score of 4 (IQR 3-4; scale of 1-5) and physical exertion rated at a median of 5 (IQR 5-7; scale of 0-10). Users engaged for a median duration of 14 (IQR 0-34) minutes per session, with use times ranging from 0 to 34 minutes. Strength workouts were most common, comprising 40% (234/585) of the sessions, followed by endurance, flexibility, and balance workouts. Most workouts (429/585, 73.3%) were aimed at beginners, with only 5% (29/585) targeting expert levels, reflecting the app's focus on older adults. Notably, 77% (23/30) of users expressed no preference for a specific type of exercise, suggesting a wide acceptance of the available workout options.

Learning Modules

The distribution of the learning modules comprised 255 read articles across 6 different topics: mental health, social well-being, physical well-being, nutrition, sleep, and risk of falling. Physical well-being was the most frequently engaged with topic, with 26.3% (67/255) of the total read articles. Nutrition followed with 17.3% (44/255) of the read articles, whereas mental health comprised 16.9% (43/255) of the read articles.

Community Calendar

Only 3 activities were added to the participants' community agenda, all of which were organized walks.

Manual Entries in Diary

The analysis of 545 external activities showed a median *general feeling after exercise* score of 4 (IQR 4-4) on a scale from 2 to 5, indicating generally positive responses. The range of perceived exertion scores was broader, with a median of 5 (IQR 5-7) indicating a balance between lower and higher levels of perceived effort. Walking emerged as the most popular activity (210/545, 38.5% of external activities), followed by cycling with electric assistance (78/545, 14.3%); cycling without electric assistance (66/545, 12.1%); and other activities such as padel, tennis, strength training, and running. The duration of these activities varied significantly, with a median time of 60 (IQR 40-90) minutes ranging from 5 to 400 minutes, indicating diverse engagement levels. The data revealed that a quarter of the participants (8/30, 27%) engaged in activities for <40 minutes, whereas a significant portion spent ≥90 minutes.

Chatbot

During the 5-week period, the chatbot was consulted 66 times. Most of the interactions involved feedback, accounting for 48% (32/66) of instances. Communication regarding exercise differentiation occurred 15% (10/66) of times, whereas

medical-related queries were raised 5% (3/66) of times. Technical issues led to 9% (6/66) of consultations, and motivational support prompted 17% (11/66) of interactions. The remaining 6% (4/66) of consultations fell into other categories.

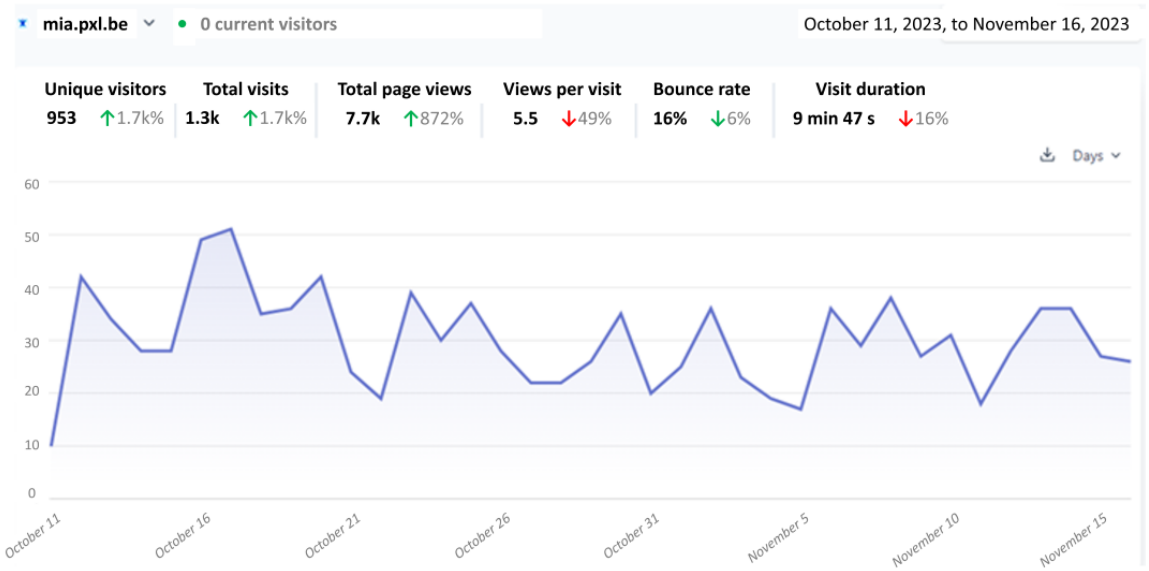
Adherence

During the 5-week intervention, app adherence was measured by tracking both the frequency of use and interaction patterns. Rather than requiring daily use, the study sought to assess whether participants engaged with the app according to the personalized goals and self-determined use frequencies they had set. The intervention, guided by self-determination theory [33], prioritized autonomy, enabling participants to select their own goals and decide how often to use the app. Engagement levels varied, with participants using the app between 3 and 7 times per week, with a median of 5 (IQR 4-6) times per week. Adherence rates averaged 135%, with individual rates ranging from 21% to 271%, reflecting the diverse levels of user interaction throughout the intervention.

On average, participants engaged with the app 32.88 (SD 14.06) times, ranging from 11 to 59 times used, which translates to an approximate daily use rate of 0.94 (SD 0.40) times. This indicates near-daily use of the app among the study cohort.

Despite the considerable variability in workout interactions within the app, with a median workout frequency of 17 sessions (IQR 11.2-28.5), motivation remained notably stable throughout the study, with some dips during the weekends. Participant engagement and interaction patterns throughout the 5-week intervention are visualized in Figure 6. Daily engagement varied between 0.66 and 3 sessions per day; however, there were no discernible fluctuations in adherence over time. Unlike the common pattern of an initial surge in activity followed by a dip and potential recovery, participants demonstrated consistent interaction with the app across the 5-week intervention.

Figure 6. Participant engagement and interaction patterns over the 5-week intervention. The y-axis shows the number of visits to the More In Action app.



Qualitative Analysis

Think-Aloud Method

The thematic analysis of the *think aloud* data resulted in the identification of 3 major key themes presented in Textbox 2. The other results and functionality are briefly described in the following sections.

Participants began interacting with the MIA app by opening it and completing their profiles. The welcome screen was inviting and easy to navigate, but some participants encountered difficulties with the profile questionnaire, highlighting a need for clearer guidance. When exploring the home screen, the interface was straightforward, with large icons and a simple layout. However, some features such as mood indicators were confusing, indicating a need for better explanations. The workout section was well received for its variety and suitability for different fitness levels, enhancing user experience. However, navigating the calendar feature proved challenging for some, with issues in adding or removing items pointing to a need for a more intuitive design. The learning module page was appreciated for its informative content, although some noted a lack of retirement-related topics, suggesting room for expansion. The diary functionality faced some hurdles as users found it difficult to add past activities, needing more flexible controls. Visually, the app was praised for its appealing design with bright colors and clear typography, making it esthetically pleasing and not overly complex. However, specific challenges such as difficulties with the profile questionnaire and mood indicators revealed that clarity in guidance is also crucial. Thus, while the app's visual appeal contributes to its overall usability, the complexity of certain features points to the need for balancing esthetics with intuitive guidance.

Textbox 2. Key themes of the think-aloud protocol.

Usability and accessibility

- The participants' experiences reveal that usability and accessibility are crucial for a successful app. Challenges with completing profiles, navigating calendars, and adding diary entries highlight areas in which the app could improve. Ensuring that the app is intuitive and easy to use can lead to a better user experience.

User interface and design

- The overall design and layout of the app play a significant role in user satisfaction. The positive feedback on the app's simplicity, large icons, and bright colors shows that a visually appealing and straightforward design enhances usability. This theme indicates that maintaining a clean and user-friendly interface is essential.

Feature functionality and clarity

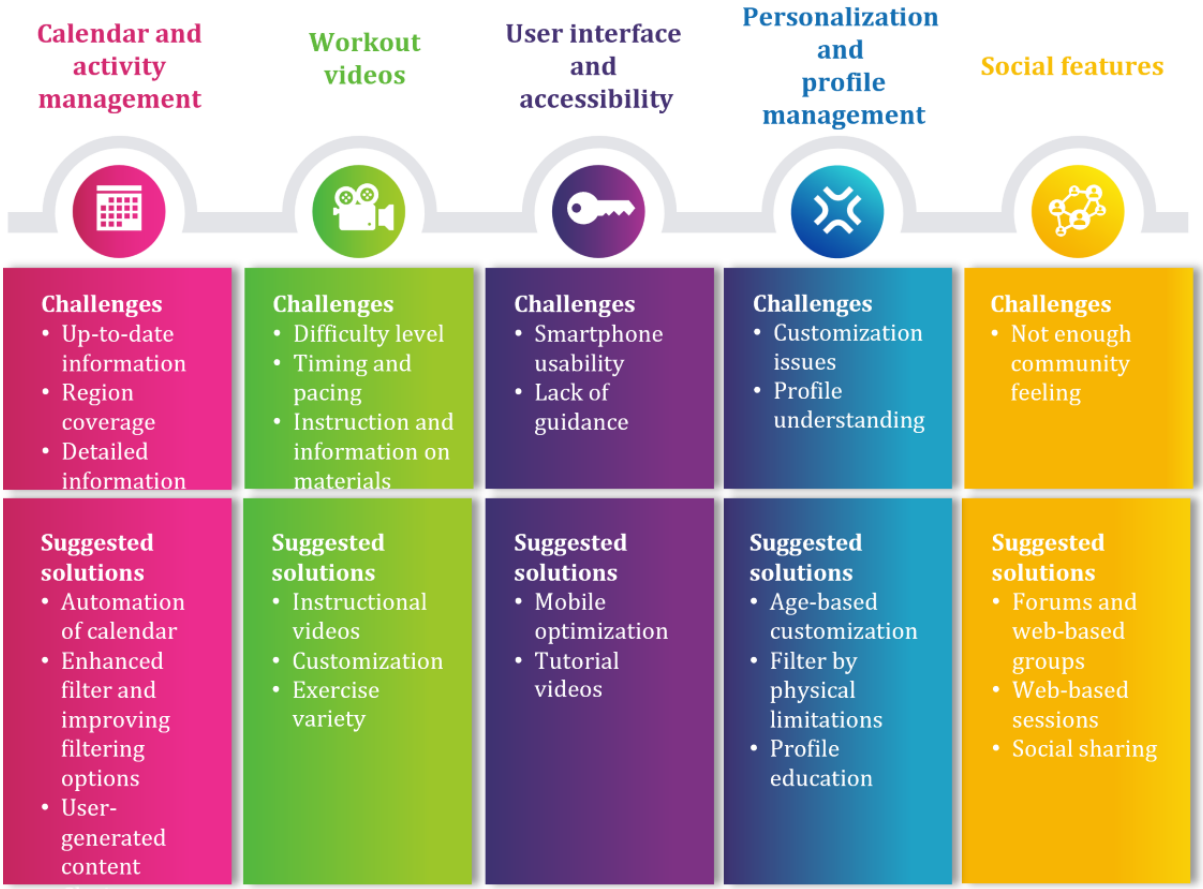
- The confusion regarding certain features, such as the mood indicators and the calendar, suggests that functionality and clarity are important. Ensuring that each feature is well explained and operates smoothly can lead to a more satisfying user experience. This theme points to the need for clear communication and improved design in specific areas of the app.

Focus Groups

Overview

The transcripts of these focus groups led to identifying 5 key themes, presented in Figure 7: calendar and activity management, workout videos, user interface and accessibility, personalization and profile management, and social features. Participants valued the community calendar for fostering social connections, but engagement in activities was low. Tailored workout videos were appreciated for their adaptability, although more flexibility in goal setting and detailed instructions were desired. Feedback highlighted the intuitive interface but suggested improvements in flexibility, readability, and tracking. Personalization features such as the chatbot were appreciated, although users wanted better clarity in activity plan customization. Social features, including a buddy system, were seen as ways to boost user interaction and engagement. Each of these themes is further detailed in the following subsections.

Figure 7. Key themes of the postassessment focus groups.



Calendar and Activity Management

Participants valued the community calendar for enhancing social connections but reported limited participation in the listed activities. A participant aged 68 years highlighted the following:

> *The agenda is there because of the social connection with others. I really liked it, although I didn't go to an organized activity. You should definitely keep it in there.*

Others suggested that participation might increase with better visibility and advertising of the activities, along with reminders and notifications to prompt more active involvement.

Workout Videos

The tailored workout plans and videos were popular among users. A participant aged 67 years wanted greater control over his workout goals, saying the following:

> *The target of 150 minutes per week is good, but I would like to choose my target minutes myself, for instance, 500 minutes.*

This comment indicated that some users prefer more flexibility in setting personal goals. Another participant aged 72 years commented the following:

> *The algorithm when a workout is too challenging works well; the next video suggestion is indeed tailored to my level. I tested it to see if it would work.*

This adaptability was valued, but users pointed out that the video instructions could sometimes be too quick to follow. Another participant aged 70 years who was already active and doing a lot of cardiovascular exercise mentioned the following—"The app and the exercises made me realize I need to work on my strength as well"—suggesting that the app can broaden users' fitness horizons.

Participants also suggested improvements such as being informed about required materials in advance. A participant aged 69 years noted the following:

> *It would be good to know which materials to use in advance.*

This feedback suggests that clearer preparation instructions could enhance user experience.

User Interface and Accessibility

Various aspects of the app's interface and accessibility were highlighted, noting strengths and areas for improvement. The calendar feature was appreciated for fostering social interactions, although it lacked sufficient engagement tools. Users found the manual diary and progression monitor helpful for tracking activities. Still, they criticized their limited functionality, particularly the inability to edit past entries and the short view range of 7 days. Suggestions included enhancing flexibility and extending tracking capabilities to improve usability.

The *Learning* section received mixed reviews; while the content was engaging, users suggested features such as checkboxes to track articles read, indicating a need for more interaction and relevance to older adults. Although the app's layout was praised for its esthetic and ease of navigation, calls for better readability and customization were prominent.

Feedback on the chatbot was mixed, with some users finding it motivating whereas others saw room for personalization. General usability issues related to smartphone optimization and intuitive navigation were raised but reportedly resolved quickly, demonstrating effective technical support. While the app was generally well received, users desired more robust features and personalization to enhance their experience.

Personalization and Profile Management

Users appreciated features that allowed for personalization, such as the chatbot and manual diary, recognizing their value despite some limitations. A user aged 68 years praised the diary feature, stating that "The diary was great. It is really good to track your activities," but also recommended enhancements, suggesting that "It would be nice if the diary could go back in the past, more than now." In addition, it became apparent that users were unaware that the initial registration questions were intended to personalize their plans as a user stated the following:

> *I didn't know we could adjust the information in the PA plan.*

This misunderstanding also led to them not expecting the system to adapt over time.

Nonetheless, several participants acknowledged the app's added value in promoting PA. A participant aged 66 years noted the following:

> *Getting the push notifications motivated me; it was like a digital motivator in being more active.*

Social Features

The social features such as the community calendar were highlighted as significant opportunities to enhance user engagement. A participant aged 66 years suggested a buddy system to increase interaction:

> *Perhaps a buddy system where I can see my friend and we can motivate each other.*

Suggestions for Improvement

Multimedia Appendix 7 summarizes the suggestions and iterations from the focus groups, offering insights into lessons learned during the development process.

Integration of Quantitative and Qualitative Analysis

The NASSS framework [72] provided a structured approach to integrating the quantitative and qualitative results, revealing barriers to and facilitators of adoption and the interactions influencing scalability and sustainability. It enabled comparisons among user experiences, usability scores (eg, SUS and CSAT), and app interaction data while incorporating qualitative insights from focus group feedback on usability challenges and user perceptions. This enabled us to identify alignment and discrepancies between users' perceived value of the MIA app and their actual app interactions, as well as broader contextual factors influencing sustained use. Figure 8 visualizes this analysis, emphasizing how the NASSS framework bridges the gap between numerical data and user narratives.

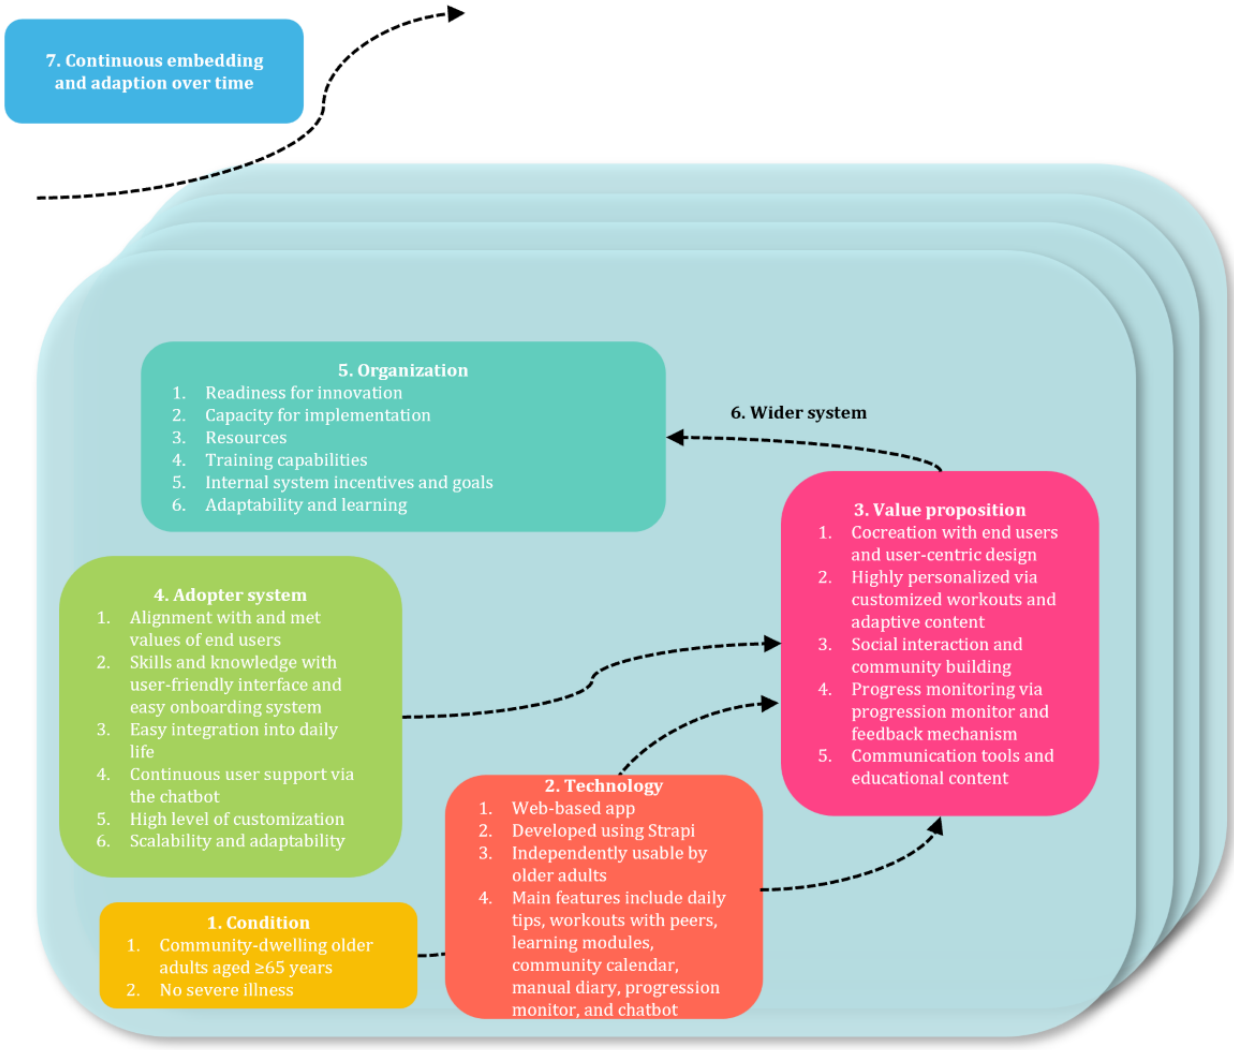
Addressing physical inactivity among older adults is challenging due to varying digital literacy, physical abilities, and health conditions. A key facilitator was the app's customization, allowing users to adjust exercise recommendations, leading to positive SUS and CSAT scores. The app's technical stability and responsive support further encouraged adoption among digitally literate users.

However, barriers such as navigation difficulties and insufficient guidance on features such as profile setup and calendar use limited engagement, with 30% (9/30) of the users classified as passive and 17% (5/30) classified as detractors in the NPS, indicating a risk of user churn. While users appreciated tailored workouts and real-time feedback, some sought greater control over goal setting, suggesting the need for enhanced personalization.

The NASSS analysis identified opportunities to boost engagement, including social features such as a buddy system to align with older adults' social preferences. Integration with health care systems could facilitate broader adoption if endorsed by providers. Alignment with health policies and partnerships may also expand the app's reach.

Despite these strengths, challenges such as technological intimidation, market competition, age-related declines, and data privacy concerns pose risks to long-term adoption. Adherence to ethical standards mitigated some concerns. Sustained engagement depended on the app's adaptability to user feedback, requiring continuous updates and technical support to maintain user interest. Detailed information is available in Multimedia Appendix 8.

Figure 8. Nonadoption, Abandonment, Scale-up, Spread, and Sustainability framework adapted for the feasibility study of the More In Action app.



Discussion

Principal Findings

In recent years, the intersection of aging and technology has gained recognition as a vital factor in enhancing quality of life for older adults [73]. Technology holds substantial potential to improve everyday living for this demographic, yet adoption barriers remain a significant concern as outcomes often rely on user-driven interactions, which can vary significantly [10,34,74,75]. Effective technology design for older users is best achieved through *user involvement and cocreation*, a

strategy that leverages the unique insights of users, who are experts in their own experiences [19,20,61,76,77]. This participatory approach not only results in products that better meet older adults' specific needs, desires, and challenges but also counters age-related stereotypes in gerontechnology [78]. MIA exemplifies this by having been developed through a collaborative cocreation process with older adults. However, to achieve acceptable technologies for older adults, an in-depth understanding of their acceptability, feasibility, and usability is necessary [79]. Against this backdrop, the main aim of this study was to thoroughly explore the acceptability, feasibility, and usability of the MIA app in promoting PA and encouraging sustained, active, and healthy behaviors among its users.

The app received positive feedback, achieving an SUS score of 77.4 and a high CSAT rate of 86.6%. The NPS stood at 33.34, indicating a good level of customer loyalty, with half (15/30, 50%) of the participants categorized as promoters. Feedback on the app was positive for its clarity and engagement. In addition, feasibility and adherence levels were comparable to those observed in other apps evaluated. For example, StandingTall showed acceptable usability, with exercise adherence improving over time [35], whereas Physitrack reported a high study retention rate of 95% and an adherence to prescribed exercises of 84% [40]. Similarly, Fit for All [43] recorded an adherence rate of 82%, supporting the app's potential in facilitating engagement and promoting PA among users. The workout videos on the MIA app received a commendation, although some participants suggested improvements. The learning module and diary functions were praised for their utility, yet some users noted challenges with navigation and desired the ability to edit past diary entries. The progression tracker and chatbot were also seen as valuable, although there was a call for more detailed tracking and enhanced personalization. Analysis showed strong engagement with the workout videos, especially strength-focused sessions, and high satisfaction levels with these workouts. Insights from the think-aloud protocols and focus groups highlighted the need for clearer guidance on profile management, workout customization, and calendar functionality. Participants also expressed a desire for more engaging social features, such as a buddy system. In general, the app was well received for its educational content and tracking features. However, there were recommendations for improving the user interface, enhancing social connectivity, and further personalizing the content.

There are 3 reasons why the MIA app offers more value compared to other alternatives (Table 2). First, the development and design process of the MIA app was based on the design thinking method and user-centered approach, guided by older adults at every stage. Their input was pivotal, ensuring that the app's features were tailored to their specific needs and preferences. Moreover, most existing apps in this domain predominantly cater to the younger segment of the older population, typically those aged 50 to 55 years [10,12,13,80-82]. This demographic focus leaves individuals aged ≥65 years underrepresented. The MIA app addresses this gap by concentrating research and design efforts on the age group of ≥65 years, thereby providing a more inclusive and representative technological solution for older adults.

Second, the MIA app incorporates behavior change theories such as the BCW [29], self-determination theory [33], and self-identification theory [30] to enhance user engagement.

Finally, the MIA app is engineered to dynamically adapt to the diverse capabilities and fluctuating motivations of its users [83,84]. It features an extensive repertoire of 195 distinct exercises encompassing various PA domains such as strength, coordination, balance, flexibility, and endurance, as well as incorporating activities pertinent to daily living. During the feasibility study, sending push notifications with personalized health messages was linked to increased user engagement. In addition, research indicates that users are more likely to interact with the app within 24 hours when push notifications are sent at midday on weekends [85-87]. Personalization is achieved by accounting for the inherently dynamic nature of motivation, which is known to vary not only from day to day but also within a single day [88]. To systematically capture these fluctuations, the app uses the technique of ecological momentary assessment [89]. This approach involves the intensive and recurrent collection of data on an individual's behavior and motivation in a real-time environment [90-92]. Moreover, the app continuously refines its exercise recommendations based on user interactions and feedback. If an exercise is deemed excessively challenging, the algorithm records this, adjusting future workouts to better match the user's current abilities and psychological state. This ensures that subsequent sessions are both enjoyable and attainable, fostering ongoing engagement and facilitating progressive improvement.

To ensure long-term retention and motivation, new videos and activities are regularly added to the app. Future updates to the MIA app will emphasize social features and gamification, including a buddy system for users to connect with exercise partners for mutual support, as well as earning badges, completing challenges, and participating in leaderboards for friendly competition. These elements, along with personalized workouts, progress tracking, content refreshers, and timely reminders, aim to enhance user engagement and sustained adherence.

Strengths and Limitations

The results of this study should be interpreted in light of some limitations. First, the participant profile may not fully represent the broader older adult population. The individuals involved in this feasibility study were notably well educated and digitally literate, with nearly 60% (17/30, 57%) owning smartwatches. This contrasts with broader trends identified in a recent study [93], which found that only 25% of those aged ≥65 years use smartwatches or health apps, a number that declines to 16% among those aged >75 years. In our study, most participants already owned smartphones and were more acquainted with mobile technology. Future studies could explore the perceptions and willingness to adopt this mHealth app among older adults less familiar with such technology.

In addition, the participants who volunteered for this study might have been inherently more motivated and interested in PA than the general older adult population. This could limit the generalizability of the findings as their feedback might not reflect the perspectives of a broader, less technologically adept

audience. Involving representatives of the older people demographic was very challenging because older adults are an extremely heterogeneous group with highly varied characteristics and needs who use, modify, and interact with technologies in rather diverse ways [94]. To mitigate the limitations of this study and enhance its generalizability, several strategies need to be implemented in the future. This involves targeting individuals who are less educated and less familiar with digital technology and those who do not own smart devices. Collaborating with general practitioners can help reach this more varied participant pool.

In addition, focus groups with older adults can sometimes result in conflicting opinions regarding an app's design and features, which proves that a one-size-fits-all approach does not work for this population. Fortunately, the opinions of the older adults were well studied and were considered as much as possible during the iteration process after the feasibility study. To address the issue of conflicting opinions in focus groups, it would be beneficial to implement a more personalized approach in future studies [95,96]. This could include individual interviews that can capture a wider range of perspectives and experiences. This would allow researchers to explore deeper insights and accommodate each participant's unique needs and preferences, moving beyond a one-size-fits-all solution.

To enhance both the reliability and validity of future studies, it is recommended to incorporate randomized controlled designs that include blinding procedures. This approach will help minimize bias by ensuring that assessors do not know which participants have received the intervention, thereby providing a more objective assessment of the outcomes [97,98]. In addition, conducting longitudinal assessments could yield a richer understanding of the intervention's long-term attrition rates, further strengthening the study's findings and their applicability across different settings and populations [99,100].

Finally, unrealistic expectations surrounding an mHealth app could pose a challenge. Users might expect immediate and significant improvements, failing to recognize that behavior change is typically a gradual process [24]. Therefore, it is crucial to underscore that the app is designed to be a supportive aid in the journey toward change, not a quick fix. To address this issue, managing expectations proactively is essential. Effective communication and educational initiatives are key to establishing a realistic understanding of what the app can and cannot do. By clearly outlining the app's functionalities and limitations, users can be better prepared for their experience. This approach helps maintain sustained engagement and maximizes the app's potential as a tool for positive transformation.

Despite these limitations, this study's primary strength lay in its adoption of a mixed methods approach, which facilitated a comprehensive understanding of the app's feasibility. The methodology combined surveys using validated tools, interviews, focus groups, and Microsoft Power BI analytics. This robust approach enabled us to construct a detailed profile of user behavior within the app. Through the systematic analysis of interaction data, we identified the features that garnered the most engagement and pinpointed areas for potential enhancement to improve user experience and retention. The insights derived from this extensive data analysis are fundamental in shaping the future development strategies of the app, ensuring that it aligns more closely with user needs and preferences. Furthermore, by using these diverse research techniques, we were able to gather rich data on participants' experiences concerning the feasibility of the MIA app. This collaborative methodology proved especially beneficial, fostering meaningful dialogues between participants and researchers. These discussions yielded valuable perspectives on potential improvements to the mHealth app.

Future Use and Implications in the Field

The MIA app is currently free and open source. However, to ensure its long-term viability, partnerships with health care insurers and other market players are being explored. A willingness-to-pay analysis [101], detailed in Multimedia Appendix 9, indicated that end users are willing to pay €4.50 to €7 (US $4.66 to US $7.25 at a conversion rate of €1=US $1.04) per month for access to the app. This willingness to pay suggests a perceived value of the app beyond its initial free access, which is further supported by user behavior. Specifically, after 6 months, 43% (13/30) of the participants continued using the app daily without being prompted.

Implementing MIA in real-world settings involves integrating it into health care systems, community programs, and support networks, positioning it as a preventive tool. Partnerships with health care providers and insurers can promote MIA's role while community centers leverage its social features to encourage group activities.

As digital health technologies continue to evolve, the MIA app needs to take several opportunities into account to expand its applicability and feasibility. This offers a range of possibilities for the field.

Tailored user experience remains a very important subject to keep motivating older adults by providing relevant and achievable goals that cater to their individual fitness levels and health conditions [87,102,103]. Enhanced just-in-time interventions enabled by the app's real-time data capabilities through ecological momentary assessment could revolutionize preventive health measures [104,105]. This merges with the potential for integration with wearable technologies, promising a more holistic approach to health monitoring that could improve predictive health interventions for older adults [106-108]. Moreover, integration with wearable devices can enhance the MIA app's functionality by providing real-time, accurate data on PA levels and health metrics. This integration can promise a more holistic view of a user's health and a more precise adjustment of their activity recommendations [50].

As social engagement appeared to be a critical component in maintaining motivation for PA among older adults, the MIA app could include more robust social networking features such as support groups, cooperative challenges, and shared fitness goals [30,109,110].

Another important evolution to consider is the evolution of advanced predictive analytics [111-113]. With advancements in AI and machine learning, the app could incorporate predictive

analytics to forecast potential health risks based on user activity and health data. This feature could alert users and health care providers to potential health issues before they become severe, facilitating timely intervention.

In addition, the MIA app's potential expansion to provide targeted support for informal caregivers, especially those managing care for partners with dementia, offers a pathway to significantly alleviate caregiver burden [114,115]. This feature could become increasingly vital during crisis situations such as pandemics, where the app's adaptability could ensure continuous support for physical and mental health under restrictive conditions [116-119]. Furthermore, by enabling older adults to exercise independently, the app could empower health care professionals by reducing the frequency of in-person checkups, thereby optimizing health care resources [120].

Finally, a broader health integration more closely with health care systems allowing for a smoother exchange of information between the app and health care providers could be a great opportunity [121]. This integration could enable the development of personalized health care plans based on the app's insights, enhancing the overall health care experience by keeping physicians informed and engaged in their patients' lifestyle changes.

Conclusions

This study highlights the potential in merging aging with technology to enhance quality of life and prevention through promotion of PA. Despite some limitations, the app received positive feedback for its usability and customer satisfaction. This underscores the value of involving users in the design process, adhering to a cocreation model that caters to their specific needs and counters age-related stereotypes in technology design. However, the insights gathered suggest a need for broader inclusivity in future studies, targeting less technologically savvy older adults to improve generalizability.

The analysis revealed strong engagement with specific app features (eg, workout videos) and highlighted areas for improvement, such as user interface and social connectivity enhancements. Longitudinal studies and ongoing iterations informed by user feedback will be crucial in refining these features. Managing expectations is also essential as technology adoption among older adults often requires recognizing that behavior change is gradual. Future directions include integrating the app into health care systems to tailor health plans more precisely to individual needs and expanding the app's functionality using predictive analytics to pre-empt health issues. Ultimately, by continuing to evolve and adapt to user feedback and technological advancements, technology such as the MIA app can significantly contribute to promoting sustained, active, and healthy behaviors among older adults, demonstrating the profound impact of well-designed gerontechnology.

Authors' Contributions

KD developed the initial concept for the project and was responsible for acquiring funding. KD undertook the data analysis and curated the necessary resources while also creating visual representations of the data. KD drafted the original manuscript and led the editing and revision process. JR and KQ both contributed to the investigation process and assisted in editing and reviewing the manuscript. SV was similarly involved in the investigation and provided critical review of the manuscript drafts. JB, AS, and DH provided feedback on the manuscript. BB, aside from assisting in manuscript revision, developed the methodological framework of the study and supervised the research process, ensuring adherence to academic standards and contributing significantly to the original draft. All authors have read and approved the final version of the manuscript.

Abstract

Background: Loneliness is a significant issue among older Asian Americans, exacerbated by the COVID-19 pandemic. Older age, lower income, limited education, and immigrant status heighten loneliness risk. Information communication technologies (ICTs) have been associated with decreased loneliness among older adults. However, older Asian Americans are less likely to use ICTs, particularly if they are immigrants, have limited English proficiency, or are low income. The Technology Acceptance Model posits that perceived usefulness (PU), and perceived ease of use (PEOU) are key factors in predicting technology use.

Objective: This study aimed to examine associations between PU, PEOU, ICT use, and loneliness among low-income, older Asian Americans.

Methods: Cross-sectional survey data were gathered from predominately older Asian Americans in affordable senior housing (N=401). Using exploratory factor analysis and Horn parallel analysis, we examined 12 survey items to identify factors accounting for variance in ICT use. We deployed structural equation modeling to explore relationships among the latent factors and loneliness, adjusting for demographic and cognitive factors.

Results: Exploratory factor analysis and Horn parallel analysis revealed 3 factors that accounted for 56.48% (6.78/12) total variance. PEOU combined items from validated subscales of tech anxiety and comfort, accounting for a 28.44% (3.41/12) variance. ICT use combined years of technological experience, computer, tablet, and smartphone use frequency, accounting for 15.59% (1.87/12) variance. PU combined 2 items assessing the usefulness of technology for social connection and learning and accounted for a 12.44% (1.49/12) variance. The 3-factor structural equation modeling revealed reasonable fit indexes (χ^2_{133}=345.132; *P*<.001, chi-square minimum (CMIN)/df = 2595, comparative fit index (CFI)=0.93, Tucker-Lewis Index (TLI)=0.88). PEOU was positively associated with PU (β=.15; *P*=.01); PEOU and PU were positive predictors of ICT use (PEOU β=.26, *P*<.001; PU β=.18, *P*=.01); and ICT use was negatively associated with loneliness (β=–.28, *P*<.001). Demographic and health covariates also significantly influenced PU, PEOU, ICT use, and loneliness. English proficiency and education positively predicted PEOU (*r*=0.25, *P*<.001; *r*=0.26, *P*<.001) and ICT use (β=1.66, *P*=.03; β=.21, *P*<.001), while subjective cognitive decline and Asian ethnicity were positively associated with loneliness (β=.31, *P*<.001; β=.25, *P*<.001).

Conclusions: This study suggests that targeted interventions enhancing PU or PEOU could increase ICT acceptance and reduce loneliness among low-income Asian Americans. Findings also underscore the importance of considering limited English proficiency and subjective cognitive decline when designing interventions and in future research.

Introduction

Background

The 2019 California Health Interview Survey (CHIS) found that 1 in 4 (25.7%) Asian Americans aged 65 years and older were lonely [1]. Loneliness is defined as a subjective experience stemming from perceived isolation or a disparity in one's desired and actual social interactions [2]. In the CHIS, Asian American older adults reported significantly lower levels of perceived social and emotional support (56%) as compared with non–Asian American older adults (80%) [3]. During the COVID-19 pandemic, loneliness increased among older Americans, and even today, loneliness levels are higher as compared with prepandemic levels [4]. In 2023, the Surgeon General announced that the United States is experiencing a pandemic of loneliness [2].

As compared with younger generations, older adults are particularly at risk for loneliness and social isolation due to factors such as retirement, relocation, and shrinking social circles. Besides older age, other risk factors for loneliness include financial insecurity, low educational attainment, poor physical or mental health, being an immigrant, having a disability, and living alone [2,5-7]. A systematic review exploring factors associated with loneliness among older Asian American immigrants found that migration grief, diminished ethnic ties, mental and physical impairment, deteriorating health conditions, living alone, a lack of meaningful social connections and support networks, and fewer interactions with family members were all significant factors contributing to loneliness [8].

Among older adults, the use of information communication technologies (ICTs), including smartphones, tablets, personal computers, the internet, and social media, is associated with decreased loneliness [9,10]. ICT use can strengthen preexisting connections with family and friends, foster new social relationships, and build intergenerational bonds [9]. ICT use is also positively associated with self-efficacy, self-esteem, a sense of autonomy, independence, and greater well-being among older adults [9]. Older Asian Americans can further benefit from using ICTs to stay in contact with distant relatives and maintain a connection with their culture of origin; this is particularly relevant given that 85% of Asian Americans aged 65 years and older are foreign-born [11-13]. Furthermore, ICTs can facilitate access to information in one's native language and translation services. However, both the CHIS and the National Health and Aging Trends Study (NHATS) showed that older Asian Americans are less likely than non-Hispanic White older adults to use the internet, send emails or text messages, conduct personal tasks on the internet, or seek web-based health information, particularly if they are immigrants, have limited English proficiency, or are low income [14-16]. Furthermore, other factors, such as age, gender, educational attainment, and subjective cognitive decline significantly impact ICT acceptance and use among low-income, older Asian Americans [17,18].

A recent systematic mapping review identified 59 articles describing 119 factors that predict older adults' intention to use digital technologies [19]. However, despite a rich literature focused on this topic, the mapping revealed that most studies (68%) did not examine these factors using an established theoretical framework or model for technology acceptance. For example, although loneliness was identified as a factor associated with ICT use, it has not been analyzed through a theoretical framework or model [19].

Theoretical Framework

The Technology Acceptance Model (TAM) is the most commonly used theoretical model to study technology adoption among older adults and also among the general population [19-21]. The backbone of the TAM is comprised of perceived usefulness (PU) and perceived ease of use (PEOU). PU relates to one's perception of technology as being useful for accomplishing desired goals, while PEOU refers to how much effort one anticipates needing to make to learn to use new technology. The TAM proposes that PEOU predicts PU, PU, and PEOU predict attitudes toward technology, and these attitudes predict behavioral intention to use technology, which subsequently influences actual use [21].

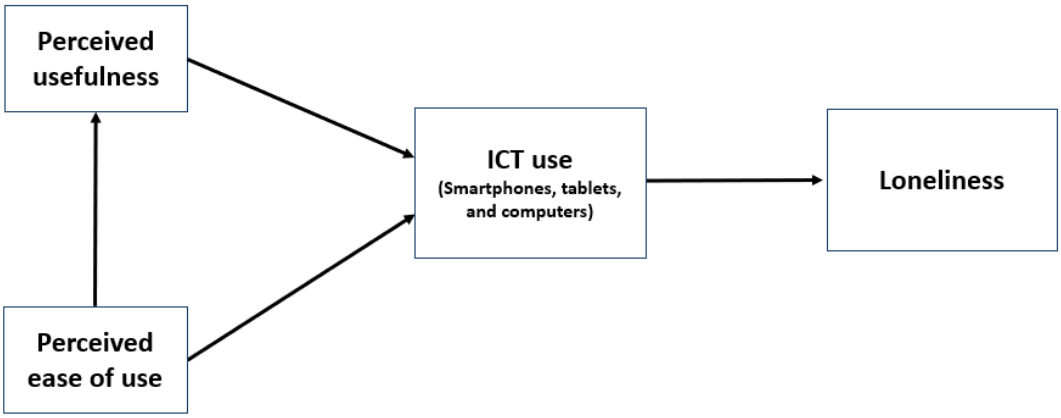
In 2 previous studies, we validated a simplified TAM to predict ICT use among low income, older Asian Americans. The simplified model removed the mediators (attitudes toward technology and behavioral intentions) and adapted the constructs of PU and PEOU from the original TAM [17,18]. In the adapted model, PU was defined as older adults' perceptions of ICTs as being useful for connecting with family and friends and learning new information and skills, and PEOU was operationalized using 6 evidence-based items that measure older adults' comfort and anxiety with ICTs [18]. However, in our previous work, we had not empirically examined the assumptions of the operationalization of PU, PEOU, and ICT use using robust statistical methods. In addition, the association between ICT use and loneliness among older Asian Americans has never previously been examined using the TAM framework.

Research Design

This cross-sectional study aimed to rigorously assess the assumptions underlying the conceptualization of PU, PEOU,

and ICT use using a series of statistical techniques. In addition, we plan to extend the simplified TAM as described in DeLange Martinez et al [18] to explore the association between technology acceptance and loneliness among low income, older Asian Americans (Figure 1). Based on previous studies, we adjusted the model for age, gender, education, English proficiency, Asian ethnicity, and subjective cognitive decline [17,18].

Figure 1. Extended Technology Acceptance Model examining the association between information communication technologies acceptance and loneliness among low income, older Asian Americans. ICT: information communication technology.



In this study, we test three hypotheses, that are (1) H1: PEOU will be positively associated with PU. (2) H2: PEOU and PU will be significant, positive predictors of ICT use. (3) H3: ICT use will be significantly negatively associated with loneliness.

Methods

Data and Sample

In the Fall of 2020, The Lighthouse Project for Older Adults was launched with the aim of developing a scalable model to address barriers to technology use among residents of affordable senior housing communities. To inform the intervention, focus groups were held with 29 residents and 13 staff across 2 communities. The discussion revealed many challenges, including high rates of social isolation, low literacy levels in multiple languages, cognitive and sensory challenges, low comfort with technology, and lack of infrastructure [22].

To address these challenges, residents were offered access to high-speed broadband internet, ICT devices, a series of digital literacy training courses, and tech support led by peer ambassadors. As part of the program evaluation, participants completed pre- and postsurveys. The surveys were evidence-based, translated into 5 languages (English, Spanish, Chinese, Vietnamese, and Korean), and pilot-tested with 20 residents and 4 staff. The final surveys were self-administered by all Lighthouse participants in their preferred language with staff available to assist as needed.

Measures

The operationalization of PU, PEOU, and ICT use were based on the theoretical constructs from the original TAM [21]. In 2 previous studies, we operationalized these 3 constructs with 12 survey items as described below, standardizing and summing the items for subsequent analysis with hierarchical linear regression [17,18]. In this study, we examined the theoretical assumptions of these constructs by using exploratory factor analysis (EFA), Horn parallel analysis, and structural equation modeling (SEM).

Perceived Usefulness

In the TAM, PU refers to whether one perceives technology to be useful for accomplishing desired goals [21]. In this study, we operationalized PU with 2 items developed by Sims et al [23] in their measure of Motivations for ICT Use. (“Technology helps me be connected with family and friends,” and “Technology helps me learn new information and skills.”) Response categories for both statements ranged on a scale of 1 (strongly disagree) to 4 (strongly agree).

Perceived Ease of Use

In the TAM, the construct of PEOU refers to how much effort one anticipates needing to make to learn to use a new technology. PEOU has been operationalized to measure feelings of confusion, frustration, or ease when using technology; predictability or intuitiveness of the system; and frequency of making mistakes [21]. In this study, we examined 6 items from 2 validated subscales that we predicted would collectively represent the construct of PEOU. Two items were included from the Senior TAM – Tech Anxiety Subscale [24] (“I feel apprehensive about using technology,” and, “I hesitate to use technology for fear of making mistakes I cannot correct.”) and 4 items were included from the Attitudes Towards Computers Questionnaire (ATCQ) – Comfort Subscale [25] (“I feel comfortable with technology” (reverse scored), “Technology makes me nervous,” “I don’t feel confident about my ability to use technology,” and, “Technology is confusing”). Response options for all statements ranged on a scale from 1 (strongly agree) to 4 (strongly disagree). Although the original ATCQ - Comfort Subscale included 5 items, one item was not included in the Lighthouse for Older Adults survey (“Computers make

me feel dumb.") based on input from staff about cultural relevance.

ICT Use

We operationalized ICT use with 4 survey items. Three items asked about the frequency of use of computers, tablets, and smartphones. ("How often do you use a desktop or laptop computer?"; "How often do you use a tablet or iPad?"; and "How often do you use a smartphone (iPhone or Android)?") Response options ranged from 0 (never, or I do not own), to 3 (about once per day). A fourth item inquired about years of experience using ICTs ("How long have you been using technology, such as a computer, laptop, tablet, or smartphone?"). Response options ranged from 0 (I've never used these) to 3 (more than 2 years).

Dependent Construct: Loneliness

Loneliness was measured using the 3-item University of California, Los Angeles (UCLA) Loneliness Scale ("How often do you feel that you lack companionship?"; "How often do you feel left out?"; and "How often do you feel isolated from others?") [26]. While the University of California, Los Angeles Loneliness Scale typically includes 3 response options (hardly ever, some of the time, often), a fourth answer option (never) was added because several residents handwrote "never" in the margins of the survey during pilot testing. During analysis, "never" responses were collapsed with "hardly ever." Therefore, in our analysis, response categories ranged on a scale of 1 (never or hardly ever) to 3 (often).

Control Variables

In our final SEM, we controlled for age, gender, Asian ethnicity, education, subjective cognitive decline (measured with 1 item, "During the past 12 months, have you experienced confusion or changes in memory that is happening more often or is getting worse?" [dichotomous response options]), and English proficiency (measured with one item, "How well do you speak English?" (response options ranged from 1 [not at all] to 4 [very well]). The full survey used in the Lighthouse Project for Older Adults is attached as a Multimedia Appendix 1.

Analytic Strategy

We began our analysis by examining descriptive statistics and conducting Pearson correlation analysis to explore relationships among all variables.

Subsequently, using IBM SPSS Statistics (version 29), we performed EFA to investigate the underlying theoretical constructs of the survey items concerning attitudes and use of ICTs. Despite having hypotheses about the latent variables, we chose to conduct EFA before confirmatory factor analysis (CFA), aiming for a more data-driven approach to thoroughly explore the underlying structure. To determine the number of factors to retain, we applied several criteria, including factors with loadings greater than .45 and using Kaiser eigenvalues-greater-than-one rule as illustrated on a scree plot [27]. We used principal axis factoring and varimax rotation with Kaiser normalization to account for the correlational nature of the factors. In addition, Horn parallel analysis was used to confirm the EFA results.

Moving forward, we used IBM SPSS AMOS (version 29) to conduct SEM, beginning with CFA. SEM integrates measurement models and structural models, allowing for validation of instruments and analysis of relationships while considering variances and covariances. It facilitates the examination of complex relationships among multiple variables and enables mediation analysis [28]. During CFA, we assessed convergent validity using criteria suggested by Hair et al [29] and Fornell and Larcker [30], calculating average variance extracted (AVE) and composite reliability. Discriminant validity was determined based on the Fornell-Larcker criterion [30].

Next, we used SEM to represent and test our 3 hypotheses, exploring relationships among PEOU, PU, ICT use, and our outcome of interest (loneliness). As shown in Figure 1, we examined a model with PU partially mediating the relationship between PEOU and ICT use, and ICT use fully mediating the relationships between PU, PEOU, and loneliness. We also examined the impact of adjusting for demographic and cognitive factors based on previous findings [15-18]. Maximum likelihood estimation was used for factor structure verification, and missing data were imputed by estimating means and intercepts. Measures of fit, including chi-square statistic (χ^2), chi-square divided by degrees of freedom (χ^2/df), comparative fit index (CFI), Tucker-Lewis coefficient (TLI), and root-mean-square error of approximation (RMSEA), were reported. Regression weights and correlation estimates among latent factors, the outcome of interest, and control factors were also provided. For all analyses, the α-level for testing significance was set to .05.

Ethical Considerations

For this study, we analyzed presurveys from 5 Lighthouse communities, collected between July 2021 and July 2022, before receiving the intervention. All participants were aged 62 years and older, based on housing eligibility criteria. In total, 31 participants were excluded from the analysis due to missing at least 1 of the dependent variables. The final dataset included 401 participants. On the basis of the HRP-210 Determination Request, the University of California, Davis, institutional review board determined that this research is exempt as it did not directly involve human participants and used deidentified secondary data (ID: 1938286-1).

Results

Overview

Participant (n=401) demographics are described in Table 1. Participants ranged in age from 62 to 97 (mean 79.07, SD 7) years, most were female, had a high school degree or less, reported limited English proficiency, and were Asian. Over a quarter of participants reported subjective cognitive decline and over a third reported loneliness.

Table 1. Participant demographics (N=401).

Participant demographics	Frequency, n	Percentage, %
Gender		
Female	276	69.2
Male	123	30.8
Ethnicity		
Non-Hispanic White	48	12.0
Asian	320	79.8
Korean	262	65.3
Chinese	50	12.5
Japanese	2	0.5
Filipino	2	0.5
Vietnamese	1	0.2
Latinx	11	2.7
Black or African American	6	1.5
American Indian or Alaskan Native	2	0.5
More than one race or ethnicity	7	1.7
English proficiency		
Very well	58	14.8
Well	62	15.8
Not well	172	43.8
Not at all	101	25.7
Educational attainment		
Never attended school	21	5.5
Some high school	127	33.0
Completed high school or general educational development	72	18.7
Some college	75	19.5
College degree	65	16.9
Graduate degree	25	6.5
Subjective cognitive decline		
No	283	72.2
Yes	109	27.8
Years of experience using information communication technologies		
More than 2 years	239	59.6
1 to 2 years	39	9.7
Less than 1 year	32	8.0
I have never used these	91	22.7
Computer use		
About once per day	87	21.7
2 to 4 times per week	28	7.0
Once or less than once per week	25	6.2
Never	261	65.1
Tablet use		
About once per day	92	22.9

Participant demographics	Frequency, n	Percentage, %
2 to 4 times per week	29	7.2
Once or less than once per week	25	6.2
Never	255	63.6
Smartphone use		
About once per day	247	61.6
2 to 4 times per week	39	9.7
Once or less than once per week	16	4.0
Never	99	24.7

About 1 in 5 participants reported they have never used a smartphone, tablet, or computer, while 6 in 10 reported over 2 years of experience using these devices. When asked about the frequency of use of each type of device, two-thirds reported that they never use a computer, slightly less than two-thirds never use a tablet, and a quarter never use a smartphone. Despite this, 89.2% (340/381) somewhat or strongly agreed that technology is useful for connecting with family and friends, and 90.4% (341/377) agreed that technology is useful for learning new information and skills.

Next, we used correlation analysis to examine relationships among items measuring ICT use, PEOU, PU, loneliness, and our control variables (age, gender, Asian ethnicity, education, subjective cognitive decline, and English proficiency). The assumptions for factor analysis were met. We observed multiple correlations among the items, most ranging from 0.30 and above. Importantly, none of these correlations exceeded 0.9, indicating no issues with multicollinearity. Correlation results are included in Multimedia Appendix 2.

EFA and Horn Parallel Analysis

The Kaiser-Meyer-Olkin measure of sampling adequacy was .83 indicating sufficient correlation among the variables. The Bartlett test of Sphericity indicated $P<.001$, allowing us to reject the null hypothesis that the correlation matrix is an identity matrix and that it is reasonable to proceed with EFA.

Three factors had an initial eigenvalue greater than one (Factor 1=4.65, Factor 2=1.89, and Factor 3=1.50). This is illustrated with the scree plot (Figure 2). The rotated factor matrix is shown in Table 2.

Figure 2. Scree plot.

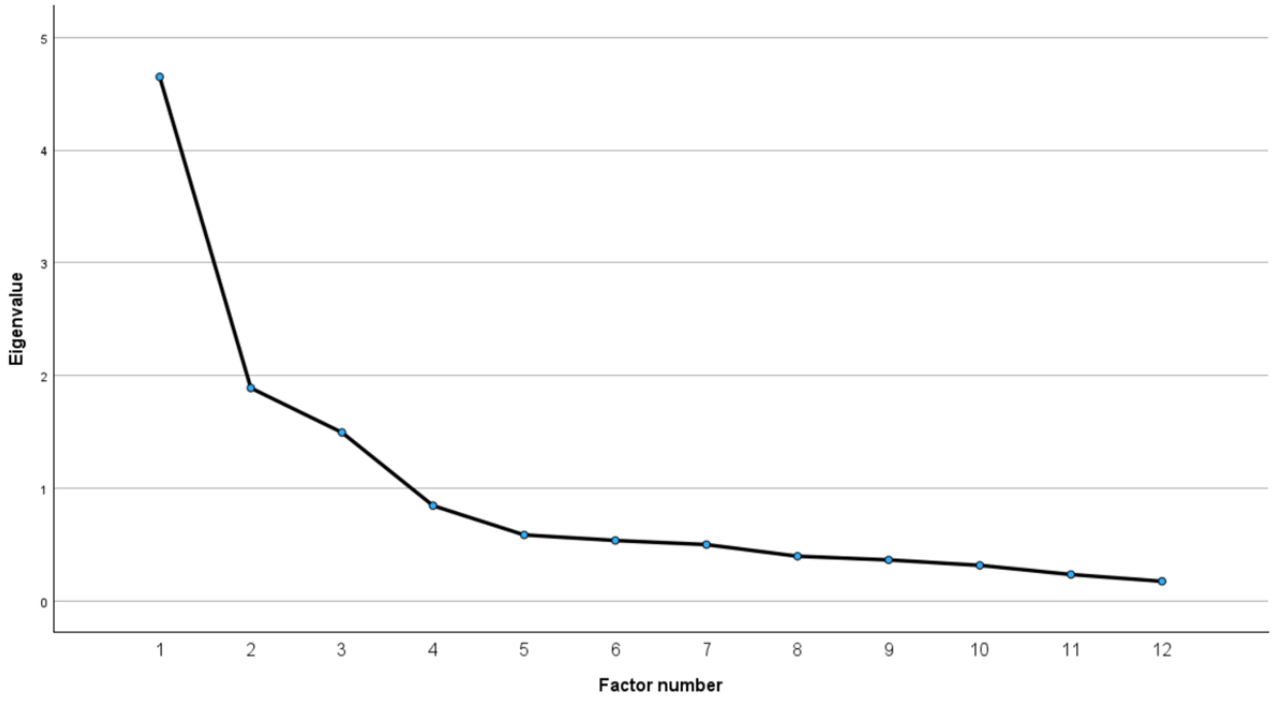


Table 2. Rotated factor matrix of independent variables.

Variables	Factor		
	PEOU[a]	ICT[b] use	PU[c]
Tech comfort	.40	.42	.35
Tech nervous	.72	.08	.01
Tech confidence	.82	.16	.10
Tech confusion	.88	.14	.08
Tech apprehension	.79	.20	.10
Tech fear	.75	.22	.10
Tech connection	.06	.07	.75
Tech learning	.09	.15	.85
Years of tech experience	.21	.60	.16
Computer use frequency	.19	.67	.03
Tablet use frequency	.03	.68	–.03
Smartphone use frequency	.11	.52	.17

[a]PEOU: perceived ease of use.

[b]ICT: Information communication technology.

[c]PU: perceived usefulness.

The first factor, PEOU, combined the 2 items from the Senior TAM – Tech Anxiety Subscale and 3 of the 4 items from the Attitudes Towards Computers Questionnaire – Comfort Subscale. One item, "I feel comfortable with technology," had a factor loading of .40. According to Tabachnick and Fidell [27], loading above 0.71 is excellent, 0.63 is very good, 0.55 is good, 0.45 fair, and 0.32 poor. Therefore, we dropped the tech comfort item from PEOU in further analyses.

The second factor, ICT use, combined 4 items: years of tech experience, computer use frequency, tablet use frequency, and smartphone use frequency.

The third factor, PU, combined 2 items: "Technology helps me be connected with family and friends," and "Technology helps me learn new information and skills."

After rotation, the 3 factors combined accounted for a total variance of 56.48% (6.78/12), with PEOU accounting for 28.44% (3.41/12) of the variance, ICT use for 15.59% (1.87/12), and PU for 12.44% (1.49/12). The 3 factors were confirmed when running a Horn parallel analysis. These factors also showed high internal reliability with Cronbach α scores of .90, .74, and .76 for PEOU, ICT use, and PU, respectively.

EFA was conducted separately for the dependent variables and generated 1 interpretable factor, loneliness, with an eigenvalue of 2.29 (Table 3). Loneliness had strong internal reliability with a Cronbach α score of .84.

Table 3. Component matrix for dependent variables using principal extraction method.

Variables	Factor (loneliness)
Lack companionship	.69
Feel left out	.93
Feel isolated	.79

CFA Findings

We ran CFA to further examine the relationships among the latent variables and to assess our conceptual model (Figure 3). As shown in Table 4, each of the items significantly loaded to form the 3 latent factors, confirming our EFA results.

Except for chi-square, all fit indices reached recommended level of fit: (χ^2_{41}=182.114; P<.001, chi-square minimum (CMIN)/df=4.44, CFI=0.92, TLI=0.87). The RMSEA of 0.09 was borderline. Since χ^2 is sensitive to large sample sizes, with a large sample of 401 participants, it was not unusual to get a significant value; for sample sizes greater than 250, a significant χ^2 value is acceptable [31].

Figure 3. Standardized results from confirmatory factor analysis to assess our conceptual model. ICT: information communication technology.

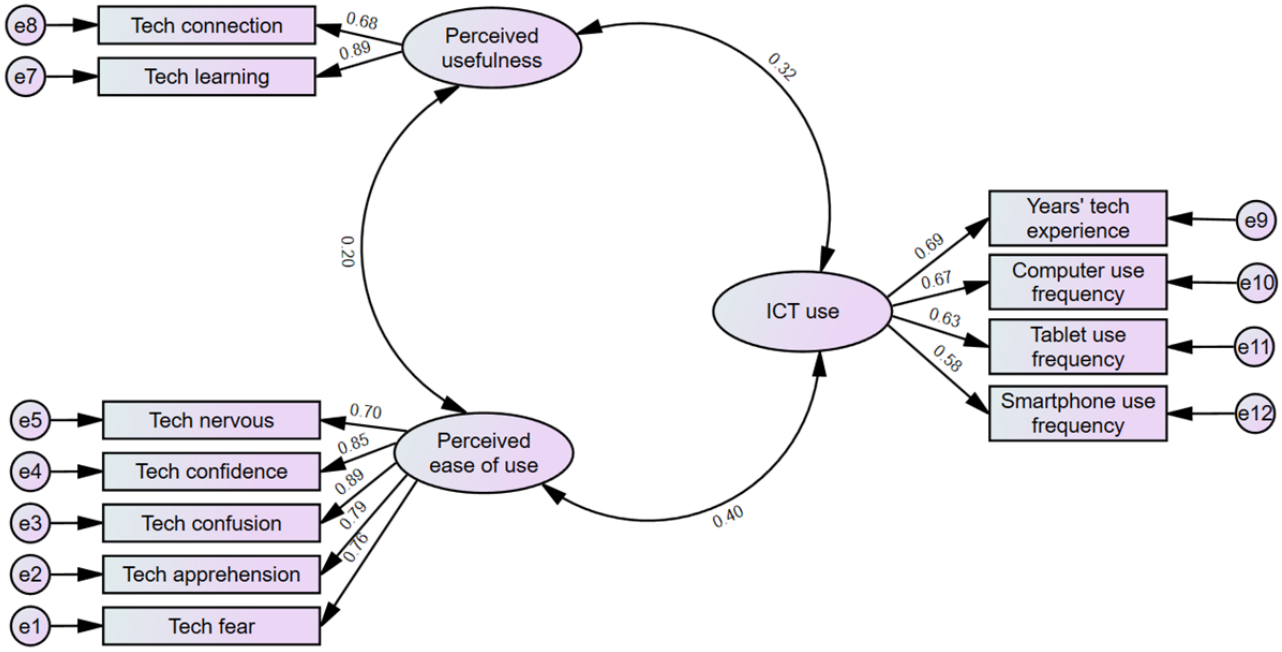

Table 4. Regression estimates of items loading into 3 factors.

Observed variables		Latent variables	Standardized regression estimate (factor loading)	Unstandardized regression estimate	SE	Composite reliability	*P* value
Tech fear	←	PEOU[a]	.76	1.00	—[b]	—	—
Tech apprehension	←	PEOU	.80	.99	.06	15.963	<.001
Tech confusion	←	PEOU	.89	1.09	.06	18.156	<.001
Tech confidence	←	PEOU	.85	1.05	.06	17.130	<.001
Tech nervous	←	PEOU	.70	.86	.06	13.797	<.001

[a]PEOU: perceived ease of use.

[b]Not applicable.

[c]PU: perceived usefulness.

[d]ICT: Information communication technology.

There was evidence for convergent validity because all three of the conditions were fulfilled, that is, (1) composite reliability values are 0.7 or greater, (2) all standardized factor loadings are 0.5 or greater, and (3) AVE values are 0.5 or greater [29]. All 3 of these criteria were met for PEOU and PU, which had composite reliability values of .90 and .77, standardized factor loadings all greater or equal to .68, and AVE values of .64 and .63, respectively.

ICT use had an AVE of .42, slightly lower than ideal [29]. However, according to Fornell and Larcker [30], if the AVE is less than 0.5, but composite reliability is higher than 0.6, the convergent validity of the construct is acceptable [30]. ICT use had a composite reliability of .74, therefore we concluded that the latent variable had convergent validity.

Discriminant validity was met, with discriminant values of .80, .80, and .65 for PEOU, PU, and ICT use, respectively, while the correlation estimates all fell below 0.4 as shown in Table 5 [30].

Finally, as shown in Table 6, the relationships between the latent variables were all significant.

Table 5. Correlations and covariances of latent variables in confirmatory factor analysis.

Latent variables			Correlation estimate	Covariance estimate	SE	Composite reliability	*P* value
PEOU[a]	↔	PU	.200	.107	.033	3.273	.001
ICT[b] Use	↔	PU	.317	.190	.042	4.501	<.001
ICT Use	↔	PEOU	.399	.269	.048	5.643	<.001

[a]PEOU: perceived ease of use.

[b]ICT: Information communication technologies.

ICT[b] Use	←	PU	.24	.31	.10	3.19	.001
ICT Use	←	PEOU	.37	.41	.07	5.75	<.001
Loneliness	←	ICT Use	-.29	-.15	.03	-4.48	<.001

[a]PU: perceived usefulness.

[b]ICT: Information communication technologies.

Structural Equation Modeling

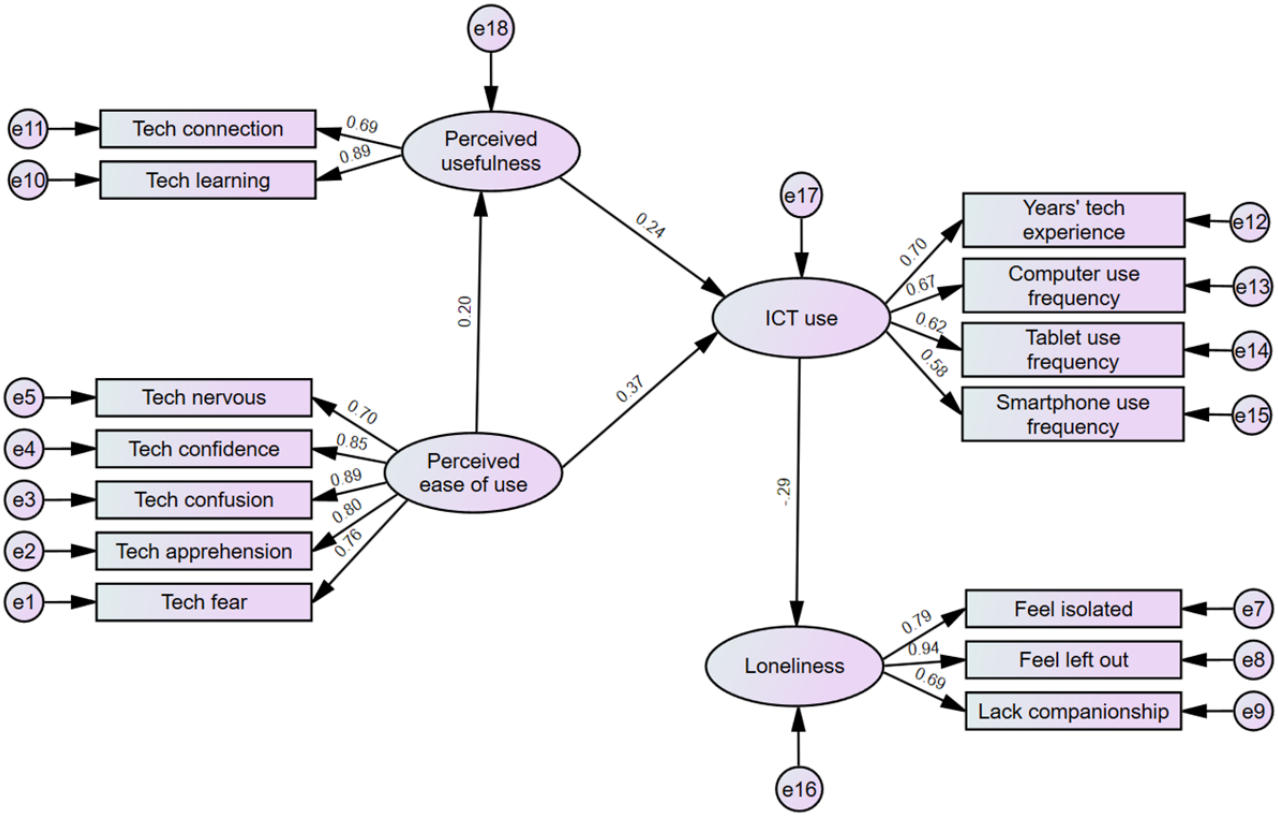
The 3-factor SEM revealed reasonable fit indexes (χ^2_{73}=231.835, CMIN/DF=3.18, CFI=0.93, TLI=0.90). An RMSEA of 0.07 was acceptable. Once again, the chi-square value was significant, which, as previously described, is acceptable for this sample size [31].

As shown in Figure 4 and Table 6, hypothesis 1 was supported; PEOU was significantly, and positively associated with PU (β=.20, *P*<.001).

Hypothesis 2 was also supported; both PEOU and PU were significant, positive predictors of ICT use (PEOU: β=.37; *P*<.001; PU: β=.24; *P*=.001).

Finally, hypothesis 3 was supported; ICT use was significantly, negatively associated with loneliness (β=–.29; *P*<.001).

Figure 4. Standardized results from structural equation modeling (unadjusted model).



Structural Equation Modeling Adjusting for Control Factors

When we reran the model adjusting for age, gender, education, Asian ethnicity, English proficiency, and subjective cognitive decline, the model fit improved (Figure 5; χ^2_{133}=345.13, *P*<.001, CMIN/DF=2595, CFI=0.93, TLI=0.88). The RMSEA of 0.06 was acceptable.

As shown in Table 7, the adjusted results continued to support Hypotheses 1, 2, and 3. PEOU continues to be significantly positively associated with PU (β=.152, *P*=.01). PEOU and PU were significant, positive predictors of ICT use (PEOU: β=.26, *P*<.001; PU: β=.179, *P*=.01). And, ICT use was significantly negatively associated with loneliness (β=–.28, *P*<.001). In addition, some of the control variables were significant predictors of the endogenous variables, PU and ICT use, and the dependent variable, loneliness (Table 7). Education was significantly, positively associated with PU (β=.19; *P*=.003). English proficiency and education significantly, positively predicted ICT use (English proficiency: β=1.66; *P*=.03; Education: β=.21; *P*<.001), while age was negatively associated with ICT use (β=–1.36; *P*=.01). Finally, subjective cognitive decline and Asian ethnicity were each positively associated with loneliness (subjective cognitive decline: β=.31; *P*<.001; Asian ethnicity: β=.25; *P*<.001).

Figure 5. Adjusted, standardized results from structural equation modeling. ICT: information communication technology.

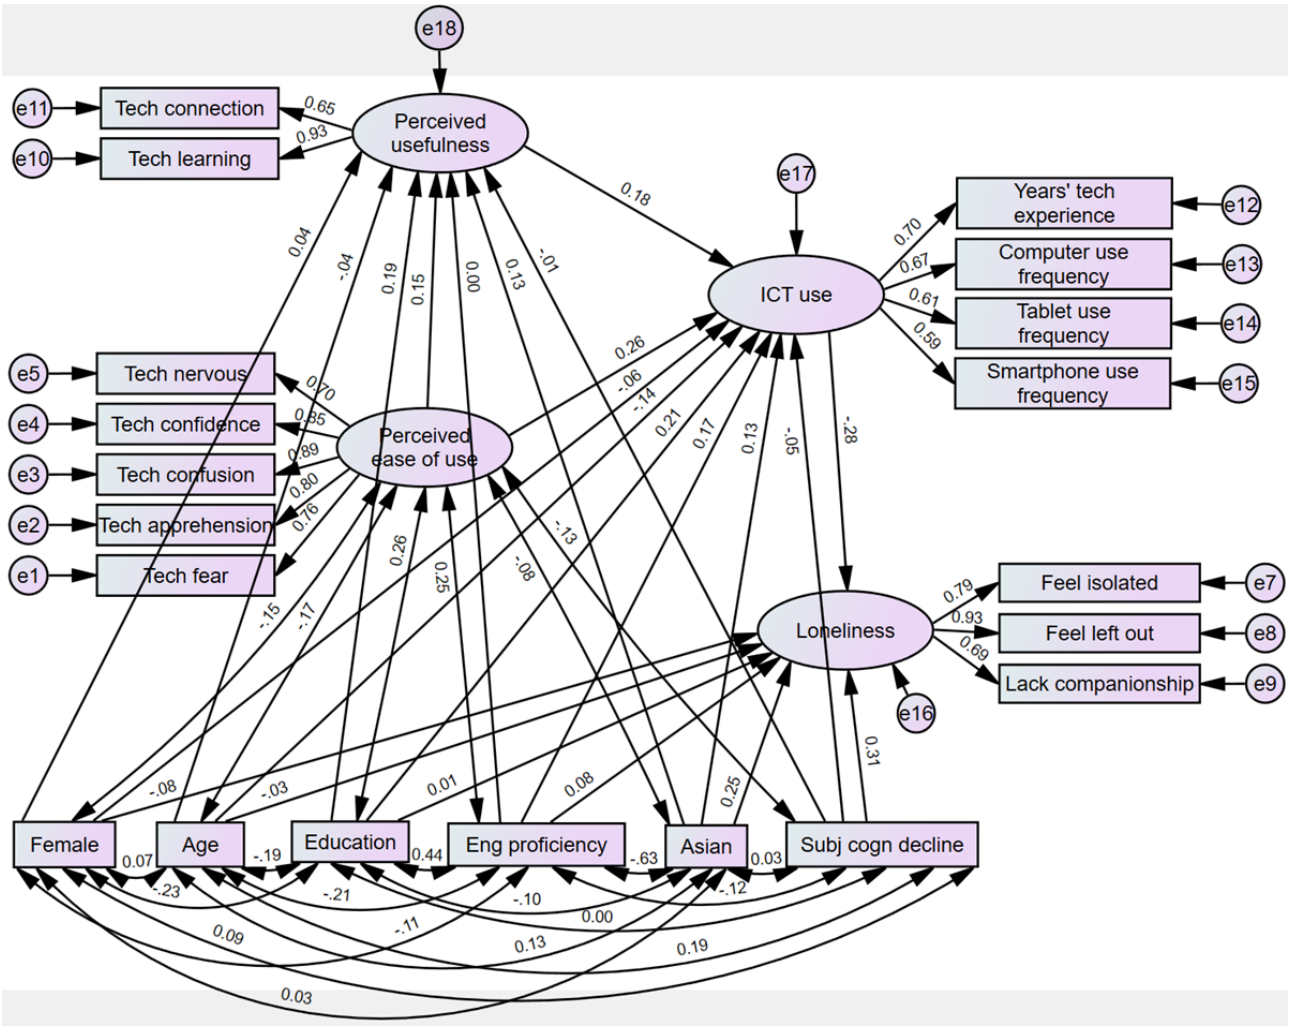


Table 7. Regression weights (adjusted model).

Variables	Standardized regression estimate	Unstandardized regression estimate	SE	Composite reliability	*P* value

[a]PU: perceived usefulness.

[b]PEOU: perceived ease of use.

[c]$P \leq .05$.

[d]ICT: Information communication technology.

While PEOU was an exogenous factor, correlation estimates reveal significant associations with all the control variables except for Asian ethnicity (Table 8). English proficiency and education were each significantly positively associated with PEOU (English proficiency: r=0.25, P<.001; Education: r=0.26; P<.001). Subjective cognitive decline, age, and female gender were each significantly, and negatively associated with PEOU (Subjective cognitive decline: r=–0.130; P=.02; Age: r=–0.18; P=.001; Female: r=–0.15; P=.01).

Table 8. Correlations and covariances of control variables with perceived ease of use (adjusted model).

Control variables	Correlation estimate	Covariance estimate	SE	Composite reliability	*P* value
Asian	–.09	–.03	.02	–1.58	.11
Subjective cognitive decline	–.13	–.05	.02	–2.40	.02
English proficiency	.25	.19	.04	4.47	<.001
Education	.26	.28	.06	4.54	<.001

Female	–.15	–.05	.02	–2.73	.01

Discussion

Principal Findings

In this study, we examined the association of PU, PEOU, ICT use, and loneliness among low income, predominately Asian American, older adults. This research built upon 2 previous studies that simplified the TAM to examine demographic and health factors that impact technology acceptance among Asian Americans aged 62 years and older living in affordable senior housing communities [17,18]. In these previous analyses, the conceptualization of PU, PEOU, and ICT use were based on the existing literature and theory around how these constructs apply to older adults. The constructs were developed by summing and normalizing 12 survey items. In this study, the assumptions underlying the conceptualization of PU, PEOU, and ICT use and the TAM framework were rigorously assessed and confirmed using a combination of statistical techniques. Initially, EFA was conducted to determine the appropriate number of factors and explore the underlying structure of the constructs. Horn parallel analysis was subsequently used to validate the EFA results. Following this, SEM (beginning with CFA) was performed to validate and confirm the factor structure identified in EFA and examine the relationships among PU, PEOU, ICT use, and loneliness.

The original TAM focused on technology acceptance in the workplace. PU was measured with items such as, "Using [chart master] in my job would enable me to accomplish tasks more quickly," and, "Using [chart master] would improve my job performance" [21]. Our research findings support a modified construct of PU that accounts for older adults' perceptions of ICTs as being useful for social connection and for learning new information and skills. We found that the item, "Technology helps me learn new information and skills," had a slightly higher factor loading than the item, "Technology helps me be connected with family and friends." Mixed methods longitudinal data from the Lighthouse Project for Older Adults supported this finding; participants reported that they most frequently used ICTs to access YouTube (eg, to view videos related to nutrition, exercise, and cultural content), followed by accessing entertainment and checking the weather [32]. The Pew Research Center reported that, in 2021 among adults aged 65 years and older, the use of YouTube experienced the most growth as compared with any other app [33]. Notably, studies suggest that app- and web-based activities among older adults vary significantly by age group and gender [23,34-36].

When it comes to PU, it is essential to note that the COVID-19 pandemic spurred an exponential increase in the use of ICTs for social connection. American Association of Retired Persons (AARP) 2021 Tech Trends reported a notable surge in the use of various communication technologies among individuals aged 50 years and above to stay connected with others. A significant portion of this demographic reported an uptick in their usage of video chats (45%, 1022/2271), texting (37%, 840/2271), emailing (26%, 590/2271), and phone calls (29%; 659/2271) compared with prepandemic levels. In 2019, approximately half had never used video chat, whereas by 2020, this figure rose to 70%, with one out of 3 engaging in video chats on a weekly basis [37].

Our findings supported the operationalization of PEOU combining 2 items from the Senior TAM – Tech Anxiety Subscale [24] and 3 items from the ATCQ – Comfort Subscale [25]. Previous studies note an array of emotions that influence technology acceptance and use, including enjoyment, effort expectancy [38], control, efficacy [24,39], confidence [40,41], comfort [25,42,43], and anxiety [24,40]. Due to the variety of existing measures and constructs highlighted in the literature (some developed in the 1980s and with highly educated, White, middle-aged adults), it can be challenging for researchers to select a concise set of items that are specific to older adults and modern technology. We believe our findings can inform future studies with Asian American older adults, who require survey modification [44]. During exploratory analysis, one item, "I feel comfortable with technology," was dropped due to low factor loading. We believe this may have been due to the item being reverse scored, which may have been confusing due to participants' limited literacy levels. Our findings align with previous research which suggests that assessment scales containing reverse-scored items impose higher cognitive processing demands, potentially resulting in measurement challenges for older adult participants [45], particularly since our participants had self-reported limited English proficiency and low educational attainment (Table 1).

Our mediating factor, ICT use, was unique in that it combined measures assessing the frequency of use of smartphones, tablets, and computers, as well as years of experience. We believe this measure is valuable to better understand ICT use since these devices are often used interchangeably among older adults for multitasking [46]. Furthermore, we are not the first to identify years of experience as an important factor in understanding technology acceptance [38].

Using CFA, we found significant, positive relationships between PU, PEOU, and ICT use. This finding is aligned with the Senior Technology Exploration, Learning, and Acceptance model [47] and the Senior Technology Acceptance and Adoption Model (STAM) [48]. The concept of reinforcement of use is consistent with a model of technology acceptance or rejection from an ease-of-learning perspective [49]. When ICTs are perceived as more useful, their usage tends to increase, forming a reinforcing cycle. Increased usage and familiarity make it easier, encouraging individuals to master new skills and diversify their usage, such as progressing from social chats to watching YouTube videos, further reinforcing their mastery and use.

SEM confirmed our modified TAM, supporting our three hypotheses. PEOU significantly, and positively predicted PU and ICT use. Further, ICT use was significantly negatively associated with loneliness. These relationships remained significant, even when adjusting for gender, age, education, English proficiency, Asian ethnicity, and subjective cognitive decline. Interestingly, English proficiency was related to PEOU and ICT use, suggesting a cultural or linguistic bias in technology and application development favoring English-speaking users. Asian ethnicity was associated with loneliness, affirming observations of the vital role technology

can play for immigrants in maintaining social and cultural connections [11]. Subjective cognitive decline was also associated with loneliness, perhaps a reflection of lower social and technology engagement [50].

This study has implications for interventions, particularly among populations with lower literacy. Both PEOU and PU are modifiable factors and could be enhanced by offering digital literacy training and support to new learners [43,51-53] or tailoring user interfaces [54,55]. The relevance of technology for the individual can be increased by demonstrating various culturally relevant use cases for devices, such as connecting with distant relatives, accessing health information, or enjoying entertainment in one's native language. In the Lighthouse Project for Older Adults, the low-income housing providers made a commitment to enhance technology use and offered the technology, training, and support to encourage adoption. This not only provided tangible support in the form of equipment and training but also created a community of learners where individuals could benefit from the experience of peers [32]. This is an example of how service providers can play a role in potentially improving quality of life and reducing loneliness by encouraging the adoption of technology.

Study Limitations

This study was partially limited by the use of a convenience sample of participants who were interested in learning more about technology, not a random sample. This potentially biases the sample toward those with more positive attitudes toward technology. Even with this bias, we observed variability in perceptions about technology but did not capture the full array of attitudes likely present in the population. In addition, participants all lived in age-restricted affordable housing communities. Therefore, our findings are not representative of older adults living in multigenerational households. We removed participants whose data were missing the dependent variable, loneliness. We retained all other participants, yet 4%-7% of responses were missing for items related to PEOU and PU.

Methodological considerations included minimizing participant burden to maximize potential engagement with technology and the most complete dataset. This required modifications to measures, to accomplish parsimony and ease of administration, potentially compromising psychometric properties. However, our CFA indicated the adequacy of the measures for crucial constructs, despite having fewer than 3 observations for each latent variable in the case of PU.

EFA and SEM were limited by the inclusion of binary and ordinal observed variables (eg, gender, Asian ethnicity, and subjective cognitive decline). While this represents a methodological weakness, these variables were included because of their known importance to the constructs of interest. Furthermore, we used the same dataset for all multivariate analyses because of the early phase of understanding relationships among our variables of interest, recognizing that typically the confirmatory analysis should be conducted on an independent sample.

Finally, many other factors potentially impact technology acceptance among older adults, including social and health factors, access to Wi-Fi and devices, and digital literacy training.

Conclusion

Despite the limitations, this study affirms the usefulness of the TAM in understanding the dynamics of technology adoption among a low-income Asian American population. At baseline, there is considerable interest in technology, affirming its relevance in the lives of older adults. The role of English proficiency in ICT use warrants further exploration to identify ways to increase equity and access for those who have another primary language. The study further highlights the potential role that technology could play in alleviating loneliness through greater engagement with family and friends and the ability to maintain cultural ties. Future studies could explore the most effective ways to overcome resistance to technology, the most meaningful ways to support novice users to adopt a new device, and ways to increase the diversity of use once a user has become comfortable with basic functions. While technology cannot replace the human touch, it has the promise to improve engagement and social connection among isolated, low-income older adults.

Acknowledgments

This work was funded by the Healthy Aging in a Digital World Initiative at the University of California, Davis and the Center for Information Technology Research in the Interest of Society (CITRIS) and the Banatao Institute.

Other acknowledgments: The University of California, Davis, School of Medicine Office of Research, Evaluation Unit, including Rebeca Giacinto, Pauline DeLange Martinez, Stuart Henderson, and Julie Rainwater, designed the Lighthouse surveys and provided oversight for data collection and entry. We thank all Lighthouse participants for their time and effort in completing the evaluation surveys. We also thank the staff at each site for their support with participant recruitment, data collection, and entry.

Lighthouse project leadership included the Front Porch Center for Innovation and Wellbeing (Davis Park, Kari Olson, Jennifer Lee), Eskaton (Therese ten Brinke, Sheri Peifer), and CITRIS (David Lindeman, Gale Berkowitz).

Data Availability

The datasets generated during and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

PDM led conceptual design, data analysis, and authorship. HMY made substantial conceptual and design contributions, providing invaluable input along all stages of manuscript preparation. MP and DJT provided oversight for the operationalization of key variables, data analysis, reporting results, and interpretation of the data. LG helped to critically revise the manuscript and agreed to be accountable for the accuracy of the work.

Abstract

Background: Malnutrition is a challenge among older adults and can result in serious health consequences. However, the dietary intake monitoring needed to identify malnutrition for early intervention is affected by issues such as difficulty remembering or needing a dietitian to interpret the results.

Objective: This study aims to co-design a tool using automated food classification to monitor dietary intake and food preferences, as well as food-related symptoms and mood and hunger ratings, for use in care homes.

Methods: Participants were 2 separate advisory groups and 2 separate sets of prototype testers. The testers for the first prototype were 10 community-dwelling older adults based in the Stirlingshire area in Scotland who noted their feedback on the tool over 2 weeks in a food diary. The second set of testers consisted of 14 individuals (staff: n=8, 57%; and residents: n=6, 43%) based in 4 care homes in Scotland who provided feedback via interview after testing the tool for a minimum of 3 days. In addition, 130 care home staff across the United Kingdom completed the web-based survey on the tool's needs and potential routes to pay for it; 2 care home managers took part in follow-up interviews. Data were collected through food diaries, a web-based survey, audio recordings and transcriptions of focus groups and interviews, and research notes. Systematic text condensation was used to describe themes across the different types of data.

Results: Key features identified included ratings of hunger, mood, and gastrointestinal symptoms that could be associated with eating specific foods, as well as a traffic light system to indicate risk. Issues included staff time, Wi-Fi connectivity, and the accurate recognition of pureed food and fortified meals. Different models for potential use and commercialization were identified, including peer support among residents to assist those considered less able, staff-only use of the tool, care home–personalized database menus for easy meal photo selection, and targeted monitoring of residents considered to be at the highest risk using the traffic light system.

Conclusions: The tool was deemed useful for monitoring dietary habits and associated symptoms, but necessary design improvements were identified. These should be incorporated before formal evaluation of the tool as an intervention in this setting. Co-design was vital to help make the tool fit for the intended setting and users.

Introduction

Background

Diet is an important component of a healthy lifestyle, and it remains one of the most common challenges among older adults in the United Kingdom [1]. Malnutrition is also a prevalent issue in this population. The World Health Organization defines malnutrition as "deficiencies or excesses in nutrient intake, imbalance of essential nutrients or impaired nutrient utilization" [2]. Approximately 10% of those aged 65 years are malnourished or are at risk of malnutrition in the United Kingdom [3], a figure that rose to 25% of those aged 60 years during the COVID-19 pandemic [4-6]. The prevalence of severe malnutrition is reported to be as high as 45% in those living in residential care homes [7] but may be worse because approximately 70% of malnutrition in the United Kingdom is unrecognized [8,9]. Malnutrition is strongly associated with frailty, as well as functional and health decline [10-12]; thus, it is important to monitor dietary intake and identify malnutrition risk before symptoms are already evident. However, tracking and understanding the impact of dietary intake is not easy. It is possible for people to become malnourished if they do not eat enough nutritionally rich foods for 2 to 5 days [6,13].

Malnutrition in older adults is commonly identified via the Malnutrition Universal Screening Tool (MUST) [14], and when individuals are classed as medium to high risk, it is recommended to document food and drink intake for 3 days. However, there are difficulties with self-reported food diaries, which can be inaccurate due to recording error, misremembering, and socially desirable responses. Additional barriers include limited staff time in care homes and the need for analysis and interpretation by a dietitian [15].

Computer-based tailored interventions may offer a solution because there is evidence that they have positively impacted dietary monitoring in the general population [16]. Automated food classification is a rapidly advancing field of artificial intelligence research that uses a computer source to identify different foods from an image [17,18]. Creating new nutrition databases or using or adapting existing databases means that it is possible to infer detailed nutritional data from photos of food [19]. Convolutional neural network algorithms are used to identify food automatically from photos, and these are linked to a nutritional database to calculate the calories in the identified foods. Machine learning techniques can then be applied to correlate dietary intake with important individual differences such as food preferences, physical symptoms, and malnutrition risk [20]. Automated food classification can consider the portion size and regularity of food intake, which is crucial to monitor in older people because this can significantly influence malnutrition risk. Linking food intake to preferences and symptoms through technology and artificial intelligence means this information could be used to identify potential risks quickly and accurately. This would provide care staff with information to help monitor older people's diet and decrease malnutrition risk. Studies that have evaluated photo-based dietary assessment tools have found measurement errors comparable to traditional methods [21], and those that have found it a valid method have focused on a younger population, reporting positive feedback [22,23].

Objectives

Consequently, following the 6 steps for quality intervention development (6SQuID) [24], we sought to co-design a prototype tool with key stakeholders, which we refer to as a "digital nutritional assessment tool." We aimed to work with advisory groups (AGs) and participants to develop the key features of a prototype tool for monitoring dietary intake, map this onto food preferences and symptoms, and test the prototype with stakeholders. It is important to note that this study reports on developmental research to identify the tool's suitability, features needed, and usability, rather than its efficacy at capturing and estimating nutrient intake, which is part of the next stage of development and testing. Its key objectives were to complete the first two 6SQuID steps: (1) defining and understanding the problem and its causes and (2) identifying which causal or contextual factors are modifiable—which have the greatest scope for change and who would benefit the most—using a co-design and coproduction approach. This inclusive approach was taken due to the wish for the resulting tool to have real-life application and translation outside of the academic setting while acknowledging the importance of specifying up front the motivations of coproduction, what outcomes are required for whom, and how these might be achieved [25]. This qualitative approach to data collection is necessarily reflective and conscious and has attempted to follow recently produced resources as a guide to quality coproduction methods in health research [26,27]. In this way, it positions end users as essential to the research process; thus, it is collaborative and equitable [27]. In this study, stakeholders were identified as older adults, the tool software designers, dietitians, and ultimately care home staff and residents themselves.

Methods

Recruitment

Participants consisted of 2 AGs and 2 separate sets of prototype testers. Both AGs comprised different older adults and dietitians. Care home staff as well as app and tool designers were consistent across the 2 groups. The testers for the first prototype were community-dwelling older adults and care home employees recruited across Stirlingshire in Scotland. For care home testing, the aim was to recruit 3 care homes, 2 staff members, and 4 to 5 residents in each care home. Care home staff and managers were recruited via social media and Scottish Care newsletters to complete a survey and semistructured interviews, respectively.

Study Design

The study used a co-design and coproduction approach [27] to determine key components of the tool to be developed and used through multiple iterations of usability feedback from older adults, care staff, and dietitians. The tool was developed using the information provided by the AGs in a collaboration between the research team and the app developers, Game Doctor. The development process involved AGs with key stakeholders in the design process (phase 1); community testing and feedback (phase 2); and care setting feasibility and usability testing, as

well as consultation and data gathering with a wider group of care home staff and managers (phase 3). This was a continual process, with feedback resulting in a new build of the tool prototype, to 3 builds. A summary of the timeline for the study design and the different groups involved is shown below in Table 1.

Procedure

Phase 1: AG Recruitment and Co-Design of Tool

According to the 6SQuID framework [24], the first step of intervention development is "defining and understanding the problem." This was achieved through the creation of the first AG (AG 1) with key stakeholders to develop ideas and identify features that would be vital for a food recognition tool in the care home setting. The study and AG role were advertised through email to the Stirling 1000 Elders email list used by ACW to recruit 2 older adults. A snowball technique was then used to recruit key stakeholders working within nutrition and care settings. Through this process, AG 1 with 6 key stakeholders (older adults: n=2, 33%; care home staff: n=1, 17%; app developers: n=2, 33%; and dietitian: n=1, 17%) was formed. The first session was run face-to-face and was used to define and understand the problem (ie, the need for a food recognition model for dietary monitoring and how artificial intelligence could be used as a potential solution). In addition, AG 1 members were asked to brainstorm key features that the tool should include, such as the identification of symptoms related to eating a particular food and potential rating scales to assess mental and physical well-being after eating. AG 1 also identified potential issues and challenges that would be faced in using the tool with older adults in a health care setting generally.

Feedback from this first AG 1 meeting provided the app developers, Game Doctor, with information on which to base the initial build of the tool and the 2 subsequent builds based on later AG meetings. The LogMeal (AIGecko Technologies SL, Artificial Intelligence and Deep Learning Food Division) photo database used by the tool to identify the foods photographed was selected in collaboration between the research team and app developers based on a review of potential existing services, considering the range of foods recognized and financial costs. The first prototype was then developed by Game Doctor, linked to the photo database, and demonstrated in a second meeting of AG 1 for prototype testing and feedback before bug fixing and independent feasibility testing.

Phase 2: Feasibility Testing of the Tool and Food Diaries

This phase was based on 6SQuID step 2: "identify which causal or contextual factors are modifiable—which have the greatest scope for change and who would benefit the most." We recruited 10 community-dwelling older adults via email to Stirling 1000 Elders. Eligibility included owning an Android mobile phone or tablet capable of downloading the tool. The older adults were provided with a pseudonymized log-in ID for the tool and asked to use it to record each meal over 2 weeks by photographing their plate before and after eating. They were also asked to select the foods present that were identified by the tool or to correct any misidentified foods by entering what the foods circled in the tool were. They could then also rate on a 5-point emoji-based Likert scale their mood, level of hunger after eating, and the presence of up to 7 further symptoms. The symptoms included in the tool were based on feedback from AG 1 and included tiredness, diarrhea, cramping, swallowing difficulties, constipation or discomfort, and bloating. A written diary to complete alongside using the tool was provided to participants to indicate the contents of each meal and note down any problems with using the tool and provide general feedback about it. A third and final meeting of AG 1 was planned to discuss the findings from prototype testing and give the members the opportunity for further testing to provide feedback to the app developer so that a third version of the prototype could be developed. Due to difficulties in arranging a final meeting, AG 1 members were asked to use the tool for a week and then complete a short web-based survey. The survey asked about missing tool features and symptoms, strategies to support the tool's integration in care settings, and other populations that would benefit from using the tool. This was then used as the basis for discussions among members of the second AG (AG 2).

Phase 3

Overview

As the tool was intended for eventual use in care homes, phases 1 and 2 were repeated with AG 2, a newly recruited group of 4 key stakeholders (older adults: n=2, 50%; care home staff: n=1, 25%; and dietitian [also an older adult]: n=1, 25%). In addition,

a new cohort of tester participants, including staff and residents, was recruited through 4 care homes.

At the first AG 2 meeting, the members discussed version 3 of the prototype and the challenges of its application in care homes.

Care Home Testing and Focus Groups

For testing, 8 care homes were contacted through existing networks with information on the study and what was expected of staff and residents. The lead researcher (JC) prepared an introduction to the tool and led a separate discussion at each care home on key features that care home staff and residents wanted to see in this type of tool. Each care home then had access to version 3 of the prototype for 2 weeks, and staff and residents were asked to record food intake and food-related symptoms. The care homes were given an Android tablet preloaded with the tool that could be used to take photos of the food. During this period, residents (n=6) were asked to take photos of all foods they consumed, while staff members (n=8) recorded food intake for other residents, across a minimum of 3 days, ensuring that each type of meal (breakfast, lunch, dinner, and snacks) was recorded at least once. The photos were then added to a timeline, and participants had the option to indicate how hungry they felt after the meal using an emoji-based Likert scale and click on any symptoms they were experiencing from a list of common symptoms, which were then added to the timeline. Participants also entered any verbal preferences and indicated whether they needed support with eating.

After prototype testing, JC conducted semistructured interviews with 5 participants (care home staff: n=4, 80%; and resident: n=1, 20%) to obtain their feedback on the usability and acceptability of the tool. Questions covered topics such as what they liked about the tool, difficulties encountered with its use, missing features (eg, physical or mental symptoms that should be included), additional features that should be included, and advice on the usability of the tool in practice (eg, who would take the photos and whether there was enough time to use the tool during a typical care home day). A second and final AG 2 meeting was convened to talk through the feedback from care homes and suggest future directions.

Care Home Staff Perspectives Survey and Manager Interviews

Concurrently with the care home testing, a web-based survey was devised for care home staff that included 16 questions under three headings: (1) “About you” (including job title, organization, and time spent in the care sector), (2) “Nutrition” (including questions about monitoring diet and dietary outcomes in their care home organization), and (3) “Routes to integrate tool.” Of the 16 questions, 6 (38%) were open ended. These were included (under the appropriate headings listed previously) to explore any care home–specific strategies or features that would improve the integration of the tool. The survey was designed to take no longer than 20 minutes to complete. This included a 7-minute video on the web showcasing the tool and its current features, which was required to be watched before completing the survey.

A total of 130 participants (care home staff) were recruited across Scotland via social media (ie, Twitter [subsequently rebranded as X] and LinkedIn), emails to existing partner care homes, and through Scottish Care. The inclusion criteria included any worker from within a UK care home. The survey was available through the advertising link, and, when clicked, the individual was taken to the participant information sheet.

After the survey, semistructured interviews were conducted with care home managers to explore the survey feedback and assess how the tool would fit within their care homes. Care home managers could sign up for these interviews via the last question in the survey.

Data Analysis

This project used systematic text condensation [28] across the different types of qualitative data collected. This is a descriptive and explorative method for gathering themes across different types of qualitative data, including interviews, observations, and written text analysis. As such, it represents a pragmatic approach that can turn total impressions of the overall chaos of the data into themes with units of meaning that can then be condensed and synthesized into descriptions and concepts.

Ethics Approval

This study was conducted in accordance with the Declaration of Helsinki and approved by the General University Ethics Committee of the University of Stirling (8857; September 7, 2023) for studies involving human participants. As a token of thanks, the participants testing the app received £50 (US $63.32) at the end, once the device had been returned. The feedback provided on the tool was anonymized in terms of users but not per care home. This was carried out in this manner to ensure feedback could be related to the size and location of the care home. Those who took part in the advisory group received £50 (US $63.32) per meeting they attended. For both the survey and the follow-up interviews, participants implied consent by clicking the provided link to take part in the survey.

Results

Participants

Participants consisted of 2 separate AGs (AG 1 and AG 2) and 2 separate sets of prototype testers. The testers for the first prototype were 10 community-dwelling older adults and care home employees based in the Stirlingshire area. Four care homes responded about participating in the study. The care home testers consisted of 14 individuals (staff: n=8, 57%; and residents: n=6, 43%) in 4 care homes across Crieff, Stirling, and Fife, differing in size and type of organization (nursing care, older adults only, mixed needs, and dementia specialty or general care). Altogether, 130 individuals completed the web-based survey, with 2 managers volunteering to take part in follow-up interviews.

Phase 1: AG Recruitment and Co-Design of Tool

AG 1 members met with the research team for 2 hours on 2 occasions over the course of 1 year to design, test, and improve the first protype. They also tested the final prototype and gave feedback before testing in community-dwelling older adults.

Game Doctor staff took part in all AGs and produced an initial prototype in March 2022. Game Doctor. They suggested that the 3-sprint model would work well for the development of up to 3 builds of the initial prototype within the project timeline and budget. At the first meeting of AG 1, key features for the prototype were discussed, and priority was assessed. The need for a food recognition model and key features it should have, such as simple and quick food recognition, were noted. How it would work in the care home environment, issues of data security and consent, symptoms that needed to be included, potential for a mood scale, and overall usability of the tool were also considered. Priorities were summarized into a set of features to be incorporated (Table 2).

Table 2. Key features identified through the advisory group, along with the priority level determined in collaboration with Game Doctor.

Feature	ID	Description	Priority
Food tracking via image recognition model	F1V1	Food tracking using off the shelf image recognition model	High
Patient profiles	F2V1	A way to create profiles for each patient or resident using the application	High
Correct food button input	F3V1	Input button to confirm that the model has recognized food accurately	High
Before or after plate recognition	F4V1	Ability of model or application to recognize plates as before or after meal	Medium
Manual input form	F5V1	Manual input form to record symptoms and mood via a 5-point Likert scale	High
Analytics	F6V1	Analytics to track user use of prototype	Medium
Opt-in or consent form	F7V1	Consent form for users during testing of prototype	High
Resident data storage	F8V1	Centralized storage of resident data so multiple devices can access resident data	High
Push notifications	F9V1	Notifications or prompts such as push notifications to attract the user back into the application	Medium

Next, Game Doctor produced a short video to guide participants on how to download the tool and use its initial features (ie, taking photos of plates of food before and after meals, logging symptoms via tick-box selections, and recording mood using a face emoji scale). The basic initial prototype was presented at the second meeting of AG 1. Game Doctor provided a walk-through of the basic prototype and presented different food recognition models Game Doctor. LogMeal was chosen as the food recognition model provider due to the size of its database and the accuracy of food recognition (refer to Table 3 for the models compared). This meeting lasted twice as long as the first session to allow for Game Doctor to talk through the functions of the tool and food recognition model, for the group to try it and test with singular foods, and then test with mixed foods over a restaurant meal. The prototype was tested by taking photos of fruits and vegetables after Game Doctor's presentation. Food in different presentations and textures was provided on plates for testing with the tool. Basic feedback was given when the group tested the tool with whole meals during dinner, with participants providing feedback on its usability. Other features identified to enhance the tool included having an "after" photo to calculate food eaten; adding an element to note whether food had been fortified (eg, high fat or additional protein added); including additional relevant medical conditions; and keeping the tool simple by, for example, using a tick-box approach and having symptom recording options appear when the "after" photo is uploaded.

Table 3. Different food recognition models available that could be integrated into the tool.

Provider	Pricing
Clarifai	Free for academic projects
LogMeal	Depends on project
FoodAI	To be confirmed
BiteAI	To be confirmed
Calorie Mama	To be confirmed

Key design issues noted in feedback included the positioning of the "confirm" screen, which sometimes overlapped the photo taken; how to enter a food if the database does not recognize it and provide a correct option; whether the highlighting circles link to each food on the plate; how to cancel the recognition system if there is an error in recognizing a food; and how plate size would be distinguished to calculate nutrition from different portion sizes. Important features discussed as being needed in the next build, based on feedback from using the tool, included (1) the ability to select resident ID and room number; (2) "before" and "after" photos; (3) adding a food fortification button to indicate the addition of butter, cream, protein powder, and so on; (4) having tick boxes for various symptoms that can be personalized to residents and structuring the page to follow the "after" photo or providing an option to enter symptoms later; (5) plate size option; (6) the option to add medical conditions to the user profile; and (7) having the symptoms page appear

right after the second photo, including options to indicate fullness, mood, swallowing difficulties, and so on.

Phase 2: Feasibility Testing of the Tool and Food Diaries

The next phase of the project involved further testing and feedback by users in their home settings. We recruited 10 community-dwelling older adults to test the tool for 2 weeks. Of the 10 participants, 9 (90%) managed to use the tool, while 1 (10%) had difficulty downloading it and withdrew from the study. Of the 9 participants, 8 (89%) used the tool for the full 2 weeks, while 1 (11%) used it for 1 week. Each day, they documented their food intake and any difficulties encountered with the tool in food diaries. In addition, members of AG 1 tested the tool in free-living conditions over 1 week and submitted comments about their experience through a brief web-based survey. The findings from the diaries and survey covered 3 topics: symptoms, features, and populations. Regarding symptoms, it was noted that the tool monitored a good range of symptoms specific to the target group; however, there were suggestions to include additional symptoms, such as thirst, confusion, and anxiety. Regarding features, it was reported that the tool was easy to use when it connected well with the food recognition model. Most of the group said that they did not feel that any key features were missing, although they noted that testing in care home settings would help identify site-specific needs. Suggested features included an "empty plate" button and a directory of foods. As for other populations and settings that might benefit from the tool, the survey responses highlighted community care, patients with dementia, family carers, and hospitals.

Phase 3

Overview

At the first meeting of AG 2, members suggested that care homes would face unique challenges in using the tool, different from those within the community. These might include potential difficulties in recognizing pureed food, fortified meals, or culturally specific foods (eg, haggis), residents with cognitive impairment not being able to use the tool, and the possibility for staff or visitors to assist with tool use. It was decided that we would trial the tool across a range of care homes with residents of varying abilities to gain direct feedback on these issues.

Care Home Testing and Focus Groups

The prototype was tested in 4 care homes with 8 staff members (n=2, 25% in each home) and in 1 care home with 6 residents (older adults: n=4, 67%; and younger adults [aged 54 y and 58 y] with learning disabilities: n=2, 33%). Of the 4 care homes, 3 (75%) did not recruit older adults for the testing due to the cognitive functioning status of their residents who would not be able to use the tool; therefore, the staff members used it themselves. The 6 residents who were recruited all tested the tool themselves. The staff recruited had from 6 months to 20 years of experience of working in the care sector. The older adults recruited were aged between 78 and 84 years and had lived in the care home for at least 6 months. After prototype testing in the care homes, the semistructured interviews with staff (4/8, 50%) and residents (1/6, 17%) identified (1) the pros and cons of using the tool in their care home, (2) how it can be adapted to enhance its usability, and (3) common symptoms reported in the tool. The resident who tested the tool was 1 (50%) of 2 younger residents with learning disabilities (aged 58 y). The main outcomes from these interviews are displayed in Textbox 1.

Textbox 1. Themes emerging from semistructured interviews with care home staff and residents.

Key design issues

- Wi-Fi issues slowed down the uploading of data
- Tool struggled to recognize pureed food
- Camera picked up patterns on plates as food
- Design features are needed to speed up the process

Key features

- Staff would prefer photo profiles of residents instead of names
- International Dysphagia Diet Standardization Initiative framework [29] and Malnutrition Universal Screening Tool [14] malnutrition risk score should be built in
- Traffic light system approach to identifying risk
- Self-choose whom to measure option
- Empty plate button
- Monitor fluid intake too
- Pureed food and fortification recognition is essential
- A notification or prompt system as a reminder

Positive feedback

- Recognized food well
- Residents liked monitoring their own food intake
- Enjoyed playing around with the tool and learned how to use it quickly

Key Design Issues and Usability

All care homes reported difficulties in using the tool when the home Wi-Fi connection was poor:

> *We had connection issues and found the app to be very slow or would freeze-could there be an easy offline system to use throughout the home that would automatically upload when a strong wifi connection was made?* [Staff, care home 2]

All care homes reported slow uploads, with the tool freezing; therefore, participants had difficulty clicking on the foods on the screen. This then led to slower identification of foods and a slow search for foods that were not identified, highlighting the need for features that would speed up this process.

A resident who was using the tool revealed that they did not have these issues because they just saved the photo to upload later when their Wi-Fi connection was stronger:

> *I found the tool easy to use, wifi is terrible here so I just waited until the signal was stronger and uploaded the photo then.* [Resident, care home 2]

Staff members expressed concern that if they did not upload photos and ratings immediately, they would not be able to do so later due to a change of shift or being given another role or task within the home. Furthermore, choking was identified as a major concern in all participating care homes, and many of the residents were on a pureed diet. The tool struggled to recognize pureed foods, highlighting the need for better pureed food recognition or an alternative solution:

> *A number of our residents are on pureed diets or we add thickening agents (which contain calories) to some of their foods, the tool could not properly detect it, although funnily enough we use molds shaped like the foods and it could sometimes pick that up.* [Staff, care home 1]

Staff members also wanted to add a measure of swallowing difficulties to the tool, which would link to food intake and the International Dysphagia Diet Standardization Initiative (IDDSI) framework [25]:

> *Having a feature and notes in IDDSI, malnutrition risk and fortification is really important for us and our residents.* [Staff, care home 4]

The current version did not link a swallowing difficulties feature, but adding this would encourage care homes to change the texture of the food.

Finally, when photos were taken of plates, the food recognition function of the tool sometimes misidentified the design patterns on the plate as food:

> *The plate was empty but it was saying the patterns were food and giving it a value.* [Staff, care home 3]

However, the more the tool was used, the less this became a problem because users worked out how to delete the circle around the patterned part that was misidentified as food. In addition, continued use improved the tool's accuracy through machine learning, reducing misidentifications over time.

Key Features Missing From the Tool

Regarding features needed in the tool for the care home setting, all homes reported the need for a resident profile instead of the current name function, which takes users straight to the diary:

> *We need a profile with the resident's picture which we choose from to quickly find the resident—we have a few residents with the same name.* [Staff, care home 2]

Staff members wanted to be able to upload a photo of each resident to click on instead of selecting a name, which would take them directly to the resident's profile. This profile would incorporate relevant information about the resident such as weight, changes in weight, issues with previous foods such as stomach problems or swallowing difficulties, risky foods and allergies, IDDSI [29] and MUST [14] scores, medications that may affect diet, and a category for food monitoring (high risk, medium risk, or low risk). Having the malnutrition risk score assessed via the tool and keeping track of IDDSI scores was a high priority for staff. These features would support staff, particularly new staff who are less familiar with a resident, in ensuring that the correct food is provided:

> *Choosing the picture would help with our new staff or our bank staff to recognize the resident, we have quite a high turnover here so a photo would quicken the recognition process.* [Staff, care home 4]

The profile would be accessed, leading to the diary, and a warning signal would be produced when a picture is taken to highlight risky foods for that resident. This was suggested as an important future feature:

> *If the tool was able to actually warn or prompt staff of certain foods it would really support our staff-we have a lot of residents here who have allergies or are choking hazards so it would support staff unfamiliar with these residents when giving them their meals.* [Staff, care home 2]

A key concern for care home staff using the tool was the time it would require to take the photo and deliver a meal to the resident while it was still hot. Some homes had 80 residents, and staff would not be able to monitor everyone in addition to their other duties. Upon further discussion, a traffic light system was suggested:

> *Having something like a traffic light system for overall nutrition risk of the resident as well as risk of the food would be brilliant. We could then monitor our resident over time and give more detailed reports when the dietitian came to who was priority.* [Staff, care home 3]

This would be a system that would categorize individuals as *green* (does not need regular monitoring), *amber* (needs monitoring but is not of major concern), and *red* (needs monitoring and may need observation or support with eating due to key issues such as swallowing difficulties or choking concerns). Care staff also wanted to be able to choose which residents to monitor because this would help reduce the time spent using the tool by prioritizing residents who needed monitoring the most while eliminating those who did do not require it.

Given concerns over staff time, methods to speed up the tool's use were highlighted as essential components to integrate. One suggestion was allowing staff to self-select individuals they needed to monitor based on their own experience of who needed support the most:

> *We know our staff well, we know who has problems when it comes to eating, and we know who to highlight to our manager, if we could choose who to monitor and have the tool to support our statements it would help.* [Staff, care home 1]

Another suggestion was to add an "empty plate" button:

> *Being able to just even say they ate everything would really help.* [Staff, care home 4]

This would eliminate the need for a second photo. A "half-finished" button was also suggested; however, it was highlighted that this could lead to users not knowing what parts of the meal had been eaten, resulting in an inaccurate estimate of nutritional intake:

> *Being able to click that they ate half would quicken things up, but saying that, we have certain residents who only eat their meat and leave their veggies.* [Staff, care home 2]

Having a database with preexisting photos based on current care home menus was identified to speed up use of the tool, with the staff only needing to take an "after" photo. Another suggestion to expedite the process was to work with the care homes to integrate their menus into the tool. Of the 4 care homes, 3 (75%) reported a 3-week menu that could be incorporated, and staff would pick from preassigned photos of each meal rather than take "before" photos of all meals. They would then only need to capture "before" photos for individuals with smaller portions or meal modifications (eg, substitution or fortification). Afterward, staff would take "after" photos of unfinished plates, using an "empty plate" button for completely finished meals.

Care staff mentioned the importance of monitoring fluid intake as well as food consumption. Linking fluid intake to bathroom breaks and urinary tract infection diagnoses would motivate staff to provide better fluid care for residents:

> *If we could monitor what they are drinking and then when we take them to the toilet, particularly during the night, it would be really useful so our staff can monitor who hasn't drank in a while. It would be even better if the tool could tell us when to stop giving them liquids or if certain liquids made them need more, to prevent them needing at night time.* [Staff, care home 3]

Staff felt that it would be useful to build a feature into the tool that gave personalized fluid feedback and indicated when best to give out fluids, the best type of fluids to give, and whether there should be any time restrictions to ensure the best level of hydration for each resident.

Given that most residents were on restricted diets—some requiring pureed food due to swallowing difficulties and others

needing fortified meals—having these dietary modifications recognized by, or incorporated into, the tool was deemed essential. Staff identified taking multiple photos as the only feasible solution that would still provide accurate nutritional information. This process would involve taking (1) a photo before pureeing, (2) a photo of the pureed meal, and (3) a photo after consumption. At the second meeting of AG 2, it was confirmed that further discussions with app developers would be needed to determine the quickest and most accurate method for implementing this approach.

Residents who tested the tool suggested having a notification or prompt system to remind them to use it. They mentioned that they sometimes forgot to log their food intake and became upset when they missed the opportunity to do so:

> *I eat at different times to the other residents, and was worried I wasn't allowed to use it out with mealtimes so I sometimes forgot to take pictures. This was annoying as I really enjoyed using the tool. Will I still have access to it?* [Resident, care home 2]

Residents reported that being able to set their own prompts or notifications would be beneficial. However, staff did not share this preference because they felt that they themselves would remember to use the tool at mealtimes as part of their work routine. The only instance in which staff considered a prompt system useful was for alerts warning them if a resident's meal contained an allergen or had previously posed a choking risk.

Care Home Staff Survey and Interviews

Altogether, 130 individuals working in the care industry completed the survey. Most of the respondents were health care staff working in a care home (62/130, 47.7%), followed by care workers (25/130, 19.2%), support staff (19/130, 14.6%), and managers (9/130, 6.9%). Of the 9 managers, 2 volunteered to participate in the postsurvey interview. Of the 130 respondents, 60 (46.2%) had worked in the care industry for >5 years, while 30 (23.1%) had worked for <2 years. When asked how they monitored residents' diets, most (114/130, 87.7%) did not provide specific examples or measurable approaches used in their care homes. Many mentioned menu planning, staff training, and nutritional analysis but without detailing the methods or explaining how food intake was tracked for each resident. Among those who provided examples, methods included written reports (9/16, 56%), diet diaries (4/16, 25%), and computer platforms (2/16, 13%). When asked about additional symptoms that they felt were important to monitor in residents but were not available in the current version of the tool, the most commonly mentioned were hunger (45/130, 34.6%), mood (41/130, 31.5%), and swallowing difficulties (39/130, 30%). However, these symptoms were already included in the tool but may need to be more visually prominent and not limited to being reported only after meals. Other suggested symptoms included tiredness and pain. When asked which features they felt should be added that were not available in the current version, the most common responses were profiles that use photos to identify resident rather than just their name (42/130, 32.3%), a traffic light system (36/130, 27.7%), and integration of IDDSI and MUST scores (36/130, 27.7%). Additional suggestions aligned with feedback from individual care homes, including a regular weigh-in section and fluid intake monitoring. These suggestions were discussed at the second meeting with AG 2, focusing on developing a basic version of the tool that meets general needs across care homes, with the option for individual care homes to add personalized features if deemed essential, provided they were willing to cover the additional cost.

The survey data were supported by the interviews with care home managers. Both managers reported using multiple methods to monitor residents' diets, although these were not always consistent across staff members or health professionals. They noted that having an app capable of tracking diet, identifying malnutrition, and monitoring associated symptoms would help standardize care across residents and life situations. The managers agreed that such a tool would allow dietary monitoring beyond the care home, including when residents were out with family or hospitalized, ensuring that symptoms could be monitored during these periods. A traffic light system that was visible to staff but not residents was considered highly important to ensure close monitoring of only residents who needed it. The managers were enthused about the tool and using it as part of care but had some concerns. They were worried about the time required to take photos and monitor symptoms, but when prompted during the interview, they came up with strategies themselves to speed up the process. Both managers expressed concerns about the cost of the tool and its uptake. While they acknowledged the tool's value, they noted that traditional paper methods were more economical unless the tool provided clear value for money. When discussing ways to make this feasible, they suggested (1) making it free for National Health Service (NHS) users, (2) implementing a tiered fee structure for access to different tool features, (3) generating revenue from external users to help subsidize the costs for care homes, and (4) finding funding to support its implementation in care homes.

Discussion

Principal Findings

We co-designed a prototype tool that enabled users to take photos of food plates using Android phones or tablets and link foods to a variety of chosen symptoms and mood ratings. The prototype was then tested in care homes. While the ultimate version of the tool would also calculate nutritional intake from the photos, the aim of this study was to co-design the tool to maximize usability. The co-design involved older adults, care home staff, dietitians, app developers, and researchers. The repeated design and test approach ensured that the prototype was co-designed with AGs, with participants' feedback used to make incremental improvements before testing whether the suggested features were usable and integral to the overall objectives of the tool. This agile methodology implemented by Game Doctor allowed for rapid prototyping and testing of each of the 3 builds by end users. Testing in the community and later in care homes revealed what worked well and what needed updating as well as features that should be included to make the tool specifically suitable for use in care home environments. This collaboration with end users was vital to developing a tool suited for diet and symptom monitoring in care homes.

Care home staff and residents provided feedback on how to ensure that the tool could be implemented in their care home and were very positive about using it overall, although it should be acknowledged that this may have been influenced by the relative experience of the staff. However, the range of experience across the testers gives us confidence that we have captured a range of views. All participants emphasized the tool's value in supporting staff; facilitating quicker diagnosis of dietary-related symptoms; and enabling earlier detection of malnutrition, which is an important issue in care homes [7]. They reported that they would not need to monitor every resident or use every aspect of the tool but that it would be very valuable to use and could additionally form part of their marketing approach to attract residents.

Care home staff and residents suggested several important features and ways to increase usability. Priority features that will be integrated into future design are enhanced resident profiles with a traffic light system, integration of IDDSI [29] and MUST [14] scores, and recognition of pureed food and fortified meals. Traffic light systems have been found to be successful in dietary monitoring previously by encouraging users to choose lower-calorie alternatives [30]. A similar approach could be applied to identifying "safe foods" in the current targeted group. This would circumvent the need for diet diaries and bringing in a dietitian to interpret data [15], potentially accelerating the recognition of malnutrition with the addition of a nutrition calculator and other tool features to enable appropriate actions to be taken before hospitalization becomes necessary. Previous tools [22,23] that have used photo-based dietary assessment have found this to be a valid, feasible, and user-friendly approach to monitoring dietary intake. However, these tools have focused on younger populations, who may have different dietary requirements and greater familiarity with technology compared to the current target group.

Regarding wider use across care homes and potential methods of commercialization, the care staff survey and manager interviews indicated a preference for the tool to be free for NHS users. This would support its adoption across services and ensure that those who most needed it could fully benefit from its features. Finding funding from the local council or government or having the cost subsidized by nonresident users was brought up as another way to keep costs low or eliminate them for care homes. Managers suggested that even staff members interested in using the tool for their own dietary monitoring could help subsidize costs. When discussing payment for the tool, managers remained positive about using it, provided it was not too expensive, which would divert funding from other activities. Their preference was to pay an annual fee that would give them access to the tool, including updates and maintenance support. A tiered fee structure was also suggested, where costs would increase based on the number of features accessed. Although the managers would prefer the tool to be free, they were still keen to use it even if it was associated with a small fee. The global revenue for nutrition apps was projected to reach US $5.4 billion in 2024, with an expected annual growth rate of 11.2% [31]. This highlights the popularity of dietary monitoring and the importance of working with care home organizations to develop a financially feasible model for the tool.

Co-design between end users, the tool developers, and the research team was integral to this tool's production. As previous tools [22,23] and reviews of image-assisted dietary assessment methods [32] have focused on younger populations, it was essential to involve older adults in the codevelopment process. The feedback gathered played a crucial role in shaping the tool's functionality and features, ensuring that it was suited to the intended environment and users. This emphasizes the importance of co-design and coproduction in this type of research and innovation [27]. Applying the 3-sprint approach to design enabled a continual process of refinement, resulting in the production of a tool created by and for older adults and staff in care homes. Without this iterative process, the research team could have estimated which features might be important for users in care homes, but direct lived-experience evidence was essential to verifying whether these were the right features to incorporate and ensuring the tool's feasibility for the intended end users. However, despite this inclusive approach to ensuring that the tool incorporated the most important features for the setting, several technical improvements are still needed, along with the integration of new features; for example, because this study focused on co-design and feasibility testing, it is not yet clear how well the tool scores in terms of the accuracy of food recognition, and further testing, as well as comparison to similar tools, will be needed to ensure that this critical aspect performs well. Future versions would need to use a specially trained model that is linked to known menus; this should improve food recognition substantially. Other tools have reported mixed accuracy estimates, ranging from 9% to 63% [33]. One advantage of our tool is that it allows manual corrections or direct entry of specific foods and can be directly linked to a care home's menu plan to increase the accuracy of food recognition. Many similar tools have been criticized for their inability to accurately assess the quantity of food eaten [33]. Our tool addresses this limitation by incorporating "before" and "after" meal photos, enabling it to calculate the actual amount consumed rather than just identifying the food on the plate. Future research is needed to evaluate food quantity estimation as well as food recognition performance. However, the tool has the potential to simplify and speed up malnutrition recognition and dietary monitoring in later life among older adults, who are at higher risk than younger populations.

Limitations

This study is not without limitations. While the use of co-design and coproduction ensured that the tool included relevant features suited to its intended setting, our testing sample lacked diversity. All care homes recruited were private rather than council funded, and all AG members and tool testers were of White British origin. However, this reflects the typical ethnic composition of the Scottish population [34], and there was diversity in terms of gender, age, occupation, and specific care home site across participants. Future research would benefit from recruiting more diverse samples, including participants from both council-funded and private care homes, as well as recruiting across a range of geographic locations, including inner-city areas where communities are more ethnically diverse. A second limitation was the specific database used, which was developed in Spain and optimized for a more European-style diet. As a result, it did

not include many foods commonly consumed in Scotland and misidentified some foods as typical Spanish dishes (eg, paella). However, a future direction for this research is to create a bespoke database of food consumed in Scottish care homes as well as exploring the possibilities of working with individual homes' menu planners to create a tool specific to each home. This approach could be fundamental to the economic model for maintaining and continually updating the tool as a way of charging for a bespoke service rather than tool *use* in future, allowing us to provide the tool free in other settings, such as the NHS. One limitation of the co-design and coproduction methodology was the diversity of feedback regarding the tool and its usability and key features. While some care homes wanted enhanced features, such as malnutrition risk scores, a traffic light system, and fluid measurement with urinary continence tracking, others preferred to keep the tool's functions simple to enable ease of use. Further discussions clarified that the enhanced features could be optional, tailored to individual care homes' needs, and potentially cost associated, which eliminated the contradictions in the feedback.

Future Directions

Building on the outlined future directions, the next steps for this research project are to incorporate the care home feedback into the next build of the tool to ensure its suitability for care homes. To do this, we plan to apply steps 3 to 6 of the 6SQuID framework [24], test the tool in a more diverse sample of care homes, link it to a specially developed database of food photos reflecting the typical Scottish care home diet, and explore cost-effectiveness options and sustainability strategies to ensure that the tool remains up to date.

Conclusions

This journey through the co-design of a digital food recognition tool has revealed both its considerable potential and areas for further design improvement and feature enhancement. As we progress toward further prototype refinement and wider testing in diverse care home settings, the feedback and recommendations from this project will guide our approach, ensuring that the tool is practical, feasible, and robustly designed to comprehensively monitor diet and identify malnutrition risk and food-related problematic symptoms in older adults in residential care homes.

Acknowledgments

The authors acknowledge the artificial intelligence company specializing in food recognition and nutrition analysis LogMeal (AIGecko Technologies SL, Artificial Intelligence and Deep Learning Food Division) for the use of its database and thank all advisory group members and tester participants. This research was funded by a UK Research and Innovation Healthy Ageing Catalyst grant (ES/X006271/1), an Economic and Social Research Council–Stirling Social Science Impact Acceleration Account institutional block award to the University of Stirling, and a specific exploratory–Impact Acceleration Account and routes to commercialization grant to JC and ACW (STI-23/24-P0001). The article processing charge was funded by the University of Stirling. Abstract

Background: Due to the progressive nature of dementia, concerns about the safety of nursing home residents are frequently raised. Surveillance technology, enabling visual and auditory monitoring, is often seen as a solution for ensuring safe and efficient care. However, tailoring surveillance technology to individual needs is challenging due to the complex and dynamic care environment involving multiple formal and informal stakeholders, each with unique perspectives.

Objective: This study aims to explore the scientific literature on the perspectives and values of stakeholders involved in applying surveillance technology for people with dementia in nursing homes.

Methods: We conducted a scoping review and systematically searched 5 scientific databases. We identified 31 articles published between 2005 and 2024. Stakeholder characteristics were extracted and synthesized according to the theory of basic human values by Schwartz.

Results: In total, 12 stakeholder groups were identified, with nursing staff, residents, and informal caregivers being the most frequently mentioned. Among stakeholder groups close to residents, values related to benevolence, security, conformity, and tradition were most commonly addressed. Furthermore, values such as self-direction, power, and achievement seemed important to most stakeholder groups.

Conclusions: Several stakeholder groups emphasized the importance of being and feeling involved in the application of surveillance technologies. In addition, they acknowledged the necessity of paying attention to stakeholders' perspectives and values. Across these stakeholder groups, values related to benevolence, security, and self-direction were represented, although various stakeholders assigned different meanings to these values. Awareness of stakeholders' perspectives demands a willingness to acknowledge each other's values and bridge differences.

KEYWORDS

surveillance technology; nursing home; stakeholders; values; dementia; safety

Introduction

Background

Globally, people are living longer. Every country in the world expects growth in the number and proportion of older persons [1]. As the population ages, diseases such as dementia are diagnosed more often because age is their strongest known risk factor [2,3]. Dementia is a major cause of disability and dependency, affecting cognitive abilities and behavior, leading to an inability to signal when help is needed, which is associated with safety concerns [3,4]. Compared with 2015, the number of people affected with dementia will triple by 2050 [3].

In several countries worldwide, the number of care professionals is insufficient to meet the growing care demands [5]. In addition, global shortages of skilled care professionals will increase due to the aging workforce [6,7]. To meet the increasing care demands, documents from the Netherlands government show that by 2024, 1 in 4 employees should work in the health care sector, a figure that should rise to 1 in 3 by 2060 [8,9]. One of the proposed solutions to this challenge is allowing people with dementia to live at home as long as possible. However, due to their increasing care demands, a need for long-term care (LTC) facilities providing high-quality intensive dementia care will continue. Studies in different countries worldwide indicate that approximately 30% to 40% of people with dementia will eventually need a care environment in nursing homes [10-12]. The Netherlands is known for its high percentage of residents receiving end-of-life care in nursing homes, which makes nursing homes the most frequent place of death [13]. Consequently, there has been a large increase in health care expenditures for the population with dementia, especially in LTC facilities [12].

One recommendation to address these societal challenges in home care and nursing homes is to foster investment in health technologies that contribute to sustainable and high-quality care for people with dementia, such as assistive and innovative care technologies [3,14,15]. Care technologies can delay or replace admission in a nursing home and reduce the workload of nursing staff and informal caregivers in community care and nursing homes [16,17]. There are different types of care technologies. One is surveillance technology, which allows visual and auditory monitoring and registration of events, including residents' activities. Surveillance technologies include tagging and tracking technology, sensors, and audio and video surveillance [18,19]. Surveillance technologies are increasingly focused on supporting autonomy and respecting privacy while enhancing safety and individualized care for people with dementia [7,20-23].

Surveillance technologies are often regarded as a solution for ensuring safe and efficient health care, including in nursing homes [14,19,20]. These technologies have the potential to provide high-quality care and relieve nursing staff as staff shortages increase [7]. Due to the potential benefits of using surveillance technologies for quality of life and care, general attitudes toward these technologies have become more positive [16]. Nonetheless, surveillance technologies can affect privacy, autonomy, and freedom of movement [16,20,21]. Therefore, the use of these technologies should comply with regulations governing privacy and involuntary care, including requirements for subsidiarity, proportionality, and expediency. In addition, the use of surveillance technologies has to be justified in the care plan [24-26].

The application of surveillance technologies for people with dementia living in nursing homes is complex in practice. Successfully implementing care technologies, including surveillance technologies in psychogeriatric nursing homes, appears to be challenging as it involves more than just implementing a technological application successfully used elsewhere [27]. One of the greatest challenges in implementing care technologies such as surveillance technology seems to be integrating technology into the care process. Surveillance technologies affect residents and other primary stakeholders, such as residents' representatives and formal caregivers [16,28]. The involvement of these primary stakeholders, also known as end users, and secondary stakeholders such as managers, information and communication technology (ICT) employees, developers, and vendors of surveillance technologies is necessary to increase stakeholder commitment [28].

Early involvement of relevant stakeholders increases the likelihood of successful implementation [29]. A prerequisite for their involvement is knowing and acknowledging stakeholders' cultures, perspectives, and interests [29]. Given the broad spectrum of stakeholders involved in applying surveillance technologies for people with dementia in nursing homes, there is a great diversity of backgrounds, resulting in differences in values and interests [27,30]. Values represent what is (most) important to people and direct their attitudes, behaviors, and actions [31,32]. Differences in stakeholder values and interests can complicate the creation of support among stakeholders [30]. In addition, dealing with different perceptions and values among a range of stakeholders is a major challenge, further exacerbated by a limited understanding of stakeholders' values [33]. Therefore, a knowledge of these values can help explain decision-making processes, attitudes, and behaviors of persons or groups in different contexts [31,34,35].

This situation necessitates exploring the stakeholder groups that are involved in implementing surveillance technologies, and their respective values. Nursing staff and informal caregivers' attitudes toward using surveillance technologies [18,36] and their ethical dilemmas when using surveillance technology in psychogeriatric nursing homes have been explored [23,36-38]. For example, Rostad and Stokke [39] noted the high complexity of the LTC setting, involving "wicked problems," such as many and changing stakeholders, competing interests, and disagreements regarding the nature of problems. However, it remains unclear what these competing interests consist of. In addition, little is known about the variation in the perspectives and values of the stakeholders.

This Study

To the best of our knowledge, no literature review has been conducted to explore the stakeholders involved, their perspectives, and values in the application of surveillance technologies for people with dementia living in nursing homes. Therefore, this scoping review aimed to explore which stakeholders are described in the scientific literature concerning

surveillance technologies for people with dementia in nursing homes. In addition, we seek to identify what is known about these stakeholders' values.

Methods

Overview

We conducted a scoping review to systematically explore, map, and synthesize the characteristics of stakeholders involved in applying surveillance technology for people with dementia in nursing homes and identify existing knowledge gaps. The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist was used as a guideline for this review [40] (Multimedia Appendix 1). The corresponding steps were followed [41]: (1) identifying research questions; (2) identifying relevant literature in databases; (3) selecting the literature; (4) charting the data; and (5) collating, summarizing, and reporting the results.

Identifying the Research Questions

The research questions formulated were as follows: (1) Which stakeholders are involved in applying surveillance technology for people with dementia residing in psychogeriatric wards in nursing homes? and (2) What is known about the values of these stakeholders?

Identifying Relevant Literature

We believed that articles of interest had been published in psychological, health care, medical, nursing, and technological journals. Therefore, we conducted a literature search using the following databases: MEDLINE, CINAHL, PsycINFO, ACM Digital Library, and IEEE Xplore. Search terms encompassed the LTC setting and the use of surveillance technology for people with dementia. A search string for each database was developed and programmed with the help of an information specialist (Multimedia Appendix 2). A search was first performed in April 2022 and fully updated in August 2023 and December 2024.

Studies were eligible for inclusion if surveillance technology was applied to people with dementia in nursing homes or a comparable 24×7 LTC setting. The use of surveillance technology was evaluated or monitored using qualitative, quantitative, or mixed methods designs. Furthermore, studies had to be peer reviewed, written in English or Dutch, and published between 2002 and 2023. The year 2002 was chosen because it was then that literature on the implementation of surveillance technologies became increasingly prevalent. In addition, studies had to mention the stakeholders who were involved in the process of applying surveillance technology. Studies mostly focusing on assistive technologies, such as automatic lights, or supportive technologies, for example, medication dispensers, health care apps for managing chronic diseases, etc were excluded. Studies conducted in an experimental or laboratory setting and nonoriginal research, such as scoping reviews and systematic reviews, were excluded.

Literature Selection

First, duplicate studies were removed. Title screening was performed by one of the authors (DvG-R), and in case of doubt, one of the other authors (AS) was consulted. Two authors (DvG-R and AS) independently screened abstracts using the literature review management tool Rayyan (Rayyan Systems Inc) [42]. The full text of articles considered eligible by both authors was reviewed for relevance. In all the selection steps, the results were compared and discussed until a consensus was reached. In case of doubt, the third author (EW) was consulted.

Charting the Data

A format for further data extraction was agreed upon and included the title, authors, year, country, aim, study design, method of data collection, study population, sample size, setting, technology type, an overview of the results per identified stakeholder, and limitations for this scoping review. Using this format, 2 authors (DvG-R and AS) independently reviewed 10 (32%) of the 31 included articles. When the reviews were compared, only minor differences were found. The remaining articles were reviewed by DvG-R, who consulted one of the two other authors (AS or EW) when appropriate. When no consensus about data extraction was reached, the other author (EW or AS) was consulted.

Collating, Summarizing, and Reporting the Results

We categorized the findings from each article per stakeholder group in data extraction forms. Subsequently, an overview of results per stakeholder group was compiled. Through an inductive process, we categorized our findings into frequently mentioned words, such as acceptance; privacy; safety; freedom of movement; person-centered care; quality of life; quality-of-care characteristics; technology characteristics; and resident characteristics, involvement, concerns, and their values. The findings were linked to human values to deepen an understanding of stakeholders' perspectives. Describing and defining values is considered complex, and analyzing them is an even greater challenge [43]. Therefore, we used the theory of basic human values by Schwartz et al [31], an empirically tested framework of values that is recognized across many cultures [44]. This theory is an important and well-known theory and is widely used to predict attitudes and behaviors in different contexts and situations [34,35]. These values are grounded in the 3 universal requirements of human existence: the needs of individuals as biological organisms, requirements of coordinated social interaction, and survival and welfare needs of groups [31]. This framework conceptualizes values ordered by importance relative to one another, and they form a system of priorities for groups, societies, and individuals [45]. The refined theory of basic human values has 19 values grouped into 4 higher-order categories as follows: openness to change, self-enhancement, conservation, and self-transcendence [31]. Table 1 presents the motivational goals of the Schwartz values based on the circular motivational continuum [31].

Table 1. The 19 values of Schwartz et al [31] explained in terms of their motivational goals based on the circular motivational continuum.

Higher order value and values	Conceptual definition in terms of motivational goals
Openness to changes	
Self-direction-thought	Freedom to cultivate one's own ideas and abilities
Self-direction-action	Freedom to determine one's own actions
Stimulation	Excitement, novelty, and change
Self-enhancement	
Hedonism	Pleasure and sensuous gratification
Achievement	Success according to social standards
Power-dominance	Power through exercising control over people
Power-resources	Power to control material and social resources
Conservation	
Face	Security and power through maintaining one's public image and avoiding humiliation
Security-personal	Safety in one's immediate environment
Security-societal	Safety and stability in the wider society
Tradition	Maintaining and preserving cultural, family, or religious traditions
Conformity-rules	Compliance with rules, laws, and formal obligations
Conformity-interpersonal	Avoidance of upsetting or harming other people
Self-transcendence	
Humility	Recognizing one's insignificance in the larger scheme of things
Benevolence-dependability	Being a reliable and trustworthy member of the ingroup
Benevolence-caring	Devotion to the welfare and well-being of ingroup members and being empathic
Universalism-concern	Commitment to equality, justice, and protection for all people
Universalism-nature	Preservation of the natural environment
Universalism-tolerance	Acceptance and understanding of those who are different from oneself

Results

General Findings

We identified 4116 unique studies. After screening titles, 298 (7.2%) abstracts were screened. After applying inclusion and exclusion criteria, we selected 91 (30.5%) articles for full-text screening. Eventually, we included 29 (32%) articles in this study. The search was updated in August 2023, and December 2024, resulting in 2 additional articles, bringing the total to 31 articles. The included studies were published between 2005 and 2023. Studies were conducted in 14 countries: The Netherlands (n=7, 23%), Finland (n=2, 6%), Denmark (n=1, 3%), Norway (n=2, 6%), Sweden (n=2, 6%), Spain (n=1, 3%), Germany (n=1, 3%), Switzerland (n=1, 3%), the United Kingdom (n=3, 10%), the United States (n=5, 16%), Canada (n=3, 10%), Mexico (n=1, 3%), Singapore (n=1, 3%), and China (n=1, 3%). A total of 10 (32%) articles had a quantitative research design, 18 (58%) articles had a qualitative design, and 3 (10%) articles had a mixed methods design. Figure 1 shows the flowchart of the selection process. The key characteristics of the included articles are available in Multimedia Appendix 3 [7,18-22,37,38,46-68].

In total, 12 stakeholder groups were identified in the publications. The most frequently identified stakeholder groups were nursing staff (23/31, 74%), residents (20/31, 65%), and informal caregivers (13/31, 42%). The stakeholder groups care managers (9/31, 29%), developers of surveillance technologies (7/31, 23%), physicians (5/31, 16%), LTC administrators (4/31, 13%), maintenance employees (2/31, 6%), ICT (2/31, 6%), vendors of surveillance technologies (1/31, 3%), project managers (1/31, 3%), and academics (1/31, 3%) were mentioned less frequently. A total of 9 (29%) of the 31 articles included 4 or more stakeholder groups in their research. Table 2 shows the stakeholders' frequency of occurrence in the included articles.

Figure 1. Flowchart of the selection process.

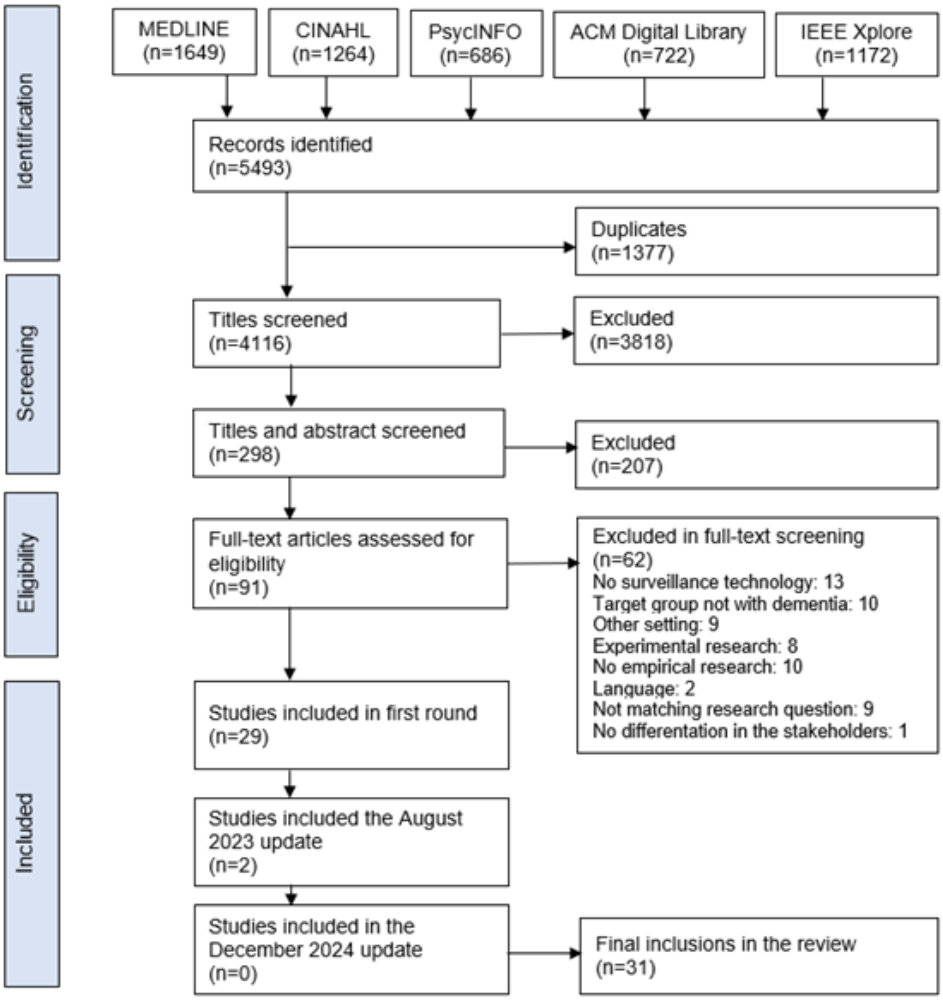

Table 2. Frequency of stakeholder occurrence in included articles and proxy perspectives[a].

Stakeholder	Frequency (N=31), n (%)	Proxy or partly proxy, n (%)[b]
Nursing staff	23 (74)	7 (30)
Residents	20 (65)	17 (85)
Informal caregivers	13 (42)	7 (53)
Managers	9 (29)	—[c]
Developers	7 (23)	—
Physicians	5 (16)	—
Long-term care administrators	4 (13)	—
Maintenance	2 (6)	—
ICT[d]	2 (6)	—
Vendors	1 (3)	—
Project managers	1 (3)	—
Academics	1 (3)	—

[a]Proxy perspective refers to the perspective of a stakeholder filled in by another stakeholder.

[b]Percentages in this column represent the proportion of articles in the corresponding cells in the "Frequency" column.

[c]Not applicable.

[d]ICT: information and communication technology.

Values of Stakeholders

Nursing Staff

Of all identified stakeholder groups, nursing staff (registered nurses, assistant nurses, and nurse aids) were mentioned in 23 (74%) out of 31 articles. Of these 23 articles, 7 (23%) articles were written from a proxy perspective of care managers (n=4, 17%), LTC administrators (n=2, 8%), and informal caregivers (n=1, 2%).

Several values of Schwartz were represented in the stakeholder group nursing staff. The values *benevolence* and *security* were strongly represented. The value *benevolence* is related to being helpful, supporting, and assisting those in need [31]. Staff's desire to be helpful and respond to the needs of residents also partly overlapped with the value *security*, which is characterized by striving to assure the safety of loved ones, taking precautions to prevent harm, and being warned in case of threats [45]. From the nursing staff perspective, surveillance technologies were most often applied to enhance the general safety of residents, mitigate the risk of falling, alert staff promptly, and contribute to efficient care [7,22,46]. Surveillance technologies can help nursing staff prioritize and direct their attention to where care and support are most needed [7,22,47]. Nursing staff expected monitoring technologies to increase the safety of residents [20], although they were aware of its limitations [21]. For example, they mentioned that surveillance technologies could not guarantee that residents would never fall [22]. Nursing staff rated residents' safety higher than they rated the experience of freedom [20], possibly due to the fear of being blamed for accidents or injuries to residents [22].

Because nursing staff felt responsible for their residents, the former expressed hesitation toward entirely relying on new surveillance technologies [48]. The values *conformity* and *tradition* were reflected in the nursing staff's conservativeness and preference to maintain their traditional routines. The nursing staff mentioned that altering their care routines was more difficult than expected. They tended to continue doing their rounds and checking on residents as usual despite the use of new technologies [49]. Managers' proxy perspectives also recognized the difficulties in altering care routines [48]. Although nursing staff tended to keep their traditions, they were generally supportive of new technologies that contributed to improvements in daily practice, particularly when the technologies functioned as intended [46]. However, new surveillance technologies never functioned properly from the outset, and implementing them often resulted in initial malfunctions [50]. These initial malfunctions, such as false alarms, poor Wi-Fi, and slow software had a negative influence on the level of acceptance, partly due to the nursing staff's great sense of responsibility for the residents [7,46,51]. These challenges limited the usability and accuracy of detecting unsafe situations and led to an even higher workload [7,22,46,48]. In addition, these challenges resulted in nurses' alarm fatigue and, as a result, nursing staff primarily relied on their previous experiences with residents' routines [21,48,51].

Moreover, nursing staff found new technologies challenging because these technologies required skills they did not previously need in their daily practice [52]. The extent to which procedures and instructions were tailored to the nursing staff's daily work, their shifts, and professional language influenced the nursing staff's openness to changes and the experienced extent of *self-direction* [7,20,51,53]. Moreover, they expected the technology vendors to help them, for instance, by providing support even outside regular business hours [7,51]. Nursing teams also felt supported when some of their colleagues took the lead in teaching them [7,47,51].

Although surveillance technologies contributed to providing optimal security and safety for residents, nursing staff expressed concerns about the impact of the use of monitoring technology on privacy, their competence in using the technologies, and the replacement of their roles [51,54]. This outcome relates to the value *self-direction.* Nursing staff expressed concerns that the monitoring technology was applied as a "big brother tool," indicating a lack of confidence [7,19,37,54]. Nursing staff preferred the application of codes of ethics and limited access by authorized professionals to protect their privacy and that of residents [7,53]. In addition, staff were concerned that monitoring had an impact on resident relationships [54] and that their role would be replaced by technology [51]. The latter was also recognized by care managers, as reflected in their proxy perspectives [51,52]. Particularly, older nursing staff expressed concerns about experiencing challenges while working with technology, resulting in a reserved attitude toward care technology [51]. The extent to which nursing staff felt involved influenced the freedom they experienced to determine their ideas and actions. This outcome impacted their openness to changes, represented by the values *self-direction in action and thought*. From a proxy perspective, care managers and administrators recognized these challenges faced by nursing staff, and they mentioned that nursing staff needed time to adapt to new care technologies before they could appreciate them [55,56].

Because surveillance technologies directly interfered with the nursing process, nursing staff expressed a desire to be involved from the beginning, for instance by being involved in discussions and decision-making processes [22], to be able to express their needs, opinions, and concerns [53]. The values *achievement* and *power* are related to the nursing staff's desire to be acknowledged and appreciated as important stakeholders.

In summary, the values *benevolence, security, conformity,tradition*, *self-direction in action and thought*, *achievement,* and *power* were represented among the stakeholder group of nursing staff.

Residents

Of the 31 included articles, 20 (65%) described residents as stakeholders, with 17 (85%) articles based on a (partial) proxy perspective of nursing staff (n=12, 47%), informal caregivers (n=4, 20%), LTC administrators (n=2, 10%), and developers of surveillance technologies (n=2, 10%).

Several residents who were interviewed, said they were aware of their dependency on care as a result of their cognitive decline. They adapted to life's circumstances, reflecting the value *humility*. Moreover, they indicated that care customized to their preferences and needs supported their independence and

contributed to their safety [52,55]. The value *(personal) security* is represented in the residents' feeling of being heard by care professionals. This means that professionals know where they are, respond to their alarms, and can care for them [22,53,57]. Consequently, surveillance technologies were perceived as part of the deal, improving their safety, and receiving individualized care [38,57]. This was recognized by nursing staff because they mentioned that surveillance technologies enhanced safety and contributed to the care, in line with residents' personal preferences, contributing to the latter's level of independence [52,53,55].

Residents knew that they partly gave up their privacy when they moved to a nursing home. Nevertheless, surveillance technologies could contribute to their feeling of *(personal) security* because the technologies protect their privacy. Coded doors, for example, could prevent other residents from unintentionally entering their rooms [19,38]. Although residents expressed a feeling of increased *(personal) security* due to surveillance technologies, they feared the consequences of these technologies as they expressed worries that these technologies would replace the valuable human contact with staff, because social contacts were an essential and highly valued part of life [37,38].

Furthermore, the values *conformity* and *tradition* seemed important to residents. These values include the avoidance of significant changes in their living environment, for instance, due to the use of surveillance technologies. Residents emphasized the importance of maintaining a feeling of homeliness [38,57]. In addition, surveillance technology should not jeopardize their feeling of homeliness or be (too) visible. Instead, surveillance technology should be aesthetically pleasing, easy to use, and not disrupt their daily routines [57,58]. Caregivers, as proxies, noticed that the extent of devices' intrusiveness to residents influenced the acceptability of devices [47,55,59]. Moreover, several residents expressed resistance to technology based on the usefulness they experienced [60]. The relevance of these factors was recognized in the proxy perspective of nursing staff and informal caregivers [47,59,61]. In addition, nursing staff experienced fewer nighttime disturbances for residents resulting in calmer nights [7,51]. Nursing staff noticed that the residents' openness to changes and the experienced *self-direction* decreased when there were more false alarms [57], which was recognized in the reluctance the latter expressed and is related to the experienced usefulness.

Residents' feelings of being stigmatized or being regarded as patients increased when their wishes regarding the visibility, appearance, and usability of surveillance technologies were not met [18]. This outcome aligns with the value *face*, which emphasizes maintaining one's public image and avoiding humiliation. Regarding this value, residents expressed greater concern about cameras than about other devices. These concerns were particularly about being recognizable in images while performing personal and hygienic activities, evoking feelings of intrusion and vulnerability [37,38,54]. This factor was similarly mentioned by managers when they expressed their concerns about the invasion of residents' privacy and dignity arising from surveillance cameras [54].

In summary, the values *humility, (personal) security, conformity, tradition, self-direction, and face* were most represented in the resident stakeholder group.

Informal Caregivers

Of the 31 articles, 13 (42%) mentioned informal caregivers (such as family caregivers and authorized representatives) as stakeholders. In total, 7 (53%) of these articles (partly) described a proxy perspective. Proxy perspectives were mostly represented by nursing staff (n=6, 46%), LTC administrators (n=2, 15%), and physicians (n=1, 8%).

Informal caregivers, mostly family members, expressed their concerns about the safety of their loved ones. Preventing (new) falls was often mentioned as a reason to use surveillance technology [19,22]. In their desire to contribute to the safety and well-being of their loved ones, deriving from the values *benevolence* and *security*, informal caregivers often valued residents' personal safety above possible threats to their privacy and freedom of movement [22,38]. This was also recognized by nursing staff and physicians, who observed informal caregivers' peace of mind when surveillance technologies were used [21,54]. In line with this value benevolence, informal caregivers felt responsible for the well-being of their loved ones. Informal caregivers feared that surveillance technologies would replace valuable human contact that arises from this value, and this fear may be reinforced by informal caregivers' awareness of the staff shortages in nursing homes [38,51]. This fear was recognized by nursing staff who indicated that they perceived it among informal caregivers [38,51]. Informal caregivers noted surveillance technologies should support nursing staff rather than replace them [38]. From a transcendent perspective, the value *universalism* seemed to be represented in informal caregivers' concerns about striving for equality and protection of people who were weak [31].

Informal caregivers mentioned they were willing to accept a wide range of surveillance technologies, including video surveillance, as long as they were convinced about the contribution these technologies made to the safety, quality of life, and well-being of their loved ones [22,37,38]. In addition, nursing staff and managers said that the level of informal caregivers' openness to changes was also determined by their perception of usefulness and their interest in technologies [53]. Informal caregivers' willingness to accept a broad range of surveillance technologies and their openness to changes reflected the value *self-direction*, embodying their ability to choose their goals and be involved in decision-making. The prerequisite of getting involved in (discussions about) applying surveillance technologies to their loved one [38,47,53,62] arises from the value *power*. Informal caregivers mentioned that these discussions should occur between all relevant stakeholders, such as residents, relatives, and nursing staff. In addition, informal caregivers wanted to be asked for formal consent as they were (authorized) representatives [38]. In practice, informal caregivers mentioned that they were not or not sufficiently informed about the available surveillance technologies [62].

In summary, the values *benevolence* and *security, universalism, self-direction, and power* were represented in the stakeholder group of informal caregivers.

Care Managers

Of the 31 articles, 9 (29%) mentioned care managers as stakeholders. Several care managers mentioned that their priority was to manage the 24×7 health care service and that surveillance technologies could contribute to achieving this aim [53,54]. The application of surveillance technologies increased the safety of residents, which is related to the values *benevolence* and *security*. Furthermore, data from these systems could be used to defend nursing homes against allegations of negligence leveled by families [19]. In line with this situation, care managers mentioned that data could help them monitor staff and hold them to account. However, care managers acknowledged that responding to an alarm was no guarantee that care was being provided [19]. The ethical objections against surveillance technologies that care managers mentioned were particularly aimed at the potential impact on residents' privacy, rather than the impact on nursing staff [19,22]. They acknowledged camera surveillance could contribute to a "big brother" effect and a culture of mistrust [19,54]. For care managers, surveillance technologies particularly seemed to represent values with a personal focus, namely, to have control over and manage the residential care facility. This outcome aligned with values such as *power* and *achievement.*

Care managers mentioned they were often insufficiently prepared for new ways of working and, subsequently, the different authority structures resulting from implementation strategies. In addition, they mentioned they were unable to make implementations a priority due to other organizational priorities [51]. The unpreparedness for changes they experienced could be a consequence of the changed ways of working, fear of the unknown, and clinging to the values *conformity and tradition*. Nevertheless, they were open to changes, although they also experienced unpreparedness for cocreation from several stakeholders [51]. This unpreparedness stems from an expectation of a tailored solution from vendors—not a realization that everyone's input including their own was a prerequisite for a joint implementation process [51]. Care managers taking the initiative in prioritizing reflections with other stakeholders to discuss dilemmas was mentioned as a facilitator for the successful use of surveillance technologies [51]. In this respect, care managers faced challenges in their *self-direction in action and thought* [31].

Furthermore, care managers felt that values *power* and *achievement* might be occasionally threatened. They indicated that they were concerned about increasing costs associated with new technologies, such as surveillance systems, while revenues remained stagnated [63]. In addition, surveillance technologies were not always as robust as they needed to be to withstand use in nursing home practice, leading to recurring costs due to damaged products [19]. Furthermore, care managers mentioned they felt restricted by rules and contractual obligations with vendors, which could hinder their access to technologies [19].

In summary, the values *benevolence* and *security* were somewhat represented in the stakeholder group of care managers. However, the values *power,achievement, conformity,tradition,* and *self-direction in action and thought* were more clearly represented.

Developers

A total of 7 (23%) of the 31 articles mentioned developers as stakeholders. Developers envisioned surveillance technologies would be used to enhance the safety of residents with dementia and improve the security of residents and nursing staff while respecting the privacy of both [19,55,58]. This outcome aligned with the value *security*.

In addition, developers mentioned they sought to use their technologies to enable nursing staff to support and assist residents with progressive diseases such as dementia. Due to the characteristics of the resident population, developers mentioned that surveillance technologies should be dynamic and scalable and be designed for failure and intensive use [55]. This outcome reflected the value *benevolence* as it underscored their determination to support and assist those in need.

Developers emphasized that by testing monitoring technologies new insights were created and improvements could be made. Testing in real life supported them to achieve success, in line with the values *achievement* and *power*. However, they acknowledged that high error rates in initial tests had an influence on the nursing staff's openness to change [52,58,60,61]. Conversely, many initial errors occurred due to unskillful use. A higher level of training for nursing staff could reduce these errors [58]. This outcome challenged developers' values *stimulation* and *self-direction* because they were generally excited about new technologies when they noticed the impact of their technologies on end users in nursing homes [60]. Furthermore, developers emphasized the importance of evaluating the effects of surveillance technologies in nursing homes [60]. Moreover, they underlined the importance of development in close collaboration with end users and specialists in dementia care to meet their needs and requirements [52,55]. Developers acknowledged that this close collaboration was an intensive process [52,55].

In summary, for the developer stakeholder group, the values *security, benevolence, achievement, power, stimulation,* and *self-direction* were most represented.

Physicians

Of the 31 articles, 5 (16%) included physicians as stakeholders in the application of surveillance technologies.

As with nursing staff and informal caregivers, the values *security* and *benevolence* were represented, as physicians agreed that providing safety was an important reason to apply these technologies. Moreover, they noted these technologies offered peace of mind to nurses and informal caregivers [21,37]. This outcome might explain physicians' high acceptance rate of surveillance technologies [55,58].

In summary, the values *security* and *benevolence* were clearly represented in the stakeholder group of physicians.

LTC Administrators

LTC administrators were mentioned in 4 (13%) of the 31 articles. LTC administrators expressed their vision of being at the forefront of implementing new technologies, especially in newly constructed nursing homes. Generally, new technologies

were considered an important solution for health care challenges [52]. In these administrators' perspectives, the values *self-direction in action and thought* and *stimulation* were reflected. However, LTC administrators acknowledged that implementing these technologies challenged institution's openness to changes because these new technologies demanded time and resources across various roles and professions [51]. LTC administrators noted that education for staff was an important issue; however, they sometimes questioned the abilities of nursing staff to master the new technologies despite offering education to the latter [37].

The values *power* and *achievement* emerged in the acknowledgment by LTC administrators that their residential care facilities were perceived as more attractive employers when they used modern surveillance technologies [37,52]. The financial investments required could force organizations to opt for a cheaper but more generic design, although this may be less suitable than preferred designs [19]. Consequently, LTC administrators could feel restricted in their control over resources. In line with care managers' perspective, LTC administrators mentioned that organizational contracts limited their scope and flexibility around product choices and ongoing maintenance [19].

In summary, the values *self-direction in action and thought, stimulation, power,* and *achievement* were represented in the stakeholder group of LTC administrators.

Values of the Other Stakeholders

The other stakeholder groups, that is, maintenance staff, ICT staff, vendors of surveillance technologies, project managers, and academics were mentioned only once or twice in the 31 articles included. Maintenance staff mentioned that although new surveillance technologies might seem to have a limited scope, only affecting night shift workers and residents, these technologies could also have an influence on janitors, cleaning staff, and substitute personnel [37,51]. In their view, maintenance staff members were also in need of information and education to accommodate the technologies in their (cleaning and maintenance) routines. When they were not informed or did not receive education, they reported difficulties, for example, in replacing sensors and reconnecting cables after cleaning [37,51]. Because a new system is only as good as the people who are responsible for operating it, the people operating the system could affect its reliability [37,51]. Maintenance staff expressed a desire to be acknowledged as important stakeholders and be involved in education, which relates to their openness to changes in the values *self-direction* and *stimulation*. In line with the apprehensions of nursing staff, maintenance staff expressed concerns about being observed [37]. For instance, maintenance staff sometimes felt threatened due to their openness to changes and *self-direction*, reducing their motivation to engage with new technologies.

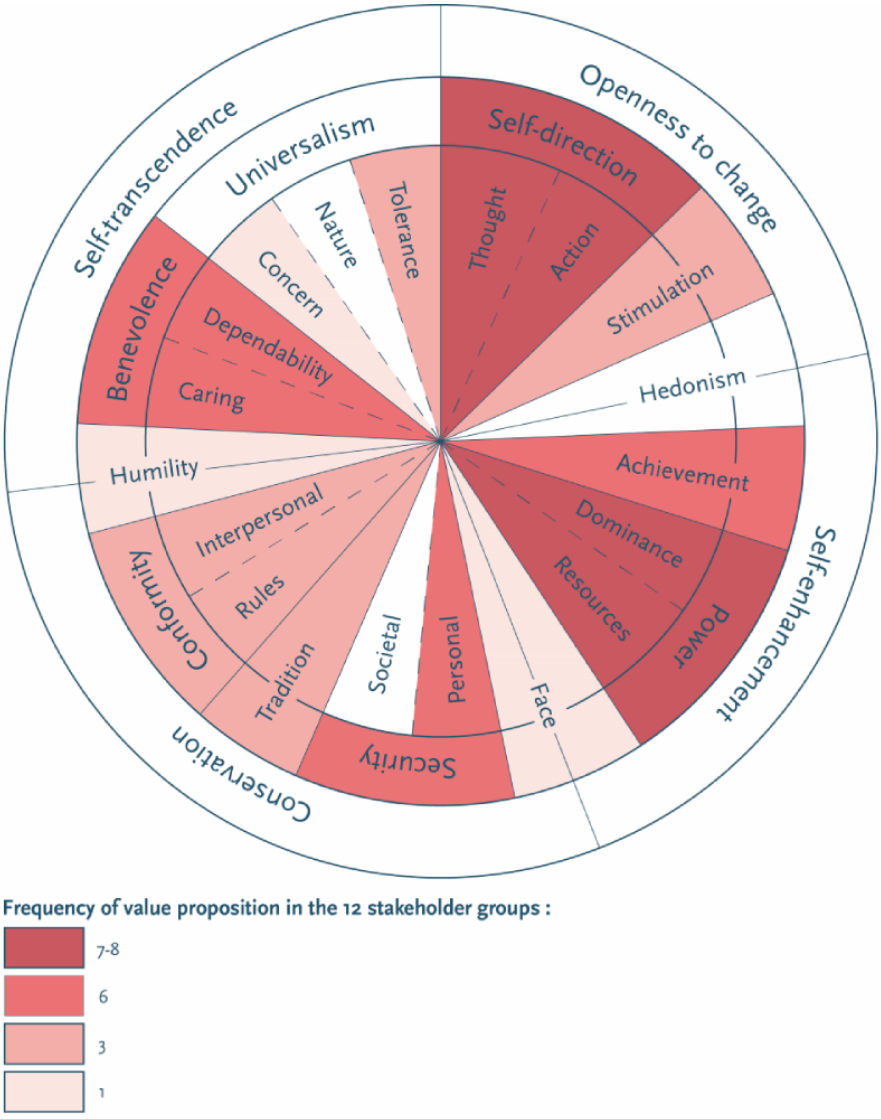
ICT staff emphasized the importance of system and component interoperability for ensuring system reliability because new systems were often installed into existing systems and infrastructure [19,51]. However, they mentioned that this interoperability between systems often was not facilitated by manufacturers [19]. Furthermore, the staff highlighted the importance of their involvement from the outset in exploring this compatibility and interoperability to prevent compromises in residents' safety and security [51]. This outcome reflected the need for ICT staff to be involved and acknowledged as stakeholders, in line with the values *power* and *achievement*. However, in practice, it was seen that ICT staff only became seriously involved when systems were unstable or errors occurred [51].

In the research by Dugstad et al [51], vendors of surveillance technologies and ICT were challenged to adopt a more socially focused approach to bridge differences between stakeholder groups. The vendors mentioned that despite their knowledge about their products, they needed the nursing staff's insights to ensure their technologies worked in specific care environments due to the great variety of care practices and infrastructure. Besides vendors striving for their own success, reflecting the values *power* and *achievement*, they were challenged to pursue a higher purpose, in line with the value *universalism*. Universalism relates to vendors' willingness to engage with other stakeholders to contribute to successful applications. In line with this value, ICT staff and vendors recognized being challenged to adopt a language that was more understandable for nursing staff who experienced differences in professional cultures and language (jargon) [51]. The ICT staff and vendors mentioned they were not used to adapting their language; therefore, misunderstandings were initially manifested due to a lack of knowledge and insight into each other's workflows. This situation challenged them to transcend their profession and jargon in order to contribute to a successful digital transformation [51]. Local project managers also underlined the importance of recognizing and bridging cultural differences as conditions for ensuring successful digital transformation. Hence, project managers identified their role as translators between different stakeholders [51], in line with the value *universalism*.

Finally, academics mentioned that the balance between freedom and security is important. They tended to value freedom of movement over security [20]. The socially focused value *benevolence* was reflected in being devoted to the welfare of others and protecting people with an increased care dependency. However, academics tend to attach great importance to residents' freedom to determine their own actions despite the dementia, which relates to the *value self-direction*.

Figure 2 presents the stakeholders' basic human values. The darker the color scheme, the more often this value is applied to various stakeholders.

Figure 2. Value palette for all stakeholders in the proposed circular structure of the 19 basic human values by Schwartz [32].



Discussion

Principal Findings

This scoping review aimed to identify the stakeholders involved in applying surveillance technologies for people with dementia in nursing homes and to describe the values of these stakeholders. Overall, 12 stakeholder groups were identified in 31 articles. The stakeholder groups of nursing staff, residents, and informal caregivers were most often mentioned in these articles. Several stakeholder groups, such as physicians, LTC administrators, maintenance staff, ICT staff, vendors, and project managers, were mentioned significantly less frequently [51,52,55].

Although many stakeholder groups emphasized the importance of being acknowledged and feeling involved as stakeholders [22,37,51,53,62], they said that their involvement should be improved [22,51,53,62]. Moreover, several stakeholders mentioned feeling dissatisfied when they did not feel sufficiently involved [53,62]. As dissatisfaction could detract from success, all relevant stakeholders should be involved [53]. Furthermore, in literature, the importance of involving both primary stakeholders, also known as end users, and secondary stakeholders (ie, more distantly involved stakeholders) is underlined as contributing to the successful implementation of care technologies, such as surveillance technologies [22,28,29].

To determine which primary and secondary stakeholders should be involved and engaged, it is important to identify these stakeholders [69]. Identifying stakeholders can be accomplished, for example, through a stakeholder analysis [69]. Several stakeholder matrices such as the power-interest matrix, the 3D matrix, and the responsible, accountable, consulted, and informed matrix offer tools to identify stakeholders and categorize their attributes such as their power, position, and level of interest [69,70]. In addition, these matrices support prioritizing who should be involved and to what extent. These matrices reflect the increased recognition of how the characteristics of stakeholders influence innovation and implementation processes [69,71,72]. Regardless of the distinction between stakeholders' level of involvement and their responsibilities, the resistance of any stakeholder can have an influence on the success of the implementation of care technologies.

Resistance by stakeholders is a challenge, necessitating the identification of alternative perspectives to a situation [73-75]. Therefore, besides identifying stakeholders when applying care technology, it is necessary to realize that care technologies strongly influence the care process and everyone involved. Therefore, cooperation between stakeholders who have previously rarely cooperated is essential. Hence, it is important to thoroughly know and acknowledge the different stakeholders and their differences and respect their differing interests [29].

Several implementation theories provide theoretical support to implementation processes, especially in complex contexts such as health care. One of the theoretical constructs for involving multiple stakeholders in implementation processes in health care is the normalization process theory (NPT) by May et al [76]. NPT provides tools to enhance an understanding of the social processes of thinking, enacting, and organizing work to implement and adopt interventions in care processes within health care organizations [77]. NPT distinguishes 4 constructs: coherence, cognitive participation, collective action, and reflexive monitoring. These 4 constructs emphasize the relevance of knowledge about the value that stakeholders assign to care technology and attention to stakeholders' willingness to participate and cooperate. NPT also focuses on keeping people engaged during the whole implementation process, including reflecting upon and appraising the effect of newly implemented technology [29,78].

A common thread across the NPT as well as other implementation theories is the need for cooperation and communication between stakeholders focusing on knowing and acknowledging each other's perspectives, values, and interests [29,79]. For instance, in the early 90s, Gregory and Keeney [72] wrote about the right of multiple stakeholders to be involved in policy decision processes and consequently balance between conflicting objectives. In addition, they mentioned that values, beliefs, cooperative potential, and stakeholders' concerns are known to influence the outcome of innovation processes [72]. Similarly, in business ethics, Dentoni et al [80] mentioned the complexity of multiple stakeholder involvement in dynamic settings because each stakeholder group has its own set of values, perceptions, and interests that may clash. This situation requires fundamentally different approaches that demand understanding differing values, complex settings, and acting upon uncertain knowledge [80].

The active participation of stakeholders challenges them to effectively collaborate with a critical and open stance toward their perspectives and values. Several stakeholders in this scoping review mentioned that this collaboration demands not only time and effort but also challenges them to adapt their jargon to interprofessional cultures and bridge their differences [51,52]. Although all stakeholders should be able to operate and communicate across boundaries between different practices with each other, collaborating with people is difficult and can lead to tensions and misunderstandings related to values and interests [81]. Such collaboration demands competence to perceive differences as learning opportunities and to cross boundaries between multiple stakeholders [81,82]. Collaboration between stakeholders is receiving increasing attention from organizations. In addition, organizations have shown a growing interest in creating value through participation and interaction with multiple stakeholders. However, until now, most of the attention has been given to creating value *for* stakeholders and not *with* them. In cases of increased awareness about stakeholders' input, values and interests may be well identified [83]. Thus, besides merely identifying and superficially involving stakeholders, it is important to pay attention to their perspectives, values, and interests.

Therefore, this scoping review also focused on what is already known about the stakeholder group values identified in the 31 articles reviewed. Several values in the theory of basic human values by Schwartz et al [31] were frequently represented among the stakeholder groups. The values *benevolence* and *security* were represented in 6 (50%) out of 12 stakeholder groups. This outcome is unsurprising given the progressive nature of dementia. Most stakeholder groups mentioned they experienced a feeling of being responsible for caring for residents with dementia and responding to their needs, in line with the value *benevolence* [21,22,37,38,55]. Concerning the value *security*, striving for safety for residents with dementia is often mentioned as a reason to apply surveillance technologies [7,22,46]. However, the meaning assigned to this value varies among the different stakeholder groups. The trade-off between safety and aspects such as privacy and freedom of movement differs among various stakeholders and appears to be related to how closely a stakeholder is involved with a resident [20]. For nursing staff, *security* is related to enhancing the safety of residents and mitigating their risk of falling [7,22,46]. This relates to the responsibility they feel for their residents because they feel accountable for accidents or injuries of residents [22,48]. For care managers, the value *security* is also related to their accountability for providing care, managing the residential care facility, assuring families that care is provided, and monitoring staff [19,54]. For residents, *security* is related to the feeling of being heard regarding their personal preferences and (care) needs and experiencing a feeling of homeliness [22,52,53,57]. Informal caregivers have concerns about their loved ones and they seem to experience more peace of mind when surveillance technologies are applied [21,54]. Consequently, informal caregivers often value safety above freedom of movement and the possible threats to privacy [19,22]. In contrast, academics, a group of stakeholders who do not have a close relationship with residents, tend to value freedom of movement above safety, giving high importance to the residents' experience of freedom and self-determination [20].

As is evident in the considerations regarding safety, surveillance technologies that are applied in practice affect the work and living environment of several stakeholder groups [37,51,53]. Accordingly, many stakeholders emphasized their desire to be and to feel involved in the application of surveillance technologies [22,53]. Arising from this desire, the values *self-direction in action and thought* were represented in 8 (67%) of 12 stakeholder groups. This outcome underlines the relevance of thoroughly involving stakeholders throughout the implementation and application process. In addition, the degree of stakeholders' openness to changes, their experienced *self-direction*, and their tendency to cling to traditional routines seem to be related to the extent to which they feel involved.

The more they feel involved, the more they are open to changes and willing to collaborate [22,38,47,53,62]. Being and feeling involved is especially an important issue for nursing staff because surveillance technologies directly interfere with the nursing process. Therefore, nursing staff were the most frequently cited stakeholders. They were mentioned in 23 (74%) of the 31 articles. Accordingly, they expected to be involved from the beginning; asked to express their needs, opinions, and concerns [53]; involved in decision-making; and acknowledged as important stakeholders [22]. Informal caregivers mentioned that they were willing to accept a broad range of technologies for their relatives as long as the former were informed about the surveillance technologies, were involved in deliberations about the technologies, and were asked for their consent regarding the application of the technologies [38,47,53,62].

Related to the value *self-direction* were the values *power* and *achievement*, representing stakeholders' desire to exert their influence on other people or use material resources and pursue success in competencies and performance. The values *power* and *achievement* were mentioned by 7 and 6 stakeholder groups, respectively. These values are a reflection that stakeholders such as nursing staff, informal caregivers, developers, ICT staff, and vendors want to feel recognized in their knowledge and experiences, and want to exert their influence in the application of surveillance technologies [22,38,51-53,61,62]. For care managers and LTC administrators, the values *power* and *achievement* are related to control over and the management of residential care facilities [53,54].

Although several values such as benevolence, security, self-direction, power, and achievement were represented by most of the stakeholders, the various stakeholder groups assigned different meanings to these values. Knowing and understanding diverse stakeholders' perspectives and attitudes, including the different meanings they attribute to values, is crucial because this knowledge and understanding influence the adoption and use of technologies [84]. Integrating multiple perspectives is valuable to fully understand the complexities of care practices [29] and dementia care technology [84]. In addition, it is challenging to distinguish whether stakeholders give meaning to a certain value based on their interests or whether they act from the resident's perspectives. This situation demands that designated persons in health care organizations have courage and take the lead in initiating meaningful and in-depth conversations where the diverse stakeholders will be challenged to communicate across their boundaries, looking beyond their own perspectives.

Methodological Considerations

A proxy perspective was often observed in the stakeholder groups of nursing staff, residents, and informal caregivers. This outcome is not unusual because proxy perspectives often originate from stakeholders with whom one works or lives [85]. In addition, proxy perspectives are often seen in stakeholder groups that collaborate and deal with matters that touch on values and interests. Hence, a proxy perspective was regularly seen among nursing staff and informal caregivers in this scoping review. Furthermore, when making assumptions, people are less understanding of others' actual motivations [85]. Accordingly, Kloos et al [86] researched the well-being of residents and found that nursing staff tended to overestimate the well-being of residents. Their study underlines the importance of combining proxy assessments with self-reports whenever possible. In addition, Kunicki et al [87] noted that the level of involvement of proxies and their sense of well-being could influence their perception of the resident's preferences. Kunicki et al [87] recommended that proxies find methods to better understand residents' preferences when residents were not able to express their preferences properly [87]. This scoping review raises the question of whether proxy perspectives of residents with dementia reveal resident's perspectives. Although it is challenging to interview residents with dementia due to the impairments related to their condition, it is possible to involve them. Therefore, in future research, residents should be made participants in research to understand their perspectives [88,89].

Strengths and Limitations

Previous studies primarily focused on facilitating and limiting factors and ethical dilemmas when applying surveillance technologies to people with dementia [18,23,36-38]. However, this scoping review is the first to explore which universally recognized human values are reflected in the experiences and opinions of stakeholders. Because values reflect human thinking and determine attitude and behavior, it is crucial to consider the underlying values that explain stakeholders' behavior and reactions [34,35,79]. Stakeholders' values were classified using the basic human values model by Schwartz. Although this model offers an empirically tested theory to predict attitudes and behaviors in different contexts and situations, it is possible that not all opinions and experiences of stakeholders could be categorized using the model. Furthermore, it is likely that the stakeholders' values do not provide a complete picture of the values that stakeholders hold in practice because the representation of stakeholders' values in this scoping review is based on information that did not primarily focus on stakeholders' values.

Recommendations for Research

Although this scoping review identified 12 stakeholder groups, most (26/31, 84%) of the articles included in the review described only 4 or fewer stakeholder groups. Therefore, various stakeholder groups were underrepresented. Future research should emphasize the involvement of all relevant stakeholders. In addition, our explorations of stakeholders' values revealed there is insufficient information about stakeholders' values. Hence, more research about the values that influence stakeholders' actions and decisions should be conducted. In exploring stakeholders' perspectives and values, a proxy perspective should be avoided where possible. In future research, inviting stakeholders to look beyond their perspectives and boundaries could be useful in mitigating language and knowledge boundaries between different stakeholders. This approach could facilitate constructive cooperation between stakeholders. In addition, efforts should be made to include residents with dementia in research to explore their perspective rather than assumptions about residents' perspectives being largely based on a proxy perspective. Listening to people with dementia can enhance the quality, relevance, and impact of

dementia research, which contributes to the enhancement of knowledge based on what we learn *from* them and their informal caregivers, in order to create knowledge *with* them [90]. Participatory research could apply to this kind of research about complex dynamic subjects; research should be conducted with rather than about stakeholders.

Conclusions

All stakeholders involved in applying surveillance technologies expressed a desire for their perspectives and values to be acknowledged. This desire stems from the human need to be acknowledged and appreciated. Moreover, all the stakeholders manifested a willingness to be engaged and participate. The broad acknowledgment and involvement of stakeholders and an understanding of their perspectives and values contribute to the successful implementation and application of surveillance technologies for people with dementia in nursing homes. Therefore, when applying surveillance technologies for people with dementia, residential care facilities are expected to intensively collaborate with an increasing number of stakeholders. Therefore, stakeholders' active engagement, with attention to everyone's perspectives and values, is more important than ever.

Acknowledgments

The authors thank information specialist C Niehot for the support in drawing up the search string for this scoping review. In addition, the authors thank Professor Dr M Verkerk for the conversations about values, interests, and ideals and Professor Dr S Schwartz, Drs D Arets, R van de Vorst, and Dr B Wernaart for the helpful feedback in using the theory of values by Schwartz et al [31] to organize the results of this scoping review according to human values.

Abstract

Background: Teleconsultation has expanded rapidly in recent years, especially during the COVID-19 pandemic, and has become standard practice among physicians. The benefits of teleconsultation, namely, improving access to care, ensuring continuity and quality of care, increasing patient satisfaction, and reducing costs and wait times, are well documented. However, its use in nursing practice, especially in long-term care settings, remains underresearched despite its significant transformative potential, particularly in resource-limited and rural settings, where it could address major challenges such as nursing shortages and access to care.

Objective: This study aimed to identify barriers to and facilitators of implementing overnight nursing teleconsultation in rural residential and long-term care centers in Quebec, Canada (*centres d'hébergement et de soins de longue durée* [CHSLDs]), with ≤50 beds.

Methods: A 6-month pilot project was rolled out sequentially in 3 rural CHSLDs in 2 administrative regions of Quebec between July 2022 and March 2023. A total of 38 semistructured interviews were conducted with managers (n=27, 71%), nursing staff members (n=9, 24%), and resident committee presidents (n=2, 5%) between February 2023 and July 2023.

Results: The study identified several barriers to the implementation of teleconsultation. The main barriers reported included union opposition (managers: 23/27, 85%), network instability (resident committee presidents: 2/2, 100%), limited technology skills (nursing staff members: 7/9, 78%), a perceived increase in workload (nursing staff members: 8/9, 89%; resident committee presidents: 2/2, 100%), and a low volume of teleconsultations (nursing staff members: 8/9, 89%). Despite the barriers, participants also identified key facilitators. These included the care setting (nursing staff members: 9/9, 100%; managers: 21/27, 78%), buy-in from senior management and managers (managers: 27/27, 100%; resident committee presidents: 2/2, 100%), collaboration between the departments (nursing staff members: 9/9, 100%), nursing staff motivation (nursing staff members: 9/9, 100%), and improvements in professional practices (nursing staff members: 8/9, 89%). Finally, the relative benefits of teleconsultation, such as enhanced mutual vision, faster assessment of clinical situations, improved resident care management quality, and greater flexibility and safety, were unanimously recognized (38/38, 100%) as contributing to its acceptability and potential for success.

Conclusions: This study provides an in-depth understanding of the barriers to and facilitators of implementing overnight nursing teleconsultation in small rural CHSLDs. This constitutes a sound basis for developing tailored strategies aimed at overcoming identified barriers and optimizing facilitators. The results also provide practical guidelines for decision makers, highlighting the need to adapt implementation approaches to the unique context of each facility. Furthermore, this study highlights the importance of further research to broaden our knowledge on the dissemination and scale-up of health care innovations. This includes the development of learning health systems capable of responding in an agile and effective way to the needs of rural and vulnerable populations both in Quebec and elsewhere.

Introduction

Background

Teleconsultation has evolved considerably in recent years, especially during the COVID-19 pandemic, when it became standard practice for general practitioners and specialists alike [1-3]. Numerous studies have demonstrated its effectiveness in improving access to care [4-6], ensuring continuity [7,8] and quality of care [9,10], increasing patient satisfaction [11-15], and reducing costs [16-18] and wait times [2,19-22]. Moreover, internet-based clinical support initiatives between novice and expert professionals are being implemented in both urban [23-25] and rural [26,27] settings specifically to address challenges related to the shortage of qualified health care workers.

Despite the increasing adoption of teleconsultation, its use in nursing practice remains largely unexplored [28-31], even though its potential to transform care, including in long-term care centers, is well recognized [32,33]. This potential is even more significant in rural and resource-limited settings, where access to health care services remains a major challenge [34-37].

The lack of data on the use of teleconsultation in nursing practice is concerning as nurses play a key role in the continuum of care, especially in rural settings and long-term care facilities, where they are often patients' first point of contact [38-40]. Although recent studies have focused on the facilitators of and barriers to implementing geriatric teleconsultation in home nursing care [33,41], its impact on nurses' and nursing assistants' workflows [35], and the costs and cost savings associated with its use in residential and long-term care centers [34], these studies remain limited.

To date, studies have not yet provided a comprehensive picture of the effectiveness and impact of teleconsultation in nursing practice. Thus, in-depth exploration of this approach is essential to optimizing its benefits and supporting nursing professionals in the adoption and integration of this technological innovation.

Context

This research gap is of concern in residential and long-term care centers (*centres d'hébergement et de soins de longue durée* [CHSLDs]) in Quebec, Canada, where continuity and quality of care are essential to residents' well-being. Directives from the Ministry of Health and Social Services (Ministère de la Santé et des Services sociaux [MSSS]) and guidelines from the Order of Nurses of Quebec (Ordre des infirmières et infirmiers du Québec) stress the need to ensure the presence of nurses 24 hours a day in these facilities. However, smaller CHSLDs, namely, those with ≤50 beds, face major challenges in meeting this requirement due to nursing staff shortages, especially during night shifts. These frequent periods when no resources are available expose residents to increased risks to their safety and well-being [42,43]. This situation is even more critical in semiremote and remote areas, where difficulties associated with recruiting and retaining nursing staff exacerbate the challenges related to access and quality of care. A better understanding of the opportunities offered by teleconsultation could help alleviate these structural challenges and help build the CHSLDs' capacity in these settings.

As a response to these challenges, the National Directorate of Nursing Care and Services of the MSSS has initiated a pilot project to assess the impact of access to overnight nursing teleconsultation in rural CHSLDs with ≤50 beds. This initiative is based on the implementation of nursing teleconsultation, a promising solution to reinforce continuity of care and reduce regional disparities in access to health care services in Quebec.

Recent studies have shown that teleconsultation can mitigate limitations related to the lack of on-site nursing staff and offer real-time clinical support, thus reducing the risk of adverse events during periods of understaffing [35,44,45].

In line with this approach, this project explored innovative solutions to build resilience in long-term care systems and respond more effectively to the growing challenges associated with nursing shortages.

Objectives

The aim of this study was to identify barriers to and facilitators of implementing overnight nursing teleconsultation in rural Quebec CHSLDs with ≤50 beds. Specifically, this study aimed to gather the views of managers, nursing staff, and resident committee presidents. Exploring these viewpoints will fill a significant gap in the current literature and suggest critical avenues to support the successful integration of teleconsultation in long-term care settings.

Methods

Study Design and Setting

The 6-month pilot project was rolled out in 3 rural CHSLDs located in 2 administrative regions of Quebec. The regions were selected by the MSSS for their alignment with the project's outlined criteria, which include facilities located in semiremote and remote areas, those already experiencing nursing shortages during the night shift, and those reporting issues and risks related to these shortages. In addition, at least 30% of all CHSLD facilities in the territory have a capacity of ≤50 beds. The rollout was conducted sequentially from July 2022 to March 2023 at different sites. Given the innovative nature of the pilot project, an exploratory qualitative study was conducted to identify the barriers to and facilitators of implementing teleconsultation in overnight nursing care.

Data Collection

An interview guide was designed, tested, and validated by the research team. The guide, comprising 12 open-ended questions, aimed to identify the barriers to and facilitators of implementing

teleconsultation. This guide provided a better understanding of the context and experiences surrounding the pilot project's deployment. This study was guided by key factors influencing the implementation of health innovations as outlined in the framework proposed by Chaudoir et al [46]. The interview guide is included in Multimedia Appendix 1.

The framework developed by Chaudoir et al [46] was selected for several key reasons that ensure that it is an appropriate framework to assess the implementation of health innovations. In fact, this model is based on a systematic review of the literature. It also captures the complexity of implementing health innovations by considering various levels of influence, such as organizational structures, health care providers, patients, and the specific characteristics of the innovation.

This holistic approach enables a more comprehensive and nuanced assessment of the factors that can affect an innovation's success. Furthermore, by incorporating levels of analysis that reflect practical realities in the field—such as the nursing staff and residents—the model provides health care professionals with an applicable and relevant framework. It helps identify the barriers and facilitators that are specific to each setting, thus facilitating the design of customized implementation strategies. Finally, the model is flexible and can be tailored to different health innovations and settings. Whether we are examining the implementation of a new technology or a care protocol, the model proposes analysis categories that can be adjusted according to the features of the innovation and environment.

The model's components can be described on five levels: (1) the structural level, which includes factors related to the broader context in which the innovation is implemented, such as health care policies, funding structures, or available resources. These variables directly or indirectly influence an organization's ability to adopt and integrate new practices. (2) the organizational level, which focuses on the specific characteristics of the organizations themselves, such as organizational culture, leadership, support systems, and communication dynamics. It examines how these internal elements facilitate or hinder the implementation of innovations. (3) the health care provider level; at this level, the focus is on the individuals responsible for implementation, such as physicians, nurses, or other health care professionals. The model assesses health care providers' attitudes, knowledge, skills, and beliefs, all of which can influence how an innovation is adopted and applied. (4) the patient level, which analyzes patients' perceptions, attitudes, and behaviors, as well as their level of innovation engagement and buy-in. Patients' psychosocial factors, such as their understanding, beliefs, or preferences, are crucial to the successful implementation of health innovations. (5) the innovation level, which examines the specific characteristics of the innovation itself, such as complexity, compatibility with existing practices, cost, and flexibility. An innovation perceived as easy to use, relevant, and beneficial is more likely to be adopted.

This framework provides a solid foundation to analyze the perspectives of managers, nursing staff, and resident committee presidents, highlighting the key factors influencing the adoption and effectiveness of nursing teleconsultation in small CHSLDs.

Participants

Participant recruitment was conducted using nonprobability sampling [47], through which participants were identified by pilot project managers in each region. This selection method is designed to maximize participants' intrinsic motivation by giving them the opportunity to become involved on their own terms. By promoting this freedom of choice, this study aimed to attract participants who were especially motivated and engaged, thereby improving the quality of the collected data as well as enhancing the relevance and validity of the findings.

Participants were initially contacted through an email that included the interview guide and a detailed consent form. The consent form outlined the context of the study, the project's objectives, the procedures and expected duration of participation, the anticipated benefits, and assurances regarding anonymity and confidentiality. A total of 38 semistructured individual interviews were conducted with managers (n=27, 71%), nursing staff (n=9, 24%), and resident committee presidents (n=2, 5%) between February 2023 and July 2023.

These semistructured interviews were carried out in French and were conducted via videoconference (Zoom; Zoom Video Communications, Inc). The principal investigator (VN) conducted the interviews. Participants were given the option to review the transcripts of each interview, but none of the participants chose to receive the transcripts. No additional recruitment process was necessary as information redundancy indicated data saturation [48].

Data Analysis

On the basis of the framework by Chaudoir et al [46], we conducted a pattern analysis of interview transcripts to identify factors describing facilitators of and barriers to implementing overnight nursing teleconsultation in small CHSLDs. This approach emphasized hierarchical coding, enabling rigorous structuring of the textual data analysis while offering the flexibility required to meet the specific needs of the study.

The analysis prioritized participants' responses, highlighting their descriptions of barriers and facilitators. To do this, we immersed ourselves in the data by reading and rereading transcripts while taking handwritten notes on emerging factors and codes. This iterative process carried out by a single coder (the principal investigator, VN) is a valid method in qualitative analysis of thematic data, enabling researchers to understand how participants gave meaning to their experiences. A handwritten thematic map was created to group data extracts into broad categories of barriers and facilitators, which fostered a thorough review process and helped generate initial codes. These codes were then applied during a second analysis phase using the NVivo software (version 14; QSR International). The initial codes were used to identify overlaps and search for emerging themes.

To ensure a comprehensive and structured analysis, the coder (VN) applied the 5 levels of the framework by Chaudoir et al [46]—structural, organizational, health care provider, patient, and innovation—as primary coding categories. Each identified barrier or facilitator was initially coded under one of these levels. The coder developed subthemes within each level, enabling a

more nuanced examination of the data. This structured approach reinforced the consistency of our analysis, ensuring that all aspects of the implementation process were thoroughly explored while maintaining alignment with established theoretical constructs.

Finally, potential factors were examined and verified across the dataset by rereading the transcripts and checking themes against identified codes. This approach ensured the robustness and consistency of the findings.

Ethical Considerations

Ethics approval was obtained from the Research Ethics Committee of the Outaouais Integrated Health and Social Services Centre before the beginning of the study (reference 2022-353_195) in Quebec, Canada. All participants gave their consent electronically before beginning the interviews. Participation was anonymous and voluntary. Study participants did not receive monetary compensation. All interviews were audio recorded with the participants' permission and then transcribed in compliance with ethical and confidentiality standards. The deidentified recordings were transcribed verbatim by a third-party transcription service bound by a confidentiality agreement. The study's findings will be disseminated through presentations at conferences and publications in peer-reviewed journals using anonymized data. The findings will also be shared through presentations to various MSSS stakeholders and the nursing community.

Results

Overview of Barriers

This study aimed to identify the barriers to and facilitators of implementing overnight nursing teleconsultation in 3 of Quebec's rural CHSLDs with ≤50 beds. The results are presented in accordance with the 5 levels of the framework by Chaudoir et al [46]: structural, organizational, health care provider, patient, and innovation.

Table 1 presents a comprehensive overview of the framework detailing the barriers identified at each level and for each participant group.

Table 1. Level, factors, and number of participants who mentioned each factor.

Level and factor	Managers[a] (n=27), n (%)	Nursing staff members[b] (n=9), n (%)	Resident committee presidents[c] (n=2), n (%)
Structural			
Union opposition	23 (85)	—[d]	—
Network instability	11 (41)	4 (44)	2 (100)
Overburdened managers	16 (59)	—	—
Lack of support from project leaders	—	6 (67)	—
Organizational			
Lack of leadership from the site manager	—	4 (44)	—
Health care provider			
Resistance to change	12 (44)	6 (67)	—
Limited technology skills	12 (44)	7 (78)	—
Insecurity about using technology	12 (44)	4 (44)	—
Increased workload associated with the technology	10 (37)	8 (89)	2 (100)
Patient			
Concerns about quality of care	—	—	1 (50)
Innovation			
Low volume of teleconsultations	14 (52)	8 (89)	—
Complexity of the process compared to a phone call with a remote on-call nurse	16 (59)	—	—
Increased time to initiate care management	—	5 (56)	—
Insecurity about the quality of nursing assessments	—	5 (56)	—
Difficulty using the tablet	—	4 (44)	—

[a]Individuals in positions of authority. They oversee operations, manage resources, and supervise personnel in health care settings. Their role is to ensure the smooth functioning of the facility.

[b]This refers to all individuals involved in providing direct care to patients or residents, including both nurses and nursing assistants.

[c]These individuals lead the residents' committee. The committee represents residents in health care facilities such as long-term care homes. Its mandate is to protect residents' rights. The committee ensures that residents are treated with dignity and that their rights and freedoms are respected. It also serves as a key spokesperson for residents. It brings residents' concerns and needs to the attention of the institution's governing bodies.

[d]Not applicable.

Barriers: Structural-Level Factors

Union Opposition

Union opposition was mentioned by most managers (23/27, 85%) as a major factor before the launch of the pilot project. According to respondents' testimonials, for several months, the union waged a disinformation campaign conveying alarming messages to health care professionals and the community.

The union disseminated messages stating that the "government was planning to replace nurses with tablets," which it claimed would "diminish the quality of care and endanger the safety of residents" (M10). Another manager (M9) specified that "They ran a lot of ads saying nurses were being replaced by tablets." Some managers reported that this campaign had a disruptive effect, creating "a shock wave and a wave of fear in the community" (M22), and the pilot project was perceived "as devaluing this client group, as if they were receiving second-class care" (M25).

The union's intervention was not confined to the public sphere; it also manifested itself directly in the workplace. Managers reported that union representatives visited CHSLDs attempting to dissuade nurses from participating in the pilot project. One manager (M8) explained the following:

> *The union would come directly into the workplace, to frighten employees.*

The union told nursing assistants that their participation was "super dangerous, because they would be going beyond their scope of practice and their professional order would turn against them," added one manager (M9). Despite this initial pressure, none of the interviewed nursing staff members (9/9, 100%) reported any problems with their union after the beginning of the pilot project. Unlike the managers, nursing staff members did not perceive union opposition as a barrier.

Network Instability

Network instability was identified as a barrier by some managers (11/27, 41%) and nursing staff members (4/9, 44%), as well as

by the resident committee presidents (2/2, 100%), especially in rural and remote areas.

Interviewees' testimonials revealed that connectivity was not uniform across the facilities. One manager (M1) explained the following:

> *It didn't necessarily work everywhere in the CHSLD.*

In total, 44% (4/9) of nursing staff members added that there were sometimes 15- to 20-minute delays in logging in. This wasted time, although occasional, can have significant repercussions on the quality of care, as mentioned by one resident committee president (RC36):

> *From time to time, it won't work there...you have to take that into account, because it would be a huge waste of time to start an intervention, then you lose the network, you have to restart another way, by telephone, etc.*

Overburdened Managers

The extra workload associated with the pilot project was a barrier for 59% (16/27) of the managers, especially for project leaders, project coleaders, and site managers. They had to reconcile their usual tasks while ensuring rapid deployment of the project within the context of a nursing shortage. One manager (M4) explained the following:

> *We weren't optimal in our monitoring, which created an obstacle, because, basically, we weren't as present.*

Moreover, daily monitoring of nursing staff practices increased the burden on site managers, who feared that implementation of the project would not be feasible without additional resources. One manager (M9) raised the following question:

> *Is the workload going to be realistic for managers who are already highly solicited?*

Lack of Support From Project Leaders

Lack of support from project leaders was identified as a barrier by 67% (6/9) of nursing staff members. This limited support manifested as reduced availability as project leaders were often overwhelmed by their many responsibilities. One nursing staff member (NS34) indicated the following:

> *We'd have liked to have a little more time, but they're kind of busy with everything.*

This created a feeling of abandonment among nursing staff, with some expressing a lack of guidance. One staff member (NS29) reported that "The project leaders didn't always have the answers to our questions."

Barriers: Organizational-Level Factors (Lack of Leadership From the Site Manager)

In one administrative region, the site manager's lack of leadership was perceived as a barrier by some nursing staff members (4/9, 44%). This lack of leadership manifested itself as a lack of proximity between the site manager and the nursing staff, namely, infrequent travel to meet the team and gaps in communication. This distance hindered the exchange of information and the understanding of the pilot project's issues, leading the site manager to become disinterested, which generated frustration and reduced nursing staff buy-in and motivation at the outset of the pilot project. However, as the project progressed, the situation improved, and they were able to overcome these challenges.

Barriers: Health Care Provider–Level Factors

Resistance to Change

Resistance to change was identified as a barrier by 44% (12/27) of managers and 67% (6/9) of nursing staff members. This resistance took the form of a reluctance to participate in training and simulations, as well as a marked preference for using the telephone, which was perceived as quicker and more effective. For example, one nurse refused to use teleconsultation to assess a resident after a fall, preferring to travel to the CHSLD herself. One manager (M3) indicated the following:

> *The nursing staff found it cumbersome.*

Indeed, nursing staff members reported that their colleagues preferred traditional methods such as on-call nursing or traveling to visit the resident in person. Even when teleconsultation would have been more appropriate, using the telephone remained the preferred method.

Limited Technology Skills

Limited technology skills represented a barrier, as identified by 67% (18/27) of the managers. One manager (M20) pointed out the following:

> *One of the barriers we encountered very, very quickly was that people were not familiar with the technology and then were not able to use it.*

According to one manager (M23), this shortcoming can be explained by "a lack of simulation and comfort as well as by constraints such as nursing shortages, heavy workloads, and COVID-19 outbreaks." One manager (M8) said the following:

> *In addition to learning new tools, our nurses had to continue providing care. At one point, they were saying, "It's just not working".... It was a real challenge to implement this on a daily basis.*

According to 78% (7/9) of nursing staff members, this barrier is especially significant among older nurses, who are often less comfortable with new technology. One nursing staff member (NS33) described this generational challenge:

> *We weren't all born with a keyboard or tablet in our hands...we have a few who are in their fifties. Not all of them were comfortable with it either.*

One nursing staff member (NS29) added the following:

> *...although the younger generation showed an initial interest, this desire was curbed by older nurses' reluctance to embrace the technology, creating a barrier to the successful integration of digital tools into professional practices.*

Furthermore, the low volume of remote activities and insufficient monitoring limited the practice of teleconsultation, resulting in the loss of acquired skills. One nursing staff member (NS33) described it as follows:

> *We had practices, and I fell on the practice that was postponed.... It was never rescheduled. So, the first time, I'd never even practiced.*

Insecurity About Using Technology

Insecurity about using technology was a concern due to the novelty of teleconsultation and was mentioned by 44% (12/27) of managers. In addition, 44% (4/9) of care staff members reported that nursing assistants in particular felt vulnerable when they were alone on-site, fearing that they would not know how to use teleconsultation properly or solve technical problems. As one manager (M4) explained, "It's my nurse who takes charge" when a resident is not doing well. Another manager (M9) confirmed this feeling of insecurity:

> *This practice, in terms of the technology, well, it caused a little insecurity at first, because we didn't know that much about it.*

Similarly, one nursing staff member (NS32) noted that "a fear of computer technology" discouraged some of the more experienced nurses from becoming involved in the pilot project.

Increased Workload Associated With the Technology

The implementation of teleconsultation led to an increased workload for remote nurses, a challenge that was highlighted by 37% (10/27) of managers, 89% (8/9) of nursing staff members, and 100% (2/2) of resident committee presidents. One nursing staff member (NS31) reported the following:

> *We were the ones who had to adapt the most.*

Before every night shift, nurses had to make sure that they had the necessary tools for teleconsultation, which often meant traveling to the CHSLD even on their days off. In addition to their usual tasks, they had to manage interdepartmental reports, fill in specific follow-up forms, and immediately document each teleconsultation. One resident committee president (RC36) explained the following:

> *We also had to foresee working time to connect, use the equipment, get everything working and then provide electronic notes afterward, transfer them, etc.*

One manager (M23) pointed out the following:

> *...the people who are working remotely, the ones who are doing the teleconsultation, are the same people who are there in the evening, during the night...it creates a great deal of anxiety.*

Barriers: Patient-Level Factors (Concerns About Quality of Care)

In the context of teleconsultation, concerns about the quality of care were primarily raised by 50% (1/2) of the resident committee presidents. He feared that teleconsultation would undermine the personal nature of care, concerned that technology would compromise the human contact that is essential to in-person interactions. Initially opposed to the project, fearing the impersonality and disempowerment of nurses, he eventually recognized the benefits of teleconsultation as the pilot progressed. One of the presidents (RC36) expressed the following:

> *My initial opposition to the project was based on what I didn't want: That it would become impersonal, that it would prevent human contact...that it would change the on-call nurse's responsibility, relying on a screen, which is not the same as what you might experience during an in-person visit.*

Barriers: Innovation-Level Factors

Low Volume of Teleconsultations

According to 52% (14/27) of managers, the low volume of teleconsultations was a barrier and could be attributed to the small size of CHSLDs, but the low volume of activity also raised important questions, as one manager pointed out (M25):

> *Was the volume low because there wasn't a need? Was the volume low because practices were already good on both sides, and [the person carrying out an intervention] acted preventively?*

Another manager (M4) added the following:

> *Nursing assistants who said, "Oh no, look, it's 4 o'clock. The nurse is coming in two hours, we'll wait two hours." Did this harm the resident? Well, indirectly, for someone who is in pain, yes it did. But there was no report of an incident or accident that could have or did cause harm to the resident's health, safety, and well-being.*

According to 89% (8/9) of nursing staff members, the low volume of teleconsultations hindered their ability to maintain their skills. One of them (NS26) said the following:

> *It had been a month since we'd had one...I forgot to fill in the smartsheet.*

Moreover, a manager (M10) observed the following:

> *...when comparing data from the previous year to [the data related to] the implementation of teleconsultation, the number of telephone calls received is equal to the number of teleconsultations over the same period.*

Complexity of the Teleconsultation Process Compared to On-Call Nursing

The complexity of the teleconsultation process compared to on-call nursing was perceived as a barrier by 59% (16/27) of managers. Unlike on-call nursing, when the nursing assistant can contact the on-call nurse directly, teleconsultation involves a series of more complex actions, such as waking up the on-call nurse to initiate the consultation and, sometimes, the need to call back the CHSLD. This complexity prolongs the time it takes to obtain a nursing assessment, as explained by one manager (M18):

> *It's too slow...the time to turn on the laptop, to connect safely.*

Another manager (M10) added that the speed of the on-call process influenced perceptions of teleconsultation:

> *It influenced the teleconsultation project.*

In addition, the necessity of having the teleconsultation on-call travel case added another layer of difficulty, especially when staff forgot the equipment, as described by one manager (M12):

> *Ah OK, but now I don't have the equipment, I have to go to the CHSLD to get the equipment.*

Increased Time to Initiate Care Management

According to 56% (5/9) of nursing staff members, the use of teleconsultation led to an increase in the time taken to initiate the residents' care management. Unlike previous practices, the nurse had to assess the resident over a digital platform before intervening, adding an extra step that delayed the response to immediate needs. This delay was exacerbated in remote areas, where unstable internet connections complicated access to teleconsultation, potentially leading to a deterioration of the resident's condition. One nursing staff member (NS26) illustrated this problem by describing a situation in which the requirement to use a tablet for teleconsultation interfered with the prompt management of a resident's pain:

> *A lady was experiencing pain.... I found the computer-based support detrimental to immediate care.... Meanwhile, the lady was in pain. You know, we are managing pain at the same time as we manage the tablet.*

Insecurity About the Quality of Nursing Assessments

There were concerns about the quality of nursing assessments carried out via teleconsultation, including the fear that visual assessment cannot adequately replace a physical examination. In total, 56% (5/9) of nursing staff members shared these concerns. One of them (NS30) explained the following:

> *I had concerns about the physical assessment in the sense that shifting to a visual assessment instead of doing it in real life...that my assessment would not be complete.*

The absence of physical contact with the resident was perceived as a limitation as nonverbal communication plays an important part in a comprehensive assessment. Another nursing staff member (NS33) illustrated this difficulty:

> *Non-verbal and verbal [messages] contradict each other in residents...with the tablet, it wasn't easy because I couldn't look at my resident's face and leg movement at the same time.*

The use of technology such as the digital stethoscope also prompted reservations. One nurse expressed unease:

> *Listening over the phone, it's not like performing the auscultation myself.* [NS31]

Difficulty Using the Tablet

When using a tablet, nursing staff members experienced physical constraints in terms of mobility and effectiveness. These constraints made it difficult to carry out teleconsultations, as one nurse described:

> *The hindrance was caused by the darn arm they set up to hold that tablet.... It would swing around. You know, to be honest, it wasn't the best.* [NS33]

A total of 44% (4/9) of the nurses emphasized the need for a stand to hold the tablet, freeing up the nursing assistant's hands.

Overview of Facilitators

Table 2 presents a comprehensive overview of the framework detailing the facilitators identified at each level and for each participant group.

Table 2. Level, dimension, and number and percentage of participants who mentioned each factor.

Level and dimension	Managers[a] (n=27), n (%)	Nursing staff members[b] (n=9), n (%)	Resident committee presidents[c] (n=2), n (%)
Structural			
Care setting	21 (78)	9 (100)	—[d]
Legitimization of the practice of overnight on-call nursing	18 (67)	—	—
Culture of on-call nursing	—	—	2 (100)

Facilitators: Structural-Level Factors

Care Setting

Testimonials from 78% (21/27) of the managers and all nursing staff members (9/9, 100%) highlighted the care setting's decisive role in the success of the pilot project. Faced with a nursing staff shortage, this initiative was viewed as a promising solution to optimize practices and the management of available resources while maintaining the quality and safety of resident care. One manager (M1) explained the following:

> *Our objective is to ensure that every nursing staff member is in the right place, playing their role to the full and that we are using our resources wisely.*

Legitimization of the Practice of Overnight On-Call Nursing

Legitimization of the practice of overnight on-call nursing factored positively in the project's success. According to 67% (18/27) of managers, the fact that this practice was framed within a specific, temporary context reassured stakeholders such as the Order of Nursing Assistants of Quebec (Ordre des infirmières

et infirmiers auxiliaires du Québec), the Quebec ombudsman, and user and resident committees. One manager (M1) explained the following:

> *This legitimization enabled nursing staff to feel they had greater authorization to use teleconsultation, mitigating fears related to professional compliance.*

Culture of On-Call Nursing

The existing culture of on-call nursing was a significant facilitator. All resident committee presidents (2/2, 100%) stated that this culture, which was already well established and accepted in CHSLDs, facilitated the implementation of teleconsultation. Considered "an innovative and adaptive solution, on-call nursing was seen as essential to maintaining optimal quality of care," as indicated by one of the presidents (RC36). He added the following:

> *...the pre-existing culture facilitated the transition to teleconsultation by normalizing the idea of a remote nurse and positioning it as a safe and effective approach.*

Implementation Monitoring

Close monitoring by the nursing department (ND) and the Support Program for the Autonomy of Seniors (SAPA) within the health care system in Quebec was a key facilitator according to 78% (21/27) of managers. Monitoring took place at three levels: (1) strategic level—committees and regular meetings with the MSSS promoted fluid communication on project advancement; (2) operational level—project leaders organized regular meetings with site managers, enabling actions to be adjusted quickly and providing immediate feedback (as one manager [M16] reported, "monitoring by the Ministry...was highly beneficial"); and (3) day-to-day level—ongoing monitoring of teleconsultation practice was implemented, including a review of ministry forms, hospital transfers, and incident reports, as well as audits in CHSLDs to ensure that nursing staff had the support they needed.

Facilitators: Organizational-Level Factors

Buy-In From Senior Management and Managers

Senior management buy-in was viewed as a facilitator by all managers (27/27, 100%), namely owing to the support of the chief executive officer of the Integrated Health and Social Services Centre of Abitibi-Témiscamingue and the Integrated University Health and Social Services Centre of Mauricie and Centre-du-Québec, as reported by one manager (M8):

> *He took it on, then he defended it.*

When senior management prioritizes a project, it motivates other managers to engage, facilitating rollout and the resolution of challenges such as acquiring equipment—"We received our equipment very quickly because it was a priority," according to one manager (M1). The resident committee presidents (2/2, 100%) also confirmed that this support was important to the project's success. One of the resident committee presidents (RC35) explained the following:

> *When senior management is supportive of the project, it sends a strong signal to the members of the organization about the strategic importance of teleconsultation. This approval from leadership can positively influence the levels of acceptance and engagement within the team.*

In addition, the managers' buy-in was unanimously recognized as a facilitator by participating managers (27/27, 100%). Their engagement made it possible to effectively navigate MSSS requirements and ensure the buy-in of the nursing staff members who were consulted, underlining the importance of creating an environment that is conducive to the implementation of teleconsultation.

Support From Project Leaders

Support from project leaders was a determining factor according to 70% (19/27) of managers. Project leaders played a key role in motivating nursing staff by clarifying objectives, allaying concerns, and fostering champions within the teams, creating a conducive environment for the adoption of teleconsultation. As one manager (M5) explained, "Having a dedicated person to answer questions and solve problems" was essential.

Support From Site Managers

According to 70% (19/27) of managers, site managers also fostered the implementation of teleconsultation. One manager (M12) reported the following:

> *Their knowledge of the environment and their existing bonds of trust played a key role in the human management of change and in nursing staff mobilization.*

The nursing staff (7/9, 78%) also appreciated this support, underlining the site managers' guidance and availability. One nursing staff member (NS32) explained the following:

> *I felt supported throughout the project. If I had any questions, I knew where to turn. I had a lot of support from my manager.*

Involvement, Motivation, and Stability of Nursing Staff

According to 56% (15/27) of managers, the involvement, motivation, and stability of nursing staff were key facilitators. Team cohesion facilitated flexibility and mutual support, as stated by one manager (M16):

> *Nursing staff demonstrated solidarity by swapping shifts during snowstorms to ensure staff availability.*

This solidarity enabled staff to respond effectively to residents' needs and maintain reasonable response times.

Collaboration Between the ND and SAPA

According to 67% (18/27) of managers, collaboration between the ND and SAPA was a key facilitator. A clear division of roles enabled the ND to manage external relationships with the MSSS and other agencies, whereas the SAPA dealt directly with the implementation of teleconsultation, ensuring effective coordination. One manager (M16) reported the following:

> *Having a single point of entry was helpful.*

This synergy promoted the cocreation of solutions to the project's challenges, namely in terms of training and monitoring, reinforcing the effectiveness and success of the initiative.

The training plan, including coaching, simulations, and tool adaptations, was tailored to meet regional needs and reinforce the safety of nursing practices. One manager (M10) underlined the following:

> *Training was customized...to reinforce safety.*

Practical guides and equipment such as headsets supported the practice of teleconsultation, and simulations boosted the nursing staff's confidence. Nursing staff members (9/9, 100%) unanimously appreciated the training, deeming it essential to the adoption of the technology and success of the pilot project.

Transfer of Knowledge and Experience

The transfer of knowledge and experience was a significant factor for most managers (21/27, 78%), facilitating collaboration and adaptation between regions and within participating CHSLDs.

Between regions, managers worked closely, sharing their experiences and adjusting approaches according to the specific needs of each region. Although support tools were not cocreated systematically, these exchanges enabled participants to adjust based on local context. Regarding collaboration and adaptation within CHSLDs, in one region, the level of sharing between 2 CHSLDs was particularly striking. Nursing staff from the first site shared their experiences with that of the second, fostering buy-in to the pilot project. For example, a manager's guide created from lessons learned was passed on to the other site, facilitating the implementation of teleconsultation in similar settings. One manager (M16) described it as follows:

> *The manager took notes on everything she had implemented...and brought it back to the ND....So, it ranged from the criteria we had to meet, to making sure we met them, to the tasks we had to carry out...all in one guide.*

Facilitators: Health Care Provider–Level Factors

Nursing Staff Buy-In

For 48% (13/27) of managers, nursing staff buy-in was a facilitator. Nursing staff members were not only favorable to the idea, they were also motivated to actively participate in the pilot project, demonstrating a willingness to move forward with teleconsultation. One manager (M5) noted the following:

> *The nursing staff were very open and aligned with the project. They wanted to move forward with the change.*

Despite initial stress, the nursing staff adapted quickly. As one manager (M24) pointed out, "Once the adaptation period was over...there was no more stress. It went well," underlining their ability to overcome resistance and make a successful transition to teleconsultation.

Nursing Staff Motivation

All nursing staff members (9/9, 100%) considered that the motivation of health care staff was a facilitator. The main sources of motivation included commitment to the team, interest in technological tools, and the desire to help resolve the nursing shortage. Nursing staff members appreciated the creation of overnight nursing assistant positions with remote support, helping address the shortage and improve the quality of care. As one staff member put it, "We're not as effective after 1 p.m" (NS28), highlighting the challenges of working long hours. Being motivated to use technological tools such as teleconsultation reflects a desire to explore innovative solutions to improve working conditions and better meet residents' needs.

Development of the Nursing Staff's Skills

Development of the nursing staff's skills was a key factor, as highlighted by 48% (13/27) of managers. Training tailored to the staff's needs fostered their preparedness and engagement, making them champions of the pilot project. Younger members showed greater mastery of computer and technological skills. In addition, the training improved nursing assistants' level of autonomy and clinical judgment, contributing to the development of clinical leadership and team management skills. One manager (M7) described it as follows:

> *When she's on her own, she also takes on a bit of a coordination role...something she didn't usually do because it was part of the nurse's role.*

Ability to Adapt and Use Technology

For 78% (7/9) of nursing staff members, the ability to use technology was directly related to computer literacy and adaptability. Despite a low level of initial fluency, some managed to overcome their difficulties. One staff member (NS33) put it as follows:

> *I'm not very tech-savvy. I managed. It went well.*

Thus, adaptability was a key factor, with nursing staff members demonstrating an ability to adjust to teleconsultation, including those who were not as comfortable with computers.

Openness to Change

Nursing staff's openness to change was essential according to both resident committee presidents (2/2, 100%). This positive attitude was fostered by the fact that the project was recognized as an opportunity for exploration. One of the resident committee presidents (RC36) said the following:

> *Given that it was a pilot project, everyone agreed to give it a try.*

RC35 added the following:

> *...the transfer of experience from nurses performing on-call nursing to teleconsultation is also a concrete example of this openness to change. The fact that the staff had prior experience in similar practices made it easier to adapt to new methods.*

Facilitators: Resident-Level Factors

Buy-In From Residents, Families, and Resident Committees

Buy-in from residents, families, and resident committees greatly facilitated the implementation of teleconsultation according to 44% (12/27) of managers. This support was reinforced by the creation of a relationship of trust through transparent

communication and regular meetings with the site manager. One manager (M17) pointed out the following:

> *The site manager kept us informed on a regular basis, establishing a climate of trust.*

Communication

Communication was a facilitator, especially in interactions with residents and their families. In total, 67% (6/9) of nursing staff members noted that proactive communication with residents and their families, namely, explaining the project, answering questions, and obtaining informed consent, facilitated resident buy-in. One nursing staff member (NS30) said the following:

> *Transparency, especially about concerns such as data leaks, fostered a positive reception to teleconsultation.*

Families generally welcomed the technology, recognizing the additional benefit to care delivery. Nursing staff members observed that there was no negative impact on residents, which could be attributed to the effective communication that reassured families about data confidentiality and security.

Facilitators: Innovation-Level Factors

Relative Benefits

Analysis of the relative benefits of teleconsultation showed that this modality represented a significant added value for the dyad composed of the remote nurse and the CHSLD nursing assistant according to all managers (27/27, 100%), nursing staff members (9/9, 100%), and resident committee presidents (2/2, 100%). Benefits included, first, improved mutual vision. All nursing staff members (9/9, 100%) agreed that teleconsultation enabled direct observation of the resident and of the nursing assistant's nonverbal cues, fostering a greater understanding of the situation than was possible through on-call nursing. One staff member (NS31) pointed out the following:

> *The way [the nursing assistants] report it to us over the phone and the way we see it through our own assessment, are two different things. Sometimes it's minimized, and sometimes it's exaggerated.*

This visual component enhanced the remote nurse's ability to carry out a more accurate and thorough assessment. One of the resident committee presidents (RC35) stated the following:

> *...the use of video in teleconsultation provides a clear advantage in terms of assessment quality compared to voice-only interactions. This ability to visualize the patient can lead to more informed decisions regarding necessary interventions.*

The second benefit was faster assessment. Teleconsultation reduced the wait time for nursing assessments, enabling more effective interventions according to all nursing staff members (9/9, 100%). One staff member (NS32) noted the following:

> *...an intervention that might have taken an hour could take only 15 minutes with teleconsultation.*

Moreover, the direct electronic transmission of nursing notes to the CHSLD promoted continuity of care. One of the resident committee presidents (RC36) noted the following:

> *...that despite the implementation of teleconsultation, it is not intended to completely replace in-person visits, but rather to complement care, thus offering flexibility and adaptability in the delivery of healthcare services.*

The third benefit was improved quality of care management. The visual component of teleconsultation helped identify signs or symptoms that were not described verbally, leading to more informed decisions according to all nursing staff members (9/9, 100%). In addition, one manager (M25) reported that teleconsultation "provides visual support that the telephone does not, enabling [the nurse] to validate the on-site nursing assistant's hypothesis or to support her in her contribution to the assessment."

The fourth benefit was flexibility and safety. According to the resident committee presidents (2/2, 100%), teleconsultation did not replace in-person visits but was complementary to them, providing flexibility in the delivery of health care services. One of the presidents (RC36) mentioned the following:

> *Nurses are not prevented from physically traveling if necessary.*

This innovation also contributed to resident safety according to the other president (RC35), noting that "residents were safe with this technological innovation, reinforcing the idea that teleconsultation does not entail any compromise in terms of patient safety."

All managers (27/27, 100%) reported that the introduction of teleconsultation was perceived as a major step forward, enhancing the quality and safety of care delivery. According to them, teleconsultation provided greater safety by enabling nurses to exercise their clinical judgment under improved conditions. One manager (M4) stated the following:

> *Teleconsultation gives the manager a sense of security because they know that the healthcare professional is in a better position to exercise their clinical judgment.*

Development of Nursing Staff's Roles

The pilot project contributed significantly to the development of nursing staff's roles according to 70% (19/27) of managers. Although overnight on-call nursing was already integrated into the organizational culture, the pilot project improved the organization and quality of care by strengthening nursing staff's roles.

Key improvements included enhancement of the remote nurse and nursing assistant dyad as the nursing assistant's practice was strengthened, including more effective nursing assessments and better care planning during the night shift, and expanded scope of practice for nursing assistants as changes to nursing care procedures enabled nursing assistants to fully exercise their skills. One manager (M1) pointed out the following:

> *Nursing assistants have activities...that we've allowed them to carry out.*

Another manager (M16) added that the pilot project enabled them to "apply their entire scope of practice, enhancing the value and recognition of their role."

Improved Professional Practices

The implementation of teleconsultation significantly improved professional nursing practices according to most nursing staff members (8/9, 89%). The main observed benefits were, first, the development of nursing assistants' skills. Teleconsultation enabled nursing assistants to develop their scope of practice, acquiring new skills and playing a more active role in assessing and delivering care. Structuring communication when transmitting information also helped strengthen their communication skills. The second main observed benefit was proactive information updates. Teleconsultation facilitated the updating of therapeutic nursing plans and medication administration records, enhancing nursing assistants' autonomy. One nursing staff member explained that teleconsultation eliminated the need to constantly contact the nurse for simple decisions such as administering medication, ensuring greater autonomy for nursing assistants. This staff member (NS29) underlined that "this project has really helped to make us more autonomous...we can manage almost everything on our own."

Discussion

Principal Findings

Overview

The aim of this study was to gain a better understanding of the experiences of managers, nursing staff, and resident committee presidents involved in the pilot project to identify the factors that may promote the implementation of teleconsultation. Our multilevel analysis revealed the presence of facilitators and barriers.

Structural-Level Factors

Among the identified structural barriers, union opposition, which was reported by most managers (23/27, 85%), initially represented a significant obstacle, but it subsided once the project was in place. The union recognized that teleconsultation complied with professional standards while at the same time complementing the work done by nurses in CHSLDs without seeking to replace it. This helped dispel any initial fears. In addition, managers' leadership played a decisive role by supporting the nursing staff, responding to their concerns, and facilitating a smooth and harmonious transition.

However, network instability in rural areas was a barrier for some managers (11/27, 41%) and nursing staff members (4/9, 44%). Connectivity issues coupled with the lack of overnight technical support led to delays and interruptions, compromising the effectiveness and reliability of teleconsultation. These difficulties highlighted the limitations of technological infrastructures in these environments and created situations in which interventions were delayed, compromising continuity of care. This problem is corroborated by studies that underline the importance of stable network connectivity to ensure the smooth operation of teleconsultation services. Indeed, network quality is a determining factor in ensuring the fluidity of exchanges and the effectiveness of remote consultations, as highlighted by several research studies [28,49-52]. In these settings, ensuring reliable network coverage and efficient technical support is imperative to avoid interruptions that could adversely affect the quality of care.

Overburdened managers, who had to juggle their usual responsibilities with the demands of the pilot project, led to suboptimal management according to 59% (16/27) of managers. This double workload, compounded by a nursing shortage, made it difficult to adequately monitor the project and led to management being less present and reactive. This finding is in line with observations found in the literature, which stress that work overload is a major challenge in project management, especially in settings with limited resources [53]. Thus, managers' inability to respond optimally to project requirements due to the pressure of their day-to-day responsibilities contributed to the suboptimal implementation of the initiative, underlining the need for greater support for managers during the implementation of complex projects.

Lack of support from project leaders was a barrier for 67% (6/9) of nursing staff members. Insufficient training and monitoring limited the nursing staff's ability to use teleconsultation effectively. This situation reflects the importance of organizational support, which studies have shown to be a key factor in the success of training and implementation programs [54]. Indeed, constant support and adequate coaching help build the staff's skills and ensure the successful adoption of new technology, such as teleconsultation, in care settings.

However, several facilitators contributed to the project's success. The context of the health care system, marked by a nursing shortage that was exacerbated by the COVID-19 pandemic, acted as a catalyst for the implementation of teleconsultation according to several managers (21/27, 78%) and all nursing staff members (9/9, 100%). Perceived as an effective solution to the shortage, teleconsultation enabled better management of human resources, which reduced excessively long shifts and improved the nursing staff's working conditions. This approach is supported by studies demonstrating that technology can optimize the use of human resources during a shortage [55,56].

Some managers (18/27, 67%) highlighted that legitimization of the practice of overnight on-call nursing played a key role in nursing staff's acceptance and adoption of teleconsultation. According to the literature, framing new clinical practices within a defined, transparent, and temporary framework is essential to reassuring stakeholders such as professional orders, user committees, and regulatory bodies [35,57,58]. Such a framework helps build an environment of trust, reducing reluctance to adopt innovative practices and ensuring compliance with professional standards.

The preexisting culture of on-call nursing facilitated the acceptance of the pilot project by making the transition to teleconsultation smoother according to the resident committee presidents (2/2, 100%). Familiarity with remote practices fostered acceptance of the new technology. This observation is supported by the literature, which indicates that preexisting practices and organizational cultures play a decisive role in the acceptance of health care innovations [35,59].

Finally, close monitoring at several levels was a key factor in the successful implementation of teleconsultation for a large proportion of managers (21/27, 78%). By integrating strategic, operational, and daily monitoring, the project benefited from rapid adjustments, ensuring compliance with project objectives and requirements. This systematic monitoring not only facilitated proactive management of challenges but also enhanced responsiveness to emerging issues, helping maintain coherent and fluid processes. According to the literature, structured and sustained monitoring is essential to optimizing the implementation of new practices, especially in a context of technological transformation, helping overcome barriers and ensure project sustainability [60,61].

Organizational-Level Factors

According to the nursing staff in 1 of the 2 administrative regions (4/9, 44%), one of the barriers at the organizational level was the site managers' lack of leadership. This lack of leadership, characterized by minimal presence and limited communication with nursing staff, was viewed as a barrier to the implementation of teleconsultation. The perceived distance between the site managers and care teams created a climate of frustration and disengagement. This situation is corroborated by the literature, which underlines that weak leadership can hinder the implementation of change initiatives by generating feelings of frustration and disengagement among health care teams [62-64].

As part of the implementation of teleconsultation, several organizational factors facilitated its rollout, highlighting the importance of a coordinated approach and sustained engagement at all levels of the organization. Buy-in and active support from senior management and managers were crucial to the project's success according to all managers (27/27, 100%) and resident committee presidents (2/2, 100%). The literature supports this observation, stating that the engagement of organizational leaders is a key factor in the success of change initiatives in health care facilities [65,66]. This engagement helped mobilize the necessary resources and promote a culture conducive to innovation.

The role of project leaders and site managers was considered essential by 70% (19/27) of managers. Their availability and expertise not only enabled the effective resolution of operational issues but also played a key role in maintaining the nursing staff's level of motivation.

Specifically, nursing staff members (7/9, 78%) stated that regular meetings and personalized support helped clarify objectives, allayed concerns, and ensured constant monitoring, which helped overcome challenges and optimize implementation processes. These results are in line with the literature, which emphasizes the importance of management practices and managers' commitment to the success of digital transformation initiatives [67,68].

According to some managers (15/27, 56%), the involvement, motivation, and stability of nursing staff members were also facilitators. The staff's ability to adapt and maintain a high level of service despite challenges was facilitated by increased motivation and cohesiveness, which is supported by the work by Nabelsi et al [35]. Their research shows that staff motivation and stability are essential elements to ensuring efficient processes in health care. The solidarity and cooperation observed within the teams helped maintain high levels of service even under difficult conditions.

Another facilitator was the collaboration between the ND and the SAPA according to all nursing staff members (9/9, 100%) and several managers (18/27, 67%). This collaboration clarified the division of roles, avoided duplication, and ensured smooth project management. A clear division of responsibilities and coordination between departments are essential [35]. This model of cross-directorate collaboration helped maximize efficiency and avoid overlaps that might slow down the implementation process.

Finally, most managers (21/27, 78%) said that the transfer of knowledge and experience between regions and within CHSLDs played a significant role in localizing the project. This approach, which centered on collaboration and the sharing of best practices, enhanced the effectiveness of the pilot project [35]. The study by Nabelsi et al [35] shows that knowledge sharing between teams and sites not only fosters the adoption of technology, it also enables better management of the challenges encountered in the field by adapting to local needs and constraints.

Health Care Provider–Level Factors

Resistance to change was a barrier to the implementation of teleconsultation, especially for certain nursing staff members (6/9, 67%). Their marked preference for the telephone, perceived as faster and more effective, highlighted their resistance to the adoption of teleconsultation. The literature on organizational change in health care indicates that this resistance may be fueled by the perception of being overloaded and by deeply ingrained habits, making it difficult to accept new technology [28,69,70].

According to nursing staff members (7/9, 78%), a lack of skill in using new technology was also a limiting factor, especially among older nursing staff members, who were not as comfortable with technological tools. This shortcoming is a recognized factor in the failure to implement technology in health care [44,71,72]. Work overload, exacerbated by crises such as the COVID-19 pandemic, added a further dimension to this challenge, creating a cognitive overload that complicated the effective integration of new technology.

Insecurity about using technology was another barrier for a small proportion of managers (12/27, 44%) and nursing staff members (4/9, 44%). Nursing assistants in particular felt vulnerable due to their lack of familiarity with teleconsultation and fear of dealing with technical problems. The literature on technology acceptance underlines that insecurity and fear of the unknown can reduce user motivation and performance [73,74].

The increased workload associated with technology was also a barrier. The implementation of teleconsultation led to increased management of reports, specific forms, and detailed documentation, an issue recognized by most nursing staff members (8/9, 89%) as well as all resident committee presidents (2/2, 100%). Studies show that increased workloads can cause

stress and reduce job satisfaction, negatively influencing the implementation of new practices [75,76].

Among the facilitators, nursing staff buy-in was important, although it was mentioned by a lower proportion of managers (13/27, 48%). The nursing staff's willingness to participate in the pilot project and their positive attitude toward teleconsultation were key to its success. The literature on organizational change in health care suggests that stakeholder buy-in is important to the success of change initiatives [77,78].

Nursing staff members' motivation also played a significant role in the pilot project's success, a factor unanimously recognized by all staff members (9/9, 100%). Commitment to the team, interest in technological tools, and the desire to help solve the nursing shortage were all motivating factors. Research shows that motivation is a facilitator of the acceptance and successful use of health technology [79,80].

Development of the nursing staff's skills was a facilitator, although it was mentioned by a lower proportion of managers (13/27, 48%). Adequate training strengthened nurses' readiness and commitment, enabling them to become project champions. The literature indicates that skill development is key to the successful adoption of new technology [66,81,82]. Customized training and support tools such as practical guides and simulations helped build the nursing staff's skills and confidence [35].

The ability to use the technology was also crucial to the success of the pilot project, as underlined by nursing staff members (7/9, 78%). Rapid adaptation to new technology is indeed a facilitator, as confirmed in research on technology acceptance [74,80].

Finally, openness to change facilitated the implementation of the project, a factor that was unanimously recognized by resident committee presidents (2/2, 100%). This openness to change led to smoother adoption of teleconsultation, which is supported by studies demonstrating that acceptance of change is essential to the success of transformation initiatives [83].

Resident-Level Factors

The only barrier was fear concerning the quality of care provided via teleconsultation, which was mentioned by 50% (1/2) of the resident committee presidents. One of the presidents expressed concerns about the reduction in human contact, which could lead to perceived depersonalization of care. However, these concerns were dispelled as the pilot progressed, and he eventually recognized the benefits of teleconsultation. This fear that technology would disempower nurses and create a sense of impersonality represented a barrier to the acceptance of teleconsultation. Studies indicate that concerns about quality of care and depersonalization can negatively influence acceptance of telehealth technology by residents and their families [50,72,84,85].

According to some managers (12/27, 44%), buy-in from residents, families, and resident committees was a facilitator of the implementation of teleconsultation. The managers observed that transparent communication and regular meetings with these stakeholders helped establish a climate of trust. This approach is in line with the literature, which stresses the importance of trust and effective communication when fostering acceptance of health technology by patients and their families [86-88].

For most nursing staff members (6/9, 67%), effective communication itself was a facilitator. Research shows that managing expectations and clarifying the benefits of new technology are important to their acceptance by residents and their families. The ability to clearly explain the benefits of teleconsultation and address residents' concerns contributed greatly to their buy-in [35].

Innovation-Level Factors

The low volume of teleconsultations was recognized as a barrier by more than half (14/27, 52%) of the managers. Several possible explanations were put forward. Some managers suggested that this low volume may reflect a lack of real need, the preexisting effectiveness of preventive practices, or some nursing staff members' reluctance to use teleconsultation. However, when comparing data from the previous year with the data related to implementation of teleconsultation, findings reveal that the number of telephone calls received was equal to the number of teleconsultations over the same period. In addition, the low volume of consultations impacted the nursing staff's ability to maintain their skills. Most nursing staff members (8/9, 89%) reported a decrease in their level of comfort with the technological tools due to sporadic use.

The complexity of the teleconsultation process was also a barrier for more than half (16/27, 59%) of the managers. Compared to traditional on-call nursing, teleconsultation involves more complex technological processes. Connolly et al [89] underline that this complexity can reduce the effectiveness of interventions and increase staff frustration, hindering the adoption and effectiveness of technology [51,90].

Another barrier was the increased time to initiate care management according to over half (5/9, 56%) of nursing staff members. Using digital platforms for assessments can increase response times, a problem that is exacerbated by technological limitations and connectivity issues. The research by Pilosof et al [91] shows that these delays can adversely impact the quality of care by affecting the responsiveness of interventions.

Concerns about the quality of assessments conducted via teleconsultation were noteworthy. Just over half (5/9, 56%) of nursing staff members expressed concern about the ability of visual assessment to effectively replace a physical assessment, highlighting the potential risk of compromising quality of care. This fear is corroborated by studies revealing that telemedicine can sometimes alter the quality of clinical assessments if not properly integrated into care practices [85-87,92-95].

Finally, the difficulty of using a tablet for teleconsultations represented a barrier for a small proportion of nursing staff members (4/9, 44%). Srinivasan et al [85] highlight that ergonomic issues and difficulties in handling technological equipment can reduce the effectiveness of interventions and user satisfaction, complicating the integration of teleconsultation [86,87,89].

Despite these challenges, several innovation-level factors facilitated the implementation of teleconsultation. The relative

benefits of this technology were viewed positively by all managers (27/27, 100%), nursing staff members (9/9, 100%), and resident committee presidents (2/2, 100%). They appreciated the improved mutual vision and faster assessment. Teleconsultation solutions offer significant benefits in terms of visual communication and speed of intervention [35]. This perception of the benefits fostered acceptability and support for the project.

The development of nursing staff's roles was another facilitator according to several managers (19/27, 70%). The project strengthened professional practices and broadened the nursing assistants' skills. The work by Nabelsi et al [35] indicates that teleconsultation technology can support the expansion of professional roles and improve quality of care.

Moreover, the implementation of teleconsultation led to improved professional practices for most nursing staff members (8/9, 89%). Research has shown that technology integration improves professional skills and care management, highlighting the potential of innovations to positively transform practices in care settings [35,91,96].

Limitations and Future Research

This study has a number of limitations that must be taken into account when interpreting the results. First, this study was conducted in only 2 Quebec regions, including a total of 3 CHSLDs. This limited scope may restrict the generalizability of the results to other geographical settings or types of facilities. In addition, the small number of sites included in the study may not enable researchers to capture the diversity of practices and challenges encountered in other regions or in facilities of different sizes. Second, this study focused exclusively on smaller facilities with ≤50 beds. While this is in line with the study's objective of targeting small CHSLDs, the results may not be directly applicable to larger facilities, which may have different organizational structures and needs. Finally, this study's evaluation period was short, making it impossible to observe the long-term impact of nursing teleconsultation, especially in terms of the continuous improvement of nursing practices, the sustainability of interventions, and the changes in stakeholder perceptions.

Furthermore, this study used a nonprobabilistic sampling method, which may have resulted in the inclusion of participants who were more inclined to view teleconsultation favorably or who had a particular interest in the topic. To mitigate this potential selection bias, the team researcher actively sought a diversity of perspectives during data collection, encouraging participants to share both supportive and critical viewpoints regarding the implementation of teleconsultation. Moreover, a rigorous qualitative analysis was conducted, with particular attention given to dissenting opinions and negative experiences, ensuring a comprehensive representation of the facilitators and barriers encountered. Despite these efforts, the inherent limitations of qualitative research, including the subjectivity of self-reported experiences, necessitate further investigation through complementary methodologies. A quantitative study conducted through a survey would strengthen the robustness of our findings and allow for a more generalizable assessment of the impact of teleconsultation

To broaden our understanding of the implementation of nursing teleconsultation in long-term care, it would be relevant to conduct studies in a larger number of CHSLDs, including facilities of various sizes located in different regions, to assess the transferability of this study's findings and their effectiveness on a larger scale. Longitudinal research would also be needed to assess the long-term effects of nursing teleconsultation on quality of care, resident satisfaction, and human resource management in CHSLDs, as well as to identify any adjustments needed to ensure the sustainability of these practices.

It would also be useful to study the impact of teleconsultation on nurses' well-being and workload, namely by examining how this technology can be optimized to effectively support their role without increasing their stress level or mental load. Finally, economic studies could help quantify the costs associated with implementing nursing teleconsultation and compare them with potential savings in terms of decreased hospitalizations, adverse events, and improved quality of care.

Conclusions

This study provides the first in-depth analysis of barriers and facilitators related to the implementation of overnight nursing teleconsultation in small long-term care facilities. The findings provide a better understanding of these barriers, which can be used to develop strategies to overcome them during implementation. These findings are also particularly relevant to decision makers who are responsible for designing health initiatives as their choices influence the implementation and scaling-up process.

Broadly, the results provide a comprehensive overview of the factors influencing the successful implementation of teleconsultation in long-term care. This can help identify key factors to consider when scaling up teleconsultation in CHSLDs. The framework developed by Chaudoir et al [46] highlights the concept of adaptability, emphasizing the importance of adjusting the deployment of an innovation to suit the specific context. When scaling up teleconsultation, it is important to consider the specific characteristics of each CHSLD and region and tailor the implementation of teleconsultation accordingly.

While resistance to change is often considered a major barrier to implementing new health care technologies, our findings challenge this assumption. In the rural CHSLDs studied, the preexisting on-call nursing culture not only facilitated the adoption of teleconsultation but also eased its integration into clinical practice. This contrasts with previous research suggesting that health care professionals may resist new technology due to concerns about workflow disruptions or unfamiliarity with remote care models. In this context, previous experience with remote support likely mitigated these challenges, highlighting the importance of accounting for contextual factors when implementing teleconsultation. Furthermore, the identification of a low volume of teleconsultations as a barrier contradicts the common assumption that a phased rollout is always beneficial. Instead, our results suggest that achieving a critical mass of teleconsultations is essential to maintaining staff engagement and competencies. These findings provide new insights into teleconsultation implementation by demonstrating how preexisting practices

and use patterns can significantly influence the adoption and sustainability of technological innovations in long-term care settings.

Efforts to implement overnight nursing teleconsultation in long-term care are more likely to succeed if they are based on an understanding of the forces driving the dissemination and scale-up of teleconsultation. Therefore, further research is needed to develop and strengthen the conceptual and applied foundations of the dissemination and scale-up of health care innovations, especially in the context of Quebec's emerging learning health care systems.

Acknowledgments

This study was funded and supported by the Ministry of Health and Social Services (Ministère de la Santé et des Services sociaux) in Quebec, Canada. The authors are most grateful to the health professionals and managers of the Integrated Health and Social Services Centre of Abitibi-Témiscamingue and the Integrated University Health and Social Services Centre of Mauricie and Centre-du-Québec. The authors wish to thank everyone who participated in interviews and discussions.

Authors' Contributions

VN conceptualized and designed the study, collected the data, conducted the interviews, conducted the analysis, and wrote the first draft of the manuscript. VN and VP have read and revised the manuscript. All authors (VN, VP, and MCL) approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Disability profoundly affects older adults' quality of life and imposes considerable burdens on health care systems in China's aging society. Timely predictive models are essential for early intervention.

Objective: We aimed to build effective predictive models of disability for early intervention and management in older adults in China, integrating physical, cognitive, physiological, and psychological factors.

Methods: Data from the China Health and Retirement Longitudinal Study (CHARLS), spanning from 2015 to 2020 and involving 2450 older individuals initially in good health, were analyzed. The dataset was randomly divided into a training set with 70% data and a testing set with 30% data. LASSO regression with 10-fold cross-validation identified key predictors, which were then used to develop an Extreme Gradient Boosting (XGBoost) model. Model performance was evaluated using receiever operating characteristic curves, calibration curves, and clinical decision and impact curves. Variable contributions were interpreted using SHapley Additive exPlanations (SHAP) values.

Results: LASSO regression was used to evaluate 36 potential predictors, resulting in a model incorporating 9 key variables: age, hand grip strength, standing balance, the 5-repetition chair stand test (CS-5), pain, depression, cognition, respiratory function, and comorbidities. The XGBoost model demonstrated an area under the curve of 0.846 (95% CI 0.825 - 0.866) for the training set and 0.698 (95% CI 0.654 - 0.743) for the testing set. Calibration curves demonstrated reliable predictive accuracy, with mean absolute errors of 0.001 and 0.011 for the training and testing sets, respectively. Clinical decision and impact curves demonstrated significant utility across risk thresholds. SHAP analysis identified pain, respiratory function, and age as top predictors, highlighting their substantial roles in disability risk. Hand grip and the CS-5 also significantly influenced the model. A web-based application was developed for personalized risk assessment and decision-making.

Conclusion: A reliable predictive model for 5-year disability risk in Chinese older adults was developed and validated. This model enables the identification of high-risk individuals, supports early interventions, and optimizes resource allocation. Future efforts will focus on updating the model with new CHARLS data and validating it with external datasets.

disability; prediction model; older adults; China Health and Retirement Longitudinal Study; CHARLS; medical resources allocation

Introduction

The aging of the population presents a significant global challenge, with profound implications for health care systems, economic stability, and social services [1,2]. In China, where the older population is rapidly increasing, the prevalence of disability among older adults has become a pressing concern. According to the Chinese Centers for Disease Control and Prevention, the number of older individuals with disabilities reached 52.71 million in 2020 and is projected to exceed 77.65 million by 2030. By 2030, disabled older adults are expected to account for over 57% of the total disabled population, potentially rising to more than 70% by 2050 if no preventive measures are implemented [3]. Disability in older adults encompasses various limitations or difficulties in performing daily activities independently, typically due to chronic degenerative changes in function. It is commonly assessed through activities of daily living (ADL) and instrumental activities of daily living (IADL). This growing burden of disability impacts quality of life and places a significant strain on families and public resources. Therefore, accurate prediction of disability is crucial for early intervention and effective management.

Despite significant research efforts to forecast disability in older adults, existing models often lack sufficient precision and fail to account for the complex, multifactorial nature of disability.

These models typically overlook the broader context of risk factors and offer limited utility for public health decision-making [4-6]. For instance, a study by Sun et al [5] identified depressive symptoms as a significant predictor across different types of disability. However, many existing models still fail to incorporate mental health factors alongside physical health indicators, limiting their real-world applicability. Furthermore, cognitive impairment has been found to be a strong predictor of disability in specific ADL and IADL tasks [6], highlighting the importance of integrating mental, cognitive, and physical health factors in predictive models. Disability, as a complex health issue, is influenced by multiple risk domains, including chronic diseases, polypharmacy, aging, mental health problems, unhealthy lifestyles, and the family social environment. A comprehensive predictive model should serve as a vital tool to improve early identification of at-risk individuals, inform public health strategies, and optimize resource allocation.

This study seeks to address the limitations in existing research by developing a disability prediction model specifically designed for the older Chinese population, using longitudinal data from the China Health and Retirement Longitudinal Study (CHARLS) collected between 2015 and 2020 [7]. While previous research has developed disability prediction models based on CHARLS data from 2015 to 2018 [8], the release of the 2020 survey data enables the extension of the analysis over a longer time frame. This study will leverage the validated Extreme Gradient Boosting (XGBoost) algorithm [8] to explore disability predictors in greater depth. In addition, by integrating variables such as sarcopenia and frailty-related indicators, which have previously been underexplored in predictive models for disability, we offer a more nuanced understanding of the physical, cognitive, physiological, and psychological factors contributing to disability risk. We aim to create a predictive model that not only offers high precision but also provides practical insights for health care professionals and policymakers.

Methods

Study Population

The data for this study were sourced from the CHARLS, initiated in 2011 by the National School of Development at Peking University. The CHARLS used a stratified, multistage Probability Proportional to Size random sampling method, covering 150 counties and 450 villages and urban communities across 28 provinces, involving 17,708 individuals from 10,257 households. Follow-up surveys were conducted in 2013, 2015, 2018, and 2020, with detailed methodology available in other publications [7].

Initially, 21,095 participants from the 2015 baseline survey were included. The final cohort consisted of 2450 individuals after applying the following exclusion criteria: (1) no information on biomarker or blood data; (2) younger than 60 years (for this study, older adults were defined as individuals aged 60 years or older, in accordance with the World Health Organization and the Chinese government’s standard for aging population classification); (3) missing ADL or IADL data in 2015; (4) missing follow-up ADL or IADL data in 2020; (5) having ADL and IADL limitations or any form of disability in 2015, including physical, intellectual, visual, auditory, or significant speech impairments; and (6) other relevant data missing.

Ethical Considerations

The Institutional Review Board of Peking University (IRB No. IRB00001052-11014) approved the research, and all respondents provided informed consent. CHARLS adheres to the Declaration of Helsinki and China's Personal Information Protection Law. The CHARLS database adheres to strict privacy protection and anonymization principles during data collection and processing to ensure the security of participants' personal information.

Assessment of Disability

Disability in this study was defined as impairment in performing ADL and IADL, which is commonly used in geriatric research to evaluate functional limitations in older adults. ADL assessed the ability to perform fundamental self-care tasks such as dressing, bathing, eating, getting out of bed, toileting, and managing urination and bowel movements. IADL measured more complex daily tasks, including household chores, cooking, shopping, phone use, financial management, and medication adherence. Responses were categorized into four levels: (1) no difficulty, (2) difficulty but can still do it, (3) difficulty and need help, and (4) cannot do it. To create a binary outcome, responses of (2) “Difficulty but can still do it,” (3) “Difficulty and need help,” and (4) “Cannot do it” were coded as 1 (indicating ADL and IADL disability), while the response “No difficulty” was coded as 0 (no disability). Participants were classified as having ADL and IADL disabilities if they reported any level of difficulty (levels 2 - 4) in at least one ADL or IADL item [9].

Predictive Variables

Clinical Factors

Laboratory assessments included a range of biomarkers: white blood cell count, hemoglobin, hematocrit, triglycerides, total cholesterol, glucose, uric acid, creatinine, blood urea nitrogen (BUN), high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, cystatin C, C-reactive protein, and glycated hemoglobin.

Depressive symptoms were evaluated using the 10-item Center for Epidemiologic Studies Depression Scale (CES-D) [10]. CES-D scores ranged from 0 to 30, with higher scores indicating more severe symptoms. The CES-D has been validated for Chinese middle-aged and older populations [11]. A score of 10 or above was used to indicate depression, while scores below 10 indicated no depressive symptoms [12]. Cognitive function was assessed using a modified version of the telephone interview for cognitive status (TICS) questionnaire [13]. The overall cognitive score was calculated by summing the scores from four domains: (1) orientation (5 points), (2) computation (5 points), (3) memory (20 points), and (4) drawing (1 point), with a total possible score of 31 points [14]. Higher scores indicate better cognitive performance.

Physical Performance

The physical examination included measurements of systolic and diastolic blood pressure, pulse, and respiratory function. Respiratory function was measured using a peak flow meter.

Participants were instructed to stand, take a deep breath, and blow as hard and fast as possible into the mouthpiece. The highest value from 3 attempts was recorded for analysis. Physical performance was assessed using gait speed, the 5-repetition chair stand test (CS-5), and standing balance. Gait speed was measured to evaluate lower limb function and mobility. A walking course of 2.5 meters was set up, and participants were instructed to walk the course twice at their usual pace. The average gait speed was calculated by dividing the distance by the time taken. The 5-repetition CS-5 was conducted to assess lower limb strength and endurance. Participants were asked to sit in a chair with their arms folded across their chest and, upon the examiner's command, to stand up and sit down 5 times consecutively at their fastest pace without using their arms for support. The total time required to complete the 5 repetitions was recorded, with a longer duration indicating poorer lower limb function. The standing balance assessment involved maintaining a standing position for 10 seconds in three distinct foot placements: (1) side-by-side, (2) semitandem, and (3) full tandem. Handgrip strength, the primary indicator of muscle strength, was measured for each participant using a Yuejian WL-1000 dynamometer (Nantong Yuejian Physical Measurement Instrument Co). Handgrip strength was measured in both the dominant and nondominant hands, with 2 measurements per hand. The higher value for each hand was recorded, and the average value for the 2 hands was taken to represent the handgrip strength. Together, these assessments provided a comprehensive evaluation of physical function and performance.

Appendicular skeletal muscle mass (ASM) was estimated using a formula specifically developed for the Chinese population, which closely corresponds with dual-energy X-ray absorptiometry measurements [15,16]. The formula accounts for weight, height, sex (1 for males, 2 for females), and age as follows:

$$ASM = 0.193 \times \text{weight (kg)} + 0.107 \times \text{height (cm)} - 4.157 \times \text{sex} - 0.037 \times \text{age} - 2.631$$

Potential Covariates

Covariates for our study were identified from previous literature and grouped into 2 main categories. The first included social and lifestyle factors: age, gender, BMI, marital status, residential area, daily sleep hours, and alcohol and tobacco use. BMI categories were defined as underweight (BMI <18.5 kg/m^2), normal weight (BMI =18.5 - 24 kg/m^2), and overweight (BMI ≥24 kg/m^2). The second category addressed pain, incidents of falling, and number of comorbidities (hypertension, dyslipidemia, diabetes, cancer, stroke, heart disease, lung disease, liver disease, kidney disease, digestive disease, mental health disorders, memory disorders, asthma, and arthritis) [14,17]. The comorbidity classification was based on the CHARLS questionnaire design. Neurological disorders, including Parkinson disease and Alzheimer disease, are included under memory-related diseases.

Statistical Analysis

The preprocessed dataset was split into a training subset with 70% data and a testing subset with 30% data. Continuous variables were described using medians and IQR, with comparisons using the Mann–Whitney *U* test. Count variables were expressed as frequencies and percentages and assessed using the χ^2 test. Model development and testing were performed using the training and testing sets, respectively.

Initial correlation analysis identified potential multicollinearity. Variable selection was conducted exclusively on the training set using LASSO regression with 10-fold cross-validation to prevent information leakage and ensure an unbiased evaluation of model performance. LASSO regression was chosen over other methods due to its ability to perform simultaneous variable selection and regularization, reduce overfitting, and enhance model interpretability. In addition, ablation experiments were conducted to evaluate the effect of removing specific features related to sarcopenia and frailty on model performance. The logloss metric was used to assess the performance of the models with and without these features. The selected variables informed the development of an XGBoost model, a machine learning algorithm that uses gradient boosting through decision trees to iteratively minimize prediction errors. For the optimization of the XGBoost model, hyperparameter tuning was performed using a grid search approach. Key hyperparameters were tuned, including the number of boosting rounds (nrounds), which determines the number of iterations for boosting, and the maximum tree depth, which controls the complexity of each individual tree. The learning rate (eta) was adjusted to control the weight of each update during training. In addition, the minimum loss reduction (gamma) for tree splitting, the feature subsampling ratio (colsample_bytree), and the minimum child weight were optimized to control the model's complexity and prevent overfitting. The subsample ratio (subsample) was also tuned to control the fraction of training data used in each boosting round. The optimal parameters were selected based on the lowest logloss value obtained during cross-validation.

Model performance was assessed using receiver operating characteristic (ROC) curves and area under the curve (AUC) values, with higher AUC indicating better discrimination. Calibration curves evaluated the agreement between predicted and observed outcomes. Decision curve analysis (DCA) and clinical impact curves (CIC) aided in determining optimal application and estimating the model's impact on patient management. SHapley Additive exPlanations (SHAP) values were used to interpret variable importance and model transparency. Four key SHAP plots were generated: (1) a summary plot, (2) dependence plot, (3) interaction plot, and (4) force plot. The model has been deployed on a web-based platform.

Analyses were conducted with R software (R Foundation for Statistical Computing), version 4.3.2. A *P* value <.05 was considered statistically significant.

Results

Baseline Characteristics

This study assessed a cohort of 2450 older adults initially in good health. Over a 5-year follow-up period, 610 participants developed disabilities, resulting in a disability incidence rate of

24.90%. The dataset was split 7:3, with the training set consisting of 1715 individuals (427 with disabilities) and the testing set comprising 735 participants (183 with disabilities). Baseline characteristics of both sets were detailed in Table 1 and Figure 1. Except for differences in sleep duration and white blood cell counts, no statistically significant differences were observed between the 2 groups ($P>.05$).

Table . Baseline characteristics in the training and testing subset.

Variable	Total	Training set	Testing set	*P* value
	N=2450	N=1715	N=735

Predictor Selection

Figure 2 represented the interrelations among the continuous independent variables measured in the study. The matrix used varying shades of color and circle sizes to illustrate the magnitude and direction of correlation coefficients. The analysis revealed significant correlations, such as a negative association between hand grip and age, and a positive association between CHO and high-density lipoprotein (P<.001).

To identify the strongest predictors of disabilities, the training dataset was normalized to account for different measurement units across variables. With disability as the dependent variable, 36 potential predictors were evaluated using LASSO regression. The compressive variable coefficient was used to avoid overfitting and improve predictive accuracy. The parameter λ was selected based on the largest λ within 1 SD of the minimal binomial deviance to enforce stricter penalty constraints. The LASSO regression retained 9 predictors with non-zero coefficients (Figure 3): age, hand grip, standing balance, CS-5, pain, depression, cognition, respiratory function, and the count of comorbidities.

Following LASSO regression, Table 2 summarizes the results of the ablation experiments, which evaluates the impact of removing specific sarcopenia- and frailty-related features (hand grip, CS-5, and standing balance) on model performance. Logloss was used as the primary metric to evaluate the model's performance, with lower values indicating better predictive accuracy. The results showed that removing these features increased the logloss, with the most significant increase observed when all 3 features were removed simultaneously. These findings suggest that including sarcopenia-related parameters is crucial for maintaining the model's predictive accuracy.

Figure 2. Correlation matrix of continuous independent variables. *: *P*<.05; **: *P*<.01; ***: *P*<.001. ASM/Ht2: appendicular skeletal muscle mass and height 2, CS-5: five-repetition chair stand test, Systolic and Diastolic BP: systolic blood pressure, WBC: white blood cell, HGB: hemoglobin, HCT: hematocrit, TG: triglycerides, CHO: total cholesterol, GLU: glucose, UA: uric acid, CRP: C-reactive protein, HbA1c: glycated hemoglobin, CREA: creatinine, BUN: blood urea nitrogen, HDL: high-density lipoprotein cholesterol, LDL: low-density lipoprotein cholesterol. Positive correlations are represented by blue tones, and negative correlations by red tones, with the intensity of the color indicating the strength of the correlation. Circle size is proportional to the absolute value of the correlation coefficient.

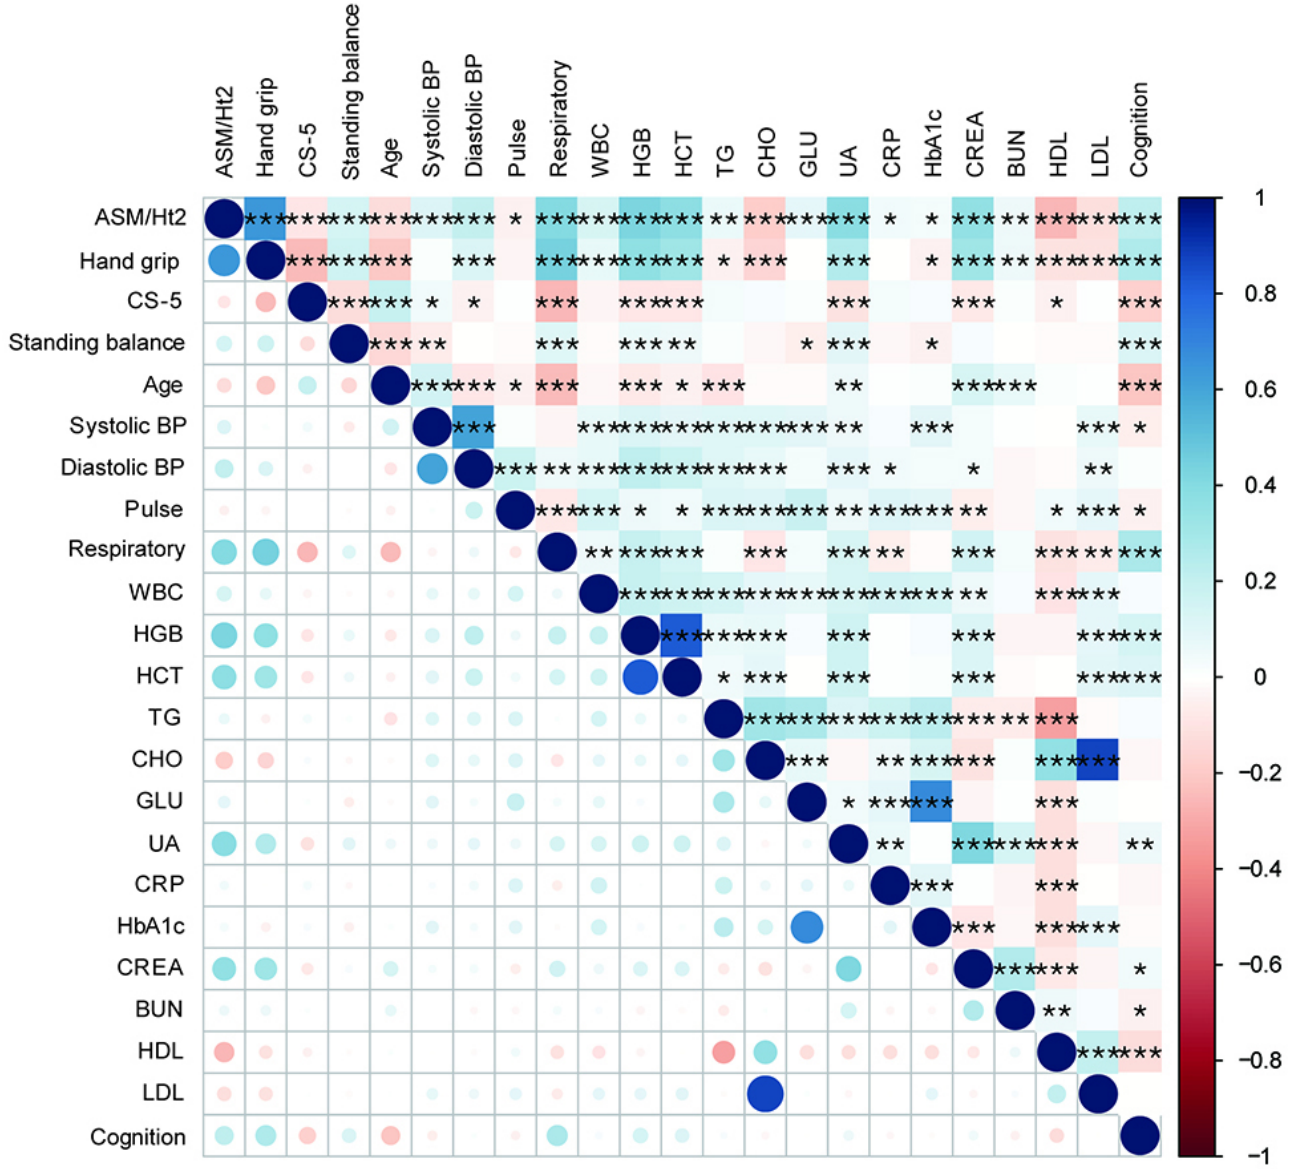

Figure 3. Variable selection via LASSO regression model. (A)Optimal parameter selection in LASSO regression. This plot illustrates the choice of the optimal λ, displaying log(λ) on the horizontal axis and regression coefficients on the vertical axis. (B)LASSO regression parameter (λ) selection via binomial deviance plot. Each point represents the model's deviance at varying log (λ) values, with the vertical dotted line indicating the λ value that minimizes the binomial deviance.

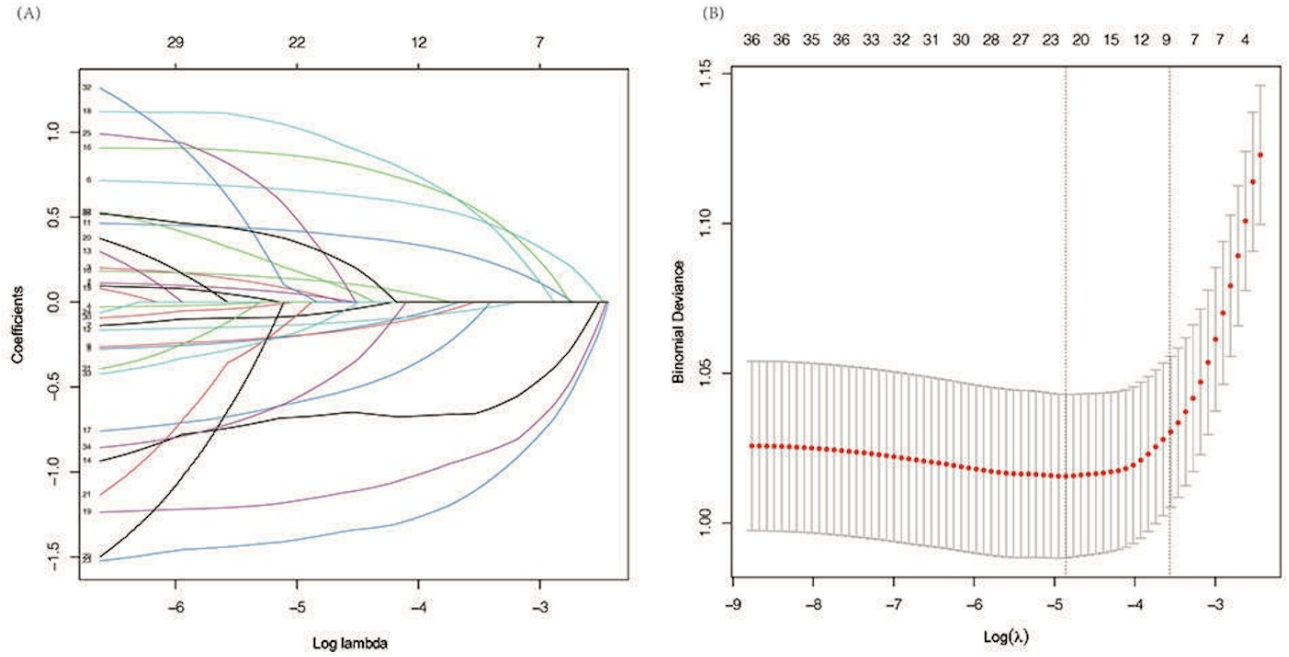

Table . Performance comparison of ablation experiments on model performance.

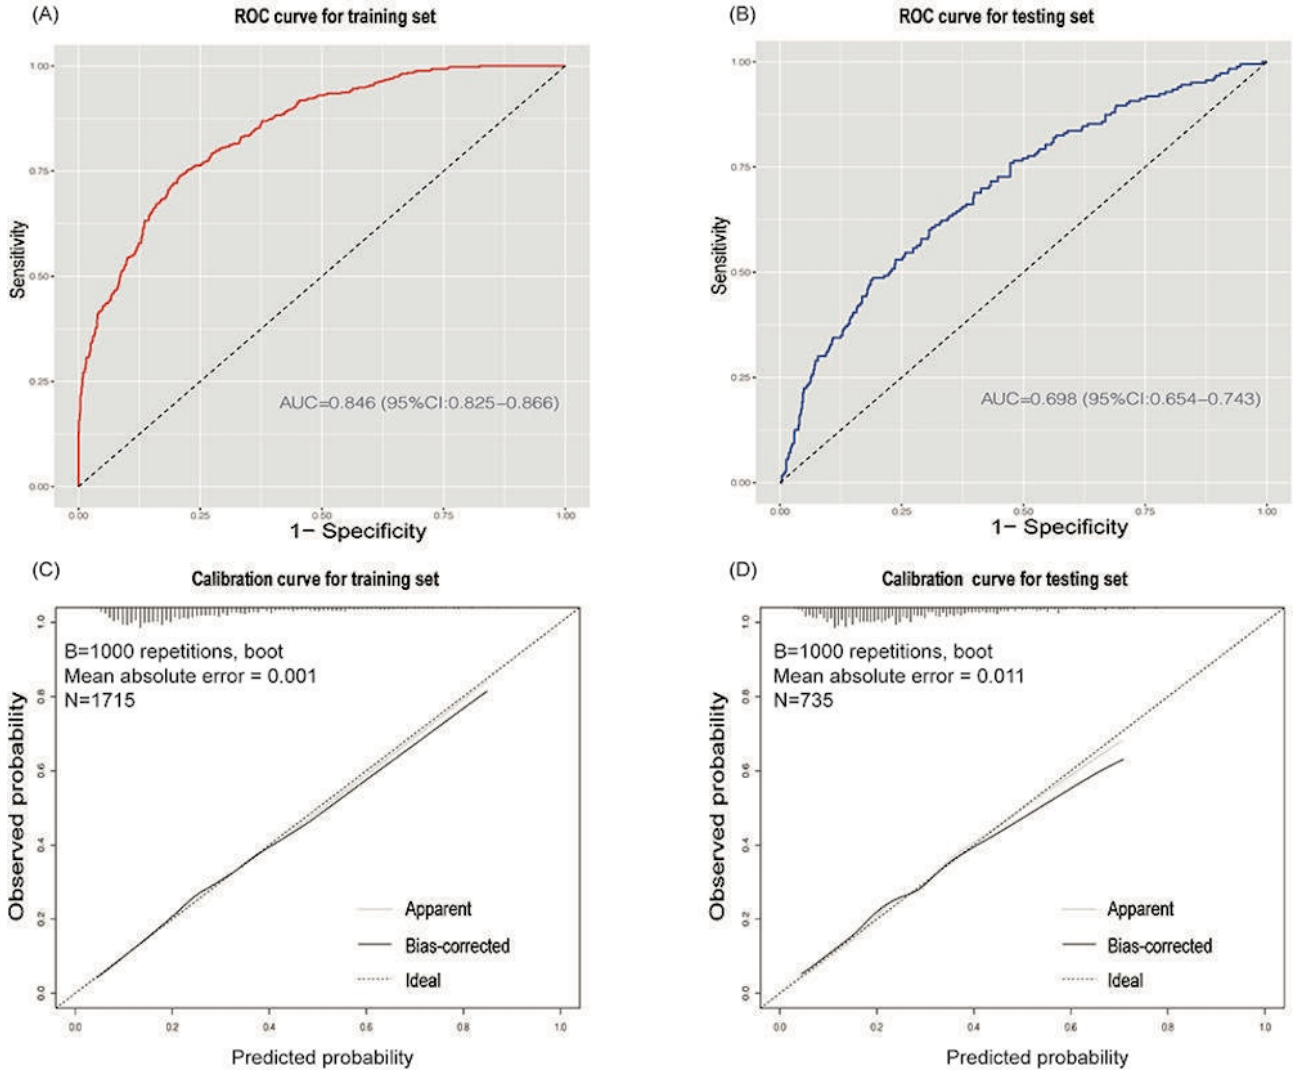
Construction and Assessment of the Predictive Model

Using disability outcomes from 2020 as the dependent variable and 9 predictors selected through LASSO regression, a predictive model was constructed using the XGBoost algorithm. The model's hyperparameters were optimized through grid search and cross-validation. The best parameters identified were: nrounds=100, max_depth=3, eta=0.1, gamma=0.1, colsample_bytree=0.8, min_child_weight=3, and subsample=0.8. These parameters were used to train the final XGBoost model, which was then evaluated on the testing dataset.

The performance of the XGBoost model was evaluated using ROC curves to assess its discrimination ability. In the training set, the model achieved an AUC of 0.846 (95% CI 0.825 - 0.866), indicating good discrimination (Figure 4A). In the testing set, the AUC was 0.698 (95% CI 0.654 - 0.743), reflecting moderate predictive accuracy (Figure 4B).

Figure 4. Receiver operating characteristic curves.

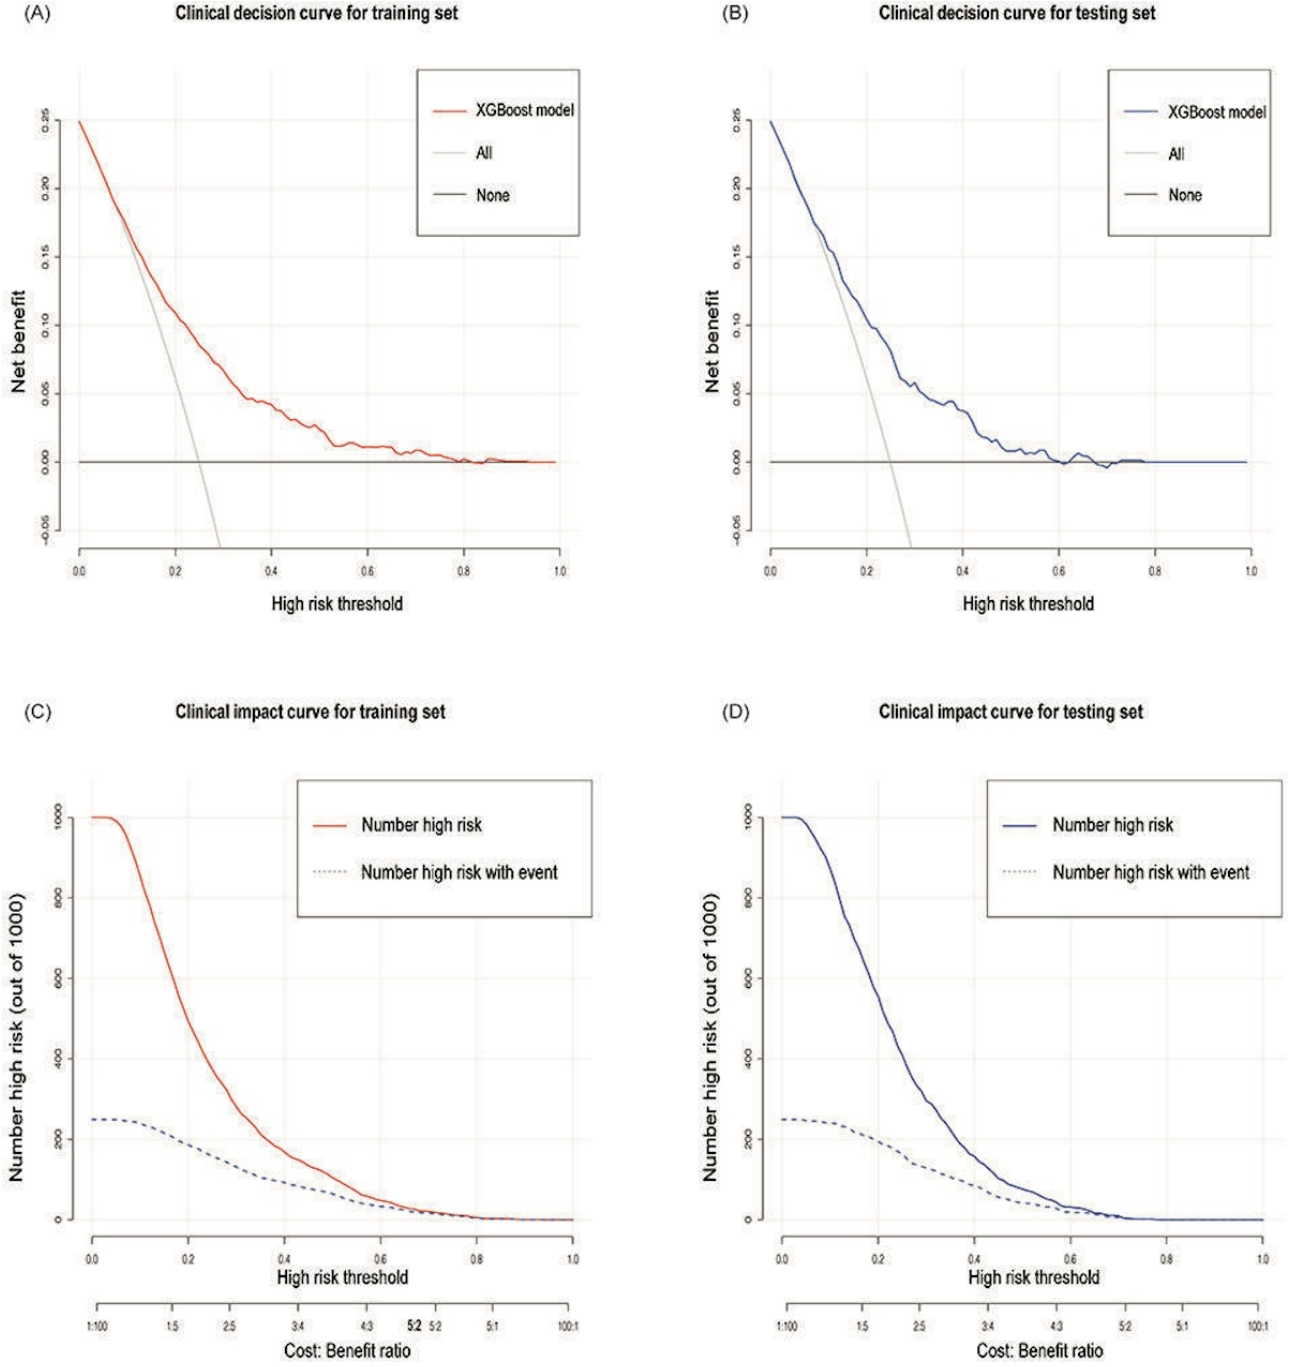


Calibration curves for the training and testing sets assessed the model's predictive accuracy. The training set showed a mean absolute error of 0.001 (Figure 4C), suggesting high precision, while the testing set had a mean absolute error of 0.011 (Figure 4D). Both curves closely approximated the ideal line, confirming the model's reliable prediction of disability risk.

Clinical decision analysis demonstrated the effectiveness of the XGBoost model in predicting disability across different risk thresholds. In the training set, the DCA showed that using the XGBoost model to identify high-risk patients provided a net benefit (Figure 5A). For example, at a chosen risk threshold of 0.30, applying the model's predictions would result in a better net benefit than treating all patients or treating none, highlighting the model's clinical utility in improving decision-making. The testing set also demonstrated a similar net benefit (Figure 5B), confirming the model's robustness and clinical applicability in an independent dataset.

In both datasets, the "Number high risk" line decreased steeply with increasing thresholds, indicating fewer individuals were classified as high-risk under stricter criteria (Figure 5C and D). In contrast, the "Number high risk with event" line, representing individuals who experienced disability, showed a more gradual decline. These trends highlight the model's ability to focus predictions on a targeted group as thresholds increase, demonstrating its utility in guiding clinical decision-making and optimizing interventions for those most likely to benefit. For a more comprehensive evaluation of the model's performance, the specificity, accuracy, positive predictive value (PPV), and negative predictive value at thresholds of 0.2 and 0.5 are provided in Multimedia Appendix 1.

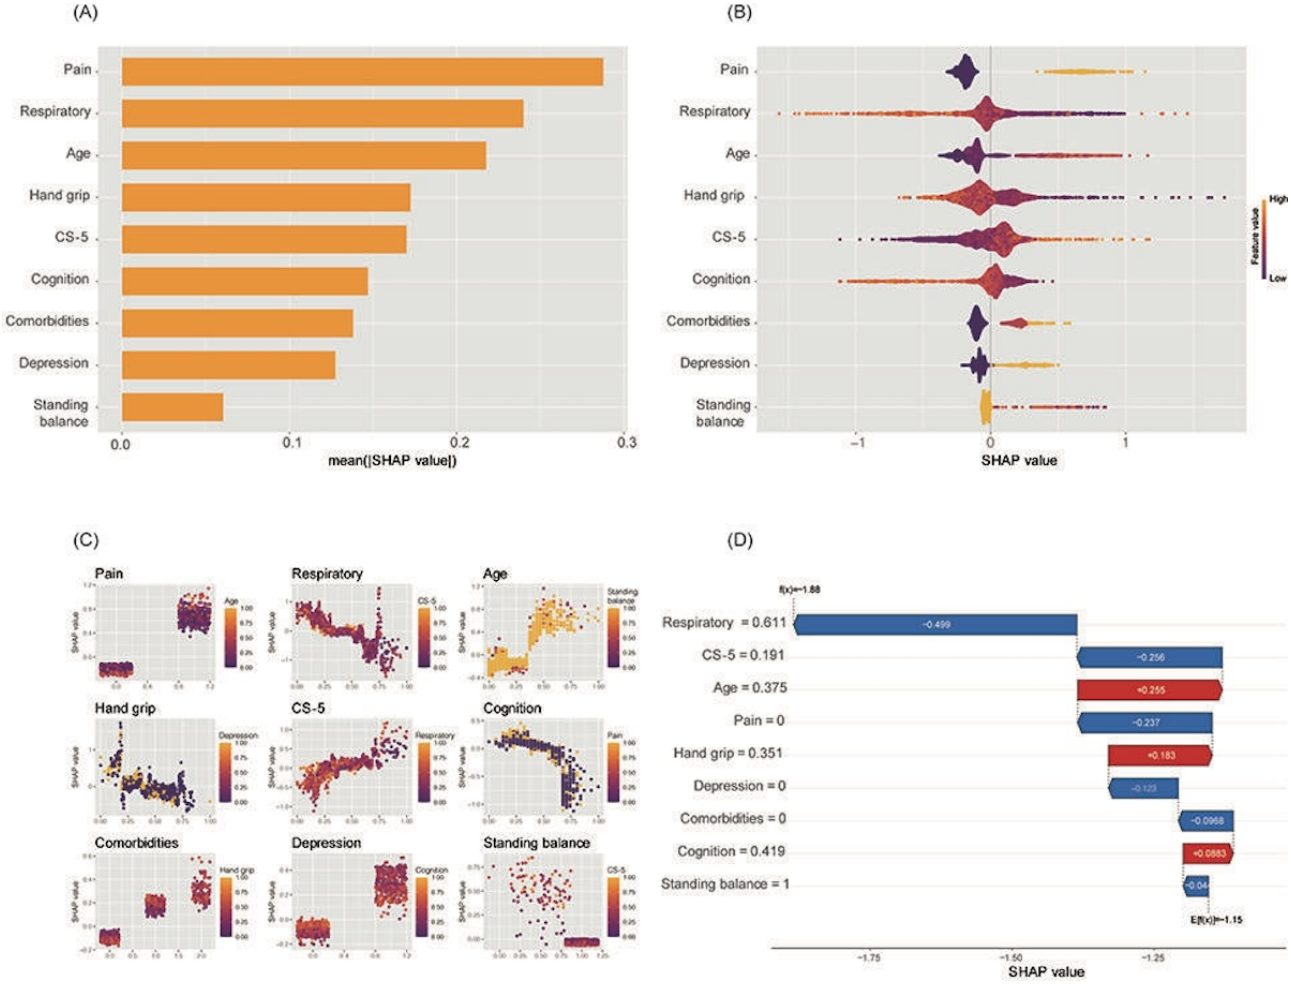
Figure 5. Clinical decision curves and impact curves for XGBoost model. (A)The red line represents the net benefit of the training set. (B)The blue line represents the net benefit of the testing set. The 'all' line indicates the benefit when all patients are treated, and the 'none' line when no patients are treated. (C-D) The solid lines depict the total number of individuals identified as high risk, and the dashed lines represent those at high risk who experienced the true event.



SHAP for Model Interpretation

We used SHAP values to assess the influence of each variable on the 5-year disability risk. Figure 6A ranked predictors by their mean SHAP values, reflecting their average contribution to the model's output. Pain had the highest mean SHAP value, followed by respiratory function and age, indicating their strong overall influence on disability prediction. Figure 6B showed the SHAP value distributions, where pain, respiratory function, and age exhibited the broadest ranges, suggesting their dynamic and individualized impact. Hand grip and CS-5 also significantly influenced the model, highlighting their importance in predicting physical function-related disability, while cognition, comorbidities, and depression showed more consistent contributions. Balance had the least impact.

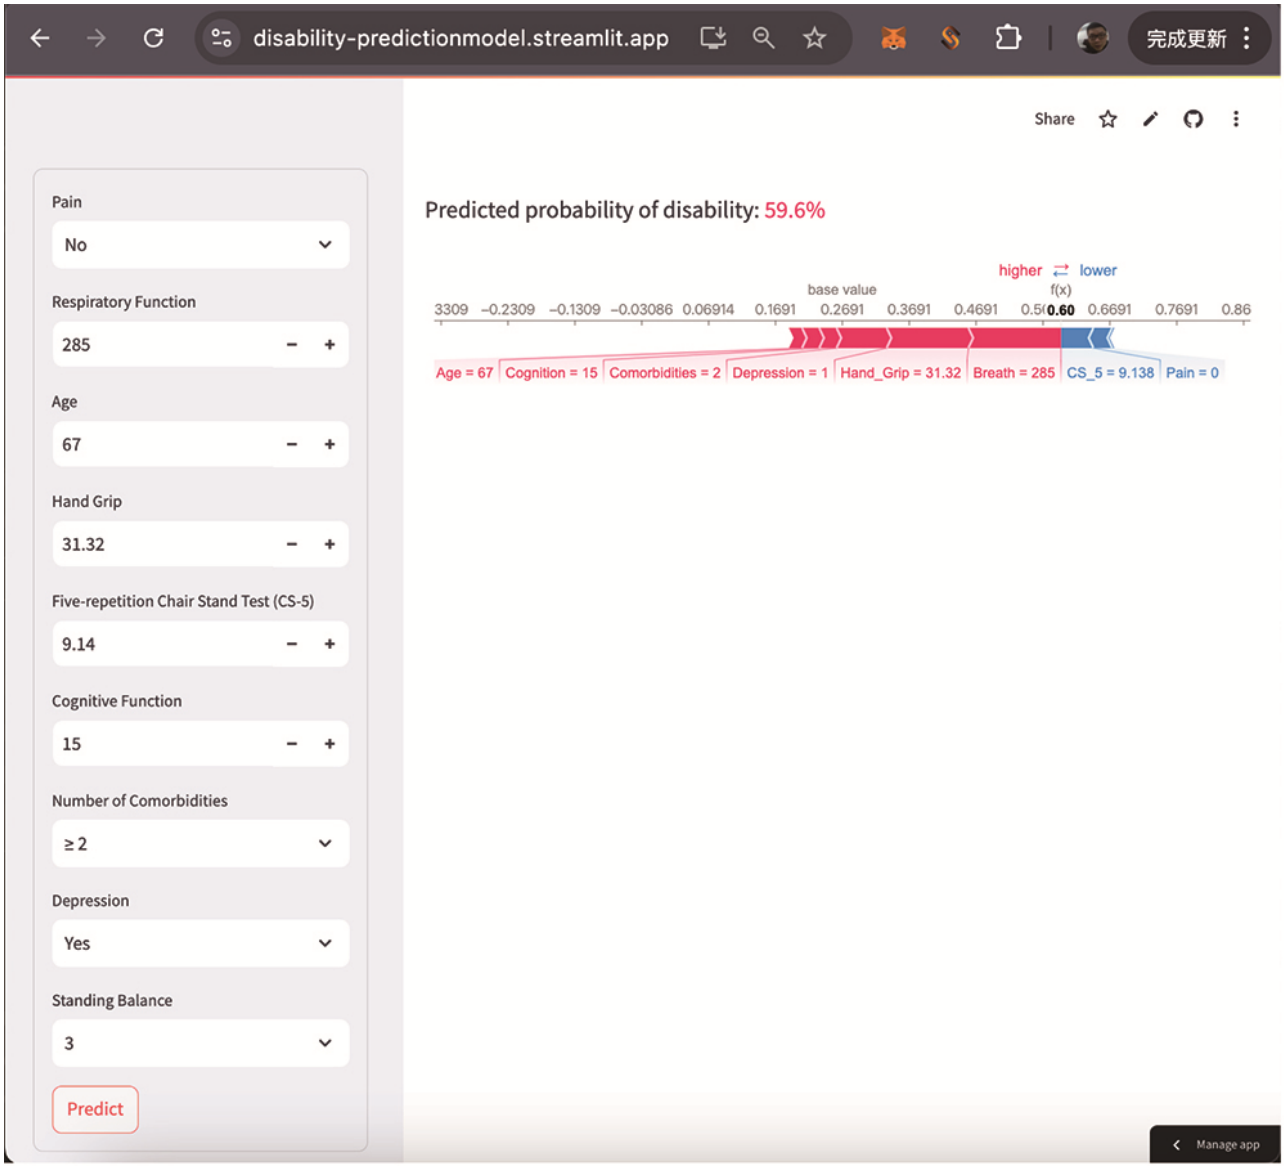
Figure 6. SHAP: SHapley additive exPlanations value interpretation diagram for predicting disability.(A)Variable importance in the predictive model as measured by SHAP values.(B)SHAP value distribution for predictive model variables. SHAP values for model variables are shown as violins. The color represents feature value intensity, and the width indicates impact density. (C)Scatterplot matrix of SHAP values for model predictors. Each plot reveals the influence of a single variable on the model output, with color intensity indicating the magnitude of the feature value. (D)Individual sample SHAP value analysis for disability risk prediction.



The SHAP summary plot (Figure 6C) provided an overview of the overall influence of each predictor on the model's output, revealing that pain, age, and respiratory function had the most substantial and wide-ranging influence on the predicted disability risk. The SHAP dependence plot (Figure 6D) visualized the individualized impact of these predictors on a single patient's disability risk profile, offering insights into the model's decision-making process at both macro and micro levels. Together, these plots provided a comprehensive understanding of the predictors' contributions to disability risk prediction.

A web-based calculator [18] enables clinicians to estimate the 5-year disability probability by entering patient-specific data [18], aiding in personalized clinical decisions (Figure 7).

Figure 7. Online calculator for individual disability prediction.



Discussion

Principal Findings and Comparison With Previous Works

This study constructed an effective 5-year disability prediction model using baseline data from CHARLS 2015 to forecast disability occurrence in 2020. The model identified 9 key predictive variables (pain, respiratory function, age, handgrip strength, CS-5, cognitive function, depression, comorbidities, and standing balance) that are closely associated with disability incidence in Chinese older adults. Calibration curves demonstrated the model's strong discrimination and consistency in both training and test sets, while DCA and CIC highlighted its positive clinical and social application value. The use of longitudinal data from CHARLS allowed for a more accurate, data-driven understanding of aging-related disability trends, leveraging demographic and health-related variables highly relevant to the Chinese context. In addition, the inclusion of sarcopenia and frailty-related diagnostic indicators as predictive variables represents a novel aspect of this research. These indicators enhance the model's sensitivity to physical, cognitive, physiological, and psychological changes associated with aging that contribute to disability. This model offers a practical tool for improving disability prevention and management in older adults.

One notable observation in this study is the difference in AUC values between the training set (0.846) and the testing set (0.698). This discrepancy suggests potential overfitting, where the model may have captured noise or random fluctuations in the training data that do not generalize to unseen data. The observed discrepancy may be due to the imbalance in the dataset with respect to the outcome variable (disability status). To address this, we attempted oversampling to balance the data. However, this approach increased model complexity by retaining additional statistically significant predictors, raising concerns about overfitting. As a result, we proceeded with the original dataset to prioritize model simplicity and reduce overfitting risks. Although the model's discriminative performance decreased in the test set, the overall trends remain robust, providing valuable insights into disability prediction for older populations. Moving forward, we plan to conduct external

validation using additional datasets or longitudinal CHARLS follow-up data to further assess the model's generalizability across diverse settings and time points. We selected the XGBoost algorithm for modeling based on its demonstrated ability to handle complex datasets and address class imbalance by assigning higher weights to the minority class [8]. This approach enhances the model's ability to predict the minority class accurately. XGBoost's advantages over other algorithms include its superior performance with structured and unstructured data, its regularization techniques to reduce overfitting, and its efficiency in training large datasets. In addition, its gradient boosting framework captures complex variable interactions, making it more suitable than traditional linear models. To optimize performance, we used advanced techniques such as cross-validation and hyperparameter tuning, including a comprehensive grid search over key parameters. This rigorous process ensured the model was robust and well-calibrated, improving its predictive performance. By extending the analysis to the latest 2020 CHARLS data, this study offers a more comprehensive 5-year prediction window compared with previous work focused on shorter time frames.

SHAP summary charts clarified the role and importance of each variable in predicting disability, providing transparency and interpretability to the model. According to the SHAP chart, pain, respiratory function, and age were the top 3 factors in importance, with the wide distribution of SHAP values. This indicates that changes in these variables significantly alter the risk of disability. Chronic pain, particularly lower back and neck pain, is a leading cause of disability globally, as highlighted by the Global Burden of Disease Study 2015. These types of pain are major causes of years lived with disability in many regions, including Latin America, the Caribbean, most regions of Asia, Oceania, and sub-Saharan Africa [19]. Chronic pain is closely linked to functional disability and poor physical performance in the older, as supported by various studies [20,21]. Respiratory function declines with age in older people, and respiratory impairment accounts for 20.7% of all types of disability [22]. Maximal inspiratory pressure and maximal expiratory pressure are correlated with hand-grip strength and skeletal muscle mass index [23,24]. Respiratory sarcopenia, characterized by a decrease in respiratory muscle strength alongside systemic skeletal muscle with aging [25], can lead to deterioration in respiratory force generation, adversely affecting activities of daily living [26]. Overall, respiratory impairment is prevalent among older individuals and is linked to physical inactivity and poor performance-based mobility [27]. Age is an independent risk factor for disability, with intrinsic capacity and functional ability declining with age. Disability levels are highest in the oldest patients [28], and age correlates with increased pain and respiratory impairment. Older adults are more likely to experience these issues, further increasing their disability risk [29]. In summary, higher pain scores, poorer respiratory function, and older age are associated with a greater risk of disability. Clinically, this suggests the need for emphasis on pain management and respiratory exercises in old people, particularly for those with chronic respiratory diseases.

The concentrated distribution of SHAP values for handgrip strength, CS-5, and cognitive function indicates these variables significantly influenced disability prediction. The ablation experiments further confirmed the impact of handgrip strength and CS-5 on the model. When these sarcopenia-related features were removed, the model's performance was notably affected, as indicated by a significant increase in logloss. This finding aligns with the SHAP analysis results, which showed a wide distribution of values for these variables. Weak handgrip strength is identified as a key component of sarcopenia, strongly associated with subsequent disability and mortality [30]. Reduced handgrip strength and lower extremity strength, as measured by the CS-5, are strong predictors of functional impairment, disability, and low health-related quality of life, significantly increasing the risk of severe disability, frailty, and other health limitations in older adults [31,32]. Cognitive function is another crucial risk factor for disability. Studies have shown that cognitive decline is associated with ADL disability [33], and longitudinal research indicates that cognitive impairment may precede ADL disability, serving as a predictor of intermediate and late-stage ADL loss [34]. Physical and cognitive functions are closely related, with physical activity enhancing neurogenesis in the adult brain. Dual-task training, which enhances both cognitive and physical functions, has shown positive effects on cognitive function and physical activity in older individuals [35]. In summary, declines in handgrip strength, lower extremity strength (CS-5), and cognitive function are positively correlated with an increased risk of disability. This underscores the importance of targeted interventions, such as early muscle strength training for the upper and lower limbs and cognitive function exercises, to help reduce the risk of disability.

Although the roles of depression, comorbidities, and standing balance are less significant in predicting disability, they still contribute to its progression in the elderly and remain non-negligible factors. Depression, in particular, is a common psychological disorder among older adults and continues to be one of the most prevalent and disabling biopsychosocial conditions in this population. A Chinese cross-sectional study provided evidence of the association between depressive symptoms and ADL disability [36]. There is also a strong association between depression and physical activity, with significant mental health benefits gained from being physically active, even at levels below public health recommendations [37]. This may explain why depression can affect disability progression through physical function measures such as handgrip strength and CS-5. Similarly, comorbidities and standing balance are associated with disability and are critical factors in the multifactorial process of disability [38,39]. Comorbidity, the coexistence of 2 or more chronic diseases in older adults is a well-documented risk factor for increased mortality, reduced quality of life, and functional decline, ultimately leading to disability [40]. As a consequence of managing multiple chronic conditions, polypharmacy, defined as the concurrent use of multiple medications, becomes increasingly common in older populations [41]. Polypharmacy has been associated with a higher risk of falls, frailty, cognitive impairment, and adverse drug interactions, further exacerbating health deterioration and disability [42]. However, in this study, medication use was categorized in the CHARLS questionnaire only as Chinese traditional medicine or Western modern medicine, without

detailed data on specific medications. This limitation prevented a comprehensive analysis of polypharmacy's impact. The decline in standing balance in older adults indicates decreased postural control and increased risk of falls, often seen in populations with sarcopenia and frailty, which eventually progresses to disability [43]. Overall, these findings suggest that we should consider the combined effects of mental health, management of multiple chronic diseases, and balance function when predicting disability and formulating prevention strategies.

In our study, we evaluated the treatment benefits of the model using DCA. Figure 6A shows the net benefit across different risk thresholds. At low thresholds (<0.2), the net benefit was high but gradually declined as the threshold increased, approaching zero around 0.6. The model outperformed both all-treatment and no-treatment strategies across most thresholds, demonstrating its clinical utility. In practice, selecting an appropriate threshold is critical for clinical decision-making and resource allocation. A low threshold is suitable for high-sensitivity scenarios, such as community screening for early intervention in older adults. A medium threshold balances sensitivity and specificity, making it ideal for resource-limited settings where the model can precisely identify high-risk individuals for targeted interventions. Many clinicians have used DCA to test various disease prediction models, such as those for 30-day mortality in MIMIC-III patients with sepsis-3, major adverse cardiovascular events in older patients, and hypertension risk in patients with type 2 diabetes mellitus [44-46].

- We evaluated the model's predictive efficacy at different risk thresholds using CIC. As shown in Figure 6C, at thresholds below 0.2, the model identifies over 500 high-risk patients, with approximately 200 actual events, resulting in a high false-positive rate and increased resource consumption. This range is suitable for early widespread screening when follow-up resources are available. At thresholds between 0.2 and 0.5, the number of high-risk patients identified aligns more closely with actual events, balancing sensitivity and specificity while improving cost-effectiveness. This range is ideal for resource-limited settings. At thresholds above 0.5, the number of high-risk patients decreases significantly, nearly matching actual events but potentially missing some high-risk cases. The CIC provides clinicians with a visual tool to balance sensitivity and specificity, optimizing disability prediction and intervention strategies in older adults. CIC is commonly used to evaluate the predictive accuracy and clinical value of clinical prediction model for various diseases [47-49]. However, they are rarely used to evaluate the clinical usefulness of disability prediction models in older adults.

The 9 variables selected through LASSO regression form a streamlined yet effective set of predictors that can be easily integrated into routine clinical practice. Specifically, the inclusion of sarcopenia and frailty-related features provides health care professionals with clear and actionable insights into the ability of older adults to live independently, enabling timely interventions to prevent disability. By focusing on these key variables, the model remains interpretable, reducing the risk of "black-box" complexity in clinical decision-making. To facilitate practical application, we developed a web-based application via the Streamlit platform that uses these 9 predictors to calculate the 5-year risk of disability for individual patients. This user-friendly tool allows clinicians to input patient-specific data and receive immediate risk assessments, integrating predictive analytics into clinical workflows and bridging complex data models with everyday decision-making. Future applications of this model can aid healthcare professionals in identifying individuals at high risk of disability and implementing early, targeted interventions. This approach has the potential to delay the onset of disability and improve the quality of life for older individuals.

Limitations

The limitations of this study include the selection of predictor variables. While the selected predictors are based on the best available evidence, other important variables, such as activity intensity, were not included due to high missing values. In addition, the model generalization and optimization is a limitation. The model performs well on the internal test set but lacks external validation due to the unavailability of a suitable external dataset. We plan to collect data from multicenter older care communities for external validation to further improve and optimize the model. As the CHARLS database updates, the model may need periodic updates to maintain accuracy and usefulness. Moreover, predicting long-term disability risk is challenging due to complex time interactions that may alter the risk trajectory.

Conclusions

Our research incorporates parameters aligned with the diagnostic criteria for sarcopenia and frailty. These physical function measures are combined with predictors from cognitive and psychological health dimensions, recognizing the complex interplay of physical capability, aging, and mental health in the development of disability. This approach enhances the model's precision and considers the need for the efficient identification of at-risk individuals and the optimization of medical resources in clinical practice. Consequently, the model provides a highly reliable disability prediction tool for older patients, health care workers, and policymakers. In the future, we will adjust the model based on updates to the CHARLS database to ensure its suitability for the older population in China. In addition, we will seek appropriate external databases for validation and promote the model's application across different ethnic groups.

Acknowledgments

Abstract

Background: Understanding the dementia disease trajectory and clinical practice patterns in outpatient settings is vital for effective management. Knowledge about the path from initial memory loss complaints to dementia diagnosis remains limited.

Objective: This study aims to (1) determine the time intervals between initial memory loss complaints and dementia diagnosis in outpatient care, (2) assess the proportion of patients receiving cognition-enhancing medication prior to dementia diagnosis, and (3) identify patient and provider characteristics that influence the time between memory complaints and diagnosis and the prescription of cognition-enhancing medication.

Methods: This retrospective cohort study used a large outpatient electronic health record (EHR) database from the University of Connecticut Health Center, covering 2010 - 2018, with a cohort of 581 outpatients. We used a customized deep learning–based natural language processing (NLP) pipeline to extract clinical information from EHR data, focusing on cognition-related symptoms, primary caregiver relation, and medication usage. We applied descriptive statistics, linear, and logistic regression for analysis.

Results: The NLP pipeline showed precision, recall, and F_1-scores of 0.97, 0.93, and 0.95, respectively. The median time from the first memory loss complaint to dementia diagnosis was 342 (IQR 200-675) days. Factors such as the location of initial complaints and diagnosis and primary caregiver relationships significantly affected this interval. Around 25.1% (146/581) of patients were prescribed cognition-enhancing medication before diagnosis, with the number of complaints influencing medication usage.

Conclusions: Our NLP-guided analysis provided insights into the clinical pathways from memory complaints to dementia diagnosis and medication practices, which can enhance patient care and decision-making in outpatient settings.

Introduction

The rising prevalence of dementia, driven by an aging population, presents a profound concern for society [1-4], placing substantial burdens on individuals and imposing high financial costs [5-7]. Despite these challenges, no curative treatments are currently available [8,9], highlighting the critical need for early detection of prodromal symptoms of dementia, such as mild cognitive decline [10-13], and timely diagnosis. Early intervention can delay disease progression or alter the trajectory toward dementia [9,14,15]. However, dementia and its associated symptoms are frequently underreported and underdiagnosed in clinical practice [16,17]. As the condition progresses, patients commonly experience increased memory loss, deteriorating cognitive ability, heightened confusion, and changes in personality like agitation. The conversion from mild

cognitive impairment to Alzheimers disease has been explored using patient health data [18].

Electronic health records (EHRs) offer a valuable resource for enhancing the detection and management of disease by providing comprehensive data on patient health and history [19-23]. However, much of the nuanced patient information is embedded within unstructured clinical notes and is not accessible through structured data. Natural language processing (NLP), a subfield of artificial intelligence that enables computers to understand, interpret, and generate human language, holds promise for extracting meaningful information from vast and complex free-text EHRs [24-27]. NLP has been instrumental in automatically extracting clinical information in various medical domains, including geriatric care [28-35]. For instance, Kharrazi et al [36] showcased higher rates of geriatric syndrome extraction from unstructured EHR using NLP compared to relying solely on claim data or structured EHR data. Studies have successfully extracted cognitive status and measurement scores [37,38], as well as lifestyle exposures and discourse production for Alzheimers disease [39], from clinical documentation using NLP. Additionally, multiple studies have applied NLP methods to extract neuropsychiatric symptoms and cognitive or function impairment information [40-43]. State-of-the-art models, such as pretrained Bidirectional Encoder Representation from Transformer (BERT), have been applied in clinical settings for tasks like detecting inpatient falls [44] and classifying dementia risk [45] using clinical notes. While previous research has made significant strides in the earlier detection of cognitive decline using EHR, most studies have focused on extracting symptoms or cognitive measurement scores rather than other clinical features that affect disease progression, such as the relationship of the primary caregivers with patients.

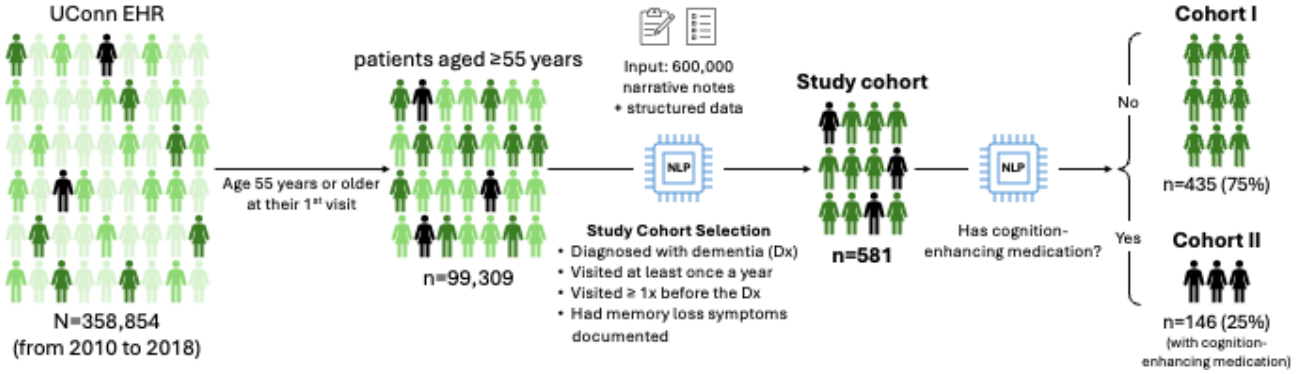
We aimed to investigate the time interval from initial memory loss complaints to dementia diagnosis and explore the association between various clinical features, including the family primary caregiver relationship, using real-world outpatient clinical notes. Additionally, we aimed to analyze the pattern of cognition-enhancing medication prescriptions before diagnosis. To achieve this, we developed a customized NLP pipeline using deep learning techniques, based on a prodromal dementia symptom ontology that we established.

Methods

Study Cohorts

This retrospective study used data from the UConn Health Center between 2010 and 2018. The use of longitudinal EHR data allowed us to track all patients' clinical information, including demographic characteristics, diagnoses, measurements, medications, and signs. The study cohort was defined as patients who met the following criteria: (1) received a dementia diagnosis, (2) had at least one outpatient visit per year, (3) had at least one visit before the dementia diagnosis, and (4) had documented memory loss–related symptoms (eg, memory loss, confusion, cognition impairment, trouble remembering, not recalling, forgetting, and blackout) in the EHR. Dementia was defined based on the presence of 3 or more *ICD* (*International Classification of Diseases*) codes used for dementia phenotyping in our study (as detailed in Multimedia Appendix 1) and dementia documentation in their clinical notes. We analyzed demographic and clinical characteristics from structured EHR data, including insurance details, the initial location (medical unit) of memory loss complaints, and the location of the first dementia diagnosis. These locations encompass various settings within this health care system, such as geriatric medicine, internal medicine, and neurology outpatient clinics. NLP was used to extract symptoms and primary caregiver (family supporter) relationship information from clinical notes. Both diagnosis and cognition-improving medication information were extracted from both structured and unstructured data. Figure 1 provides an overview of the selection process of the study cohort and the information extraction process.

Figure 1. The workflow for the study cohort selection and information extraction. EHR: electronic health record; NLP: natural language processing.



Building a Deep Learning–Based NLP Pipeline

A framework was developed to curate the prodromal dementia symptoms comprising four stages: (1) preprocessing and query expansion, (2) ontology construction and annotation, (3) NLP model development, and (4) system evaluation.

Preprocessing and Query Expansion

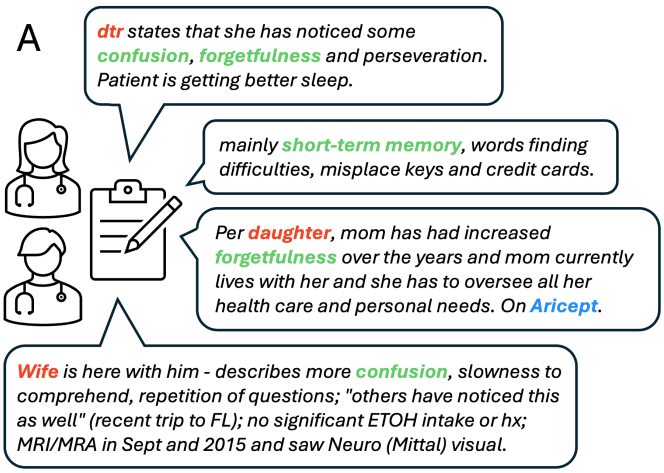
In this stage, a query was expanded to extract and identify a broad set of patient notes with documented memory loss symptoms. A list of seed terms was obtained through a manual survey of the literature and a clinical note review by a clinical researcher and domain expert. A bigram word2vec algorithm [46] was used to identify additional significant terms potentially related to memory loss symptoms to ensure the encapsulation

of an expansive cohort. The expanded, rule-based query terms provided in Multimedia Appendix 2 were subsequently applied to extract the relevant patient notes for NLP modeling.

Ontology Construction and Annotation

This stage involves the simulation of an expert's knowledge and understanding of the free text. A prodromal dementia symptom ontology was built based on the physician's opinion, a comprehensive literature review, and a clinical note review. The ontology includes 9 entities and 9 relations. The 9 entities are "memory loss symptom (Sx)," "dementia diagnosis (Dx)," "temporal," "duration," "status change: worse," "other symptoms," "cognitive test result," "caregiver relation," and "cognition enhancing medication (Rx)." The 9 relations are "has complaint date," "has diagnosis date," "has other symptom information," "has status change information," "has duration information," "has test information," "has caregiver information," "has treatment information," and "has effects" as depicted in Figure 2A. Two independent annotators manually annotated notes using Clinical Language Annotation, Modeling, and Processing (CLAMP) [47], an NLP toolkit, guided by the constructed ontology. Figure 2B shows an example note with entities and relations annotated.

Figure 2. The ontology of memory loss and the annotated sample note. (A) The ontology of prodromal dementia symptoms. In total, 9 entities and 9 semantic relations between entities were defined in the ontology. (B) A sample note that has been deidentified and annotated with prodromal dementia symptoms. In this note, the following entities have been annotated and related to each other: symptoms, relation, medication, duration, status change, test, and temporal. MRI/MRA: magnetic resonance imaging/magnetic resonance angiography, dtr:daughter, ETOH: ethanol, FL: florida, hx: history.



B

Entity	Standardized concept values	Original strings
Symptom	Memory loss	confusion
Symptom	Memory loss	forgetfulness
Symptom	Memory loss	short-term memory
Medication	Donepezil	Aricept
Relation	Daughter	drt
Relation	Daughter	daughter
Relation	Wife	Wife

NLP Model Development

The annotated notes (n=815) obtained in the previous stage were used for NLP model training. These notes were randomly split into a training set (80%, n=652, of annotated notes) and an independent validation set (the remaining 20%, n=163). The manual annotation and training processes were iteratively performed with additional manually annotated notes to enhance model performance until the model achieved an F_1-score of >0.8. For model training, a multilayer deep learning architecture was adopted, which involved transforming the text into sequential vectors of characterization through the embedding step. The vectors were then fed into a Bidirectional Long Short-Term Memory (BiLSTM), a text classification architecture based on artificial neural networks, for pattern recognition in both forward and backward directions. Finally, the patterns were sent to the next layer of a Conditional Random Field (CRF) model for prediction probability computation. BiLSTM-CRF architectures are widely used in clinical NLP tasks, demonstrating robustness in recognizing entities in sequential data like clinical notes [48] and effectively leveraging moderate-sized datasets with lower computational resource requirements.

NLP Pipeline Evaluation

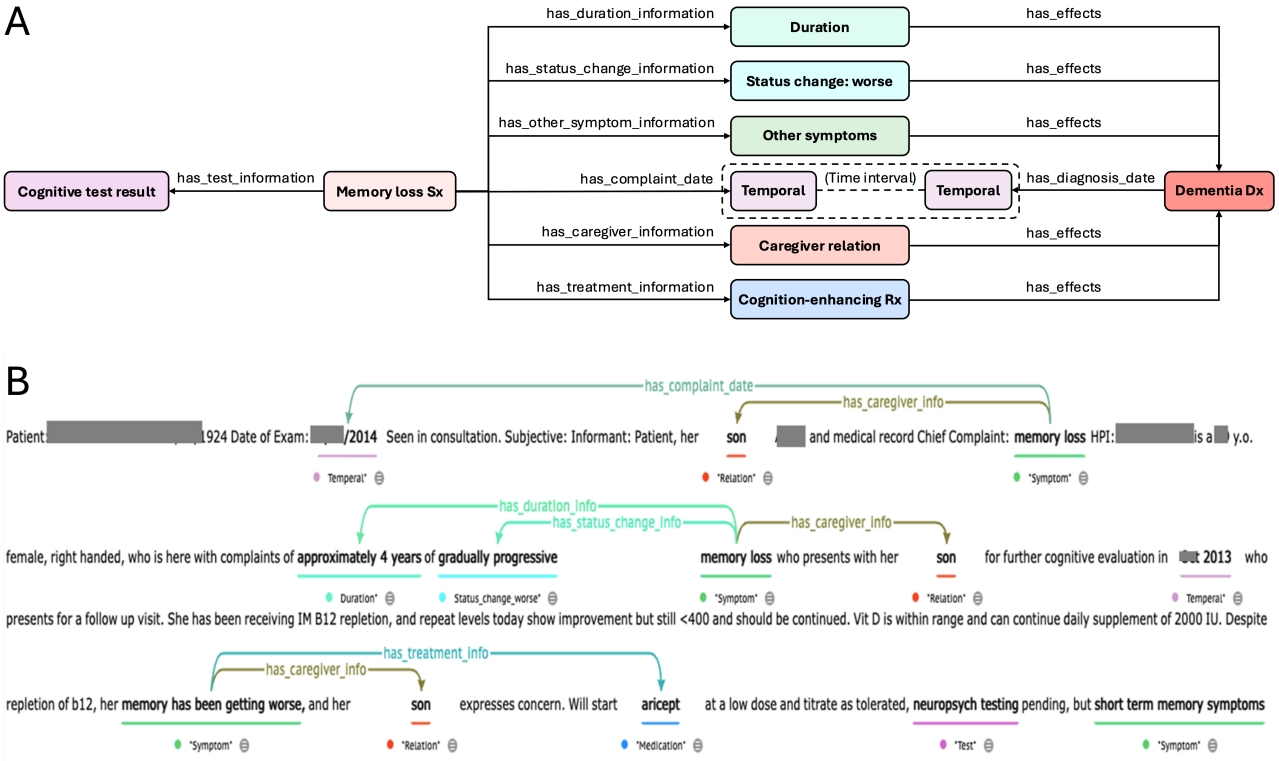
The performance of the pipeline was evaluated in the validation set through precision (positive predictive value [PPV]), recall (sensitivity), and F_1-score (a balanced score between false positives [FPs] and false negatives [FNs]). Recall was calculated as the ratio of the number of entities that were identified by the pipeline over the total number of the corresponding entities in the manually annotated gold standard (ie, true positive [TP]/[TP+FN]). Precision was measured as the ratio of the number of distinct entities returned by the correct pipeline according to the gold standard divided by the total number of entities found by our pipeline (ie, TP/[TP+FP]). F_1-score was calculated as the harmonic mean of PPV and sensitivity (ie, 2 × PPV × sensitivity / [PPV + sensitivity]).

Standardization of Concept Values Leveraging NLP

Clinical notes contain abundant information but are often heterogeneous in form. To enable use case analysis, these heterogeneous entities needed to be standardized. Figure 3A illustrates the various forms in which cognition-related concepts like forgetfulness, memory loss, short-term memory, and confusion were documented in the clinical notes. Abbreviations (eg, dtr for daughter) and mixed use of brand names and generic names of the same drugs (eg, Aricept and donepezil) were commonly found. Figure 3B provides examples of standardized concept values obtained through the NLP process. The cognition-enhancing medications discussed include donepezil, memantine, rivastigmine, and galantamine. For the analysis, the son, son-in-law, daughter-in-law, grandson, and granddaughter were classified as other adult children, while the

nephew, niece, cousin, brother, and sister were classified as other family support.

Figure 3. Clinical note standardization via NLP. (A) The diverse expressions used in clinical notes depict concepts such as memory loss symptoms, primary caregiver relationships, and cognition-enhancing medications. (B) A sample of the standardized output generated by the NLP process, representing the standardized values of the various original expressions. Dx: diagnosis; HPI: history of present illness; NLP: natural language processing; Rx: medication; Sx: symptom.



Characterization of Dementia Cohorts and Longitudinal Analysis of Dementia Trajectory

The collection of clinical information of patients was accomplished through the extraction of both structured and unstructured EHR data. The statistical analysis was performed using R software (R Core Team). A logistic regression model was used to assess the relationship between medication prescription history and other factors, such as memory loss complaints and the primary caregiver relation information, by calculating the odds ratio (OR) and 95% CI. A total of 149 patients who had memory loss complaints and diagnoses recorded on the same day were excluded from this study.

Ethical Considerations

This study involved no interaction with patients as it is a retrospective cohort study that used a deidentified dataset. As such, it was deemed as exempt from institutional review board approval.

Results

Building a Memory Loss NLP Pipeline

The performance of our memory loss NLP pipeline was evaluated using precision, recall (sensitivity), and F_1-score metrics in the validation set, with detailed results presented in Multimedia Appendix 3. Our system achieved high scores across all semantic types, including “memory loss symptom,” “dementia diagnosis,” “duration,” “primary caregiver,” and “status change” (overall precision, recall [sensitivity], and F_1-scores of 0.97, 0.93, and 0.95, respectively). For example, the precision for “memory loss symptoms” was 0.97, indicating that 97% of “memory loss symptoms” were identified by our NLP system in patients’ clinical notes, as verified against a manually curated gold standard. The recall (sensitivity) of 0.93 implies that our system correctly identified 93% of actual memory loss cases, with only 7% missed. Multimedia Appendix 3 provides comprehensive details for various semantic types and relations, enabling a thorough understanding of the NLP pipeline’s performance.

Clinical Characterization of Study Cohorts

Cohort Identification

An average of 358,854 patients visited the UConn Health system for outpatient care between 2010 and 2018, with the number of visits increasing annually from 224,488 in 2010 to 1,024,349 in 2017. There were 8686 patient visits in 2018 until the time point we collected data. Out of these patients, 99,039 patients were aged 55 years or older at their first visit. From more than 600,000 narrative records and coded data of those patients, we identified 730 patients who had at least one outpatient visit per year, at least one visit before their dementia diagnosis, and documented memory loss symptoms in their clinical notes. Of these, 149 (20.4%) patients reported memory loss complaints and were diagnosed with dementia on the same day, while 581 (79.6%) patients had at least a 1-day gap between the complaint and diagnosis. For the following analysis, 581 patients with

memory loss symptoms documented at different days were included in study cohorts (Figure 1).

Cohort Demographics

The demographic characteristics, primary insurance, and medication information of study cohorts are summarized in Table 1. Most cohort members were non-Hispanic White individuals (509/581, 87.6%) and female (381/581, 65.6%), with an age distribution of over 85 years (315/581, 54.2%), 75 - 84 years (171/581, 29.4%), 65-74 years (63/581, 10.8%), and under 65 years (32/581, 5.5%).

Table . Demographic characteristics, primary insurance, and medication information of study cohorts (N=581).

Characteristics		Values, n (%)
Age (years)		
	<65	32 (5.5)
	65 - 74	63 (10.8)
	75 - 84	171 (29.4)
	85+	315 (54.2)
Race		
	White	509 (87.6)
	African American	33 (5.7)
	Others	39 (6.7)
Sex		
	Female	381 (65.6)
	Male	200 (34.4)
Primary caregiver (family supporter) relation (n=291)		
	Husband	26 (8.9)
	Wife	39 (13.4)
	Daughter	135 (46.4)
	Son	50 (17.2)
	Other family members	41 (14.1)
	Missing	290 (49.9)
Prior medication before the first diagnosis of dementia		146 (25.1)

Primary Caregiver and Medication Information

Out of 291 patients with primary caregiver relation information, adult children were the main caregivers (n=185, 63.6%, with n=135, 46.4%, being daughters and n=50, 17.2%, being sons), followed by spouses (n=65, 22.3%, with n=39, 13.4%, being wives and n=26, 8.9%, being husbands). Other family members (eg, nephew) made up 14.1% (41/291) of the cohort. Out of 581 patients, 146 (25.1%) patients had been prescribed cognition-improving medications prior to the dementia diagnosis.

Outpatient Care Locations

Next, we investigated the outpatient care locations where the first memory loss complaints were reported and where dementia was diagnosed. Geriatrics is the most frequent location for both the first memory loss complaints made (308/581, 53%) and the diagnosis of dementia (350/581, 60.2%), followed by primary care (185/581, 31.8%, and 163/581, 28.1%, respectively) and neurology (39/581, 6.7%, and 61/581, 10.5%, respectively). The majority of the cohort was covered by Medicare (354/581, 60.9%) or Medicaid (72/581, 12.4%) as primary insurance, while 26.2% (152/581) had commercial insurance. Only a small percentage of patients (2/581, 0.3%) had no insurance coverage (Multimedia Appendix 4).

Distribution of Time Intervals Between Cognitive Symptom Complaints and Dementia Diagnosis and the Number of Complaints

Time Interval

The median time interval between the first memory loss complaints and dementia diagnosis was 342 days, ranging from a minimum of 1 day to a maximum of 1458 days in our study cohort (n=581) (Multimedia Appendix 5).

Health Care Use

Additionally, the number of complaints made before being diagnosed was analyzed, with a median of 3 complaints, ranging from a minimum of 1 complaint to a maximum of 18 complaints (Multimedia Appendix 5).

Association Analysis for the Earlier Dementia Diagnosis

We aimed to identify the clinical features that are associated with earlier diagnosis of dementia from the first memory loss

complaints. Results indicated that the location of the first complaints made and the diagnosis, as well as the relation of the primary caregiver, were significantly associated with earlier diagnosis of dementia. Patients who made complaints in geriatrics (−141 days, $P<.001$, χ^2 test) or neurology (−158 days, $P=.02$) were diagnosed with dementia earlier compared to those who made complaints in primary care. Furthermore, patients diagnosed with dementia in geriatrics had a shorter interval of 152.9 days ($P<.001$) compared to those diagnosed in primary care. Additionally, having a wife or a daughter as a primary caregiver was associated with an earlier diagnosis of dementia, with a shorter interval of 249.6 days ($P=.01$) and 176.8 days ($P=.04$), respectively, compared to those who had a husband as a primary caregiver. However, factors such as age or insurance types were not found to have a significant impact on earlier diagnosis (Table 2).

Table . Statistical analysis of time intervals between the first complaints and dementia diagnosis.

Features		Estimate (95% CI)	*P* value (χ^2 test)
Age (years)			
	<65	109.8 (–26.7 to 246.3)	.12
	65 - 74	–61.6 (–163.2 to 40)	.24
	75 - 84	0.08 (–69.4 to 69.6)	≥.99
	85+	Ref[a]	—[b]
Primary insurance			
	No insurance	36.8 (–25 to 98.6)	.24

Association Analysis for the Medication Usage

Medication was prescribed in 25.1% (146/581) of patients before dementia diagnosis. We next analyzed factors associated with the usage of cognition-enhancing medication before the diagnosis of dementia after the 1st complaints of memory loss. The only factor that was significantly associated with medication usage was the total number of memory loss complaints made; each additional memory complaint was associated with a 15% greater likelihood that cognition-enhancing medications were prescribed (OR 1.148, 95% CI 1.027 - 1.283; Table 3).

Table . An analysis of the factors associated with the usage of medication before the diagnosis of dementia.

Features		OR[a] (95% CI)

Discussion

Principal Findings

We developed a high-performance deep learning–based NLP algorithm on an EHR dataset of dementia patients to delve into the real-world trajectory of dementia, starting from initial memory loss complaints to dementia diagnosis. Our investigation focused on the time interval from the first memory loss complaints to dementia diagnosis, the proportion of prescribed cognition-enhancing medication before diagnosis during this trajectory, and the clinical characteristics associated with these features.

We found that 20.4% (149/730) of patients had same-day documentation of memory loss complaints and dementia diagnosis. Among the remaining 79.5% (580/730) of patients with at least a 1-day gap between complaints and diagnosis, over half of the patients received a dementia diagnosis within a year of their initial memory loss complaints, with a median time of 342 days. The location of the first complaint and diagnosis and the relationship with the primary caregiver emerged as influential factors in achieving an earlier diagnosis. Notably, patients who initiated complaints or were diagnosed in geriatrics or neurology received earlier diagnoses compared to those in primary care. This underscores the important role of the initial complaint's location and the dementia diagnosis's setting in the early detection and management of dementia. Our findings align with previous research indicating missed and delayed diagnoses in primary care [49]. Geriatricians and neurologists possess significantly more expertise and practical experience in diagnosing dementia and prescribing these meds than most primary care doctors. To enhance early detection in primary care, it is crucial to train primary care providers to recognize the nuances of dementia symptoms and to appreciate the importance of thorough assessments during initial consultations. This approach could significantly reduce delays in diagnosis. Furthermore, improving caregiver education regarding the signs and symptoms of dementia is essential, as it can lead to earlier recognition of concerns and encourage timely visits to health care professionals. Additionally, understanding the factors that lead patients to receive care in a geriatric or neurological department rather than primary care would be an important question for further investigation. Similar to the previous study that identified dementia severity and marital status as independent predictors of receiving a clinical cognitive evaluation [50], other factors such as more complex medical needs (eg, multiple chronic conditions and polypharmacy), severe function decline, and the primary caregiver's educational level or relationship with the patient

could be associated with visits to geriatric or neurologic departments.

Remarkably, we found that patients with a wife or daughter as their primary caregiver were diagnosed earlier and more frequently used cognitive-improving medication before the dementia diagnosis. This emphasizes the vital role of primary caregivers in the diagnosis and treatment of dementia patients. Mahmoudi et al [35] previously emphasized the importance of extracting caregiver information in dementia patient notes and developed the rule-based NLP algorithm to identify caregiver availability. In our work, we extended this by also extracting family-caregiver relationships with patients and analyzing their impact on the early diagnosis of dementia. Subsequent research should explore the underlying mechanisms and factors of caregivers in this context such as the association between the relationship of primary caregivers and visits to geriatric or neurologic departments. Contrary to expectations, our study revealed that age and insurance were not associated with earlier diagnoses.

Surprisingly, the total number of memory loss complaints emerged as the sole factor significantly linked to medication usage, with other factors showing no significant association. The correlation between increased medication prescriptions and additional memory loss complaints highlights health care providers' responsiveness to escalating symptoms and underscores the importance of proactive monitoring of cognitive symptoms. This finding aligns with the Alzheimer's Association guidelines for early identification and treatment of Alzheimers disease, particularly in its initial stages. By recognizing and documenting memory loss complaints, clinicians can better initiate appropriate therapeutic interventions, particularly those aimed at altering disease progression. Additionally, our findings emphasize the need for enhanced caregiver education on the importance of reporting memory loss and other cognitive changes.

We demonstrated that extracting cognitive symptom-related terms from longitudinally documented patient notes before dementia diagnosis could be an alternative approach to analyzing documented cognitive measurement scores during patient visits, potentially aiding in identifying dementia patients. Previous studies have highlighted a significant lack of such documentation in clinical notes [37,41,51]. For instance, Harding et al [51] found that cognitive measurement scores were rarely available in their cohorts when establishing the algorithm for identifying dementia patients in EHR. Similarly, Maserejian et al [37] demonstrated a low percentage of dementia (11%) or Alzheimers disease (24%) in patients with cognitive measurement scores such as Mini Mental State Examination (MMSE), a recall test, a clock drawing, Montreal Cognitive Assessment (MoCA), Mini-Cog, or Saint Louis University Mental Status (SLUMS) documented and suggested prompts of cognitive measurement. McCoy et al [41] attempted to extract cognitive symptom-related terms (eg, impulsive, forgetful, cognitive, and memory) and converted them into scores, given the issue of reliability and scalability of the cognitive measurement test. Consistently, the proportion of patient notes with cognitive test names, including MMSE, SLUMS, MoCA, Mini-Cog, clock drawing, trail making, Boston naming test, and Wisconsin card sorting test, was very low in our study, so these were not used in further analysis.

Our NLP approach in automatically identifying cognitive symptom-related terms and primary caregivers, and systematically analyzing these factors along with other structured data, enhanced our understanding of dementia progression and management. This approach provides a practical and scalable method for identifying cognitive impairment, especially when traditional cognitive measurement scores are lacking. Further exploration using this NLP method could significantly advance the field, providing deeper insights and more effective interventions for dementia care. Moreover, our study findings align with the Alzheimer's Association's recommendations for using simple practical tests like Mini-Cog or General Practitioner Assessment of Cognition (GPCOG), developed by a group of clinical dementia experts, during annual visits, particularly when symptoms are reported by patients or caregivers, thereby supporting current clinical practice in dementia care.

Strengths and Limitations

Our study has several strengths. First, our work presents a novel approach to understanding clinical practices in dementia by examining the time interval from the symptom complaints to the diagnosis of dementia using real-world data. Second, our study highlights how the relationship between primary caregivers and patients and the location (medical units: geriatrics, neurology, and primary care) of complaints made may influence the time to diagnosis. While existing ontologies provide comprehensive medical concepts, they often lack the specificity necessary to accurately capture the relationships between concepts. By defining the relationships between entities such as "has date" and "has caregiver information" in the ontology, our study could provide deeper insights into the clinical features that affect the time interval from the symptom presentation to dementia diagnosis in real-world contexts. Third, our study developed and validated a customized NLP model to be used to predict an outcome in a clinical setting using EHRs.

Several limitations of this study should be considered. First, the study relied on EHR data from a single health care system, which may limit the generalizability of the findings to other populations and health care settings. This system-specific reliance may introduce potential biases related to local clinical practices, documentation standards, and patient demographics, which could affect the study's findings if applied to broader or more diverse health care environments. Additionally, the patient population in our dataset was predominantly White, female, and older patients above 85 years with Medicare or Medicaid insurance, which may further limit the generalizability of the findings to other demographic groups, including younger patients, males, and individuals from diverse racial backgrounds. Future studies should aim to include a more diverse patient population in terms of age, race, and insurance type across multiple health care systems to validate and potentially broaden the applicability of the findings.

Another limitation is the potential for loss of follow-up within the EHR data, as patients with less frequent or inconsistent visits may have different clinical trajectories. We preselected patients

who had been diagnosed with dementia, had at least one documented memory loss complaint before diagnosis, and visited the health care system at least once per year to reduce the likelihood of significant follow-up loss. Nonetheless, variability in follow-up could still influence our results. Furthermore, potential biases within EHR documentation may impact the findings. For example, memory complaints may be underreported or inconsistently documented, depending on clinician practices and the completeness of note-taking. This variability could affect the accuracy of data extraction and the insights derived from the patient journey. Lastly, the study did not account for the potential impact of other medical conditions on the result. Incorporating objective measures of cognitive decline and other co-occurring neuropsychiatric symptoms could enhance the assessment of dementia.

Conclusions

Our study highlights the importance of the location of initial memory loss complaints, the location of the dementia diagnosis, and the role of the primary caregiver in the early diagnosis and treatment of dementia patients. By analyzing complex clinical dementia care practice patterns within a real-world setting on a large scale using NLP, our exploratory analysis demonstrates the potential of advanced analytical techniques in achieving earlier and more accurate diagnoses of dementia.

Abstract

Background: Urinary and defecatory dysfunction (UDD) is a significant concern among the aging population in China. However, there is a lack of longitudinal research exploring the risk factors of UDD severity in Chinese older adults.

Objective: This study uses data from the China Health and Retirement Longitudinal Study spanning 2011 to 2020 to explore UDD risk factors in the middle-aged and older adult Chinese population, focusing on epidemiological characteristics and potential influences on severity.

Methods: A longitudinal cohort of over 10,000 participants from the China Health and Retirement Longitudinal Study was analyzed across 5 waves using Bayesian logistic regression. This analysis examined associations between UDD severity and factors including demographic, lifestyle, and health-related factors, including comorbidities, BMI, and handgrip strength.

Results: Higher UDD prevalence was observed among female population, older adults, those with low education levels, and rural residents. Depression, arthritis, and low handgrip strength emerged as critical predictors of severe UDD. Additionally, abnormal BMI, both underweight (odds ratio [OR] 3.019, 95% CI 1.484 - 5.951; *P*=0.002) and obesity (OR 2.697, 95% CI 1.338 - 5.217; *P*=0.005), was strongly linked to increased severity and persistence of UDD. Participants aged 66 years and older exhibited the highest UDD prevalence, with both underweight and obese individuals facing the greatest risk of persistent and worsening symptoms.

Conclusions: This study is the first to longitudinally examine the risk factors of UDD severity in China's middle-aging and aging population. The findings underscore the need for targeted interventions focusing on muscle strength rehabilitation and comorbidity management to mitigate UDD progression, contributing to improved quality of life for older individuals.

KEYWORDS

China; characteristic; risk factors; urination and defecatory dysfunction; longitudinal cohort study

Introduction

Population aging has become a public health issue, imposing a major global challenge across countries in recent decades [1]. The population aged 60 years and older in China is projected to exceed 300 million by 2025, accounting for more than 20% of the total population [2]. Due to the decline in muscle function and disorders of the nervous system among older people, particularly hormonal changes in female population that lead to muscle changes, and urethral sphincter atrophy in male population, millions experience urinary and defecatory dysfunction (UDD) [3-7].

The World Health Organization's integrated care for older people model emphasizes the significance of UDD, particularly urinary incontinence, highlighting its impact on health systems worldwide. Additionally, the care burden associated with urinary retention, fecal incontinence, and constipation is substantial, underscoring the need for comprehensive strategies to address

these pervasive health issues [8]. UDD is defined as a disorder that affects the storage or elimination of urine and feces [9]. Recent studies on UDD reveal varying prevalence rates. Research shows 37.1% global prevalence for female urinary incontinence [10], 18.9% for constipation in older adults [11], and 8% for fecal incontinence [12]. However, these studies, mainly from China, are limited by small, regional samples and a lack of comprehensive data on influencing factors, highlighting the need for broader research to fully understand UDD's impact. This common disorder can have a negative impact on the quality of life of patients and exacerbate their economic burden, particularly in long-term or severe cases [13-16].

Numerous studies have demonstrated that UDD may be associated with chronic conditions (such as hypertension, diabetes, stroke, depression, and so on), abnormal BMI (overweight, obesity, or underweight), handgrip strength, and unhealthy lifestyle factors such as smoking and drinking [10,17-22]. Due to limitations in existing cross-sectional studies, which cannot confirm causal relationships, we established a cohort of over 10,000 participants, with an innovative focus on UDD severity, to study the factors influencing its severity.

The study aimed to use data from a 5-wave survey conducted by the China Health and Retirement Longitudinal Study (CHARLS) [23] to (1) describe the characteristics of UDD from 2011 to 2020 and (2) to identify the risk factors impacting the severity of UDD in China.

Methods

Study Design and Participants

The CHARLS, a nationally representative survey targeting individuals aged 45 years and older from 450 villages or communities in 28 provinces and 150 counties or districts across Mainland China, was conducted by the National School of Development at Peking University from 2011 to 2020 [23]. A total of 150 counties were randomly selected, with stratification by region and urban or rural classification. Administrative villages and neighborhoods were designated as primary sampling units. Households with at least 1 member aged 45 years or older were selected, and 1 individual, along with their spouse, was interviewed. The CHARLS database encompasses a broad array of variables related to demographic statistics, socioeconomic conditions, and health status. Participants in CHARLS are interviewed face-to-face every 2 years using a computer-assisted personal interview technique.

To map the characteristics and temporal trends in UDD prevalence, all participants with UDD were identified in each wave of the cross-sectional survey from 2011 to 2020. For identification of risk factors, participants with UDD who enrolled in 2011 and were continuously followed up in the subsequent 4 cross-sectional surveys were included. Detailed information about the sampling design used in the survey has been described in earlier publications [24].

Ethical Considerations

The CHARLS was approved by the Biomedical Ethics Review Committee of Peking University (IRB0000105211015) [23]. All participants provided signed informed consent forms and received modest financial compensation. Data were anonymized before release and are only available to approved researchers.

Data Collection

In each county or district, trained staff collected data at participants' homes and local community health centers as well as County Centers for Disease Prevention and Control in accordance with the reported protocol [23]. Deidentified information was collected for analysis, consisting of data on participants' demographic characteristics, health-related behaviors and outcomes, childhood conditions, community environment, cognitive and physical health, current economic status, social and family support, health insurance, health care use, comorbidities (chronic diseases such as hypertension and diabetes), and their urinary and defecation control abilities.

Referring to the World Health Organization standard, participants were divided into the following age groups: 45 - 59 years (middle-aged), 60 - 74 years (young-old), 75 - 89 years (old), and ≥90 years (very old) [25]. Residences of participants included rural and urban areas. Education levels were categorized as illiterate, primary school graduate, secondary school graduate, and college graduate or above. Regions of China were classified as Southwest, Southern, Eastern, Northwest, Northern, and Northeast.

The CHARLS did not include data from Ningxia Hui Autonomous Region, Xizang Autonomous Region, Hainan province, Hong Kong, Macau, and Taiwan province. Additionally, the 2020 follow-up survey in the CHARLS did not include participants from the Xinjiang Uygur Autonomous Region due to the impact of the COVID-19 pandemic.

Case Identification and Study Outcomes

According to the International Classification of Functioning, Disability, and Health, urinary function refers to the ability to discharge urine from the bladder, while bowel function refers to the ability to expel waste materials and undigested food in the form of feces, along with the associated physiological processes [26]. Therefore, impairment in either of these functions is classified as UDD. Based on participants' responses to the question "Do you have any difficulties with controlling urination and defecation?" in CHARLS, all participants reporting "I have difficulty" or "I cannot do it" were identified as having UDD.

The second aim of the study was to explore the risk factors for UDD. To this end, participants with UDD were divided into the 4 subgroups based on clinical expert experience and the actual disease status of the participants, each comprising, individuals with increasingly severe UDD, from group A to group D, in order, as follows:

- Group A: Participants who had never experienced UDD.
- Group B: Participants who identified as having UDD in 1 or 2 consecutive surveys, without recurrence in the later follow-ups.
- Group C: Participants who reported having experienced UDD in 1 or 2 consecutive surveys and had recovered at the time of the subsequent 1 or 2 follow-ups but eventually experienced recurrence.

- Group D: Participants who identified as having UDD in consecutive 3 or more surveys.

Statistical Analysis

To achieve the first study aim, a descriptive analysis was conducted to examine the characteristic of prevalence of UDD by sex, residence, marital status, age group, education level, and geographic region over 5 waves from 2011 to 2020. The calculation of the prevalence rate is the cumulative number of cases divided by the total number of participants followed up per year.

To achieve the second study aim, a chi-square test was initially performed to identify potential risk factors among the 4 groups. These factors were then further examined through Bayesian logistic regression analysis. Prior to regression analysis, chi-square tests were conducted to assess univariate associations. A weakly informative prior was used to ensure robust parameter estimation. Parameter estimation was conducted using Markov Chain Monte Carlo sampling, and model results are presented as odds ratios (ORs) with 95% CIs. To enhance interpretability, exponentiation was applied to the estimated coefficients, and 2-sided *P* values were calculated. R (version 64 4.4.3; R Foundation for Statistical Computing) was used for descriptive analysis and logistic regression. *P* values were 2-sided with a significance level of .05.

Results

Characteristics of Study Participants in the 5 Waves

The participants in the 5 waves comprised 17,156, 17,897, 17,715, 19,097, and 19,129 individuals, respectively. Although there were no significant differences between sexes, significant differences were found among age groups, places of residence, education levels, marital status, and regions across the 5 waves. Figure 1 shows the screening process of this study. Table 1 presents the characteristics of patients with UDD across various groups.

Figure 1. Flowchart of participant inclusion or exclusion and grouping diagram. UDD: urinary and defecatory dysfunction.

[a]Without formal education, did not finish primary school, was homeschooled.

[b]With primary school education.

[c]With middle school or high school education.

[d]With college education and above.

[e]Married with spouse present or married but not living with spouse temporarily for reasons such as work.

[f]Separated, divorced, widowed, or never married.

Trends and Distributions of UDD Prevalence From 2011 to 2020

The prevalence of UDD from 2011 to 2020 was 4.39% (n=753), 4.03% (n=721), 4.69% (n=830), 4.72% (n=902), and 5.02% (n=960), respectively. Figure 2 demonstrates that the prevalence of UDD by sex and residence rose slowly over the 10 years, with female participants or participants living in rural areas having higher prevalence than their counterparts. The prevalence of UDD by education level and marital status remained essentially stable across the decade in China, although illiterate or married participants had higher prevalence than other categories.

Figure 2. Temporal trends of prevalence of urinary and defecatory dysfunction by sex, education level, marital status, and residence among middle-aged and older people in China from 2011 to 2020.

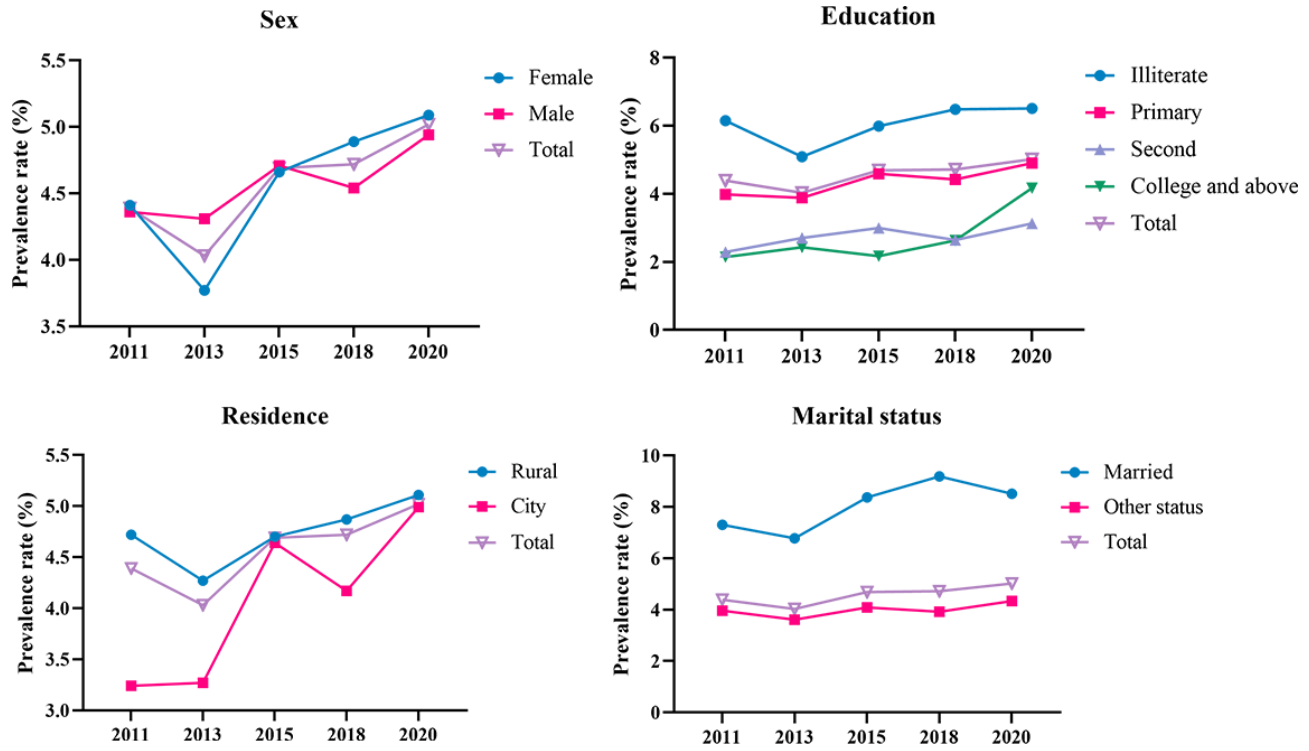

Figure 3 illustrates that the prevalence of UDD gradually increased with age over the decade, particularly among those aged 66 years and older who had a higher prevalence than the overall prevalence. The prevalence of the 4 groups aged 66 years and older slightly increased, while the corresponding figures for the 4 younger groups younger than 65 years were almost stable during the 10 years of surveys.

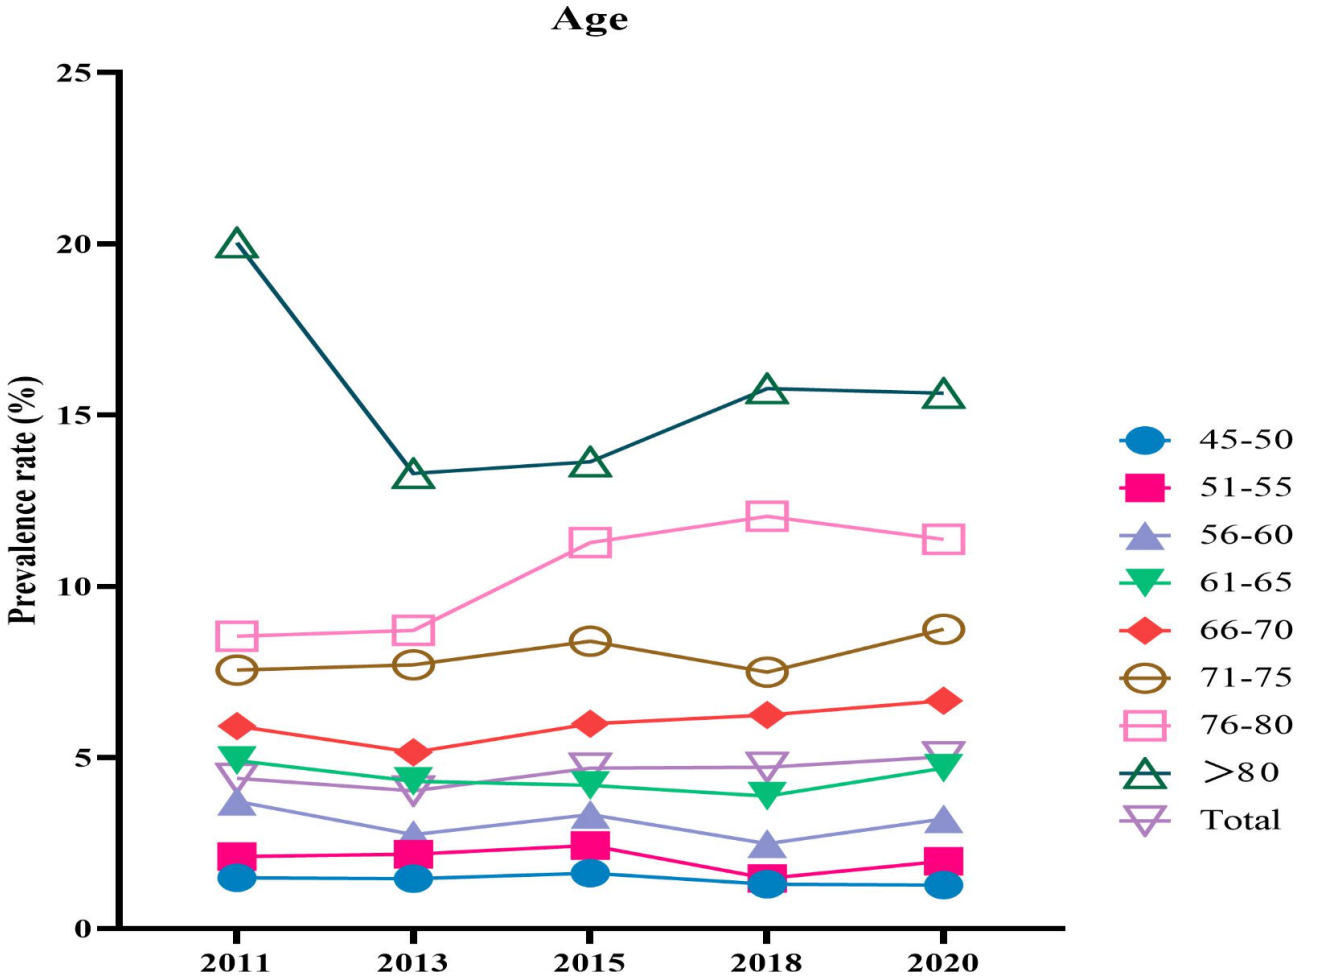
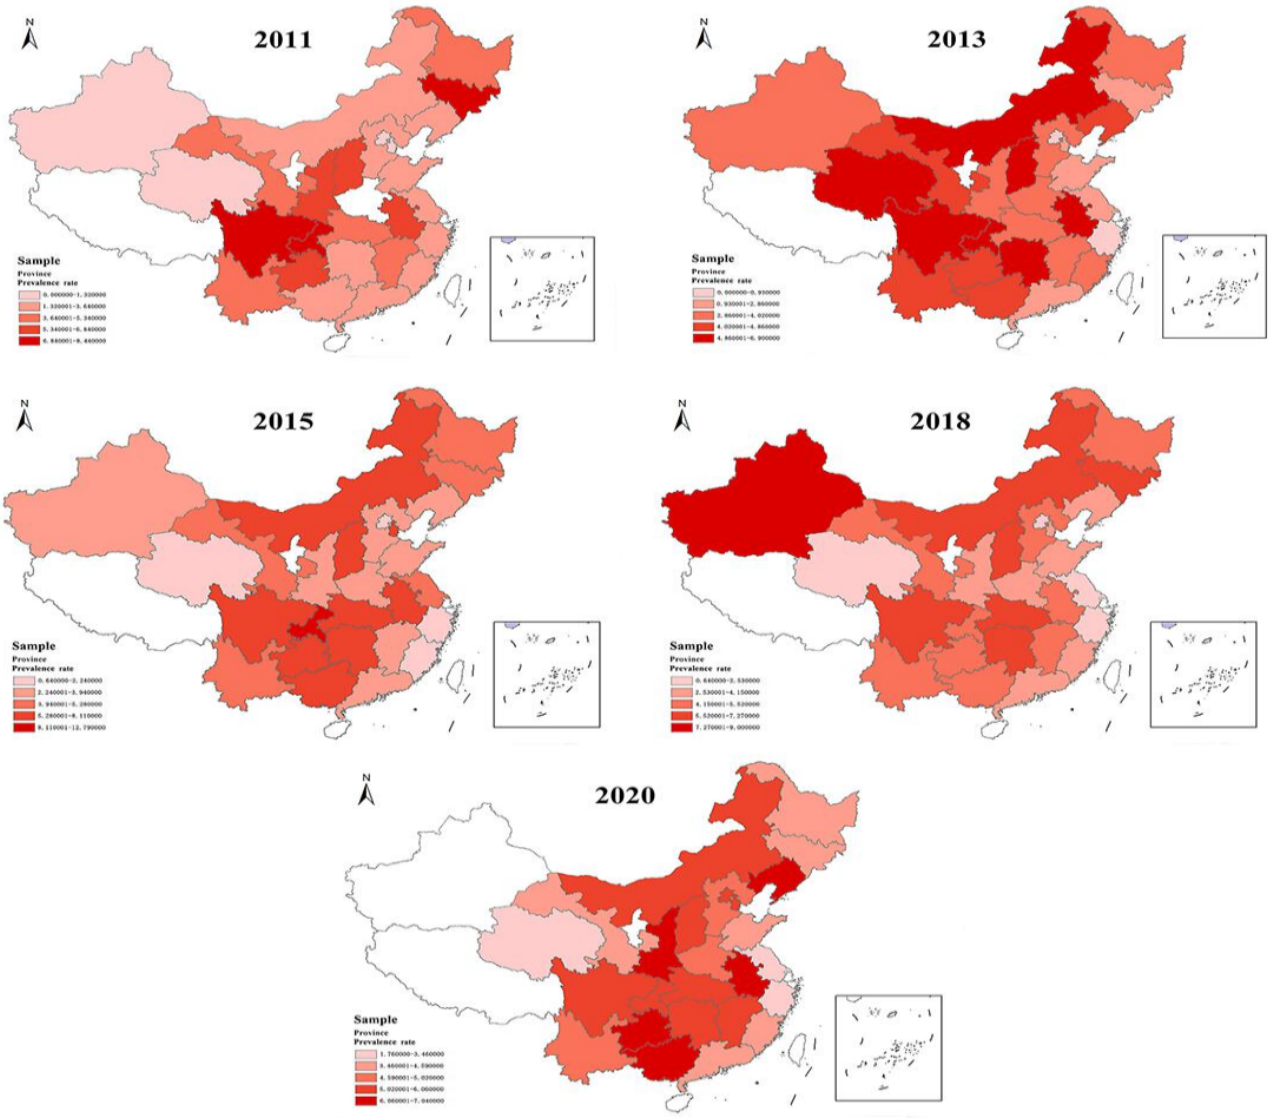
Figure 3. Temporal trends of age-specific prevalence (in years) of urinary and defecatory dysfunction among middle-aged and older people in China from 2011 to 2020.



The prevalence of UDD varied significantly across different regions over the years, being consistently higher in the Southwest region than in other regions. Both the Southwest and Northwest regions saw an increasing prevalence of UDD in the past 10 years (Figure 4).

Figure 4. Regional distribution of urinary and defecatory dysfunction prevalence among middle-aged and older people in China from 2011 to 2020 (because of the impact of the pandemic, information from Xinjiang participants in 2020 was not included in the China Health and Retirement Longitudinal Study database).



Identification of Risk Factors for Different UDD Conditions in a Cohort Study

There were 10,572 participants enrolled in the cohort study; among them, 8966 participants had never experienced UDD over the 10-year period, while 1275 had recovered, 245 reported recurrence, and 86 reported persistence at the last follow-up. There were significant differences for factors other than sex (P=.19), cancer (P=.12), and smoking (P=.39). Among all groups with various severity of UDD, the proportion of female participants was slightly higher than that of male participants. Higher proportions of participants were aged 60 - 75 years, illiterate, married, living in rural areas, living in the Southwest and East regions, with normal BMI, nonsmokers, and nondrinkers. The comorbidities of participants with UDD are shown in Table 2.

Table . Univariable analysis of 4 groups of urinary and defecatory dysfunction (UDD).

	Without UDD[a] (group A; n=8966), n (%)	Recovered from UDD[b] (group B; n=1275), n (%)	Reported recurrent[c] UDD (group C; n=245), n (%)	Reported persistent UDD[d] (group D; n=86), n (%)	*P* value[e]

[a]Participants who had never experienced UDD.

[b]Participants who identified as having UDD in 1 or 2 consecutive surveys without recurrence in the later follow-ups.

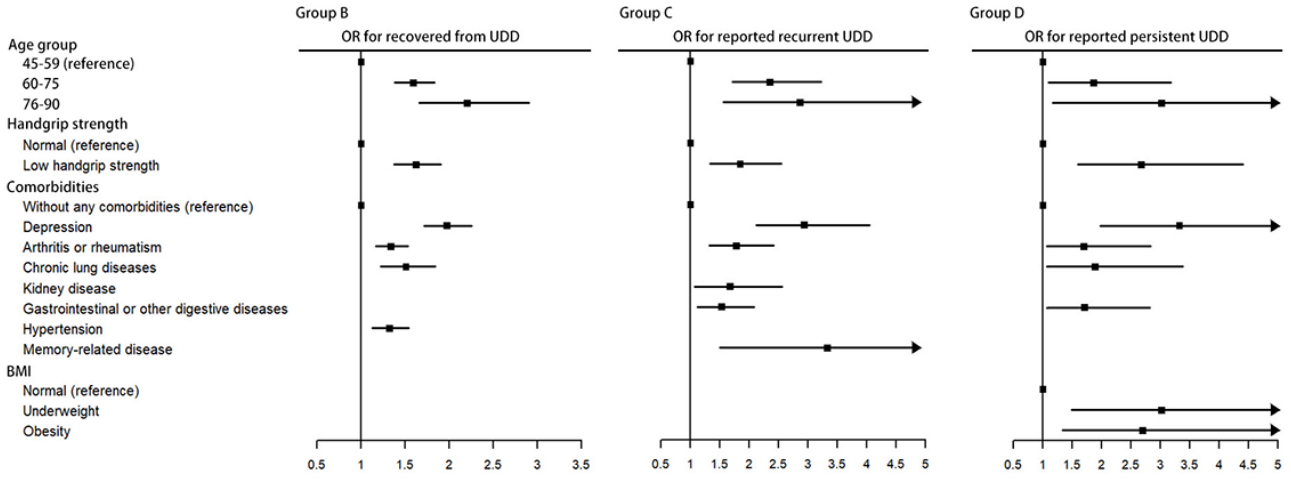
[c]Participants who reported experiencing UDD in 1 or 2 consecutive surveys and having recovered in the subsequent 1 or 2 follow-ups but eventually experienced recurrence.

[d]Participants who identified as having UDD in 3 or more consecutive surveys.

[e]Missing data: 436 for BMI, 7 for smoking, 10 for drinking, 53 for hypertension, 30 for dyslipidemia, 14 for diabetes, 27 for chronic lung disease, 4 for liver disease, 13 for heart problem, 36 for stroke, 5 for kidney disease, 37 for digestive disease, 42 for memory-related disease, 29 for arthritis or rheumatism, 52 for asthma, and 593 for handgrip strength.

Figure 5 shows the ORs and 95% CIs of the risk factors for UDD in patients with different conditions. Four common risk factors were identified across the 3 groups, namely, older age (60 - 89 years), depression, arthritis (or rheumatism), and handgrip strength. For group C and group D, who had more severe UDD than group B, participants with gastrointestinal diseases had a higher risk of experiencing recurrent or persistent UDD. Memory-related diseases (OR 3.328, 95% CI 1.505 - 6.836; *P*=.002) may cause UDD to recur. Additionally, underweight (OR 3.019, 95% CI 1.484 - 5.951; *P*=.002) and obesity (OR 2.697, 95% CI 1.338 - 5.217; *P*=.005) were identified as potential independent risk factors for the persistent nature of UDD among middle-aged and older people in China. The detailed results of the Bayesian logistic regression model are provided in Multimedia Appendix 1.

Figure 5. OR and 95% CI of risk factors for UDD in different population groups with UDD. Forest plots show ORs and 95% CIs for group (B) recovered from UDD, (C) reported UDD recurrence, and (D) UDD persisted adjusted for sex, age, education, marital status, residence, region, BMI, handgrip strength, smoking status, drinking status, and comorbidities. In the forest plot, only the significant results within each group (*P*<.05) are shown. The reference group for groups B, C, and D consists of participants who had never experienced UDD. OR: odds ratio; UDD: urinary and defecatory dysfunction.



Discussion

Principal Findings

This is the first study to use a representative sample to describe the temporal, spatial, and interpersonal distributions of UDD among middle-aged and older people in China. The study identified that over the past decade, the prevalence of UDD has remained stable across different education levels, kinds of marital status, and age groups. However, it significantly increased among both sexes, urban residents, and in the Northwest and Southwest regions. Participants who were female, illiterate, or married and those aged 66 years and older exhibited a higher prevalence of UDD. The incidence, recurrence, and persistence of UDD were more likely to be influenced by aging and comorbidities such as depression, arthritis (or rheumatic diseases), and handgrip strength in China. More importantly, being underweight or obese might contribute to the long-term persistence of UDD.

The Prevalence and Time Trends of UDD

Due to its increased prevalence, the disease burden associated with UDD has shown a gradually escalating trend in China over the past 10 years. However, despite a slight increase, the prevalence of UDD in China (5.02% in 2020) has remained lower than the global prevalence, which ranges from 7% to 55%. This lower prevalence might be attributed to lower self-report due to participants' potential embarrassment or their belief that UDD is a natural aging-related phenomenon among the Chinese population [10,21,27,28]. Approximately, 50% to 67% of patients were unwilling to report their UDD conditions to health care providers [29,30]. The slowly increasing trend in prevalence observed in this study may reflect improved awareness and diagnosis of UDD over time, leading to more UDD cases being identified.

Over the past decade, the prevalence of UDD in female individuals has consistently remained higher than that in male individuals. This finding underscores the necessity of addressing the unique physiological and reproductive health challenges that female individuals face, as the relaxation of pelvic floor muscles during childbirth significantly contributes to this increased prevalence [31]. This suggests that we should place greater emphasis on female individual's pelvic health. By implementing early interventions and training, such as pelvic floor muscle exercises, we can significantly improve the quality of life for female individuals in their later years [32].

It was notable that the Northwest and Southwest provinces—2 resource-limited regions in China—experienced an obviously higher prevalence of UDD during the 5-wave survey. The evidence aligned with other studies demonstrating that economic status may influence the prevalence of UDD, while UDD places a significant economic burden on patients too [14,15,33]. The higher prevalence of UDD among participants from resource-limited areas may be related to the insufficient health insurance or poor access to medical services, such as postpartum pelvic floor rehabilitation [34,35]. Therefore, economic development may serve as a solution to improve the quality of life of patients with UDD in these regions along with enhancing the accessibility of medical resources.

Given the impact of UDD, it is necessary to establish a surveillance system for UDD to provide more evidence for the identification of the long-term impact of UDD and the development of prevention and treatment strategies at the population level.

Population Aging, Comorbidities, and Low Handgrip Strength May Lead to All Severity of UDD Among the Chinese Population as Marked Risk Factors

Population aging is an important risk factor influencing the occurrence, recurrence, and persistence of UDD. This study suggests that the physiological senescence associated with aging may contribute to the development and exacerbation of UDD, particularly among participants aged 66-90 years. It is widely recognized that aging can lead to the occurrence or aggravation of UDD, likely due to the frailty and functional impairment associated with aging [13,36-39]. However, the potential mechanism underlying the association between frailty and UDD remains unknown. Finite element models can make it possible to explore the mechanism underpinning the relationship between frailty and UDD [40]. By comparing defecation outcomes under different parameter settings, the association between training methods and urinary and fecal control ability can be quantified, providing accurate guidance for rehabilitation.

This study demonstrated that comorbidities are the second important risk factor for UDD. For instance, depression was found to significantly impact the incidence, recurrence, and persistence of UDD, as it was usually associated with reduced serotonin function, which leads to urgency urinary incontinence [41]. Some studies argue that the medicines patients take potentially result in gastrointestinal side effects such as constipation [42]. In addition, participants with urinary and fecal incontinence and constipation exhibit significantly higher levels of depression and stress [43-49], possibly due to the production of certain gut microbiota that lead to depressive symptoms and lower levels of *g_Pseudoramibacter-Eubacterium* and *g_Candidatus-Solibacter*. [50] Functional constipation in middle-aged and older individuals may lead to a decrease in the abundance of these microbiota [51], ultimately exacerbating depression. This interaction creates a vicious cycle between depression and UDD.

In addition to depression, arthritis or rheumatism likely also contributes to the increased risk of incidence, recurrence, and persistence of UDD, although its impact on UDD might have been underestimated over the past 20 years. The most recent studies on the association between arthritis and UDD were conducted in the 1990s. These studies implied that arthritis may increase susceptibility to urinary tract infections, and atlantoaxial subluxation in the late stage of arthritis may lead to neurogenic bladder [52], which in turn increases the incidence of UDD. Medications such as misoprostol and cyclophosphamide, used to treat arthritis, may also cause UDD [52,53]. Moreover, opioids, commonly taken by patients with arthritis and rheumatic diseases, are likely to cause constipation. Additionally, the limited mobility of patients with osteoarthritis is perhaps associated with urinary incontinence [54,55].

Other comorbidities, such as hypertension and memory-related diseases, were also identified as potential contributors to the occurrence or recurrence of UDD. For instance, studies indicate a correlation between hypertension and constipation, potentially linked by shared physiological mechanisms and lifestyle factors [56]. Patients with Alzheimer disease often lose the ability to send bladder signals to the brain's urination center, resulting in an inability to urinate normally [57,58].

This study, therefore, suggested potential causal relationships between comorbidities and UDD, indicating that health care providers should pay more attention to the prevention and treatment of these comorbidities. Optimizing pharmaceutical therapy may effectively alleviate the incidence and progression of UDD in middle-aged and older individuals. Additionally, increasing physical therapy or dietary and nutritional treatments for mental health, arthritis or rheumatic diseases, and other chronic conditions could be beneficial. Dissemination of knowledge about these chronic diseases to enhance public awareness at the community level might help address the occurrence, recurrence, and persistence of UDD.

Our study also reveals a significant correlation between grip strength and the severity of UDD. Specifically, individuals with reduced grip strength exhibited a higher incidence of severe UDD manifestations, including recurrent and persistent conditions. This relationship may suggest that grip strength serves as an indirect biomarker for overall muscle integrity and functional capacity, which could influence the severity of UDD symptoms [59,60]. These results align with existing literature emphasizing the importance of muscle function in maintaining urogenital health and also underscore the need for further research into preventive strategies focusing on strength training in vulnerable populations.

Being Underweight or Obese Can Lead to Long-Term Persistence of UDD

This study found that almost half of the older Chinese population in the cohort had abnormal weight, with underweight or obesity considered independent risk factors for persistent UDD. This finding aligned with evidence from other studies showing that obesity is closely related to the occurrence of UDD [10,61-63]. The mechanism underlying this association is that metabolic changes and increased abdominal pressure caused by obesity may lead to the development of UDD. Additionally, underweight older adults might experience reduced muscle strength, particularly in the pelvic floor, possibly triggering the incidence of UDD. Some studies argue that population aging–related muscle atrophy and decreased strength are more likely to cause persistence of UDD [64,65], particularly among those who are underweight. Consequently, the improvement of nutritional intake is vital for older people in both communities and health care facilities. The awareness of healthy diet and appropriate physical exercises be enhanced among the older population, and health care providers and community health workers should develop individual tailored interventions for patients with UDD who are underweight or obese.

Strengths and Limitations

The study population was selected from 28 provinces in China, ensuring sufficient representativeness to reflect the characteristics and risk factors of UDD in the middle-aged and older Chinese populations. To achieve the second study objective, a cohort study was designed to establish clear causal relationships between the identified risk factors and the incidence, progression, and persistence of UDD in the Chinese population. Additionally, the population with UDD was classified based on the severity of UDD, facilitating the exploration of risk factors and the development of personalized interventions.

There are some limitations to this study. The CHARLS does not provide detailed information on urinary and fecal incontinence or constipation, making it difficult to distinguish risk factors for diverse UDD conditions. The CHARLS also lacks information on factors that may affect UDD, such as bladder outlet obstruction, urinary tract infections, benign prostatic hyperplasia, use of analgesics, and history of abuse, and factors such as hospital capacity, network scale, and accessibility of medical services over the past decade could not be analyzed due to the same limitations. Additionally, due to the statistical methods used in the CHARLS database, the impact of incontinence related to childbirth in female population may have been underestimated. Consequently, this study could not assess the impact of these factors on UDD. Furthermore, those who had UDD in both 2018 and 2020 could not have their UDD prognosis determined after the CHARLS survey: they may have recovered and not be included in the most-severe group, which may have resulted in misclassification bias. In addition, the emergence of recovered participants may also be related to respondents' misjudgment of their own UDD conditions. In the Results section, middle school and high school education emerged as a protective factor for the recovered population, though the underlying reasons require further investigation.

Conclusions

In summary, the prevalence of UDD increased with age and was found to be higher among illiterate individuals, married people, and those living in the Southwest and Northwest regions. Depression, arthritis and rheumatic diseases, and other chronic comorbidities contributed to the occurrence, recurrence, and persistence of UDD; further, being underweight or obese independently affected the persistence of UDD among the middle-aged and older Chinese population. Enhancing the treatment of psychological and chronic diseases and improving BMI may alleviate the occurrence, recurrence, and persistence of UDD.

Acknowledgments

This work was supported by the National Key R&D Program of China under the project "Development of Enhanced Training and Nursing Care Robot Systems for Bedridden Elderly with Urinary and Defecatory Dysfunction" (2022YFB4703300). The

authors would like to thank Fan Xuanxuan as well as Xu Ruoyu, Yang Muqi, and Yuan Qi from the School of Nursing, Capital Medical University, for their assistance in data processing and analysis (listed in no particular order).

Data Availability

The data used in this study are publicly available from the China Health and Retirement Longitudinal Study.

Authors' Contributions

HZ designed the study and drafted the manuscript. LJ supervised the study and approved the final version. J Zhang interpreted the data and reviewed the manuscript. GL and XL helped analyze the data. JK contributed to the conceptual framework and provided resources. LG administered the project and funding. RW contributed to methodological expertise and data curation. J Zhao and CZ validated the results. All authors reviewed and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: A composite outcome of hospital-associated complications of older people (HAC-OP; comprising functional decline, delirium, incontinence, falls, and pressure injuries) has been proposed as an outcome measure reflecting quality of acute hospital care. Estimating HAC-OP from routinely collected administrative data could facilitate the rapid and standardized evaluation of interventions in the clinical setting, thereby supporting the development, improvement, and wider implementation of effective interventions.

Objective: This study aimed to create a Diagnosis Procedure Combination (DPC) data version of the HAC-OP measure (HAC-OP-DPC) and demonstrate its predictive validity by assessing its associations with hospital length of stay (LOS) and discharge destination.

Methods: This retrospective cohort study acquired DPC data (routinely collected administrative data) from a general acute care hospital in Tokyo, Japan. We included data from index hospitalizations for patients aged ≥65 years hospitalized for ≥3 days and discharged between July 2016 and March 2021. HAC-OP-DPC were identified using diagnostic codes for functional decline, incontinence, delirium, pressure injury, and falls occurring during the index hospitalization. Generalized linear regression models were used to examine the associations between HAC-OP-DPC and LOS, and logistic regression models were used to examine the associations between HAC-OP-DPC and discharge to other hospitals and long-term care facilities (LTCFs).

Results: Among 15,278 patients, 3610 (23.6%) patients had coding evidence of one or more HAC-OP-DPC (1: 18.8% and ≥2: 4.8%). Using "no HAC-OP-DPC" as the reference category, the analysis showed a significant and graded association with longer LOS (adjusted risk ratio for patients with one HAC-OP-DPC 1.29, 95% CI 1.25-1.33; adjusted risk ratio for ≥2 HAC-OP-DPC 1.97, 95% CI 1.87-2.08), discharge to another hospital (adjusted odds ratio [AOR] for one HAC-OP-DPC 2.36, 95% CI 2.10-2.65; AOR for ≥2 HAC-OP-DPC 6.96, 95% CI 5.81-8.35), and discharge to LTCFs (AOR for one HAC-OP-DPC 1.35, 95% CI

1.09-1.67; AOR for ≥2 HAC-OP-DPC 1.68, 95% CI 1.18-2.39). Each individual HAC-OP was also significantly associated with longer LOS and discharge to another hospital, but only delirium was associated with discharge to LTCF.

Conclusions: This study demonstrated the predictive validity of the HAC-OP-DPC measure for longer LOS and discharge to other hospitals and LTCFs. To attain a more robust understanding of these relationships, additional studies are needed to verify our findings in other hospitals and regions. The clinical implementation of HAC-OP-DPC, which is identified using routinely collected administrative data, could support the evaluation of integrated interventions aimed at optimizing inpatient care for older adults.

Introduction

Hospitalization can impose a heavy physical and psychological burden on older adults, leading to in-hospital complications such as functional decline (the loss of independence in activities of daily living) and delirium [1]. A recent meta-analysis reported that the prevalence of functional decline following acute hospitalization was 30% in older adults aged ≥65 years [2]. Such functional decline is associated with various adverse outcomes, including prolonged hospital length of stay (LOS) and increased risks of hospital readmission and mortality within 30 days after discharge [3,4]. Similarly, delirium is estimated to affect around one quarter of older hospitalized adults [5-7], and is associated with longer stays, higher mortality, and higher health care costs [8,9].

Previous studies have developed and demonstrated the effectiveness of interventions to prevent such complications in hospitalized older adults [10,11]. While these interventions have generally focused on single complications as outcomes, they may also be effective in preventing other complications (eg, delirium prevention programs can also reduce falls) [1,12-16]. This is because in-hospital complications common in older people (often termed “geriatric syndromes”) tend to have overlapping risk factors that can be collectively targeted by complex and multifaceted interventions [1,12-16]. Mudge et al [1] proposed a multicomponent measure of “hospital-associated complications of older people” (HAC-OP) comprising common complications (functional decline, hospital-associated incontinence, hospital-associated delirium, pressure injury, or fall) among older adults admitted to acute care hospitals. In a prospective study using regular structured patient assessments as well as document review, the authors demonstrated a significant graded association between the HAC-OP measure and hospital LOS, facility discharge, and mortality within 6 months after admission. However, collecting this research measure was resource-intensive [1,17], which makes it difficult to replicate in routine practice. Routinely collected administrative data have been examined to assist clinicians, patients, and policy makers in making informed decisions [18,19]. Estimating HAC-OP from routinely collected administrative data could facilitate the rapid and standardized evaluation of interventions in the clinical setting, thereby supporting the development, improvement, and wider implementation of effective interventions.

In Japan, the majority of acute care hospitals use the Diagnosis Procedure Combination (DPC) case-mix patient classification system, which is linked to a lump-sum payment system for inpatients [20]. DPC-compliant hospitals must generate and submit DPC data to the government. These data include administrative claims and discharge abstracts containing patient-level information on diagnoses (recorded using *ICD-10* [*International Statistical Classification of Diseases, Tenth Revision*] codes), treatments, and prescribed drugs. Unlike many other countries, the required data also include activities of daily living (ADL) assessment scores at admission and discharge [20]. Prior studies have used DPC data to assess ADL scores in patients to examine the effects of rehabilitation services and to identify patients at high risk of early readmission in acute care settings [21,22]. Hospital outcomes, such as LOS and readmission within 28 days after discharge from hospital, are published annually for each DPC hospital [23]. However, in-hospital complications are not currently reported or benchmarked as they are in some other countries [24,25]. The systematic and accurate identification of HAC-OP from DPC data would support the evaluation of inpatient care and interventions that target these complications in Japan’s acute care hospitals.

Although the validity of chronic disease diagnoses in DPC data has been reported to be generally high [26], no study has tested the validity of in-hospital complications in DPC data, and complications are often underestimated in administrative datasets [27]. Understanding the current reporting of in-hospital complications and the association with important outcomes such as LOS and discharge destination could inform their use as an efficient and standardized evaluation of system-level interventions. Therefore, this study was conducted to develop a DPC data version of the HAC-OP measure (HAC-OP-DPC), describe the incidence of HAC-OP-DPC in a cohort of older acute care inpatients, and evaluate the predictive validity of this composite measure and its components by assessing associations with LOS and discharge destination.

Methods

Study Design and Patients

This retrospective cohort study was conducted using an anonymized DPC database obtained from a large general public acute care hospital (550 beds: 520 beds on general wards and 30 beds on psychiatric wards) in Tokyo, Japan. The DPC data comprised patient-level demographic characteristics, *ICD-10* codes, treatments, and prescribed drugs during all insurance-covered clinical encounters. The study used data from July 2016 to March 2021.

Patients who had been admitted to the study hospital from home or a long-term care facility (LTCF) and discharged during the study period were eligible for inclusion; the first hospitalization episode during the study period was designated the index hospitalization and included in the analysis. We excluded patients aged <65 years, patients discharged within 2 days of admission, patients who died during the index hospitalization, and patients with missing data in the study variables.

Ethical Considerations

The study protocol was approved by the Ethics Committee of the Tokyo Metropolitan Geriatric Hospital and Institute of Gerontology (approval number R18-20). All procedures followed the ethical guidelines of the Medical and Biological Research Involving Human Subjects established by the Japanese government. Opt-out consent was used because all data were anonymized before being received by the authors.

Measures

HAC-OP-DPC

Based on the original HAC-OP measure [1], we identified the following 5 conditions as HAC-OP-DPC: hospital-associated functional decline, incontinence, delirium, pressure injury, and fall. Each condition was defined using DPC data.

First, hospital-associated functional decline was defined as a decrease in ADL scores for the Barthel Index (BI) components of bathing, dressing, toileting, transfers, mobility, and feeding from hospital admission to discharge. In the BI, each component is given a score of 0, 5, 10, or 15 points (maximum scores vary among the components), with higher scores indicating greater independence in that activity [28]. BI was assessed at admission and hospital discharge by bedside nurses. Second, hospital-associated incontinence was defined as a decrease in scores for the BI components of bladder function and bowel function from hospital admission to discharge. Third, hospital-associated delirium was identified based on a recorded diagnosis of delirium (Multimedia Appendix 1) as a postadmission complication and recorded prescriptions of drugs used to manage agitation in delirium (injections of haloperidol or other antipsychotic drugs identified using prescription codes that remained constant throughout the study period). Fourth, hospital-associated pressure injury was identified based on a recorded diagnosis of pressure injury as a postadmission complication and discharge abstract records indicating pressure injury treatment during hospitalization without any similar treatment at admission. Fifth, a hospital-associated fall was identified based on a recorded diagnosis of fall as a postadmission complication. The overall multicomponent HAC-OP-DPC measure was categorized into none, 1, and 2 or more complications based on the count of conditions occurring in each patient.

Outcome Measures

The study outcome measures were hospital LOS during the index hospitalization, discharge to other hospitals, and discharge to LTCFs. LOS was calculated as the number of days between the dates of admission and discharge. Discharges to other hospitals, such as rehabilitation hospitals and LTCFs (including special nursing homes, private paid care facilities, and social welfare institutions), were identified using the relevant DPC codes indicating discharge destination.

Covariates

Using the subject hospital's DPC data, we extracted demographic variables of patient sex, age group (65-74, 75-84, and ≥85 years), and annual household income (<¥3.7 million, ≥¥3.7 million, and unknown; ¥1=US $0.0092 in 2016) at the index hospitalization [29]. Income was estimated from the available data about insurance copayments. Insurance copayment rates are the designated rates that patients pay at the point of care in Japan. For patients who have an annual household income below ¥3.7 million (approximately US $34,040; ¥1=US $0.0092), the copayment rates are 10% and 20% for patients aged ≥75 years and 70-74 years, respectively [29]. For patients aged ≥70 years who have an annual household income of ¥3.7 million or higher (¥1=US $0.0092), the copayment rate is 30%. The DPC data did not indicate the copayment rates for patients who received public medical assistance and patients aged 65-69 years. Therefore, income for these cases was categorized as "unknown."

We calculated variables for disease category, comorbidity, and frailty using *ICD-10* codes. Using previously described methods [30,31], we grouped patients into 12 disease categories based on their recorded primary diagnosis for admission. Next, we determined each patient's score in the Charlson Comorbidity Index (CCI), which is a weighted index of specific comorbidities that were identified using *ICD-10* codes [32]. CCI scores were divided into 3 categories (0, 1-2, and ≥3). Similarly, we calculated each patient's Hospital Frailty Risk Score (HFRS), which was developed to identify older adults experiencing frailty with a higher risk of adverse outcomes [33]. The total HFRS ranges from 0 to 99 and was divided into 2 categories (<5 and ≥5). To determine baseline functional dependence and incontinence levels in patients at admission, we analyzed the following 2 variables: dependence in ≥1 ADL items (BI components of bathing, dressing, toileting, transfers, mobility, and feeding) at admission and urinary and fecal incontinence (BI components of bladder function and bowel function) at admission. We dichotomized each of these 2 variables into independent (ie, scoring the maximum score on all components) or dependent (all other patients). We also determined each patient's location before admission (home or LTCF) and the surgical treatment received during the index hospitalization.

Statistical Analysis

The chi-square test was used to compare the differences in patient characteristics among the 3 HAC-OP-DPC categories. We generated cross-tabulations to examine the co-occurrences of each complication. Pearson correlation coefficients were calculated to measure the associations between each complication.

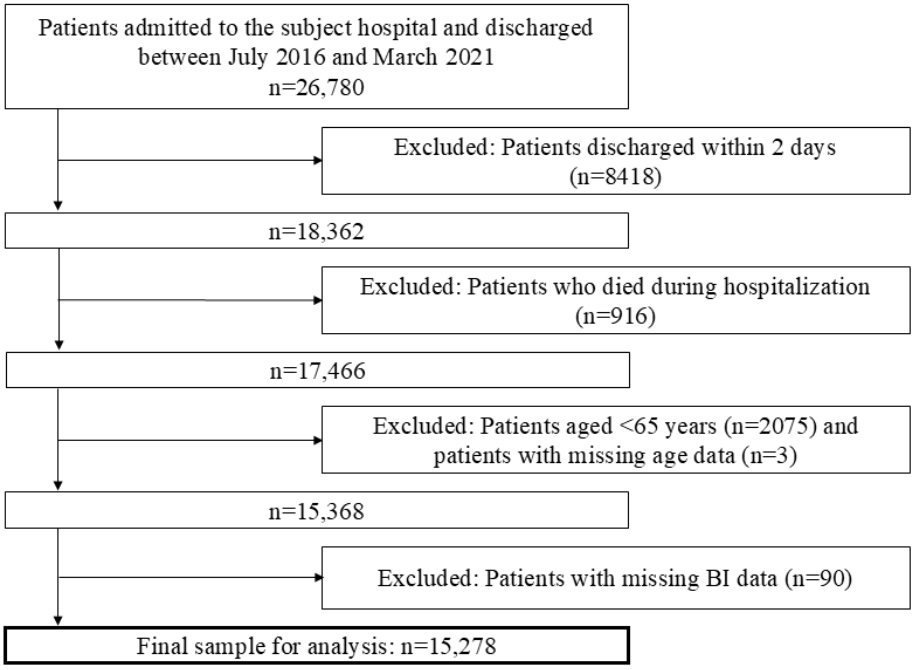
The associations between HAC-OP-DPC and LOS were examined using multivariable generalized linear regression models for gamma-distributed data with a log-link function that adjusted for all covariates. Effect sizes for 1 HAC-OP-DPC and ≥2 HAC-OP-DPC were quantified using adjusted risk ratios (ARRs) and their 95% CIs, which indicated the likelihood of having a longer LOS. Next, the associations of HAC-OP-DPC with discharge to other hospitals and discharge to LTCFs were examined using multivariable logistic regression models that adjusted for all covariates. Effect sizes for 1 HAC-OP-DPC and ≥2 HAC-OP-DPC were quantified using adjusted odds ratios (AORs) and their 95% CIs, which indicated the odds of being discharged to another hospital or LTCF. In addition to analyzing the associations between the number of HAC-OP-DPC and the 3 outcomes, we constructed models to examine the associations between individual HAC-OP-DPC components and the outcomes. For the analysis of hospital-associated functional decline, we excluded patients who were already dependent in all the BI components at admission because they could not experience any further functional decline. Similarly, for the analysis of hospital-associated incontinence, we excluded patients who were already dependent in both bladder function and bowel function at admission because they could not experience new-onset incontinence during hospitalization. We also conducted several sensitivity analyses. First, we re-ran the primary analysis for each of the 3 outcomes, excluding patients who could not experience functional decline (fully dependent on admission) or hospital-associated incontinence (incontinent on admission). Second, we recalculated the HAC-OP-DPC composite outcome excluding cases of delirium that were identified only by drug prescribing as we recognized that antipsychotic drugs might be prescribed for other indications (eg, behavioral and psychological symptoms of dementia, psychosis). All analyses were conducted using SPSS (version 28.0; IBM Corp), and the cross-tabulations were created using R (version 4.3.2; R project for Statistical Computing). *P* values (2-tailed) below .05 were considered statistically significant.

Results

Study Participant Selection

We first identified 26,780 candidate patients who were admitted to the subject hospital and discharged to home, another hospital, or an LTCF during the study period (Figure 1). After applying the exclusion criteria, the final sample for analysis consisted of 15,278 patients aged ≥65 years. Multimedia Appendix 2 shows the characteristics among 833 patients ≥65 years who died during hospitalization and without missing data at admission. These excluded participants were aged ≥85 years, had ≥2 CCI, were more likely to have ADL dependency and incontinence, and were more likely to have cancer, pneumonia, or heart failure.

Figure 1. Flowchart of patient selection. BI: Barthel Index.



Characteristics of Study Patients

Their mean age was 81.2 (SD 7.9) years, and women accounted for 55.4% of all patients (Table 1). There were 2877 (18.8%) patients who experienced 1 HAC-OP-DPC and 733 (4.8%) patients who experienced ≥2 HAC-OP-DPC during the index hospitalization.

[c]HFRS: Hospital Frailty Risk Score.
[d]ADL: activities of daily living.
[e]LTCF: long-term care facility.

HAC-OP-DPC Among This Study's Patients

The most common complication was functional decline (n=2103, 13.8%), followed by delirium (n=1345, 8.8%: recorded diagnosis of delirium (n=59); recorded prescriptions of drugs for delirium, n=1286), new incontinence (n=860, 5.6%), pressure injury (n=104, 0.7%), and fall (n=59, 0.4%). Figure 2 demonstrates the patterns of co-occurrence amongst HAC-OP-DPC. For example, among patients with functional decline, 20.6% also experienced incontinence during hospitalization, while 50.5% of patients with incontinence, 33.9% of patients with falls, and 22.5% of patients with delirium also experienced functional decline during hospitalization. While there were statistically significant correlations between most complications, the strength of these correlations was weak (maximum correlation coefficient of 0.26; Table 2). As shown in Table 1, older age, annual household income, multimorbidity, frailty, baseline functional impairment and incontinence, and living in LTCF were all significantly associated with HAC-OP-DPC. Patients with ≥2 HAC-OP-DPC had a significantly greater proportion of patients with congestive heart failure, pneumonia or acute bronchitis, metabolic diseases, and cancer as the principal diagnosis.

Figure 2. Co-occurrence of each HAC-OP-DPC among older patients aged ≥65 years (N=15,278). Values show the percentages of patients in each row who also had the column condition during hospitalization. HAC-OP-DPC: hospital-associated complications of older people-Diagnosis Procedure Combination data version.

Table 2. Within-patient correlations between each HAC-OP-DPC[a] among older patients aged ≥65 years (N=15,278). Values show Pearson correlation coefficients (r) between each HAC-OP-DPC.

Association of HAC-OP-DPC With Outcome Measures

Table 3 demonstrates the significant and graded association observed between HAC-OP-DPC and outcomes. Adjusting for all covariates, those with 1 and ≥2 HAC-OP-DPC were significantly more likely to have a longer LOS during the index hospitalization (ARR 1.29, 95% CI 1.25-1.33, and ARR 1.97, 95% CI 1.87-2.08, respectively) compared to those with no HAC-OP-DPC. They were significantly more likely to be discharged to other hospitals (AOR 2.36, 95% CI 2.10-2.65, and AOR 6.96, 95% CI 5.81-8.35, respectively), and be discharged to LTCFs (AOR 1.35, 95% CI 1.09-1.67, and AOR 1.68, 95% CI 1.18-2.39, respectively). The analyses of individual HAC-OP-DPC showed that patients who experienced hospital-associated functional decline, incontinence, delirium, pressure injury, and falls were significantly more likely to have a longer LOS and be discharged to other hospitals than patients without these complications. However, only delirium was significantly associated in this individual complication analysis with discharge to LCTFs. A sensitivity analysis (n=11,075) that excluded 4203 patients who could neither experience hospital-associated functional decline nor incontinence found that HAC-OP-DPC still had a significant and graded association with longer LOS and discharge destination (Multimedia Appendix 3), similar to the results of the main analysis. Moreover, the associations of the number of HAC-OP-DPC using delirium identified from a recorded diagnosis alone with these outcomes were similar to the results of the main analysis (Multimedia Appendix 4).

Table 3. Association of HAC-OP-DPCa with outcome measures in 15,278 participants.

Discussion

Principal Findings

This retrospective cohort study is the first to develop and apply a tool to assess HAC-OP from routinely collected administrative data and evaluate its predictive validity for hospital outcomes. Our analysis showed that almost one quarter of older inpatients with multiday stays of more than 2 days had a coded HAC-OP, and that having one or more HAC-OP-DPC was associated with longer LOS and discharge to other hospitals and LTCFs. The clinical implementation of the HAC-OP-DPC measure could support comparative analyses of clinical and policy interventions aimed at preventing these complications, thereby contributing to the optimization of acute care for older adults.

Almost 1 in 4 older patients had coding documentation of any HAC-OP-DPC in the present study, which was approximately half that of the incidence of any HAC-OP described in the Australian study [1]. Nonetheless, the incidences of each HAC-OP-DPC were ranked in similar order, with functional decline and delirium being most common. A large contribution to the disparity in incidence is likely to be reliance on DPC data to identify individual complications as HAC-OP-DPC, while the HAC-OP study used repeated patient and clinical record assessments by trained research assistants [1,17]. Although we made efforts to minimize the underestimation of delirium, falls, and pressure injuries by including additional codes and data sources in their identification criteria, it is very likely that the coding data underestimated the incidences of all complications. For example, there were no coded falls without fracture, and only 59 cases of direct recording of a delirium diagnosis. There are recognized gaps in clinician recognition and documentation of hospital complications as well as translation into coding [27]. Understanding and improving the accuracy and usability of HAC-OP-DPC may require correlation with clinical data and comparisons between sites. There are other reasons that our incidence estimates may have been lower than expected. The denominator in our main analysis included 3051 patients who could not experience further functional decline and 3803 patients who could not experience new-onset incontinence, which may have led to an underestimation of these HAC-OP-DPC. Our analyses also excluded patients who died during their inpatient stay, who may have had a higher rate of HAC-OP.

Nonetheless, our study found that the HAC-OP-DPC measure was associated with longer LOS and discharge destination, thereby demonstrating its predictive validity for outcomes in an acute care setting. Furthermore, our analysis found nonoverlapping risk estimates for LOS and discharge to other hospitals between patients with 1 and ≥2 HAC-OP-DPC, showing a significant exposure-outcome effect of a graded nature. These findings were consistent with the results of the original HAC-OP study [1] and suggest that prevention of further HAC-OP is important in those who have already acquired 1 complication. Our observations that HAC-OP-DPC was significantly associated with older age and baseline function are consistent with previous reports [1]. Importantly, our study is the first to demonstrate the strong associations of HAC-OP with higher CCI scores and HFRS, consistent with existing knowledge that comorbidities and frailty are risk factors for the individual complications included in the composite measure [13,16,34-37].

Our analysis also confirmed that the individual HAC-OP-DPC were associated with longer LOS and discharge to other hospitals, which was congruent with previous studies [6,14,35-39]. All HAC-OP-DPC have been individually recognized as important outcomes in older patients [1,6,14,17,36-42]. Although our study showed that there were patterns of co-occurrence and significant correlations among the individual HAC-OP-DPC, these correlations were weak. This suggests that these complications represent relatively distinct conditions and that they can be treated individually [1]. Moreover, a systematic review of composite outcomes in clinical trials proposed that studies should list results for all components of a composite outcome to avoid confusion and bias [43], and an outcome study using the original multicomponent HAC-OP measure demonstrated significant and clinically important improvements in individual outcomes but not in the composite measure [17]. We recommend that future studies should report the effects of interventions not only on the HAC-OP-DPC measure as a composite outcome but also on its individual complications.

Strengths and Limitations

Strengths of this study include a large, representative dataset with high levels of item completeness (including functional variables), adjustment for important covariates, and use of sensitivity analyses to explore data assumptions. We also recognize several limitations. First, we included additional information to reduce these anticipated underestimates that may have reduced precision; for example, by including drug prescribing of antipsychotics in the delirium diagnosis, we may have included some patients with other indications such as behavioral and psychological symptoms of dementia. However, our sensitivity analysis using a more stringent definition of delirium suggests that this had minimal impact on our overall findings. Second, our study was conducted in a single acute care hospital in Japan, and its findings may not be generalizable to other hospitals, regions, or countries. Nevertheless, the majority of acute care hospitals in Japan have adopted the DPC system [20], and future studies could compare the incidence of HAC-OP-DPC in each acute hospital throughout Japan. Also, although a previous study identified the validity of chronic disease diagnoses in DPC data as being generally high [26], we recognize that the performance of comorbidity scoring methods based on administrative data may vary between health systems [44]. Third, we could not infer a causal relationship between HAC-OP-DPC and LOS because we were unable to identify the date when each complication occurred, and we cannot

exclude reverse causality between HAC-OP-DPC and LOS [1]. Fourth, our study did not examine the association between HAC-OP-DPC and mortality, which had been analyzed in the original HAC-OP study [1], because there are no BI scores assigned on discharge for in-hospital deaths to calculate functional decline and incontinence of HAC-OP-DPC, and DPC data lack information on death after discharge. Future studies could link DPC data with mortality data to examine the associations between HAC-OP-DPC and mortality. Finally, our database lacked information on potentially important confounders, such as residential status (eg, living alone or with others), the presence of caregivers, and disease severity that could be included in future studies.

Conclusions

This study showed that almost one quarter of older acute care inpatients in a Japanese hospital have coding indicating a HAC-OP and demonstrated the predictive validity of the HAC-OP-DPC measure for longer LOS and discharge to other hospitals and LTCFs. To attain a more robust understanding of these relationships, additional studies are needed to verify our findings in other hospitals and regions. The clinical implementation of HAC-OP-DPC, which are identified using routinely collected administrative data, could support the efficient evaluation of integrated interventions aimed at optimizing inpatient care for older adults.

Abstract

Background: Consumer wearable devices could, in theory, provide sufficient accelerometer data for measuring the 24-hour sleep/wake risk factors for dementia that have been identified in prior research. To our knowledge, no prior study in older adults has demonstrated the feasibility and acceptability of accessing sufficient consumer wearable accelerometer data to compute 24-hour sleep/wake rhythm measures.

Objective: We aimed to establish the feasibility of characterizing 24-hour sleep/wake rhythm measures using accelerometer data gathered from the Apple Watch in older adults with and without mild cognitive impairment (MCI), and to examine correlations of these sleep/wake rhythm measures with neuropsychological test performance.

Methods: Of the 40 adults enrolled (mean [SD] age 67.2 [8.4] years; 72.5% female), 19 had MCI and 21 had no cognitive disorder (NCD). Participants were provided devices, oriented to the study software (myRhythmWatch or myRW), and asked to use the system for a week. The primary feasibility outcome was whether participants collected enough data to assess 24-hour sleep/wake rhythm measures (ie, ≥3 valid continuous days). We extracted standard nonparametric and extended-cosine based sleep/wake rhythm metrics. Neuropsychological tests gauged immediate and delayed memory (Hopkins Verbal Learning Test) as well as processing speed and set-shifting (Oral Trails Parts A and B).

Results: All participants meet the primary feasibility outcome of providing sufficient data (≥3 valid days) for sleep/wake rhythm measures. The mean (SD) recording length was somewhat shorter in the MCI group at 6.6 (1.2) days compared with the NCD group at 7.2 (0.6) days. Later activity onset times were associated with worse delayed memory performance (β=−.28). More fragmented rhythms were associated with worse processing speed (β=.40).

Conclusions: Using the Apple Watch-based myRW system to gather raw accelerometer data is feasible in older adults with and without MCI. Sleep/wake rhythms variables generated from this system correlated with cognitive function, suggesting future studies can use this approach to evaluate novel, scalable, risk factor characterization and targeted therapy approaches.

Introduction

Twenty-four-hour sleep/wake characteristics, which are objectively measurable using accelerometer-containing devices, are related to both dementia biomarkers and dementia risk. Prior studies have shown that sleep/wake rhythm disruption, including fragmentation of 24-hour sleep/wake rhythms, temporally precedes the incidence of mild cognitive impairment (MCI) and dementia [1,2]. Even among adults with normal cognition, rhythm fragmentation correlates with greater brain amyloid deposition [3,4]. Over time, 24-hour rhythm fragmentation has been associated with increased risk and faster rates of cognitive decline in people with MCI and mild-to-moderate dementia [1,5] .

The above-mentioned studies linking sleep/wake rhythm disruption with cognitive impairment and neurodegenerative processes in aging raise the potential that accelerometer-based sleep/wake monitoring may have useful clinical applications. For example, wearable accelerometers could potentially be used to identify individuals who have established sleep/wake risk factors for dementia, assign targeted interventions, and track sleep/wake patterns throughout clinical trials. Compared with researcher-focused accelerometer devices, consumer wearables (which also contain triaxial accelerometers) could yield more widely scalable, and clinician and user-friendly, systems for developing and testing potential applications. Our prior pilot study demonstrated that it is possible to collect 24-hour accelerometer data from the Apple Watch and generate standard 24-hour sleep/wake rhythm measures [6]. However, this prior study was limited to a convenience sample of young adults.

Prior to studies evaluating the use of consumer wearable-based sleep/wake monitoring for dementia risk stratification and targeting prevention approaches, we sought to establish the feasibility of using a consumer wearable device to assess 24-hour sleep/wake patterns in older adults (including those with elevated dementia risk by virtue of having a diagnosis of MCI). Our first aim was therefore to evaluate the feasibility of using the Apple Watch and a software platform called myRhythmWatch (myRW) to obtain 24-hour accelerometer data assessing sleep/wake rhythms in older adults with and without MCI. Second, we sought to validate that the sleep/wake rhythm data collected from this system is relevant to cognition. To do so, we evaluated if sleep/wake rhythm variables extracted from this system correlated with cognitive function similar to prior published studies that used researcher-focused accelerometer devices.

Methods

Participants and Study Protocol

Participants were identified by referral from either local studies that adjudicated MCI diagnoses or a local research recruitment registry that is led by the University of Pittsburgh Clinical and Translational Science Institute (Pitt+Me). The inclusion criteria were (1) being 50 years of age or older; (2) passing the San Diego Brief Assessment of Capacity to Consent [7] with scores ≥14.5; (3) have a score of >27 on the Telephone Interview for Cognitive Status (TICS) [8]; (4) having a TICS score of either ≤34 (high-risk group) or ≥39 (no cognitive disorder or NCD); and (5) have a prior adjudicated diagnosis of MCI (high-risk group) or reporting no concerns regarding cognitive decline (ie, NCD). The exclusion criteria included (1) self-reporting active behavioral health treatments for insomnia or depression; (2) self-reporting of performing the prescribed exercises; and (3) self-reported use of sleep medications every night or nearly every night. After explaining the study purpose and procedures, we obtained verbal consent to screen interested individuals for eligibility. Of 82 potentially eligible participants who completed the verbal eligibility screening, 35 were ineligible, 6 refused, and 41 were enrolled. One participant withdrew after enrollment, resulting in an analytic sample of 40 individuals (19 high-risk (ie, having a low TICS score and prior MCI diagnosis) and 21 low-risk (ie, having a high TICS score and no prior MCI diagnosis), as shown in Figure S1 in Multimedia Appendix 1 (ie, a flow diagram illustrating how we arrived at our analytic sample).

After completing web-based written informed consent forms, participants completed baseline procedures and assessments via Health Insurance Portability and Accountability Act (HIPPA)-compliant video-conferencing. We sent participants the following study devices: an Apple Watch 8, iPhone SE 2nd generation with active data plans, and nonstock 40-Watt charger. After the participants received the devices, we conducted an additional study visit to instruct them on logging in and using the myRW application. We specifically instructed participants that about 20 - 30 minutes of charging a day is sufficient, and asked them to wear the watch whenever it was not charging for a week.

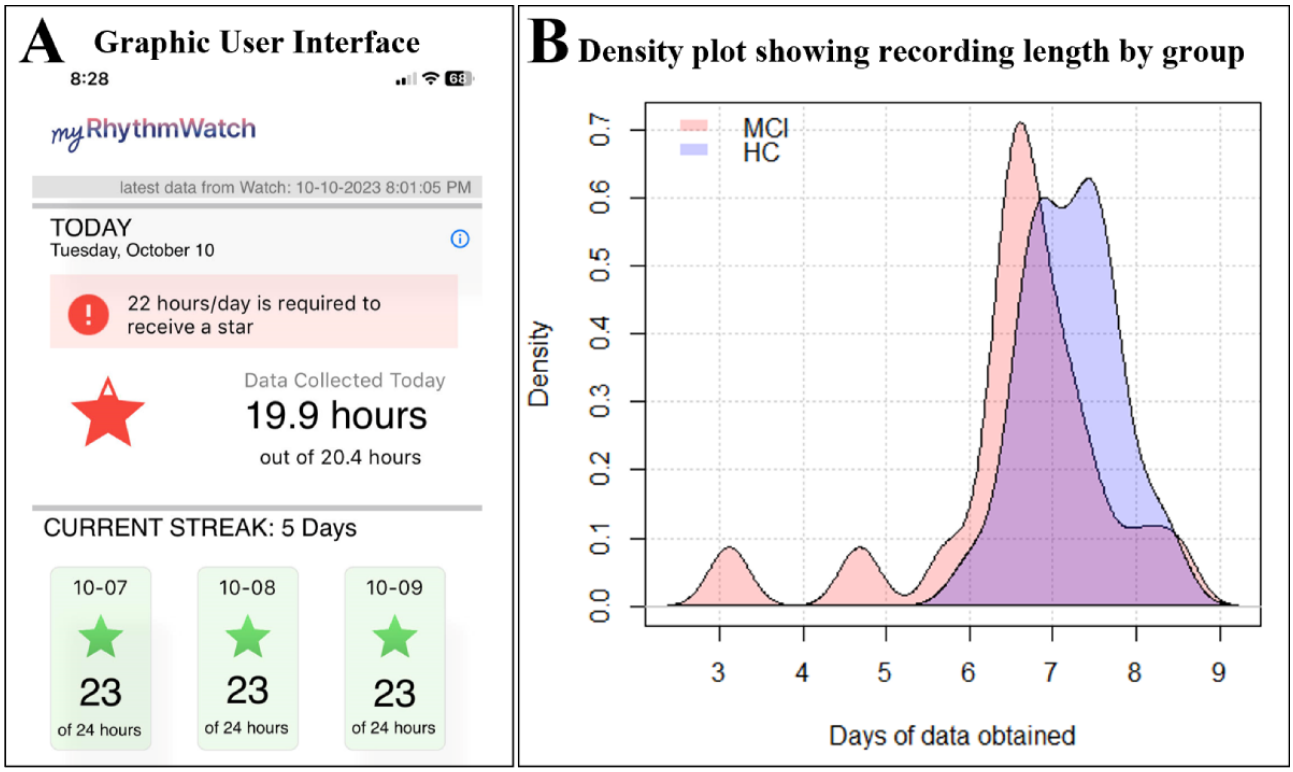
Ethical Considerations

All study procedures were approved by the University of Pittsburgh Institutional Review Board (identifier: STUDY22080033). All the participants completed web-based written informed consent forms

Study Application

The myRW software system, developed by the corresponding author, extracts triaxial accelerometer data that are recorded at 50 hertz on the Apple Watch. After bandpass filtering, we aggregate across axes and into 30-second counts, and transmit data for storage and further computations on the Amazon Web Services platform. To encourage data collection, we depict the amount of data collected per day graphically by proportionally filling and color coding a star (Figure 1). We explicitly told participants that sufficient data were required to “get a star,” that the goal was to get 7 stars in a row, and we also displayed information on how many days in a row participants obtained stars (to encourage data collection “streaks”). Participants received reminders three times daily to check in to the application. Other features, including personal data graphs and sleep/wake metrics, were disabled for this study to prevent the feedback from potentially altering the users’ behavior/typical sleep/wake patterns.

Figure 1. Illustrations of the graphic user interface (left) and the amount of accelerometer data collected in the sample (right). The difference in the mean (SD) recording length between the no cognitive disorder (NCD; 7.2 [0.6]) and mild cognitive impairment (MCI; 6.6 [1.2]) groups is shown visually in the density plot (*P*=.04).



Sleep/Wake Measures

Consistent with prior publications using researcher-focused accelerometers [9-11], we required participants to have at least 3 valid continuous days of accelerometer data to consider the recording adequate for processing. Valid days were defined, consistent with National Sleep Research Resource data processing standards [12], as those with no more than 4 hours of nonwear time or any nonwear time during the main sleep period. Invalid days and remaining data missing within days were censored (not imputed). Although we applied this aforementioned 20 hours per day criterion, to maximize data collection, note that the app was programmed to reward participants with a green star only if they collected at least 22 hours of data per day.

Following previously published technical definitions, we calculated extended cosine-based [13] and nonparametric [14-17] sleep/wake measures using the R package 'RAR' and custom code. From the extended-cosine models, we extracted measures of 24-hour robustness (pseudo-F statistic, indicating how well the observed data fits the 24-hour curve); activity onset time (up-mesor, the time which the modeled activity level passes the middle modeled rhythm height prior to the peak); and activity offset time (down-mesor or the time which the modeled activity level passes the middle modeled rhythm height prior to the nadir). From the nonparametric method, we calculated the cross-daily stability (inter-daily stability, measuring the consistency of circadian sleep/wake activity rhythms across days); rhythm strength (relative amplitude, measuring the standardized peak-trough difference of 24-hour activity rhythms); and sleep/wake rhythm fragmentation (intradaily variability or IV, measuring the frequency and extent of transitions in activity levels). Although sleep/wake rhythm fragmentation is typically measured using differences in activity levels every hour, it can also be computed on a range of timescales [16,17]. For all nonparametric metrics, we used all-time series data and did not subsample to hourly activity levels, as described previously [14]. To explore the relevance of fragmentation timescale, we computed IV values using numerator timescales ranging from 5 to 60 minutes, but holding the denominator constant as done previously [16].

Neuropsychological Measures

Cognitive performance was measured using the Hopkins Verbal Learning Test (HVLT; PAR, Lutz, FL) and the Oral Trail Making Test (O-TMT).

The HVLT is a verbal list learning measure with three trials of 12 words from multiple representative semantic categories, and includes delayed recall and delayed recognition memory components [18,19]. For the delayed recall, participants were asked to repeat as many terms as they could recall from the word listed presented to them thrice, 30 minutes earlier. For delayed memory recognition, participants were asked to recognize those same terms appearing on a broader list containing semantically related terms, ie, "horse" must be differentiated from "dog," which was not part of the original term set. The HVLT assessed encoding, storage, and retrieval of noncontextual verbal information.

Processing speed was measured as the time taken on Part A of the O-TMT, which requires the subject to verbally count upwards from 1 to 25 as quickly as they are able [20]. Set-shifting, an aspect of cognitive function, was measured as

the time taken using Part B of the O-TMT, which requires the subject to alternate between listing numbers and letters in sequence (“1, A, 2, B,” etc). Note that longer times on both parts of the O-TMT indicates worse performance [21].

Statistical Analyses

To compare recording lengths between the MCI and NCD groups, we used an independent sample *t* test and density plots illustrating recording length distributions by groups. To examine relationships of sleep/wake rhythm measures with cognitive function, we first adjusted for key confounders by taking the residuals from linear regression models (one for each cognitive outcome variable) that had the confounders age, sex, education (college degree vs less than college degree), and accelerometer recording length as predictor variables. We used the residualized values as age, sex, education, and recording length-adjusted cognitive outcome variables in a series of linear regressions (one per sleep/wake predictor variable). Since there were many conceptually similar or highly inter-correlated intradaily variability metrics, for related analyses, we only report Benjamini-Hochberg corrected false discovery rates (which are here referred to as *q* values instead of *P* values) [22] to account for the 12 statistical tests relating intradaily variability metrics within each cognitive outcome.

Results

Sample Characteristics

The sample included older adults, with a mean (SD) age of 67.2 (8.4) years; the majority of the participants were females with college degrees (Table 1).

Table . Sample characteristics.

Characteristics	Value
Age, years, mean (SD)	67.2 (8.4)
Female sex, n (%)	29 (72.5)
College degree or greater, n (%)	29 (72.5)
Prior diagnosis of MCI[a], n (%)	19 (47.5)
Accelerometer recording length, days, mean (SD)	6.9 (0.9)
Immediate memory, mean (SD)	26.7 (5.2)
Delayed memory, mean (SD)	8.7 (2.8)
Processing speed, seconds, mean (SD)	10.3 (2.8)
Set shifting executive function, seconds, mean (SD)	40.1 (31.6)

[a]MCI: mild cognitive impairment

Accelerometer Recording Lengths in People With and Without a Diagnosis of MCI

In both the groups, all participants achieved the minimum data requirement for computing 24-hour sleep/wake rhythm assessments. There was, however, a statistically significant difference in the mean (SD) recording lengths of about a half a day when comparing the NCD (7.2 [0.6] days) and MCI groups (6.6 [1.2] days), with the Satterthwaite test assuming unequal group variances (*df* 25.033; *t* value −2.15; *P*=.04). This difference was due to 3 individuals in the MCI group who collected 3 - 6 days of data each (Figure 1).

Associations of Sleep/Wake Characteristics With Cognitive Performance

As shown in Table 2, there were small effect size associations of later activity onset time with lower delayed memory performance (β=−.28, 95% CI −0.55 to - 0.02; *t*=−2.17, *df*=38, *P*=.04) and more stable rhythms with better processing speed and performance (β=−0.27, 95% CI: −0.54 to 0.00; *t*=−2.00, *df*=38, *P*=.05). None of the other sleep/wake measures listed in Table 2 were associated with the cognitive outcomes. Regarding sleep/wake rhythm fragmentation, greater fragmentation levels in the 40 - 60-minute timeframe was significantly associated with worse processing speed and performance (Table 3; β point estimate range: 0.36, 0.40; *q*=.022). When repeating analyses in the subgroup with at least 6 days of data, results were not substantively altered (n=37; see Tables S1 and S2 in Multimedia Appendix 1).

To illustrate the accelerometer data collected in this study and visualize 24-hour sleep/wake fragmentation, Figure 2 shows data from example participants with lower and higher degrees of 24-hour sleep/wake rhythm fragmentation.

Table . Associations between 24-hour sleep/wake rhythm variables and cognitive performance.

Variable	Immediate memory[a]		Delayed memory[a]		Psychomotor speed/attention[b]		Set shifting executive function[b]	
	β (95% CI)	*P* value	β (95% CI)	*P* value	β (95% CI)	*P* value	β (95% CI)	*P* value
24 h robustness	.06 (−.22 to .34)	.67	.17 (−.11 to 0.44)	.22	−.09 (−.38 to .20)	.53	−.18 (−.48 to .11)	.22
Cross-daily stability	.11 (−.17 to .39)	.44	.13 (−.14 to .41)	.34	−.27 (−.54 to .00)	.05	−.11 (−.42 to .19)	.45
Rhythm strength	.08 (−.21 to .36)	.59	.04 (−.23 to .32)	.75	−.04 (−.33 to .24)	.76	−.12 (−.42 to .18)	.43
Activity onset time	−.13 (−.41 to .15)	.36	−.28 (−.55 to -.02)	.04	.04 (−.24 to .33)	.76	−.11 (−.41 to .19)	.46
Activity offset time	−.03 (−.32 to .25)	.81	−.07 (−.35 to .21)	.60	−.12 (−.41 to .16)	.40	.17 (−.13 to .47)	.26

[a]Higher scores on the memory tests indicates better performance (as the outcome is number of items recalled)

[b]For psychomotor speed/attention and set-shifting, higher scores indicate worse performance (as the outcome is the duration of time to complete Oral Trails A and B, respectively)

Table . Associations between 24-hour sleep/wake rhythm fragmentation on various timescales with cognitive performance.

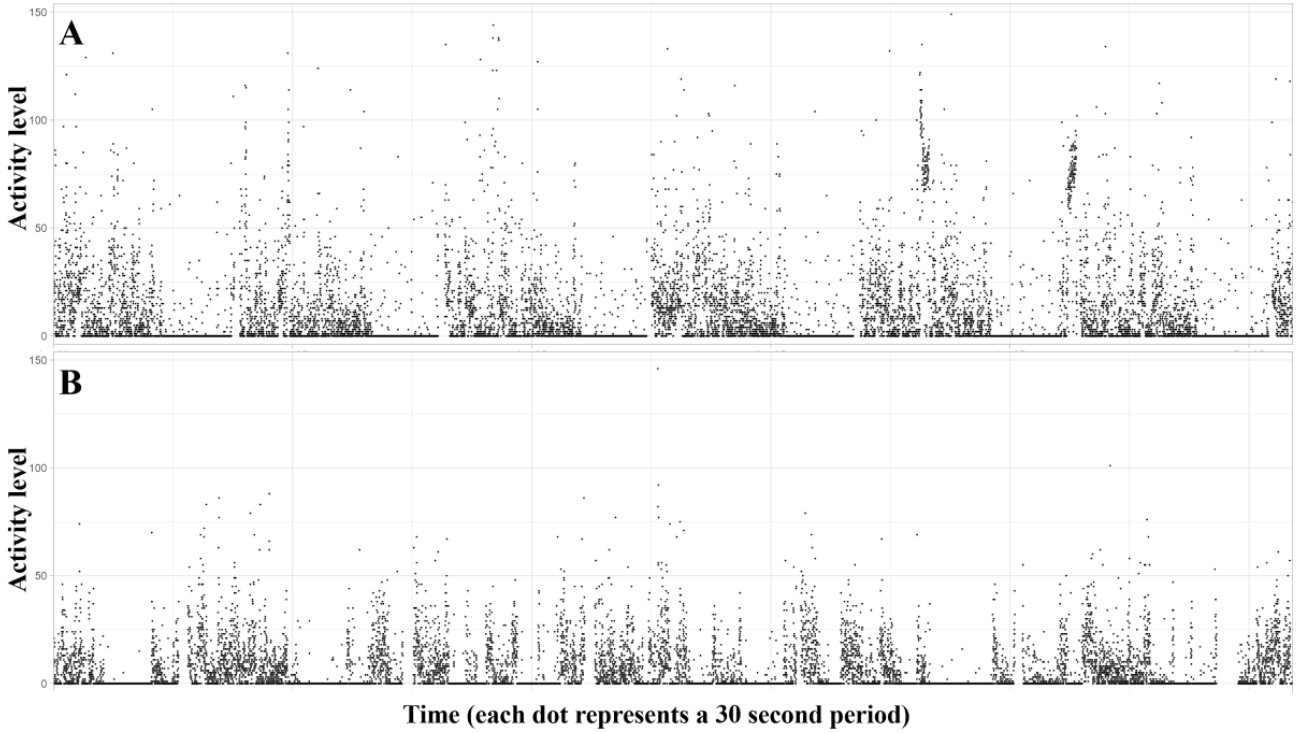
[a]Higher scores on the memory tests indicates better performance (as the outcome is number of items recalled).

[b]For psychomotor speed/attention and set-shifting, higher scores indicate worse performance (as the outcome is duration of time to complete Oral Trails A and B, respectively).

Figure 2. Accelerometer data from two participants. Top: The participant was in the low risk (no cognitive disease) group and had relatively lower sleep/wake rhythm fragmentation. Bottom: The participant is from the high-risk (mild cognitive impairment) group and had relatively higher sleep/wake rhythm fragmentation.



Discussion

These results demonstrate that it is feasible to collect raw accelerometer data and characterize 24-hour sleep/wake rhythms in older adults with and without MCI using the Apple Watch and myRW system. Each individual in our sample met the minimum data requirement to derive sleep/wake rhythms measures. Notably, however, several individuals in the MCI group generated shorter recordings. Thus, while supporting the feasibility of using the Apple Watch and myRW system to assess sleep/wake rhythms in people with MCI who are at risk for dementia, our findings also suggest that some individuals with MCI may require additional support (eg, additional human support or programmed reminders) and data imputation [23] to monitor sleep/wake rhythms over longer periods with this system.

With regard to our second aim, we found that sleep/wake rhythm variables extracted from the Apple Watch accelerometer data were correlated with cognitive function. We found small-to-medium effect size correlations between sleep/wake measures and cognitive performance. Specifically, we found that later activity onset times were related to worse delayed memory performances. In addition, less stable and more fragmented rhythms were correlated with worse processing speed. Detecting these signs of disrupted sleep/wake rhythms early on could help target prevention strategies, given prior research demonstrating that sleep/wake rhythm fragmentation [1], worse memory [24,25], and slower processing speeds [26] are all associated with the risk of developing dementia.

The study had several limitations. This was a cross-sectional observational study limited to accelerometer and neuropsychological measures, so there is no way to determine causality or the mechanisms underlying associations between the variables examined. The sample size was relatively small; therefore, there is a risk of false negative associations and effect size estimates (relating sleep/wake measures with cognition) that should be deemed less reliable than those from large epidemiologic studies. We failed to detect some associations that were expected based on prior literature examining dementia risk (eg, previous findings linking low rhythm strength with dementia risk [27]). Larger studies examining the relationships between these sleep/wake factors and specific domains of cognitive function, earlier in the disease processes, will be needed to verify our findings. We made efforts to minimize data loss as described above, but did not use data imputation, which could be applied in future studies. Additionally, given the small sample, future studies will be required to confirm results of using this system in samples that are more broadly representative, eg, samples including more ethnically diverse population subgroups. Finally, we note that determining the mechanism underlying these relationships between sleep/wake rhythm disruption, cognition, and dementia risk is outside the scope of this work. Recent literature has notably suggested that sleep/wake rhythm fragmentation relates to neurodegeneration of the locus coeruleus [28], which could hasten dementia pathology and cognitive decline [29,30].

In summary, we have demonstrated that it is feasible to use the Apple Watch and myRW system to gather accelerometer data and characterize sleep/wake risk factors for dementia in older adults including adults with MCI. A strength of this study is the use of the Apple Watch, which is already voluntarily being used by millions of people, as it may provide increased scalability for applications of sleep/wake risk factor monitoring into the general public and general practice settings. One implication

of this research is that it is feasible for future research to be conducted for evaluating if monitoring sleep/wake disruption using consumer wearable-based systems improves upon existing dementia risk factor detection and management approaches. Future studies will also be needed to examine if tailoring interventions using information on sleep/wake patterns derived from this system improves outcomes among older adults who are at risk for dementia.

Abstract

Background: Hospitalized, frail older adults have an increased risk of developing hospital-acquired disability associated with hospital practices of restricted physical activity and immobilization. The use of activity tracking wearable devices may allow identification and prevention of mobility decline, reducing hospital-acquired disability.

Objective: This study aimed to identify the optimal wearable device and wear location for monitoring mobility in older hospitalized patients. Specific objectives included (1) comparison of the feasibility and acceptability of ActiGraph wGT3X-BT (ActiGraph LLC), MOX1 (Maastricht Instruments), MetaMotionC (mBientLab), and Fitbit Versa (Google) for continuous mobility monitoring and (2) determination of the concurrent validity of the selected device for detecting body posture and step count.

Methods: Participants were recruited for this observational study in the acute medical care unit of an academic hospital in Hamilton, Ontario, Canada. Eligible patients were aged 60 years and older, able to undertake the mobility protocol, and had an anticipated length of stay greater than 4 days. The study was divided into 2 experiments. Experiment 1 evaluated the feasibility of 4 wearable devices and validated the derived data for body posture and step count. Experiment 2 involved a mobility assessment session and a 24-hour monitoring and feasibility period with the selected device from experiment 1.

Results: The ActiGraph wGT3X-BT emerged as the most feasible device, demonstrating superior usability, data acquisition, and management. The thigh-worn ActiGraph accurately detected sedentary behavior, while the ankle-worn device provided detailed information on step counts and body postures. Bland-Altman plots and intraclass correlation coefficients indicated that the ankle-worn ActiGraph showed excellent reliability for step counting, with minimal bias and narrow limits of agreement. Patients expressed a high willingness to wear a continuous mobility tracking device at the hospital and at home.

Conclusions: Thigh- and ankle-worn ActiGraph are optimal for assessing and monitoring mobility in older hospitalized patients. Challenges such as discomfort and device removal observed during the 24-hour monitoring period highlight areas for future studies. Overall, our findings support the integration of wearable technology in hospital settings to enhance mobility monitoring and early intervention strategies. Further research is warranted to evaluate the long-term use of wearable data for predicting health outcomes post hospitalization and informing clinical decision-making to promote early mobility.

Introduction

Research indicates that a significant proportion of the adverse functional and health outcomes experienced by older adults during hospitalization may not be directly linked to their underlying health conditions or the reasons for hospitalization [1-3]. Instead, they may arise from certain hospital practices, such as restricted physical activity and immobilization, which may be harmful for older patients, especially for those who are frail [1]. Studies have consistently shown that older patients

spend a minimal amount of time standing or walking during their hospital stay, typically just 3% of the time [4-7]. This limited mobility can have significant consequences for function, with each day spent in bed associated with a 1% - 5% loss in muscle strength [3]. On the other hand, there is evidence showing that older adults who regain their prehospitalization level of function after discharge have lower mortality rates and maintain their functional levels 1 year post discharge. Therefore, early detection and prevention of mobility decline during hospitalization is critical to improving patient outcomes and reducing health care utilization [8].

Wearable technology provides a direct means of assessing and monitoring mobility, by gathering continuous information on patients' physical activities and mobility patterns. This capability would allow practitioners to create and monitor tailored mobility care for each patient, which may improve functional outcomes. Several wearable monitors have been validated in healthy individuals including among older adults living in the community [9,10]. However, experiment protocols, including population type, settings, sensor type, activity, and wear location (eg, wrist vs thigh) can influence the validity of these devices [11-14]. Despite the increased use of wearables in clinical settings, the feasibility, validity, and reliability of these devices have not been fully established in older hospitalized patients [15,16]. Collecting data accurately with wearables in hospitalized patients presents significant challenges, as they tend to be more sedentary and walk slower [17]. In addition, hospitalized patients often have medical devices attached to them, such as intravenous lines or heart monitors, which can impede mobility and make it challenging to select the optimal wear location for data collection.

The overall objective of this study was to identify the optimal wearable device and wear location for assessing and monitoring mobility in older hospitalized patients. Specifically, we aimed to (1) compare the feasibility and acceptability of different wearable devices to assess mobility for long-term continuous monitoring during inpatient hospital stays among older hospitalized patients, and (2) for the selected device from aim 1, determine its concurrent validity for detecting body posture and step count. To fulfill the study aims we performed 2 experiments with 2 independent samples. In the first experiment, we used a standardized protocol to test the feasibility of data collection with the ActiGraph wGT3X-BT, MOX 1, MetaMotionC (MMC), and Fitbit Versa over a short period of time, while validating the data collected for detecting body posture and step count using a standardized protocol. The second experiment was divided in 2 parts where patients wore the selected wearable from experiment 1 in 3 different body locations and performed a standardized activity protocol, followed by a 24-hour free-living protocol. This investigation was crucial for understanding the practicality of wearable devices for mobility monitoring in older adults in a hospital setting, as well as identifying potential barriers or limitations that may impact their utility.

Methods

Participants

Patients were recruited from the acute medical care unit of the Juravinski Hospital, Hamilton, Ontario, Canada. Inpatients were initially identified by the admitting physician, who sought approval before study personnel approached them. Patients were only included if, based on the judgment of the admitting physician, they were deemed capable of providing informed consent. A study coordinator, not directly involved in patient care, then contacted the eligible patients to obtain informed consent. During data collection, a hospital physical therapist, who accompanied all participants and assisted with data collection, ensured safety and facilitated communication when necessary.

Eligible patients were aged 60 years and older, able to undertake the mobility protocol with or without assistance, had an anticipated length of stay of more than 4 days, and able to provide written informed consent. Experiment 1 was conducted from November to December of 2019 and experiment 2 from September to December 2020.

Ethical Considerations

This study was approved by the Hamilton Integrated Research Ethics Board (HiREB #7145) and all participants provided written informed consent before participation. At the time of consent, we recorded information regarding participants' demographics, preadmission functional performance, and health status. All participants had the right to withdraw from the study at any time without any adverse consequences. All data were anonymized. Participants did not receive compensation for their participation.

Measurement Instruments

For the feasibility and device performance of experiment 1, 4 devices were compared, that is, the MetaMotionC (MMC), Fitbit Versa 1, MOX1, and the medical-grade monitor ActiGraph wGT3X-BT. The MMC by mBientLab was chosen for its open platform enabling on-board programming, in addition to its lower cost. The Fitbit Versa 1 (Google) was widely recognized in the community at the study's time, despite lacking direct access to raw sensor data extraction. For both devices, a Python algorithm was developed to extract the raw data. The MOX1 device (Maastricht Instruments , Netherlands) presents a triaxial accelerometer sensor and is equipped with proprietary software. During the study period, the proprietary software of the MOX1 did not offer direct access to the raw data and step count data. To address this limitation, the company provided us with a MATLAB function for extracting the raw data. Finally, the medical-grade ActiGraph wGT3X-BT (ActiGraph), often viewed as the gold standard in accelerometry movement analysis for research, features a built-in triaxial accelerometer that captures high-resolution raw acceleration data. The ActiLife software (ActiGraph LLC, version 6.11.4) was employed to initialize, process, and download data, extracting step counts and body posture measures (time spent lying down, sitting, and standing). In experiment 2, we used the ActiGraph wGT3X-BT as it was the selected device from experiment 1.

Protocols

Experiment 1

Patients from the first experiment were engaged in the activity data procedures to test the feasibility of 4 different wearable devices (ActiGraph wGT3X-BT, MOX1, MMC, and Fitbit Versa), as well as the concurrent validity of the ActiGraph in detecting body posture and step counts. Each patient wore all 4 devices on the waist, 3 devices on the thigh, and 3 on the ankle simultaneously and interchangeably, that is, up to 10 devices per patient. An elastic band equipped with Velcro on both ends was used to attach the devices securely to the body. The waistband featured 4 pockets, while the thigh and ankle bands had 3 pockets each, providing the flexibility to interchange the devices as needed during the study. The waistband was positioned at the level of the anterior superior iliac spine, the thigh band above the kneecap, and the ankle band above the malleolus. After positioning the elastic bands, the wearable devices were randomly assigned to each pocket. Once wearable devices were placed, patients performed the mobility protocol that included body posture tasks (standing, sitting, and lying) and the timed up and go (TUG) [18] mobility test.

During the body posture tasks, patients were asked to lie down, sit on the edge of the bed, and then stand with or without support for 5 minutes. The time spent in each body posture was observed and recorded by a physiotherapist. Following, the patients performed the TUG which is a reliable and valid test to assess mobility and balance in older adults [18]. It measures, in seconds, the time taken by an individual to stand up from a standard armchair, walk 3 meters, turn, walk back to the chair, and sit down. The participants wore their customary walking aid (none, cane, or walker), and no physical assistance was given. The recording initiated as the patient raised from the chair and stopped as the patient sat on the chair again. The time and the number of steps taken to complete the test were also counted and recorded. Following the activity procedures, patients were invited to complete the acceptability questionnaire (Textbox 1). The protocol took approximately 45 - 60 minutes to complete.

Textbox 1. Feasibility questionnaires for experiments 1 and 2.

Experiment 1

1. Have you ever used a device to measure physical activity in the past? (Responses: yes, no)
2. Would you be willing to wear the device for a longer period, 5 to 7 days, as part of a research study? (Responses: very likely, somewhat likely, not likely)
3. What part of the body would you prefer to wear the device? (Responses: waist, thigh, ankle)
4. Which of these devices would you likely use? (Responses: ActiGraph, MOX1, Versa, MetaMotionC)
5. How easy would it be for you to remember to use the device every day? (Responses: very easy, easy, very difficult, difficult)
6. Do you think this device would interfere with your daily routine? (Responses: no effect, minor effect, major effect)
7. Would you feel more motivated to move when wearing the device? (Responses: yes, no, no answer)

Experiment 2

1. Have you ever used a device to measure physical activity in the past? (Responses: yes, no)
   a. What devices did you use?
   b. What activity (or activities) did you track with the devices?
   c. How long ago was it that you used the devices?
   d. If you stopped using the devices, why did you stop?
2. Would you be willing to wear a device to measure physical activity for 5 to 7 days while in the hospital? (Responses: likely, uncertain, unlikely, very likely, very unlikely)
3. Would you be willing to wear a device daily to measure physical activity once you return home from the hospital, for a period of up to say 3 months? (Responses: yes, no)
4. What part of the body would you most prefer to wear the device? (Responses: wrist, waist, thigh, ankle, other)
5. Would you feel more motivated to move when wearing a device to measure physical activity? (Responses: yes, no)
6. Prior to being in the hospital, how many days per week on average did you engage in 30 minutes or more of physical activity, which was enough to raise your breathing rate? (Responses: 1, 2, 3, 4, 5, 6, 7, none)

Experiment 2

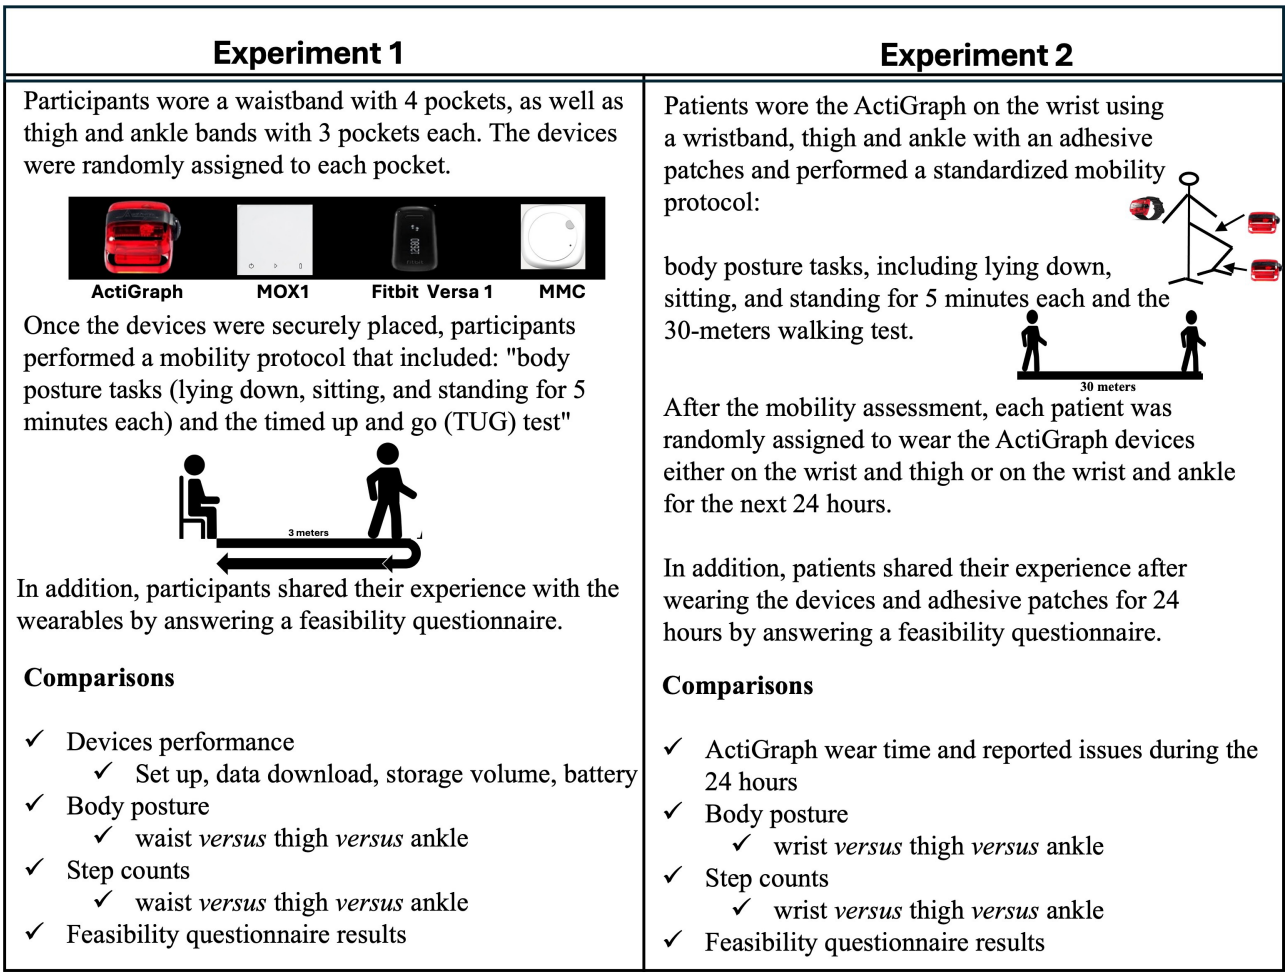
We conducted 1 mobility assessment session where patients wore the chosen device from experiment 1 (ActiGraph) in 3 different body locations (wrist, thigh, and ankle) and performed a standardized mobility protocol under the supervision of a trained physiotherapist. Patients wore the ActiGraph on the wrist using a wristband. At the thigh, the ActiGraph was attached to the anterior aspect of either the left or right thigh just above the kneecap, and at the ankle, the device was attached just above the malleoli. The Hypafix Stretch Non-Woven Adhesive (BSN Medical) was used to affix the devices. The

mobility protocol included the same body posture protocol as the first experiment, followed by a step count task recorded during a 30-meter walking test (30MWT) [19,20]. Patients were asked to stand up from a chair, walk 30 meter, turn around, and walk back at a comfortable pace using their usual walking aid if necessary. The time and the number of steps taken to complete the test was counted and recorded. The mobility protocol in experiment 2 lasted approximately 30 - 45 minutes.

After the mobility assessment, each patient was randomly assigned to wear the ActiGraph devices on either the wrist and thigh or wrist and ankle for the next 24 hours. We assessed the acceptability and feasibility of the wearable devices by location, as well as their acceptability of

wearing the adhesive patches over a 24-hour duration in the hospital. We also documented any interruptions or issues encountered during the 24-hour monitoring period. If patients removed or stopped using the device, the research assistant recorded feedback from both the patient and the attending nurses regarding the reasons for discontinuation. Figure 1 illustrated the variations within each experiment.

Figure 1. Summary of procedures for experiment 1 and 2.



Data Reduction

Experiment 1

Data were collected at 100 Hz for MOX1, and at 50 Hz for the other devices. In the second experiment, the ActiGraph data were collected at 30 Hz. Custom Python algorithms were created for the MMC and Fitbit devices to enable continuous saving and downloading of raw accelerometer data, necessitating the use of a companion device, a tablet. The MOX1 device was initialized using its proprietary software and data were downloaded using the provided MATLAB function. Raw data from these devices were not subjected to further processing; our focus was solely on recording downloading time, as well as the quantity and quality of the saved data.

In both experiments, the ActiLife software (version 6.11.4) was used to initialize, download, and process the ActiGraph data. Data were aggregated into 60 seconds time-stamped epochs. The following measures were obtained from the ActiLife: wear time, counts per minutes, activity intensity, step counts, and body posture (time spent in lying down, sitting, and standing). The following measures were obtained from the ActiLife algorithms: wear time, counts per minute, activity intensity, step counts, and body posture (time spent lying down, sitting, and standing). For step counts, since the ActiLife algorithms measures strides when attached to the thigh, we doubled the stride numbers to determine the actual number of steps taken. This adjustment is necessary because each stride recorded by the device corresponds to two steps—one for each leg—so the raw stride count is multiplied by 2 to obtain an accurate step count.

In addition, we applied the ActiGraph manufacturer's step algorithm, the low-frequency extension filter, to the step count data. This filter is designed to detect lower-amplitude movements, enhancing the accuracy of step detection [21]. Body posture classification in both experiments was obtained using the thigh-worn algorithm from the ActiGraph that relies on movement and the thigh angle to accurately classify lying and sitting versus standing positions [22]. The first and last 45 seconds of data from each activity were discarded to avoid potential participant error in recording time and to exclude the transition times.

Experiment 2

For the 24-hour protocol, the accelerometer data from the ActiGraph was screened for wear time using the method described by Choi et al [23]. Based on the activity counts determined by the ActiLife algorithms, and using an epoch length of 60 seconds, nonwear time was defined as 90 consecutive minutes of zero counts, with an allowance of 2 minutes of nonzero counts, provided there were 30-minute consecutive zero counts before and after that allowance. Based on the wear time, we determined the average amount of time the patients wore the devices at the wrist, thigh, and ankle during the 24-hour protocol.

Statistical Analysis

Descriptive data were analyzed using measures of central tendency and dispersion. Absolute percentage errors were calculated between the observed body posture time and step count against the values obtained using the ActiGraph algorithm (absolute percentage errors=[(observed data–ActiGraph data)÷observed data]×100). Intraclass correlation coefficients ($ICC_{2,1}$) [24] were used to examine criterion validity between step count taken from the ActiGraph compared with those observed during the TUG and 30MWT. By convention, an ICC ≥0.75 was considered excellent, 0.60 - 0.74 good, 0.40 - 0.59 fair, and <0.40 poor [25].

Bland-Altman plots [26,27] were constructed to show the variability of the ActiGraph in recording step count compared with the observed data. With this technique, the mean error score and the 95% prediction intervals can be examined in graphical form. Comparisons that are in closer agreement will have a mean bias close to zero and tighter 95% prediction intervals. Statistical analyses were conducted with SPSS version 26 (IBM Corp) with the α level set at .05.

Results

Overview

A total of 25 older adults (n=17, 65% women) with a mean age of 79.6 (SD 8.1) years participated in experiment 1, and 30 participants (n=24, 80% women), with a mean age of 81.4 (SD 8.8) years, participated in experiment 2 (Table 1). The patients were hospitalized due to the following conditions: cardiac conditions (n=6) including hypertension, congestive heart failure, atrial fibrillation, and coronary artery disease; urinary tract infection (n=5); deconditioning (n=5); falls (n=3); acute kidney injury (n=3); exacerbation of COPD (n=2); shortness of breath (n=2); sepsis (n=2); pneumonia (n=1); syncope (n=1); leg pain (n=1); vertigo (n=1); gastroenteritis (n=1); and back pain (n=1). Table 1 describes the patients' demographics and clinical characteristics. In general, patients were more independently mobile before admission.

Table . Demographics, comorbidities, and mobility characteristics of the patients.

Variables			Experiment 1	Experiment 2
Demographics, n			25	30

Experiment 1

The acceptability questionnaire showed that out of 25 patients, 24 patients (96%) reported no previous experience with wearables. However, 20 patients (80%) expressed their willingness to wear a wearable for a period of 5-7 days. In terms of the preferred body location, the ankle was selected by 14 patients (58%), the waist was selected by 7 patients (29%), and the thigh by 4 patients (17%). Furthermore, 1 patient did not answer this question. Among the wearable devices, the Fitbit Versa was selected by 12 patients (48%), the ActiGraph was chosen by 6 patients (24%), and the MOX1 and MMC were selected by 3 (12%) and 2 (8%) patients, respectively.

We observed that both the ActiGraph and MOX1 devices were easy to set up and enabled faster data downloads compared with Fitbit and MMC devices. Of the 4 devices, only the ActiGraph retrieved 100% of the collected data. The MATLAB function from the MOX1 retrieved 72% of the files, with 1 file containing missing data, and 7 files having a lower frequency than the specified 100 Hz setup. In addition, the MATLAB function provided by the manufacturer did not include time stamps. The algorithms on the Fitbit Versa were able to retrieve 79% of the data, with the primary issue being missing data. Similarly, the MMC algorithms retrieved 81% of the data, although some data were missing due to a time stamp error that was not identified until later in the data collection process. In addition to its high performance, the ActiGraph device also had the longest battery life and storage volume compared to all other devices. The proprietary software offered by ActiGraph allowed us to process, quickly view and extract the data using a comprehensive selection of independently developed and validated algorithms. Given the ease of data collection using the ActiGraph in the above experiment, it was selected as the most user-friendly device for further evaluation.

For the body posture assessments, the waist- and thigh-worn ActiGraph identified the lying down position correctly 73.6% and 78.2% of the time, respectively. For the standing posture, both the thigh- and ankle-worn ActiGraph achieved high identification rates of 83.8% and 82.3%, respectively. However, all devices exhibited poor performance in identifying the sitting position, ranging from 25.4% to 49.6% (Table 2).

Table . Percentage of times the ActiGraph correctly detected body posture compared with the physiotherapist recordings during experiment 1 (n=25).

Patient body posture	Experiment 1 devices' attachment								
	Waist, %			Thigh, %			Ankle, %		
	Lie[a]	Sit	Stand	Lie	Sit	Stand	Lie	Sit	Stand
Lie	74[b]	0	0	78[b]	54	0	54[b]	0	0
Sit	11	41[b]	38	0	25[b]	15	0	50[b]	15
Stand	0	57	61[b]	1	1	84[b]	0.1	48	84[b]
Off[c]	16	1	1	21	20	1	45	3	3

[a]Lie: laying down.

[b]Percentage of time the ActiGraph device correctly identified the body postures.

[c]Off: percentage of time that the device detected it was off.

Table 3 displays the results of the ICC analysis, comparing the step counts during the TUG tests recorded by the ActiGraph devices worn on the waist, thigh, and ankle compared with direct observation by the physiotherapist. Data from 2 participants were excluded due to errors in registering the start and end of the tests. The ankle-worn device demonstrated the highest agreement with the physiotherapist ($ICC_{2,1}$=0.94, 95% CI 0.85-0.97), the lowest bias (average of the mean difference=0.9 steps), and a lower percentage of error counting steps (12.8%). The waist-worn device also shows excellent agreement with direct observation ($ICC_{2,1}$=0.85, 95% CI 0.65-0.94) but higher bias (1.4 steps) and a higher percentage of error counting steps (21%). The thigh-worn device has the lowest agreement ($ICC_{2,1}$=0.75, 95% CI −0.21 to 0.93), the highest bias (overcounted on average 7.3 steps), and the highest percentage of error counting steps (28.8%).

Table . Intraclass correlations and percentage of error in counting steps between the physiotherapist (observer) step count and ActiGraph during the timed up and go test in experiment 1 (n=23).

Body location	Bias	ICC[a]	95% CI	*P* value	Percentage error counting steps
Waist	1.4	0.85	0.65 to 0.94	.001	21
Thigh	7.3	0.75	−0.21 to 0.93	.001	28.8
Ankle	0.9	0.94	0.85 to 0.97	.001	12.8

[a]ICC: intraclass correlation coefficient.

Experiment 2

The acceptability questionnaire was completed by 25 patients. Their responses indicated that 22 (88%) had never used a wearable before, 19 (76%) would wear a device for 5 to 7 days while in hospital, and 16 (64%) were willing to wear the device daily at home, up to 3 months, as part of a research study. Furthermore, 12 (48%) patients felt motivated to move when wearing a device, and 8 (32%) would prefer to wear the device on the wrist. Intercurrences during the 24-hour protocol, include the following challenges with the devices: 1 participant had the thigh device removed and reapplied by nurses, while another participant removed both the ankle and wrist devices due to discomfort and itching. In 1 case, the wrist device was taken off because of itchiness, and another participant forgot the purpose of the devices, leading to the removal of both the wrist and thigh devices. In addition, the wrist device was loosened because of swelling, 1 participant had to remove the ankle device for 24 hours due to a major infection on the lower leg, and another was unable to wear the thigh device because the tape caused irritation.

Of the 30 patients, the ActiGraph devices were positioned on the wrist and ankle in 11 (37%) patients and on the wrist and thigh in 19 (63%) patients for the 24-hour protocol. One thigh-worn device recorded only 1:36 of data during the 24-hour protocol so the data were not included in the analysis. On average, the patients wore the device on the wrist for 22:45 (range 20:58-25:51), on the thigh for 24:36 (range 23:33-26:51), and on the ankle for 20:11 (range 8:03-26:16). Intercurrences reported while wearing the devices included itchiness at the wrist and thigh, patients removing devices due to forgetting their purpose, and patients loosening the device due to joint swelling.

The ActiGraph algorithms for the thigh-worn devices have recently changed, combining lying down and sitting as sedentary posture and including stepping detection (Table 4). The thigh-worn devices identified 100% of sedentary posture while the patient was lying down, 98% while they were sitting, and 91% while they were standing. The ankle-worn devices best identified lying (89%) and standing (84%) postures, and poorly identified the sitting posture (43.2%). In addition, the ankle-worn devices classified the position as sedentary on average 93% of the time when lying, but only 49% while the patients were seated. The wrist-worn devices performed poorly compared with the thigh- and ankle-worn devices, identifying lying down between 49% and 52% of the time and sitting and standing around 15% - 25% of the time. The wrist-worn devices were able to identify 80% of the sedentary posture while the patient was lying down, and 71% while sitting (Table 4).

Table . Percentage of times the ActiGraph correctly detected body posture compared with the physiotherapist recordings during experiment 2 (N=30).

Patient's body posture	Experiment 2 devices' attachment										
	Wrist, %			Thigh, %				Ankle, %			
	Sed[a]	Lie[b]	Sit	Stand	Sed	Stand	Step	Sed	Lie	Sit	Stand
Lie	84	50[c]	34	8	100[c]	0	0	92	89[c]	3	1.3
Sit	72	46	26[c]	23	98[c]	1	1	47	4	43[c]	49
Stand	76	10	66	24[c]	8	91[c]	0	13	0	13	84[c]
Off[d]	—	8	5	0	—	—	—	—	6	4	2

[a]Sed: sedentary (lying down + sitting).

[b]Lie: laying down.

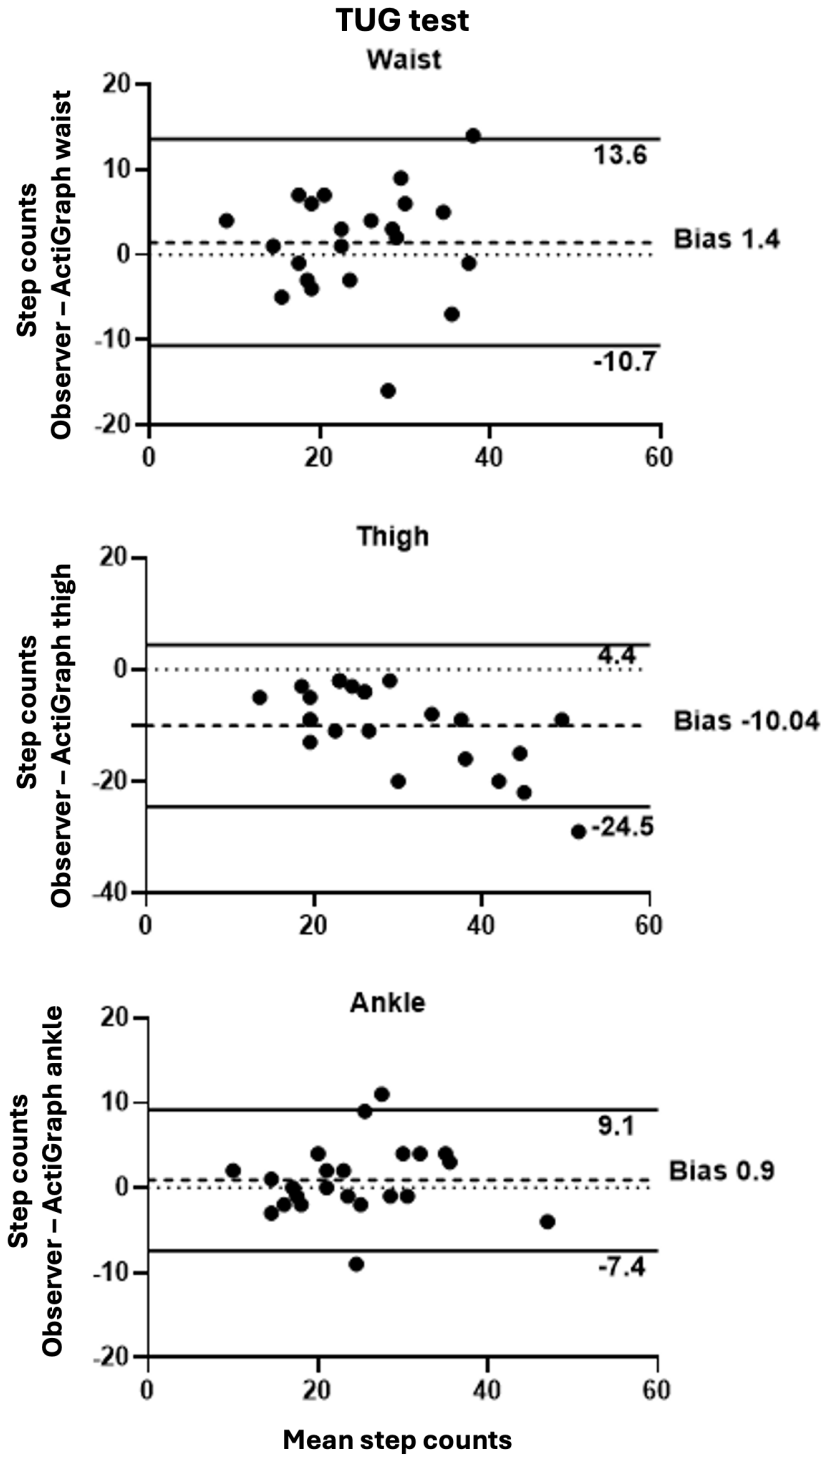
[c]Percentage of time the ActiGraph device correctly identified the body postures.

[d]Off: percentage time that the device detected it was off.

[e]Not applicable

Figure 2 shows the Bland-Altman plots of the difference between the observed step count and the ActiGraph placed on the waist, thigh, and ankle during the TUG test during experiment 1. Visual interpretation of the plots shows less bias (0.9), narrower limits of agreement (−7.4 to 9.1), and more observations closer to zero for the ankle-worn ActiGraph. In contrast, the thigh-worn device showed a larger limit of agreement, suggesting poor agreement between the 2 measurements, and a tendency to overcount steps.

Figure 2. Bland-Altman plots comparing observer measurements with ActiGraph data from devices worn on the waist, thigh, and ankle during the TUG test in experiment 1. The dashed lines denote the 95% limits of agreement (SD 1.96) of the mean difference, with darker dashed lines highlighting the mean difference or bias. TUG: timed up and go.



During the 30MWT in experiment 2, the wrist- and thigh-worn devices showed poor ICC values and a high percentage of miscounted steps. The ankle-worn devices showed excellent reliability and on average overcounted the number of steps by 1.9% (Table 5).

Table . Intraclass correlation coefficients and absolute percentage error of steps between the physiotherapist step count and the ActiGraph during the 30-Minute Walk Test in experiment 2 (n=30).

Body location	Bias	ICC[a]	95% CI	*P* value	Percentage error counting steps
Wrist	–42.1	–0.032	–0.217 to 0.218	.62	49.4
Thigh	–36.0	0.331	–0.149 to 0.706	<.001	56.8
Ankle	1.6	0.959	0.915 to 0.981	<.001	1.9

[a]ICC: intraclass correlation coefficient.

The Bland-Altman plots in Figure 3 illustrate the agreement between observer-rated step counts and ActiGraph step counts at the wrist, thigh, and ankle locations during the 30MWT. Among the 3 locations, the ankle-worn device demonstrated the best agreement with observer ratings, exhibiting a small bias and most observations falling within the 95% limits of agreement. In contrast, the wrist-worn device exhibited poor agreement, with the largest bias and widest limits of agreement.

Figure 3. Bland-Altman plots comparing observer measurements with ActiGraph data from devices worn on the wrist, thigh, and ankle during the 30 MWT in experiment 2. The dashed lines denote the 95% limits of agreement (SD 1.96) of the mean difference), with darker dashed lines highlighting the mean difference or bias. 30 MWT: 30-meter walk test.

Discussion

This study aimed to identify the optimal wearable device and wear location to assess and monitor mobility among older patients during hospitalization. We observed a high level of acceptability and feasibility regarding the usability and accuracy of wearable devices for detecting and monitoring activity in older patients hospitalized for acute medical illness. Although most patients had limited experience with activity monitoring devices, they were willing to wear one while hospitalized. Patients showed a preference for the Fitbit and ActiGraph devices, worn at the ankle or waist. Both the ActiGraph and Mox1 devices were easy to set up, but only the ActiGraph allowed for the retrieval of all data collected. Overall, the ActiGraph wGT3X-BT emerged as the preferred device with superior usability, data acquisition, and management.

The ActiGraph wGT3X-BT is widely recognized as the gold standard research-grade device for wearable mobility tracking, which is consistent with the findings of this study in our population. Its previous use in hospital settings underscores its utility for monitoring physical activity and posture in clinical contexts [28-30]. For example, other studies have employed the ActiGraph to predict hospital-acquired disability [28] and demonstrated its accuracy in quantifying postures and activity levels among hospitalized adults [29]. This study supports the device's reliability and validity among older hospitalized patients with unique challenges such as slower movement patterns and increased sedentary behavior.

However, when planning a cohort study in a hospital setting, it is crucial to consider multiple factors beyond just device accuracy, including accessibility to raw data and patient acceptability. During our study, the Fitbit Versa 1 was a popular device choice but lacked the option to download raw data directly. Instead, the download process relied on a companion device, a tablet, and any miscommunication between the 2 devices resulted in data lost. The MMC was selected for its affordability and open-source platform. However, we encountered challenges with the downloading process, which was time-consuming, and we also noted timestamp errors. The MATLAB function provided by the MOX 1 also resulted in missing data and lack of time stamps. Despite the challenges encountered with the MMC, MOX 1, and Fitbit devices in our study, it is plausible that these issues have since been addressed and resolved, underscoring the potential advancements made by these companies in their software and device functionalities. Our study highlights the importance of considering broader factors, such as data accessibility and device functionality, when evaluating the feasibility of wearable technology for hospital-based cohort studies.

Studies have suggested the lack of physical activity and immobilization during hospitalization may be more related to aspects of hospital care rather than to the patient's diagnosis [1,31]. While performance-based mobility tests can predict functional decline and hospital discharge, they are not commonly integrated into hospital measures [32-34]. Conducting a gait speed test, for example, is time-consuming and might not be feasible on a day-to-day basis in the hospital setting. Therefore, the use of wearable technology could be an attractive option, requiring minimal time investment for both patients and health professionals. There is a substantial body of literature on the utilization of wearables in hospitalized patients [16,28,34,35]. However, the research on patient feedback regarding their experiences and perceptions of wearing the devices while hospitalized is limited [17], which is crucial for optimizing their use in health care settings. In addition, we were particularly concerned about the potential interference of these devices with patients' medical conditions. Prolonged sitting and fluid intake, common in hospitalized patients, can lead to swelling, particularly in the ankles and wrists. We observed instances of wrist and ankle swelling in patients that resulted in the devices being removed, underscoring the importance of considering these issues when implementing wearable technology in hospital settings. Furthermore, we also considered the possibility of the devices interfering with medical equipment commonly used during hospitalization, including colostomy bags, urinary catheters, and wound dressings, as any disruption to these essential devices could compromise patient care and safety. For instance, in our first experiment, we applied an elastic band with pockets to the patient's waist, thigh, and ankle. We noticed that the waistband was problematic because it would interfere with heart sensor wires and colostomy bags. In addition, the thigh elastic band would easily fall from the participant's leg. Thus, in the second experiment, we disregarded the waistband and used an adhesive patch, which could also bring discomfort due to skin itchiness, as observed in our study. Considering these factors before launching a larger cohort is crucial and might save time and effort for both patients and researchers.

Our findings highlight the importance of considering both practical and contextual factors when selecting wear locations for mobility monitoring in hospital settings. While the literature supports the thigh for measuring postural behaviors and the waist or ankle for step counts, these locations may not always be feasible in clinical environments. Wrist-worn devices, although convenient and widely accepted, presented challenges such as patient discomfort due to swelling and skin irritation. This study serves as a preliminary exploration of acceptable and practical wear locations in a hospital setting, emphasizing the need to balance feasibility with the specific mobility metrics of interest.

It is well-established that sedentary behavior in hospitalized older adults is associated with a heightened risk of hospital-acquired disability (HAD) and functional decline [28,29]. Therefore, accurately measuring sedentary behavior in this population is essential for timely intervention and management strategies within the hospital setting. Body posture poses a challenge in accurate measurement, ideally requiring the use of at least 2 devices. For instance, thigh-worn devices have been reported as optimal for placing accelerometers to determine sedentary behavior (ie, lying and sitting). In this regard, the thigh-worn inclinometer algorithm provided by ActiGraph uses a movement threshold and thigh angular orientation to distinguish lying and sitting from standing and stepping [36]. Compared with other algorithms such as the activPAL, the ActiGraph's thigh angular parameter improves the classification of sitting posture, even when the participant

has their legs crossed or stretched, in both laboratory and free-living conditions [22,37]. Waist-worn devices are effective for differentiating lying from sitting but not from sitting and standing, while ankle-worn devices distinguish lying and standing. In our study, we tested the ActiGraph on the waist, thigh, and ankle, and in experiment 1, all wear locations performed well for lying and standing but poorly for sitting. We believe that the thigh elastic band likely changed position when participants transitioned from lying to sitting, changing the orientation of the ActiGraph, thus affecting the algorithms' ability to detect sitting posture. In experiment 2, we incorporated a wrist-worn device due to its user-friendly nature. To mitigate the issue encountered in experiment 1 with the elastic band, we adopted adhesive patches to secure the devices on the thigh and ankle. The thigh device exhibited the highest performance across various postures, followed by the ankle device, which showed adequate accuracy in detecting lying and standing postures. However, the wrist device, despite its ease of use, performed poorly in detecting all body postures. Our findings are supported by the literature [17,29], and we recommend using an accelerometer on the thigh and ankle to capture more detailed information on sedentary behavior.

Our investigation on step counts showed that the ankle is the most accurate body position to capture this metric. This finding aligns with previous research examining the validity of ankle-worn ActiGraph devices in conjunction with the lower frequency extension filter for step counting among hospitalized older adults [16,38]. In their study, Webber and St John [38] demonstrated that the ActiGraph positioned on the ankle was comparable with direct observation (ICC=0.94, median absolute error=2.5%) for monitoring step counts during the 10-meter walk test in hospitalized older adults. In addition, Anderson et al [16] reported that the ActiGraph positioned on the ankle (mean difference=−0.85 steps, ICC=0.99) accurately records step counts in hospitalized adults during free self-selected walking. By leveraging the ankle and thigh as the placement site for capturing mobility, researchers and health care practitioners can enhance the accuracy of monitoring and promote more effective interventions aimed at improving mobility and overall health outcomes in hospitalized adults and similar populations.

A potential limitation of this study is the bias introduced by patients wearing multiple devices simultaneously in experiment 1. The discomfort or inconvenience of wearing several devices may have influenced their feedback, as they were likely focused on the overall experience rather than evaluating each device individually. However, the primary goal of experiment 1 was to assess the feasibility of using multiple devices in a hospital setting, with a focus on understanding the practical and real-world challenges of device wearability, data retrieval, and integration in a clinical environment. While this may introduce some bias in the acceptability results, it does not diminish the value of these insights into how devices function together in practice.

Building on these findings, our study has several strengths, including identifying optimal devices and placement sites for wearable data collection, as well as validation through comparison with a gold-standard observer. However, it is important to note that our free-living protocol in experiment 2 was limited to a 24-hour duration. Despite this constraint, we were able to gather valuable insights, particularly regarding the feasibility and integration of wearable technology in hospital settings.

In conclusion, our study found that the ActiGraph wGT3X-BT was the most feasible device for assessing and monitoring mobility among older hospitalized patients. The ActiGraph's thigh-worn algorithm accurately detects sedentary behavior under supervised conditions and, when paired with a device at the ankle, provides detailed information on lying and sitting postures. In addition, our findings indicate that step counts can be accurately detected using the low-frequency extension with devices on the ankle. Therefore, we recommend the use of two devices, at the thigh and ankle, to accurately measure sedentary behavior and step count among older people in a hospital setting. Longer-term studies are warranted to evaluate the use of wearable data for predicting health outcomes after hospitalization and for informing clinical decision-making and efforts to promote early mobility among older hospitalized patients.

Acknowledgments

This project was supported by grants from the McMaster Institute for Research on Aging, McMaster University. MB holds a Tier2 Canada Research Chair in Mobility, Aging and Chronic Disease (CRC-2020-00043) and an Early Researcher Award from the Government of Ontario. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Authors' Contributions

LG, MD, and MB contributed to the conception and design of the work. RK, CC, and PN contributed to the acquisition and analysis of data. PN and RK contributed to the interpretation of data. YH, RZ, and SR contributed to the development of the software for data analysis of the MetaMotionC wearable. All authors contributed to drafting the work (or substantial revisions). All authors have read and approved the final manuscript and agree to be accountable for all aspects of the work.

Conflicts of Interest

None declared.

Abstract

Background: Dementia is characterized by impairments in an individual's cognitive and functional abilities. Digital cognitive assessments have been shown to be effective in detecting mild cognitive impairment and dementia, but whether they can stage the disease remains to be studied.

Objective: In this study, we examined (1) the correlation between scores obtained from BrainCheck standard battery of cognitive assessments (BC-Assess), a digital cognitive assessment, and scores obtained from the Dementia Severity Rating Scale (DSRS), and (2) the accuracy of using the BC-Assess score to predict dementia stage delineated by the DSRS score. We also explored whether BC-Assess can be combined with information from the Katz Index of Independence in activities of daily living (ADL) to obtain enhanced accuracy.

Methods: Retrospective analysis was performed on a BrainCheck dataset containing 1751 patients with dementia with different cognitive and functional assessments completed for cognitive care planning, including the DSRS, the ADL, and the BC-Assess. The patients were staged according to their DSRS total score (DSRS-TS): 982 mild (DSRS-TS 10 - 18), 656 moderate (DSRS-TS 19-26), and 113 severe (DSRS-TS 37-54) patients. Pearson correlation was used to assess the associations between BC-Assess overall score (BC-OS), ADL total score (ADL-TS), and DSRS-TS. Logistic regression was used to evaluate the possibility of using patients' BC-OS and ADL-TS to predict their stage.

Results: We found moderate Pearson correlations between DSRS-TS and BC-OS (r=−0.53), between DSRS-TS and ADL-TS (r=−0.55), and a weak correlation between BC-OS and ADL-TS (r=0.37). Both BC-OS and ADL-TS significantly decreased with increasing severity. BC-OS demonstrated to be a good predictor of dementia stages, with an area under the receiver operating characteristic curve (ROC-AUC) of classification using logistic regression ranging from .733 to .917. When BC-Assess was combined with ADL, higher prediction accuracies were achieved, with an ROC-AUC ranging from 0.786 to 0.961.

Conclusions: Our results suggest that BC-Assess could serve as an effective alternative tool to DSRS for grading dementia severity, particularly in cases where DSRS, or other global assessments, may be challenging to obtain due to logistical and time constraints.

Introduction

Dementia is characterized by impairments in an individual's cognitive and everyday functional abilities. Although the pattern and advancement of these impairments vary among patients, the disease is usually considered as having 3 main stages: mild (early-stage), moderate (middle-stage), and severe (late-stage) [1]. The distinction between these categories lies in the extent to which a patient's physical, cognitive, and psychosocial well-being deteriorates. The rate of deterioration widely varies and progresses through subtle changes in daily functioning to complete loss of independence and the need for a caregiver [1]. Staging of dementia has important implications for practical

decision-making and research [2]. From the practical standpoint, knowledge of disease severity is helpful for selection of appropriate intervention options, for prognosis and communication with patients and their family about expectations, care needs, as well as early planning for the future [3-5]. From the research standpoint, staging patients is needed to determine their eligibility for participation, to achieve better clinical efficacy, and to obtain homogeneous sampling in research studies [4], particularly clinical trials.

As noted earlier, dementia is not a monolithic disease; therefore, both cognitive and functional abilities need to be measured to accurately assess its severity and progression. Standardized cognitive tests can provide objective measures of cognitive functioning in different domains such as memory and executive function. Brief cognitive screening tests such as the Montreal Cognitive Assessment and the Mini-Mental State Examination are widely used in clinical practices, but they are rarely used to grade dementia severity [6,7]. Formal neuropsychological tests provide a more comprehensive evaluation of cognitive functioning to support differential diagnoses [8,9]. However, these tests typically take hours and require administration by specialists. Digital cognitive assessments are emerging as an efficient solution due to their self-administration capability, remote accessibility, and automated scoring. Although these types of assessments have been shown to be effective in detecting mild cognitive impairment and dementia [10-12], their ability to stage dementia is not yet clear. Functional assessments quantify the ability to perform activities of daily living through questionnaires such as the Katz Index of Independence in activities of daily living (ADL) [13,14]. Functional assessments are valuable for helping to evaluate dementia severity and also for providing proper guidance to patients and their caregivers.

In clinical practice, both cognitive and functional deficits can be measured using global staging scales. These scales typically come in the form of a questionnaire or interview, relying on subjective judgments and reports from patients or their knowledgeable informants. Compared with other scales, such as the Global Deterioration Scale [15] or the Functional Assessment Staging [16], the Clinical Dementia Rating (CDR) [17-19] scale appears to be the most well-studied and best-evidenced for dementia staging [20,21]. However, the use of this instrument is often impractical in many situations where time and cost are concerns, due to its semi-structured nature, long administration time (30 - 60 min), and requirement of clinical judgment from a trained professional during administration and scoring [18,22]. In response to this, brief instruments have been developed to mirror the CDR, including the Dementia Severity Rating Scale (DSRS) [23]. The DSRS uses a multiple-choice format in which the caregiver rates the patient's cognitive and functional ability in 12 categories [23,24]. The DSRS has been shown to be effective in staging and determining the progression of dementia [23,25,26].

While cognitive tests have been shown to correlate with the above dementia staging tools [4,27,28], previous research primarily focused on traditional paper-based cognitive tests. The increasing adoption of digital solutions and tools in health care calls for the re-evaluation of dementia staging tools and digital cognitive assessments. The first goal of this study was to examine the correlation between scores obtained from the BrainCheck standard battery of cognitive assessments (BC-Assess), a digital cognitive assessment, and scores obtained from the DSRS, a global staging scale. The second goal of this study is to evaluate the effectiveness of using the BC-Assess score to predict dementia stage delineated by the DSRS score. We also explored whether BC-Assess can be combined with information from ADL to obtain enhanced predictive capability.

Methods

Data Source

This retrospective study analyzed a real-world dataset of patients who received cognitive care planning services from their providers through BrainCheck Plan. These patients and their caregivers had completed a series of assessments, including DSRS, ADL, and BC-Assess, and received a comprehensive and personalized cognitive care plan. Inclusion criteria for this study were (1) patients 60 years of age or older; (2) assessments of cognitive care planning completed in English on an iPad; and (3) Dementia Severity Rating Scale total score (DSRS-TS) ≥10. The criterion for DSRS-TS was to only include patients that were rated by DSRS to have mild, moderate, and severe dementia [29].

Patients that showed evidence of moderate to severe depression, defined by a Geriatric Depression Scale score of 9 or above [30], were excluded. This is to avoid including reversible causes of dementia, which may have poorly correlated impacts on cognitive and functional measures. Given that depression is common among patients with dementia [31-33], patients with mild depression were not excluded to avoid overfiltering of the data. For patients having multiple care plans, only the latest record was considered. To reduce the impact of practice effect, only data from providers who had completed ≥20 cognitive care planning services for their patients were included. In total, data from 1751 patients with their cognitive care plans completed between February 2022 and April 2024 across 48 providers were included for this analysis.

Measurements

The DSRS is a brief informant-based questionnaire made up of 12 items that measure functional abilities, including memory, orientation to time, orientation to place, decision-making, social interaction, home activities, personal care, eating, toileting, mobility, recognition, and speech and language. DSRS-TS is calculated by adding up scores across 12 functional areas, ranging from zero (no impairment) to 54 (extreme impairment) [25]. The patients could be categorized into 3 groups of different dementia severity levels based on their DSRS-TS. The majority 56% (n=982) were mild-stage patients (DSRS-TS 10 - 18), moderate-stage patients (DSRS-TS 19 - 26) accounted for 37.5% (n=656), and the remaining 6.5% (n=113) were severe-stage patients (DSRS-TS 37 - 54). The 3 severity levels serve as class labels in a logistic regression analysis in this study to predict patients' conditions based on their BC-Assess and ADL data.

The BC-Assess, completed by the patients, consisted of 6 individual cognitive assessments: Immediate Recognition and

Delayed Recognition (memory), Digit Symbol Substitution (processing speed), Stroop (executive function), Trails Making Test A, and Trails Making Test B (attention or mental flexibility). Detailed descriptions of these tests can be found in previous studies [12,34]. The raw score for each assessment is calculated using assessment-specific measurements based on accuracy or reaction time (Table S1 in Multimedia Appendix 1). The BC-Assess raw overall score is the average of raw scores from all completed assessments after each score has been transformed from its natural range into a common range [0,100] using the formula in Table S1 in Multimedia Appendix 1. A *z*-score is then calculated for each assessment score and for the overall score using the corresponding age- and device-specific mean and standard deviation values from the BrainCheck normative database. Assessment standardized scores and BC-Assess overall standardized score (BC-OS) are reported by rescaling the *z*-scores to have a mean of 100 and a standard deviation of 15.

The ADL is an informant-based 6-item survey that measures an individual's ability to independently perform basic activities of daily living, including bathing, dressing, going to the toilet, transferring, continence, and feeding. It is calculated by adding up scores from the 6 categories, each of which takes a value of 1 for independent and 0 for dependent, resulting in an ADL total score (ADL-TS) ranging from 0 to 6. An ADL-TS of 2 or less indicates severe functional impairment, 3 - 4 indicates moderate impairment, and 5 - 6 indicates full function [13,35].

Statistical Analysis

Data analyses were performed using Python (version 3.8.5). Descriptives were presented for demographics and each score. The χ^2 test was used to examine whether the distribution of gender was similar in patients from the 3 groups. The Kruskal-Wallis test was used to compare the mean age of patients across groups.

A 3-way multivariate analysis of variance (MANOVA) was used to examine the joint variation of ADL-TS and BC-OS as a function of dementia stage, age group, and gender. Post-hoc analysis employed 1-way MANOVAs to compare these 2 scores across dementia stages for each individual age and gender group. Tests for statistical significance of the mean differences across stages, age groups, and genders were also performed separately for each score using 3-way ANOVAs. For these statistical comparisons, age is treated as a factor with 3 levels: 60 - 69, 70 - 79, and 80+.

Logistic regression was used to investigate the effectiveness of using the patients' BC-OS and ADL-TS to predict their dementia stage, where age and gender served as covariates. In this analysis, age is treated as a continuous variable, and gender is treated as a binary variable: 1 for male and 0 for female. Although the 3 dementia stages form ordinal classes, separate binary logistic regressions were used to classify mild versus moderate; moderate versus severe; and mild versus severe, because the proportional odds assumption was not satisfied for both BC-OS (P=.01) and ADL-TS (P<.001) from Brant's Wald test [36], suggesting ordered logistic regression was not appropriate.

The binary logistic regression model for predicting a patient's condition is:

$$(1)\text{logit}(p)=\beta0+\beta1\cdot\text{stBC}+\beta2\cdot\text{stADL}+\beta3\cdot\text{stAge}+\beta4\cdot\text{stGender}$$

where p is the probability of predicting the patient as having a pre-specified positive class. In each of the above binary classifications, we chose the more severe stage to be the positive class. stBC,stADL,stAge,stGender are standardized values of predictor variables BC-OS, ADL-TS, age, and gender. The coefficients βi`s (i=1 - 4) represent the effects of the 4 predictors, and β0 is the intercept.

Model fitting was based on weighted loss functions to take into consideration class imbalance across the 3 dementia groups. Model performance was evaluated using 5-fold cross-validation with stratification, repeated 20 times (100 iterations), such that on each iteration, all training and testing subsets had roughly the same proportion of patients from each group as in the original dataset. We compared four different models:

(1) full model that included all 4 predictors as in equation (1)

(2) reduced model 1 that included BC-OS and ADL-TS:

$$(2)\text{logit}(p)=\beta0+\beta1\cdot\text{stBC}+\beta2\cdot\text{stADL}$$

(3) reduced model 2 that included BC-OS, age, and gender:

$$(3)\text{logit}(p)=\beta0+\beta1\cdot\text{stBC}+\beta3\cdot\text{stAge}+\beta4\cdot\text{stGender}$$

(4) reduced model 3 that included only BC-OS:

$$(4)\text{logit}(p)=\beta0+\beta1\cdot\text{stBC}$$

An receiver operating characteristic (ROC) curve was generated for each model on each cross-validation iteration. Paired-samples *t*-tests were used to compare areas under the receiver operating characteristic curves (ROC-AUC) across models.

Ethical Considerations

This study was conducted using existing deidentified data collected through BrainCheck. The dataset contained no personal identifiers, and no attempt was made to reidentify the individuals. As such, the research does not meet the definition of "human subjects research" as outlined by HHS 45 CFR 46.102. Therefore, this study did not require ethics review or approval by an institutional review board.

Results

Demographics and Assessment Performance

Table 1 summarizes the demographic characteristics of the patients in this study. Group sample size decreased with increasing severity for both genders. The distribution of gender was similar across the 3 groups (P=.84). Although the range of age was similar, mean age significantly increased with severity (P<.001; pairwise comparisons: P<.001 for mild vs moderate and mild vs severe, P=.02 for moderate vs severe). Statistical comparisons were not performed for education level and race due to a lot of missing information.

Table . Demographics and summary statistics of scores across dementia severity groups and the total sample.

Demographic characteristics	Mild group (n=982)	Moderate group (n=656)	Severe group (n=113)	Total (N=1751)
Gender, n (%)[a]				
Female	589 (60)	394 (60.1)	71 (62.8)	1054 (60.2)
Male	393 (40)	262 (39.9)	42 (37.2)	697 (39.8)
Age, years[b]

[a]P=.84 (χ^2 test): distribution of gender was not significantly different across groups.

[b]P<.001 (Kruskal-Wallis test): mean age of patients was significantly different across groups.

[c]P<.001 (χ^2 test): distribution of age bucket was significantly different across groups.

[d]DSRS-TS: Dementia Severity Rating Scale total score.

[e]BC-OS: BrainCheck standard battery of cognitive assessments overall score.

[f]ADL-TS: activities of daily living total score.

The means and standard deviations of DSRS-TS, ADL-TS, and BC-OS are provided in Table 1. Overall, the BC-OS and ADL-TS decreased with increasing severity delineated by the DSRS-TS. Figure 1 shows the distributions of BC-OS and ADL-TS across patients within each group. For both scores, the distribution was systematically skewed toward the high values for the mild group, toward the low values for the severe group, and more evenly distributed for the moderate group. Table 2 shows the number and percentage of cases in each group that fall in different BC-Assess and ADL-TS score intervals.

Figure 1. Box plots of the distributions of BrainCheck standard battery of cognitive assessments overall score (BC-OS; left) and activities of daily living total score (ADL-TS; right) for each patient group: green=mild, yellow=moderate, and red=severe. Normally distributed random noise was used to add displacements along the x-axis for patients within each group (left and right) and along the y-axis at each ADL-TS value (right).

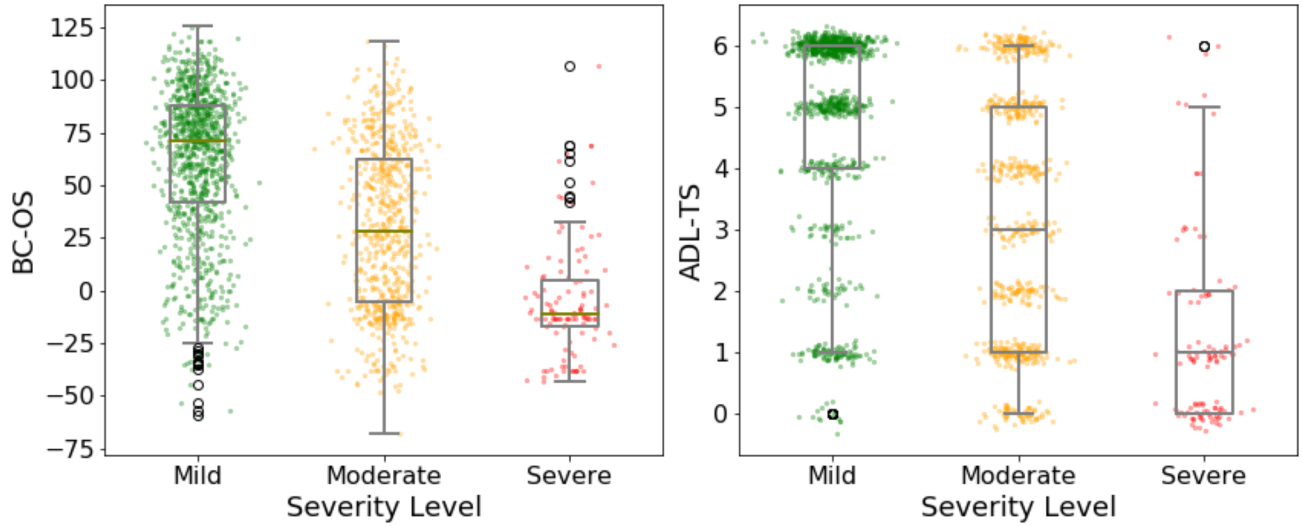

Table . ADL-TS[a] and BC-OS[b] distributions across dementia severity groups.

Score	Mild group (n=982)	Moderate group (n=656)	Severe group (n=113)
BC-OS, n (%)			
Beyond 2 SD of normative mean[c]	480 (48.9)	532 (81.1)	112 (99.1)
Within 2 SD of normative mean	502 (51.1)	124 (18.9)	1 (0.9)
ADL-TS, n (%)			
0 - 2 (severe)	137 (14)	275 (41.9)	96 (85)
3 - 4 (moderate)	119 (12.1)	142 (21.7)	10 (8.8)
5 - 6 (Full function)	726 (73.9)	239 (36.4)	7 (6.2)

[a]ADL-TS: activities of daily living total score.

[b]BC-OS: BrainCheck standard battery of cognitive assessments overall score.

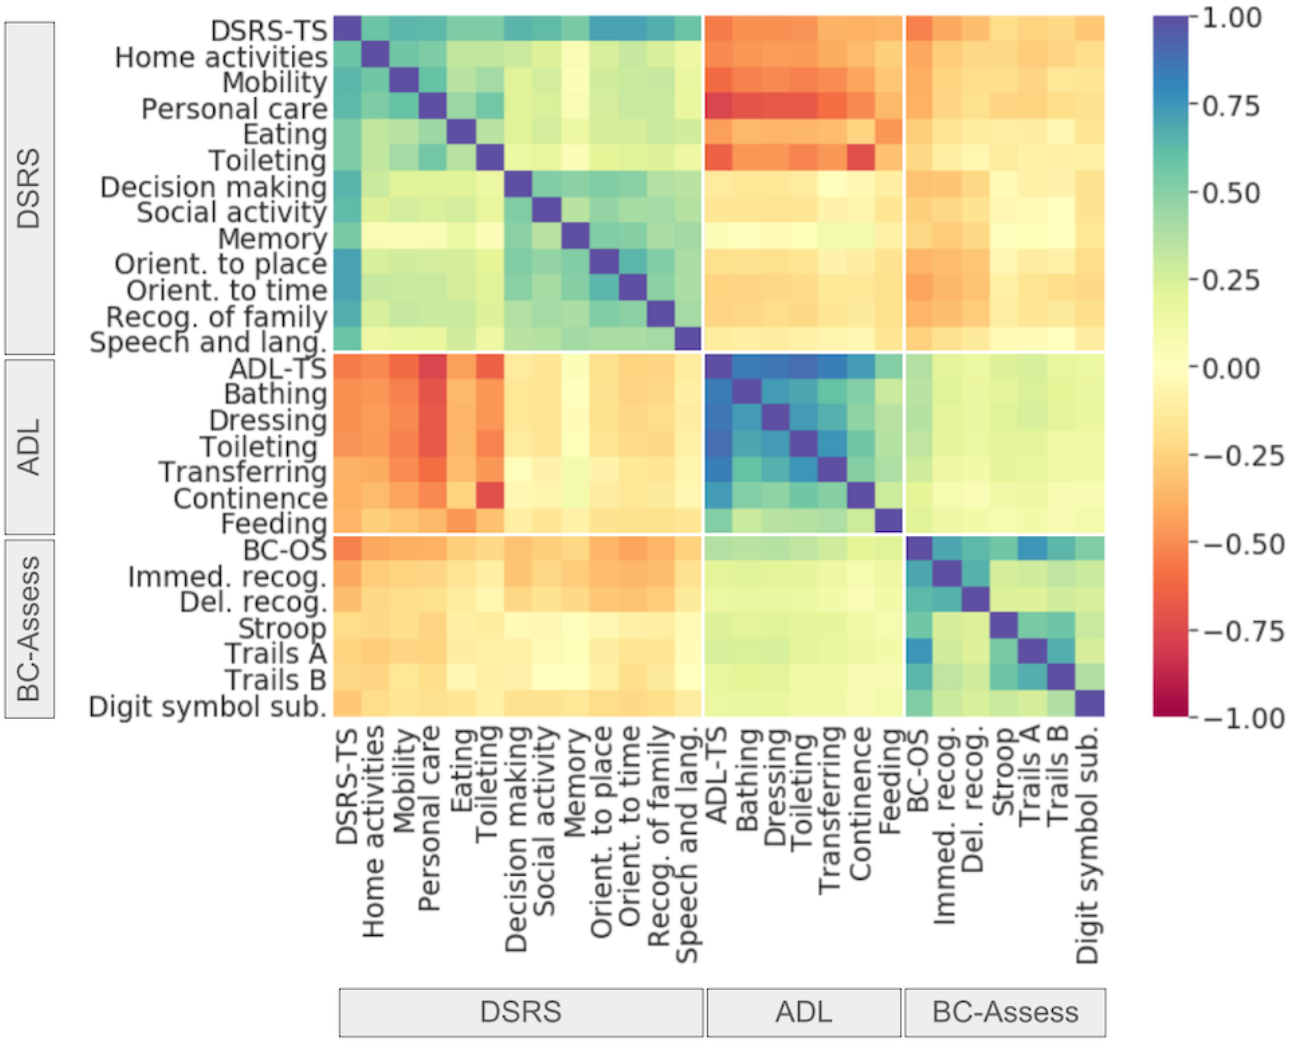
[c]Based on a BC-OS normative mean of 100 and a standard deviation of 15.

Correlations Between Assessments

We found moderate Pearson correlations between DSRS-TS and BC-OS (r=−0.53; P<.001), between DSRS-TS and ADL-TS (r=−0.55; P<.001), and a weak correlation between BC-OS and ADL-TS (r=0.37; P<.001). Since DSRS covers both cognitive and functional performance of a patient, moderate associations between DSRS-TS with BC-OS and ADL-TS were as expected. The weak correlation between ADL-TS and BC-OS suggests that cognitive and functional abilities are associated with each other, but certain discrepancies exist between the two.

The heatmap in Figure 2 plots Pearson correlations across DSRS, BC-Assess, and ADL subscores. Compared with BC-Assess subscores, BC-OS showed stronger correlations with DSRS and ADL subscores. However, these correlations were weak. Among DSRS subscores, BC-OS was most associated with home-activities (r=−0.41; P<.001), mobility (r=−0.39; P<.001), personal-care (r=−0.39; P<.001), orientation-to-time or orientation-to-place (r=−0.43 and −0.37; P<.001), and recognition-of-family (r=−0.37; P<.001). Among ADL subscores, BC-OS was most associated with dressing (r=0.36; P<.001), bathing (r=0.35; P<.001), and toileting (r=0.33; P<.001). Although weaker, a clear trend can be observed from Figure 2 for BC-Assess subscores. With regard to the DSRS, assessments of memory (Immediate or Delayed Recognition) were most associated with memory-demanding activities such as memory, orientation-to-time, orientation-to-place, recognition-of-family, and decision-making, whereas assessments of executive function, attention, or mental flexibility (Stroop, Trails Making A/B) were most associated with home-activities, mobility, and personal-care. With regard to the ADL, BC-Assess subscores were more associated with bathing, dressing, and toileting than with categories that are more essential, such as feeding, continence, and transferring. Between ADL and DSRS subscores, correlations mainly occurred within a subset of DSRS activities that are of the same types as those rated by the ADL such as eating, home-activities, mobility, personal-care, and toileting. Of these, the strongest correlations were found between DSRS toileting and ADL continence (r=−0.72; P<.001), and between DSRS personal-care and ADL bathing (r=−0.70; P<.001), dressing (r=−0.68; P<.001), and toileting (r=−0.68; P<.001).

Figure 2. Correlations between BC-Assess (BrainCheck standard battery of cognitive assessments), DSRS (Dementia Severity Rating Scale), and ADL (activities of daily living) subscores. DSRS-TS: DSRS total score; ADL-TS: ADL total score; BC-OS: BC-Assess overall score.



Comparison of BC-OS and ADL-TS Across Dementia Stages, Age Groups, and Genders

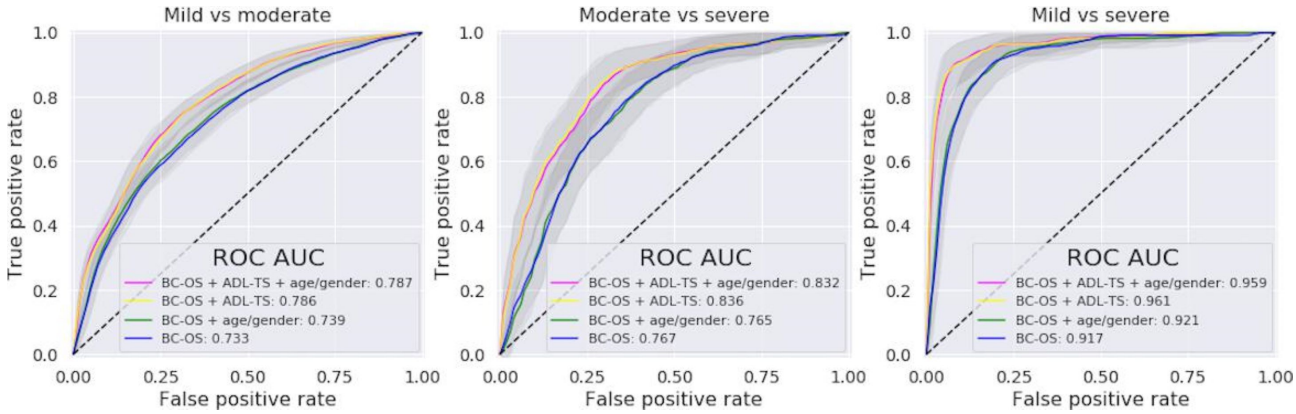
Given the correlation between BC-OS and ADL-TS, we analyzed the differences in these two scores across dementia stages, age groups, and genders by running a 3-way MANOVA (*BC-OS + ADL-TS~ Dementia Stage * Age Group * Gender*). Results based on the Pillais Trace method showed a significant effect of Dementia Stage (Pillais Trace =0.046 , $F_{43,466}$=20.5; *P*<.001) whereas the effects of age and gender and all interaction terms were not significant. Post hoc 1-way MANOVAs (*BC-OS + ADL-TS~ Dementia Stage*) were run to compare BC-OS and ADL-TS combined between mild versus moderate and between moderate versus severe separately for each age and gender group. Except for the 60 - 69 and female group (n=136) showing a nonsignificant difference between moderate versus severe, significant differences were observed for all other cases. We further performed 3-way ANOVAs where BC-OS (*BC-OS~ Dementia Stage * Age Group * Gender*) and ADL-TS (*ADL-TS~ Dementia Stage * Age Group * Gender*) were considered separately. For BC-OS, we found a significant main effect of Dementia Stage only ($F_{21,733}$=270.31; *P*<.001). The insignificant differences in BC-OS across age groups were as expected as this score had been standardized to adjust for age differences. For ADL-TS, we found significant effects of Dementia Stage ($F_{21,733}$=278.87; *P*<.001), Age Group ($F_{21,733}$=4.77; *P*=.009), and Gender ($F_{11,733}$=7.82; *P*=.005). For both scores, no interaction terms were significant.

Logistic Regression to Examine the Roles of BC-OS, ADL-TS, Age, and Gender in Predicting a Patient's Condition

ROC analysis (Figure 3) showed a comparable performance between the full model (*BC-OS + ADL-TS + age or gender*: ROC-AUC=0.787 for mild vs moderate; 0.832 for moderate vs severe; and 0.959 for mild vs severe) and reduced model 1 (*BC-OS + ADL-TS*: ROC-AUC=0.786 for mild vs moderate; 0.836 for moderate vs severe; and 0.961 for mild vs severe), and between reduced model 2 (*BC-OS + age or gender*: ROC-AUC=0.739 for mild vs moderate; 0.765 for moderate vs severe; and 0.921 for mild vs severe) and reduced model 3 (*BC-OS* only: ROC-AUC=0.733 for mild vs moderate; 0.767 for moderate vs severe; and 0.917 for mild vs severe). The small differences in ROC-AUC generated by the omission of age and gender suggest that they are not important predictors. Moreover, including these demographic factors appears to have led to some degree of overfitting where reduced model 1 performed slightly but significantly better than the full model (mild vs severe:

P=.002; moderate vs severe: *P*<.001) and reduced model 3 performed slightly but significantly better than reduced model 2 (mild vs moderate: *P*<.001; moderate vs severe: *P*=.04; mild vs severe: *P*<.001).

Figure 3. Model comparisons for the classification between mild and moderate (left) and between moderate and severe (right): receiver operating characteristic curves and mean area under the receiver operating characteristic curve (ROC AUC) for the full model (BrainCheck standard battery of cognitive assessments overall score [BC-OS] + activities of daily living total score [ADL-TS] + age and gender; magenta), reduced model 1 (BC-OS + ADL-TS; yellow), reduced model 2 (BC-OS + age and gender; green), and reduced model 3 (BC-OS only; blue). The shaded area along each curve represents the corresponding standard deviation across cross validation iterations. In each classification, the more severe condition was chosen to be the positive class.



The 2 models that include ADL-TS (full model and reduced model 1) performed significantly better than the 2 models without ADL-TS (reduced models 2 and 3) (*P*<.001 for each pairwise comparison), suggesting the important role of ADL. For all binary classifications, although BC-OS alone can serve as a fairly effective predictor with an ROC-AUC of at least 0.733, including ADL-TS in the model significantly improved prediction accuracy.

As age and gender were not important factors, we excluded them from further analysis. We examined the diagnostic performance of reduced models 1 (*BC-OS + ADL-TS*) and 3 (*BC-OS* only) at the optimal cut-points from their ROC curves. These are points on the ROC curves that maximize true positive rate and minimize false positive rate. Table 3 shows sensitivity (true positive rate) and specificity (1–false positive rate) at the optimal cut-point for each model and classification. When included, ADL-TS improved the sensitivity and specificity by 3% - 5%. For reduced model 3, which included only BC-OS, we found that the optimal cut-point corresponded to a BC-OS of 52 (roughly 3 standard deviations below the normative mean) for the classification between mild versus moderate, and a BC-OS of 0 for the classification between moderate versus severe.

Table . Sensitivity (Se) and specificity (Sp) by model and classification: mean (SD) across cross-validation iterations. In each classification, the more severe condition was chosen to be the positive class.

Classification	BC-OS[a] + ADL-TS[b]		BC-OS only	
	Se, mean (SD)	Sp, mean (SD)	Se, mean (SD)	Sp, mean (SD)
Mild versus moderate	0.74 (0.04)	0.72 (0.04)	0.69 (0.05)	0.68 (0.05)
Moderate versus severe	0.84 (0.06)	0.76 (0.05)	0.77 (0.07)	0.72 (0.07)
Mild versus severe	0.92 (0.04)	0.93 (0.03)	0.89 (0.04)	0.86 (0.04)

[a]BC-OS: BrainCheck standard battery of cognitive assessments overall score.

[b]ADL-TS: activities of daily living total score.

The fitted model coefficients are provided for reduced models 1 and 3 in Table 4. The 1-sided *P* value obtained from bootstrapping for each coefficient is shown in the parentheses.

Table . Coefficients (*P* values) of the fitted reduced models 1 (*BC-OS*[a] + *ADL-TS*[b]) and model 3 (*BC-OS* only).

	Regression coefficients, β (*P* value)				
	Reduced model 1			Reduced model 3	
Classification	β0 (Intercept)	β1 (stBC)	β2(stADL)	β0 (Intercept)	β1 (stBC)
Mild versus moderate	−0.071 (.01)	−0.757 (<.001)	−0.717 (<.001)	−0.053 (.002)	−0.890 (<.001)
Moderate versus severe	−0.819 (<.001)	−0.989 (.03)	−1.059 (<.001)	−0.453 (<.001)	−1.215 (<.001)
Mild versus severe	−2.443 (<.001)	−1.611 (<.001)	−1.517 (<.001)	−1.557 (<.001)	−2.076 (<.001)

[b]ADL-TS: activities of daily living total score.

Discussion

By conducting a retrospective analysis of patient data in real-world clinical settings, this study sought to investigate the relationship between cognitive performance in a battery of digital cognitive assessments, BC-Assess, and dementia severity measured by the DSRS. We found a statistically significant moderate correlation between the BC-OS and the DSRS-TS. This correlation is comparable with that between the ADL-TS and the DSRS-TS. Both BC-OS and ADL-TS significantly decrease with increasing severity. BC-Assess demonstrated to be a good predictor of dementia severity, with ROC-AUC of classification using logistic regression ranging from 0.733 to 0.917. When BC-Assess was combined with ADL, higher prediction accuracies were achieved, with ROC-AUC ranging from 0.786 to 0.961.

Our results suggest that BC-Assess could serve as an alternative tool to DSRS for grading dementia severity, particularly in cases where DSRS, or other global assessments, may be challenging to obtain due to logistical and time constraints. Unlike DSRS, BC-Assess, as a brief digital cognitive assessment, offers the advantage of flexible choice of self-administration or administration by clinical support staff, runs on common consumer technology, and does not require availability of an informant. The significant improvement of prediction accuracies when BC-Assess is combined with ADL indicates the synergetic relationship between cognitive and functional measures in grading dementia severity. Previous studies have shown that patients' loss of independence to manage activities of daily living is nonlinearly related with their cognitive decline [37], and their correlation weakens as the disease progresses [38]. This is consistent with the finding of relatively low correlation (r=0.37) between the 2 measures in this study and elsewhere [39,40]. Together, these findings suggest that ADL carries additional information of functional abilities that is partially independent of cognitive abilities measured by BC-Assess. When combined, the 2 measures provide a more comprehensive understanding of a patient's condition.

While the BC-OS and the ADL-TS from the mild and severe groups separate well from each other, scores from the moderate group vary widely among patients and largely overlap with both the mild and severe groups. This is reflected in high sensitivity and specificity (.86 or higher) for the classification between the mild and severe groups, and moderate sensitivity and specificity (0.83 or lower) for the classifications of the moderate group. Overall, however, a gradual change in the distribution of each score across stages can be observed. In line with current knowledge about the progression and stages of dementia [1,41], this pattern of results suggests that cognitive and functional declines do not happen in the same way across patients with dementia, and that there might only be subtle differences in cognitive or functional performance, or both, across patients within 2 successive stages.

Implicit in this study is the assumption that the staging of dementia severity based on the DSRS-TS had accurately identified each patient's underlying degree of severity. Previous studies demonstrated that the DSRS has high test-retest and inter-rater reliability [25] and good concurrent validity with high correlations with the CDR, the Mini-Mental Status Examination, and the Consortium to Establish a Registry for Alzheimer's Disease [23,25]. Other studies showed that the DSRS-TS can effectively differentiate between individuals with dementia, MCI, and healthy controls [42], and that it changes at a constant linear rate throughout the entire clinical course of dementia [25]. However, the psychometric properties of the DSRS in distinguishing between patients with mild, moderate, and severe dementia have not been studied. The DSRS-TS cut-offs used for staging of dementia severity have been suggested based on the mapping of the DSRS-TS onto CDR stages where a CDR global score of 0, 0.5, 1, 2, and 3 represent no, questionable, mild, moderate, and severe dementia. However, it has been shown that there is a large variability in the degree of severity among patients placed in a particular CDR stage, and patients with the same degree of severity can be placed in different CDR stages [2,43,44]. Furthermore, the precision of severity grading depends on the scoring approach to the CDR, ie, the item-response-theory approach is more precise than the sum-of-the-boxes approach, which is more precise than the global score approach [43]. On top of that, the mapping of DSRS-TS to CDR global score was based on a limited sample of patients with dementia that might not be representative of patients at different severity stages in general [23]. These limitations are possible contributing factors to the widespread distributions and overlaps of BC-OS and ADL-TS across patient groups delineated by the DSRS-TS in this study. To allow for more systematic investigations into the effectiveness of using these scores in dementia staging, future research needs to address these limitations and establish more fine-grained and well-defined staging criteria as well as optimize

the scoring methods for the DSRS, the CDR, and other assessments of dementia severity.

Suboptimal and inconsistent data quality in a dataset acquired outside typical clinical research settings is another factor that potentially causes large variabilities of scores observed in this study [45]. While real-world data may better represent diverse clinical environments, which is desired to obtain a generalized relationship between assessments, limited control over the data collection process and differences in clinical practices may result in reduced accuracy and consistency of the data. Inconsistencies exist across clinical sites and across units within each site due to differences in internal policies, staff training, workflow, and expertise. Inconsistencies also come from the different patient or caregiver populations each site serves. Patients may also have different dementia pathologies, leading to significant differences in the pattern of scores.

The ADL and BC-Assess also have their own limitations that one should take into consideration when interpreting the current results. The ADL measures 6 basic activities of daily living and employs dichotomous scoring, which allows only 2 possible scores for each functional category, ie, 1 for *independent* and 0 for *dependent*. Therefore, it lacks the resolution to capture intermediate levels of dependence. Furthermore, as it is subjective ratings from informants, for cases with small changes in functional activities, patients may end up receiving substantially different scores depending on their caregivers' judgments, resulting in low interrater variability [46,47]. In this study, with only patients with dementia included (based on their DSRS-TS), we found high variability in the ADL-TS across patients within each group, especially for the moderate group. As for the BC-Assess, besides measurement errors that exist in any assessment and technical difficulties older adults may have when using smart devices for the assessment, it might have limited utility in severity staging because patients with extremely severe conditions might not be able to complete it [48], and it could also suffer from a floor effect, a common limitation of psychometric tests [49].

Our data show a high imbalance in the number of patients across the 3 groups, with mild, moderate, and severe dementia accounting for 56%, 37.5%, and 6.5%, respectively. Although the trend is similar, higher proportions of patients estimated to be in the moderate (31%) and severe (21%) stages of Alzheimer's Disease were reported in a previous study [50]. As patients included in this study were those that received cognitive care planning services from their providers through the BrainCheck Plan platform within a 2-year period, our data do not necessarily reflect the prevalence of each stage. The fact that we only included patients with DSRS, ADL, and BC-Assess data also limited the number of patients in later stages who might be too impaired to take the BC-Assess. Furthermore, given its main goals are to help patients and their families better understand the patients' condition and needs, to offer strategies to improve their overall quality of life, and to plan for the future when their condition gets worse, cognitive care planning is more meaningful for patients in early stages. Patients in the severe stage of dementia are completely dependent on their family or caregivers, and many of them require specialized care and attention in facilities. These institutionalized patients tend to have been diagnosed and given care plans tailored to their specific needs by the institution.

In addition to the findings of this study, the growing field of ecological digital assessment tools offers valuable insights into monitoring and predicting dementia progression using digital biomarkers in real-world settings. For example, Buegler et al [51] show how these tools provide individualized, context-sensitive data to better understand cognitive performance. Integrating ecological tools with measures like BC-Assess could enhance its utility by capturing real-time data and offering a more comprehensive view of a patient's condition. These tools could also address challenges in tracking cognitive and functional abilities over time, particularly when in-person assessments or informants are unavailable. Further research into combining ecological tools with BC-Assess could refine dementia severity assessments and improve patient outcomes across stages of the disease.

Despite the limitations, this study shows that BC-Assess could be a promising solution for measuring dementia severity. The use of BC-Assess for this purpose will be particularly useful in primary care settings, where DSRS or other comprehensive global assessments may pose implementation challenges. Due to its flexibility, efficiency, and ease of use, BC-Assess can help streamline the assessment process, supporting timely diagnosis and management of dementia. This, in turn, can improve patient outcomes and ease the burden on caregivers.

Abstract

Background: Dementia is a progressive neurodegenerative condition that affects millions worldwide, often accompanied by agitation and aggression (AA), which contribute to patient distress and increased health care burden. Existing assessment methods for AA rely heavily on caregiver reporting, introducing subjectivity and inconsistency.

Objective: This study proposes a novel, multimodal system for predicting AA episodes in individuals with severe dementia, integrating wearable sensor data and privacy-preserving video analytics.

Methods: A pilot study involving 10 participants was conducted at Ontario Shores Mental Health Institute. The system combines digital biomarkers collected from the EmbracePlus (Empatica Inc) wristband with video-based behavioral monitoring. Facial features in video frames were anonymized using a masking tool, and a deep learning model was used for AA detection. To determine optimal performance, various machine learning and deep learning models were evaluated for both wearable and video data streams.

Results: The Extra Trees model achieved up to 99% accuracy for personalized wristband data, while the multilayer perceptron model performed best in general models with 98% accuracy. For video analysis, the gated recurrent unit model achieved 95% accuracy and 99% area under the curve, and the long short-term memory model demonstrated superior response time for real-time use. Importantly, the system predicted AA episodes at least 6 minutes in advance in all participants based on wearable data.

Conclusions: The findings demonstrate the system's potential to autonomously and accurately detect and predict AA events in real-time. This approach represents a significant advancement in the proactive management of behavioral symptoms in dementia care.

Introduction

Background

Dementia is a neurodegenerative condition that leads to a progressive decline in cognition and is one of the leading causes of death, disability, and hospitalization in Canada and worldwide. Currently, dementia is the seventh cause of death worldwide [1]. Worldwide, over 55 million individuals are living with dementia; as the ratio of older people increases, this number will grow to 78 million by 2030 and 139 million by 2050, making dementia a major global health crisis [1]. In addition to cognitive and functional decline, people living with dementia also experience noncognitive neuropsychiatric symptoms (NPS) during their illness [2]. NPS commonly includes agitation, aggression, apathy, symptoms of psychosis, delusions, hallucinations, and disturbances of sleep and appetite. Among NPS, agitation and aggression (AA) occur frequently

in severe cases and are a common source of distress for patients and caregivers [3]. They commonly occur during care and are believed to be manifestations of perceived or real unmet needs [3]. Behaviors of AA include pacing, rocking, gesturing, restlessness, shouting, throwing objects, and destroying property [4]. These symptoms are the leading cause of hospitalizations, extended length of stay of inpatients, and increased demand for placement in long-term care facilities [5]. AA enormously burdens people living with dementia, their families, caregivers, and health care systems.

In current practices, AA is commonly assessed through caregiver reports. Many observational methods have been developed, including the Neuropsychiatric Inventory [6] and the Cohen-Mansfield Agitation Inventory [7]. These assessments are based on manual observations, which are subject to potential bias depending on the caregiver's memory or emotional state. It is possible to address these limitations by using artificial intelligence (AI) and predictive algorithms to predict episodes of AA in people living with dementia. In 2025, AI technologies are expected to be worth an estimated US $36 billion [8]. There is growing evidence that combining AI and sensory technologies to develop a solution for NPS detection will guide the provision of personalized interventions for people living with dementia [9-11]. The timely detection of critical events in people living with dementia using digital technologies is gaining wide acceptance [12,13]. Predicting and managing AA in people living with dementia requires innovative approaches that integrate multiple data sources. Wearable sensors and video-based monitoring systems provide unique opportunities for the real-time detection of AA and preagitation behaviors, but challenges such as privacy concerns and scalability have limited their adoption in clinical settings. This study addresses these challenges by combining biometric data from wearable sensors with AI-driven video analysis, enabling real-time detection and prediction of AA. This integrated approach aims to facilitate timely interventions, reduce care costs, and improve outcomes for both patients and caregivers. We conducted a pilot study in the Geriatric Dementia Unit (GDU) and the Geriatric Transitional Unit at the Ontario Shores Center for Mental Health Sciences [14]. We combine biometric data from the EmbracePlus wristband [15] and video data from CCTV cameras installed in common areas in both units. Machine learning and deep learning techniques, including Extra Trees, Gradient Boosting, Random Forest, multilayer perceptron (MLP), and recurrent neural networks (RNNs), are used to analyze biometric and skeletal data extracted from both the wristband and the video cameras. We achieved high accuracy in detecting AA from the EmbracePlus wristband through comprehensive data preprocessing, feature extraction, the Extra Trees classification algorithm for personalized models, and the MLP algorithm for the general model. Additionally, AA detection was enhanced by analyzing real-time video feeds with skeletal key points and using RNN-based neural networks, particularly long short-term memory (LSTM) and gated recurrent unit (GRU) [16]. These networks, optimized for real-time processing, facilitate timely interventions. The pilot study demonstrated the system's effectiveness through both the wristband and video detection.

Related Work

The growing number of people living with dementia causes significant challenges for health care systems and caregivers. One of these challenges is to deal with symptoms of AA that increase with the severity of dementia. Recent advancements in multimodal sensing technologies, including cameras and wearable wristbands, have shown promise in monitoring and managing AA in people living with dementia [10,17,18]. Wearable devices, capable of capturing physiological signals such as acceleration, heart rate, and skin conductance, have demonstrated potential for real-time AA detection [19-21]. Recent advancements in wearable sensor technology and AI have shown promise in addressing the early detection of AA behavior when focusing on signal processing and machine learning to extract features and classify AA events [22].

However, real-time video-based monitoring systems to monitor AA behavior in dementia patients are an area of interest for researchers today [10,17,23]. These systems use cameras positioned in patients' rooms or common areas to consistently record and monitor patients' behavioral data. Some research [24,25] used video cameras to detect AA from previously recorded videos at the Specialized Dementia Unit, Toronto Rehabilitation Institute, Canada. Their system focused on offline AA detection. Another work collected the training dataset from healthy people who imitated agitated hand movements [26]. Researchers have highlighted the importance of real-time feedback, which allows for timely interventions and reduces the severity and duration of AA events. This can help improve the quality of life and reduce the stress caused by agitated behaviors in both patients and caregivers. Researchers have also considered privacy factors and concerns while ensuring the accuracy of these systems. The work done in studies by Mishra et al [24] and Marshall [26] has proposed different masking methods for the people in the video frames that allow for AA detection while keeping the patients' identities and features hidden.

Multimodal sensing, which combines data from multiple sensors, types, and sources, has emerged as a promising approach to understanding AA in people living with dementia [27,28]. It enhances the detection of early signs of AA and the identification of relevant triggers [23,29]. Clinical trials evaluating the use of multimodal sensing in the context of dementia and AA behavior are crucial in this type of research. These trials assess the feasibility and efficacy of monitoring systems that combine various data sources to inform clinical decision-making. The results of these trials will provide valuable insights into the practical implications of multimodal sensing in real-world health care settings. Most existing studies on video systems and wearable sensors for AA detection in real-time have been conducted in controlled laboratory settings or residential care facilities with limited datasets [18,30]. Research is needed to use more diverse and general datasets gathered and applied in real hospital settings. This is essential since the data from hospitals would be more representative of people with severe dementia who are more prone to AA. Research in such a real-world setting with data gathered from real patients is vital for developing realistic and applicable solutions and ensuring

effective treatment and care for people living with dementia [18,30].

Moreover, it is challenging to identify the actual start and end times of AA episodes. This is because the AA events are extracted from nurse notes, which are not accurate and prone to human or individual error. Many AA episodes may also be overlooked and mislabeled as nonagitation. In addition to the datasets, there is a high demand for accurate and reliable end-to-end real-time monitoring solutions to actively predict and respond to AA events. There is also still a need for an in-depth investigation of AI and its features in addition to an in-depth investigation of preagitation patterns and signs that could trigger AA in people living with dementia. These investigations are necessary to indicate the usefulness of preagitation signs and patterns in early prediction. Digital biomarkers can help detect and predict AA early in real time [31]. The investigation by Alam et al [32] shows the correlation between motion biomarkers collected from the accelerometer and the early AA signs, which is particularly useful for personalized AA detection models.

This paper presents a unique system that combines video analysis and wearable sensor data to predict AA in people living with dementia. The video feeds are crucial for identifying the precise start and end of each AA episode. This precise timing enables us to incorporate data analysis from both the wristband and video footage into our research. We focus on AI and advanced feature engineering to improve the detection accuracy of AA in people living with dementia. We significantly enhance our chances of detecting AA by using 2 distinct yet cooperative models (one based on physiological data and the other on video analysis). This integrated approach also opens the doors to incorporating additional predictive methods, such as audio-based AA detection. The combined use of video-based systems and wearable wristbands offers deeper insights into AA management. While notable advancements have been achieved, further enhancements are needed, especially in real-time accuracy and system applicability. We are confident that our current research explores a vital area and will contribute new knowledge to the field and lay a solid foundation for future advancements.

Methods

Ethical Considerations

The research commenced in 2019. This study was approved by the Joint Research Ethics Board (JREB) at Ontario Shores Centre for Mental Health Sciences and Ontario Tech University (JREB Number: 21-011-B). Informed consent was obtained from all participants' substitute decision makers, as the participants had advanced dementia and were unable to provide consent themselves. Data collected by the cameras were masked, with any identifiable objects in the video frames blurred (a video demonstration was provided to the research ethics board [REB] chair and privacy officer). All information obtained from participants was kept confidential. Computer-based data were stored in password-protected databases, and paper-based files were kept in locked cabinets. Access to all data were restricted to authorized study personnel, who followed the confidentiality regulations of the JREB. Participants were not compensated for their participation.

This study was approved by the JREB at Ontario Shores Centre for Mental Health Sciences and Ontario Tech University (JREB Number: 21-011-B). Informed consent was obtained from all participants' substitute decision-makers, as the participants had advanced dementia and were unable to provide consent themselves. Data collected by the cameras were masked, with any identifiable objects in the video frames blurred (a video demonstration was provided to the REB chair and privacy officer). All information obtained from participants was kept confidential. Computer-based data were stored in password-protected databases, and paper-based files were kept in locked cabinets. Access to all data was restricted to authorized study personnel, who followed the confidentiality regulations of the JREB. Participants were not compensated for their participation.

Study Design

A significant challenge was presented using video cameras to document the behaviors and activities of patients, staff, and visitors in the public spaces of hospital inpatient units. Consent was secured for these patients through substitute decision makers considering their advanced dementia condition. At admission, capacity assessments were performed, and substitute decision makers were approached for permission to involve patients in potential research. The recording of video cameras was restricted to the common areas where patients usually gather during the day, and audio capture was turned off throughout the data collection period.

This study collected participant data using an EmbracePlus wristband [15] and video cameras installed in the GDU and the Geriatric Transitional Unit at the Ontario Shores Center for Mental Health Sciences. A total of 10 participants were recruited based on inclusion criteria, including being aged 60 years or older, a diagnosis of moderate to severe major neurocognitive disorder as determined by the Mini-Mental State Examination [33], and the ability to ambulate independently with or without a walking aid. Additionally, participants had to meet the agitation criteria defined by the Agitation Definition Working Group of the International Psychogeriatric Association [34], with a Functional Assessment Staging Tool scale score between 6a and 6e [35]. Moreover, each unit was equipped with a single AXIS M3077-PLVE Network Camera [36], and one AXIS P3225-VE Mk II camera [37] was installed in the hallway of the GDU to capture relevant footage. Participants wore the EmbracePlus wristband for 24 to 72 hours on 3 separate occasions within a 6-week study period. The wristband collected physiological parameters such as heart rate, electrodermal activity, and skin temperature.

During data collection (Multimedia Appendix 1), clinical staff, who are part of the research team of this study, monitored participants for episodes of AA, noting the start and end times of each event. CCTV cameras recorded footage to provide precise timestamps and additional context, as there can be a delay between observed behavior and recorded notes. To maintain privacy, faces and identifiable features in the video footage were blurred. Once an AA event is identified by the

staff in the video, the skeletal points of the recruited participants are extracted and added to the dataset, and all other skeletal points are discarded. The skeletal key points were analyzed using deep learning models to classify episodes of AA. Data from wearable sensors and clinical notes were integrated and analyzed to identify physiological and behavioral patterns preceding episodes of AA. The collected data formed the basis for developing and evaluating our multimodal system for real-time AA detection. The results demonstrate the system's feasibility and effectiveness in detecting and analyzing AA episodes.

Event Classification

The proposed system collects the biomarkers using the EmbracePlus wristband, which is considered the state-of-the-art wearable device for continuous health monitoring in the market today [15]. The device combines digital biomarkers, robust sensors, and a user-friendly design to continuously monitor participants with various health conditions. It collects electrodermal data of detected slight changes in skin conductance from the skin surface, and the data of a photoplethysmogram that calculates the pulse rate and pulse rate variability measurements, skin temperature, and raw accelerometry data for motion detection. The collected signals are sent to the cloud-based EmbracePlus Care platform [15] through a Bluetooth-connected gateway (eg, a smartphone).

The first type of data we deal with is the raw data from the accelerometer, heart rate, temperature, and electrodermal signals. We follow several preprocessing steps to clean, filter, and apply 1-minute window segmentation for the raw signals [21,38]. We then extract features from the signals, as shown in our previous work, from the statistical, time domain, frequency domain, and time-frequency domain with around 150 features [21,38]. Lastly, we evaluate multiple classification techniques, namely Random Forest, Extra Trees, and Gradient Boosting, to classify AA events. The performance of each model is evaluated using standard classification metrics such as accuracy, precision, recall, area under the curve (AUC), and F_1-score. Furthermore, we collect the digital biomarkers that are preprocessed data derived from Empatica's algorithms and calculate them minute-by-minute. The second type is the digital biomarkers, which include pulse rate variability, respiratory rate, movement intensity, accelerometer magnitude SD, steps, skin conductance level, wearing detection, temperature, and sleep detection as shown in Table 1. Digital biomarkers can effectively and accurately oversee human health from a distance, consistently, and without causing disruption. This applies across a spectrum of health conditions [15]. Figure 1 shows the classification workflow from the EmbracePlus wristband using raw data and digital biomarkers.

Table . The digital biomarker data description from the EmbracePlus wristband.

Digital biomarkers	Definition
PR[a]	The algorithm uses the photoplethysmogram and accelerometer data for PR monitoring with estimates on 10-second windows.
PRV[b]	The algorithm analyzes the photoplethysmogram for intermittent PRV, using accelerometer signals with nonoverlapping windows.
RR[c]	The algorithm processes the photoplethysmogram and accelerometer data to calculate RR values expressed in breaths per minute.
Movement intensity	The algorithm calculates activity count, steps, and accelerometer SD from the accelerometer sensor.
SCL[d]	SCL estimation from EmbracePlus electrodermal activity signal, output every 1 minute with nonoverlapping windows.
Wearing detection	The algorithm correlates device status with the photoplethysmogram patterns, indicating wearing time.
Temperature	The algorithm analyzes EmbracePlus data for continuous peripheral temperature estimation.

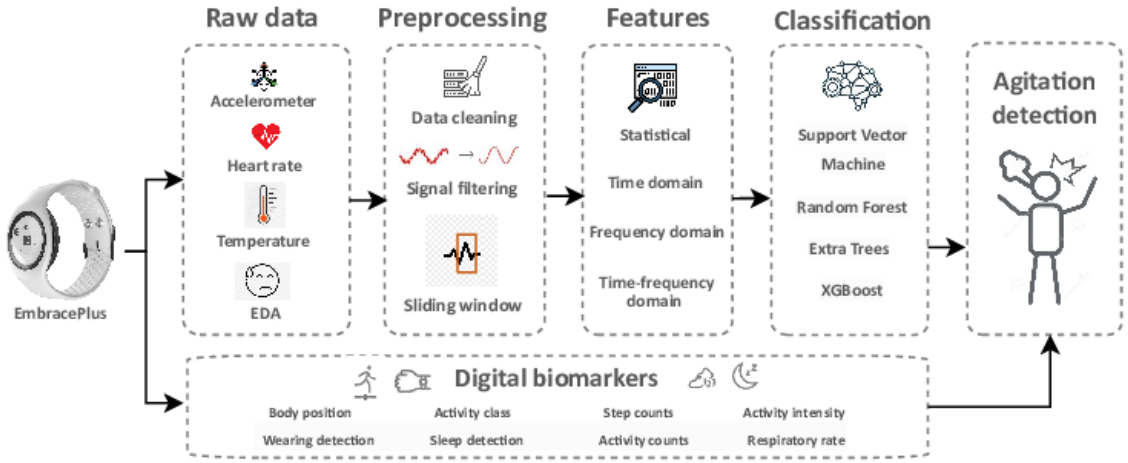
[a]PR: pulse rate.

[b]PRV: pulse rate variability.

[c]RR: respiratory rate.

[d]SCL: skin conductance level.

Figure 1. The workflow of the proposed classification system using the EmbracePlus wristband. EDA: electrodermal activity.



The proposed work focuses on investigating the data from people living with dementia using machine learning, 2 of which were thoroughly investigated in our previous work [21,38]. The results concluded the most important features for this problem after performing feature engineering and proved that personalized models on individual patients outperform generic models. In this work, we report the results of the personalized model on 10 different participants from the Ontario Shores Mental Health Institute. We test our system in real-time once we determine the optimal classification system to predict AA events. In the real-time detection phase, real-time raw data is transmitted from the wristband. Following this, features are extracted from each 1-minute window, and these specific features are fed into the customized model to classify whether the data is considered normal or indicative of AA. The outcomes are subsequently transmitted to the backend system, and the health care provider is notified if the patient is agitated.

Video-Based Analysis

In addition to collecting data on physiological biomarkers, this study incorporates video analysis data for AA prediction. This approach uses an extra cooperative model, which improves our overall AA detection system and allows us to get the precise duration, including start and end times, of the collected AA episodes. Moreover, once an AA episode is detected, the cameras record a previously set preagitation, making it easier to observe any visual preagitation signs. We aim to provide real-time alerts to health care providers for timely intervention. The setup includes 3 CCTV cameras installed and a PC in the attending psychiatric office with access to this footage. Our system operates in 2 phases: the offline phase for manual labeling and model training, and the real-time stage for running the model. To protect the privacy of the participants and the staff present, we blur all faces and run OpenPose (Carnegie Mellon University) to capture the movement data of the participants [39-42]. OpenPose is an advanced real-time system for multiperson 2D pose estimation. It also helps to anonymize individuals in video frames. OpenPose uses convolutional neural networks to detect human body parts and map their skeletal structure onto the image or video frame. This allows for a detailed representation of movement data present in the collected frames. The model is trained on features extracted from skeletal point coordinates instead of the raw video frames. This approach has been recently used by researchers for AA detection in people living with dementia and has proven to be as successful in detecting AA while preserving the privacy of the people present [24,26].

After this, we use a preprocessing phase to enhance the generalizability of the model across various environments and datasets. This phase involves the elimination of extraneous noise that could otherwise impede model performance. The model considers the variations in camera angles and participant positioning within the frame, which can significantly influence the coordinate data. We calculate Euclidean distances and angle measurements between specific skeletal coordinates to determine movements. For example, the measured distance between the torso and feet is useful to identify potential kicking actions, which may indicate AA in certain contexts. Table 2 summarizes all 47 features extracted from these distance and angle measurements. Before training, a feature analysis step is introduced to remove highly correlated features and reduce the dimensionality of the model. This process reduced the features to 39 features. We tested the system on the same 10 participants whose wearable sensor data was used earlier.

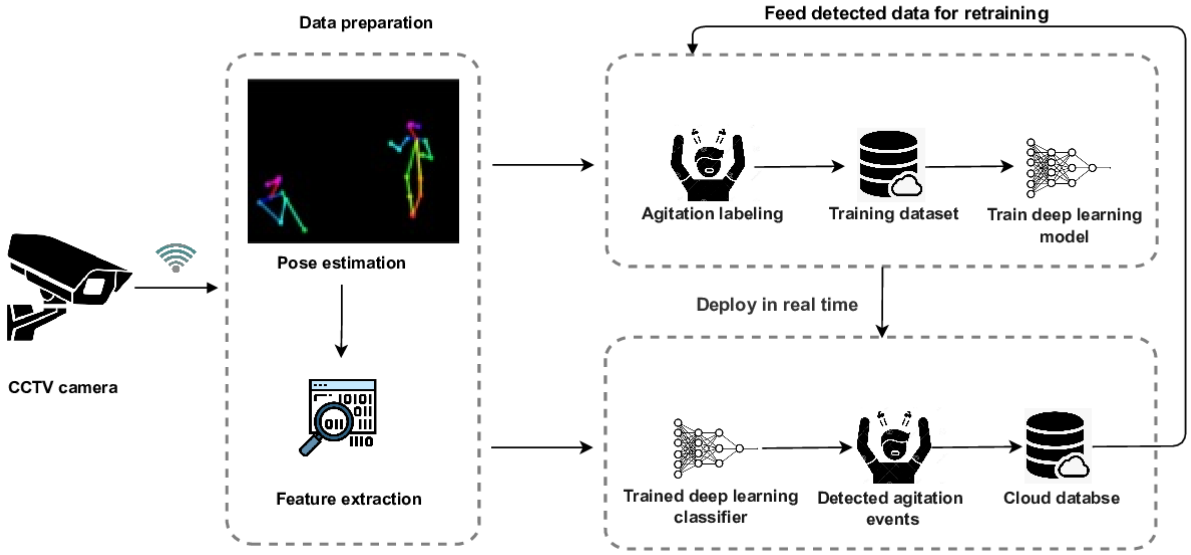
Table . Description of the extracted features from the skeletal data.

Feature	Description
eu_1-eu_14	Euclidean distances between different key point pairs; eu 1 represents the Euclidean distance between key point 1 and the previous position of key point 1
eu_1_3-eu_1_14	Euclidean distances between key point 1 and various other key points
por_2_1-por_14_1	POR[a] values between key points 2 - 14 and key point 1
ang_1_2-ang_1_14	Angles between key point 1 and key points 2 - 14

[a]POR: point of reference.

The offline and real-time (online) stages of the system are detailed in Figure 2. In the offline stage, we preprocess and extract features from skeletal data, which are then labeled using nurse notes from patient medical records. Access to the collected videos is restricted to the computer in the psychiatric office, and they are retained only until the AA episodes are accurately labeled with their start and end times. Once the dataset is finalized, all videos are securely discarded. Using this dataset, we train a deep learning model to differentiate between AA and nonagitation events. Our focus is on capturing a range of behaviors, from violent or aggressive actions to repetitive motions such as pacing or chair rocking. Hence, we use models that consider sequences of actions, such as RNN-based neural networks, to effectively recognize these sequences of actions. We specifically use and compare the results of the GRU and LSTM models. Both are adept at analyzing sequences of actions. The LSTM model is designed to capture long-term dependencies within sequences. The sophisticated cell structure of LSTM cells makes it highly effective in maintaining context over long intervals. However, the GRU model uses a simpler architecture that aims to achieve results comparable to LSTM models but with lower computational costs. Both models used in our research are composed of a single LSTM or GRU cell, followed by a fully connected sigmoid layer for the binary classification of AA episodes.

Figure 2. The system architecture of the video-based detection system.



In the real-time stage, we deploy our offline-trained model to classify AA in real-time. The model first processes real-time video data from hospital cameras. Video frames are analyzed using OpenPose, extracting features similar to those in the offline stage. We use a fixed-size window to input frame sequences into the classifier. Upon detecting AA, the system records the event, including a 5-minute buffer before and after the incident to capture the entire context. This approach helps identify potential triggers and patterns that lead to AA. The psychiatrist reviews these detected events for accuracy and confirms AA events, which are then added to our training dataset with appropriate labels. The model is then retrained in the offline stage with the added data. The primary goal of retraining the model is to continuously adapt and improve the model with newly detected data.

Results

Overview

A pilot study was conducted to validate the effectiveness and feasibility of the proposed system at Ontario Shores Mental Health Hospital. This initial investigation aimed to provide valuable insights into the system's functionality, usability, and overall potential before the implementation on a larger population. Details of the enrolled participants and the data

collected can be found in Table 3. Upon enrollment, the participants wore the EmbracePlus wristband for 24 to 72 hours. We turned on the cameras installed in the unit during the data collection days to record the participants' activities. Lastly, we assigned a nurse to observe the participant and provide a detailed report of behavior, AA events, and any abnormal behavior. During the 3 days, we collected 6 AA events, ranging from 2 to 23 minutes per AA event, with a total of 20 - 32 minutes of AA labels and 560 - 581 minutes of normal labels for each participant. The following sections will present the results from the EmbracePlus wristband and video cameras in detail.

Table . Overview of the demographic of the participants and the total collected data.

Participant	Gender	Age	Recruitment date	Total collected data (hours)
1	Female	83	August 2023	54.21
2	Female	63	January 2024	48.13
3	Female	77	March 2024	45.3
4	Female	78	March 2024	96.4
5	Female	79	March 2024	99.4
6	Male	79	May 2024	46.7
7	Male	67	August 2024	36
8	Male	68	August 2024	35.5
9	Male	85	September 2024	95.5
10	Male	86	September 2024	54.6

Performance Evaluation

The EmbracePlus Wristband Raw Data

This study uses raw data obtained from 4 wristband signals and personalized models, which achieved superior accuracy in AA detection from people living with dementia in previous research [21,38]. Subsequently, we conducted a comparative analysis of multiple machine learning and deep learning algorithms for AA detection, including Random Forest, Extra Trees, Gradient Boosting, and MLP. We trained and tested a personalized model for every participant and reported the evaluation results in Table 4. The dataset for each participant was randomly split into 70% for training and 30% for testing.

Table . Comparative performance metrics using raw data.

Participant	Extra Trees			Gradient Boosting			Random Forest			MLP[a]		
	Acc[b]	AUC[c]	Recall	Acc	AUC	Recall	Acc	AUC	Recall	Acc	AUC	Recall
1	0.98[d]	0.99[d]	0.99[d]	0.97	0.98	0.98	0.98[d]	0.99[d]	0.99[d]	0.97	0.98	0.98
2	0.90[d]	0.98[d]	0.96	0.88	0.96	0.93	0.88	0.96	0.94	0.88	0.96	0.97[d]
3	0.99[d]	0.99[d]	0.99[d]	0.98	0.99[d]	0.99	0.98	0.99[d]	0.98	0.99[d]	0.99[d]	0.99[d]
4	0.91[d]	0.99[d]	0.97[d]	0.89	0.97	0.96	0.88	0.97	0.99	0.89	0.96	0.98

[a]MLP: multilayer perceptron.

[b]Acc: accuracy.

[c]AUC: area under the curve.

[d]Bold text indicates the best results for each participant in each metric.

The Extra Trees model outperformed the rest of the models for most of the participants, followed by the MLP model, which achieved similar results for 4 of the 10 participants. For example, the Extra Trees model achieved an accuracy of 98.67%, an AUC of 99.1%, and a recall of 99.76% for participant #1. It achieved the highest accuracy and AUC for participant #2 of 90% and 98%, respectively. For participants, #3, #6, #9, and #10, both the Extra Trees and MLP models achieved 99% across all evaluation metrics. These results underscore the efficacy of the chosen features, preprocessing methodologies, and up-sampling techniques. When tested on all 10 participants together, the Extra Trees model achieved a lower accuracy of 85%. The Gradient Boosting and Random Forest achieved higher accuracies in comparison with 98% and 93%, respectively. The Random Forest model, however, performed very poorly in other evaluation matrices, with a recall of 67% for the general model. The MLP model achieved a slightly higher accuracy than Gradient Boosting of 99% and even a higher AUC and recall of 98%, performing very similarly to the personalized models. This highlights the potential for a general model when enough data are collected.

Table 5 presents a summary of the statistical analysis of model performance metrics across all models. As expected, Extra Trees is the top-performing model for participant-level predictions, with the highest mean accuracy of 0.95 and a 95% CI of 0.928-0.986. This indicates consistent performance across the evaluation set. Pairwise statistical tests further confirmed the superior accuracy of Extra Trees compared to Gradient Boosting (P=.001), Random Forest (P=.006), and MLP (P=.002). Although MLP demonstrated a comparable mean accuracy of 0.94 and even outperformed Extra Trees in the general model setting, it exhibited a broader CI (0.909-0.979) and a similar SD (0.04). In terms of other metrics, Extra Trees also achieved the highest mean AUC of 0.98 and a narrow CI of 0.970-0.990. MLP and Gradient Boosting delivered competitive results in AUC 0.97 and recall 0.96. These findings suggest that while MLP performed well in the general model, Extra Trees consistently outperformed other models in the personalized model evaluations. This consistency identifies Extra Trees as the most reliable model for this multimodal system. Additionally, the observed trends highlight the importance of focusing on personalized models to consider individual variations.

Table . Statistical analysis of model performance metrics across all models.

Metric	Extra Trees	Gradient Boosting	Random Forest	MLP[a]
Mean accuracy	**0.95**[b]	0.94	0.94	0.94
SD (Acc[c])	0.04	0.04	0.05	0.04
95% CI (Acc)	0.928-0.986	0.912-0.976	0.905-0.977	0.909-0.979
Paired P value (vs Extra Trees)	—[d]	0.001	0.006	0.002
Mean AUC[e]	**0.98**[b]	0.97	0.96	0.97
SD (AUC)	0.01	0.01	0.01	0.01
95% CI (AUC)	0.970-0.990	0.960-0.980	0.950-0.970	0.960-0.980

[a]MLP: multilayer perceptron.

[c]Acc: accuracy.

[d]Not applicable.

[e]AUC: area under the curve.

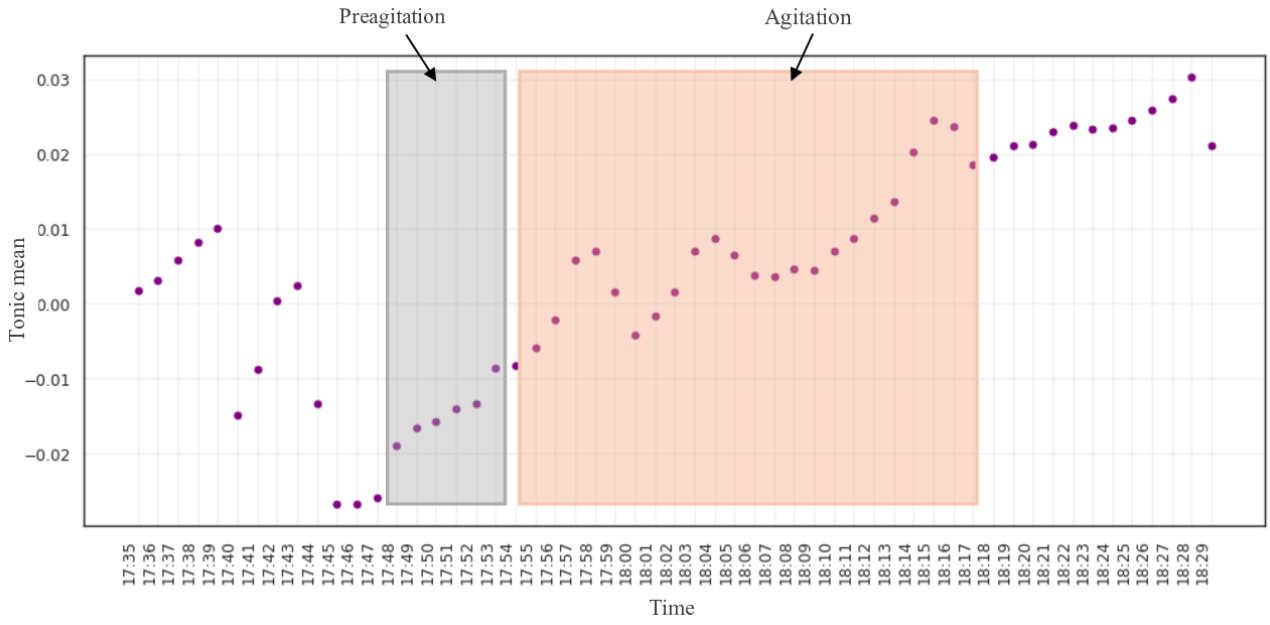
Furthermore, we studied the importance of different features for every participant (Multimedia Appendix 2). For participant #1, the top 10 features contributing to accurate AA classification using the Extra Trees model revealed that 5 were from electrodermal activity, 3 from the accelerometer, 1 from heart rate, and 1 from temperature. Notably, the electrodermal tonic mean was the most critical feature, suggesting a strong link between AA episodes and fluctuations in electrodermal activity, which is commonly associated with emotional arousal. For participant #2, the most important features were primarily the accelerometer and temperature signals. Features related to energy, root mean square, and variability in acceleration played a key role in AA classification. Additionally, temperature fluctuations were also significant, suggesting that both movement patterns and body temperature changes could indicate agitation onset in this participant.

For participant #3, the temperature-related features were the most dominant in identifying AA episodes. The maximum temperature value, temperature root mean square, and energy were among the top contributors, highlighting a strong correlation between changes in body temperature and agitation. These findings emphasize the individual variability in AA predictors, reinforcing the necessity of personalized models for accurate classification. While some participants exhibit agitation-related physiological changes in electrodermal activity, others may show significant patterns in movement or temperature variations, underscoring the importance of a multimodal feature selection approach.

As the electrodermal tonic mean was the top feature to classify AA for participant #1, we investigated the AA labels. Figure 3 shows the tonic mean values of participant #1 from the electrodermal signal during labeled AA events from the camera

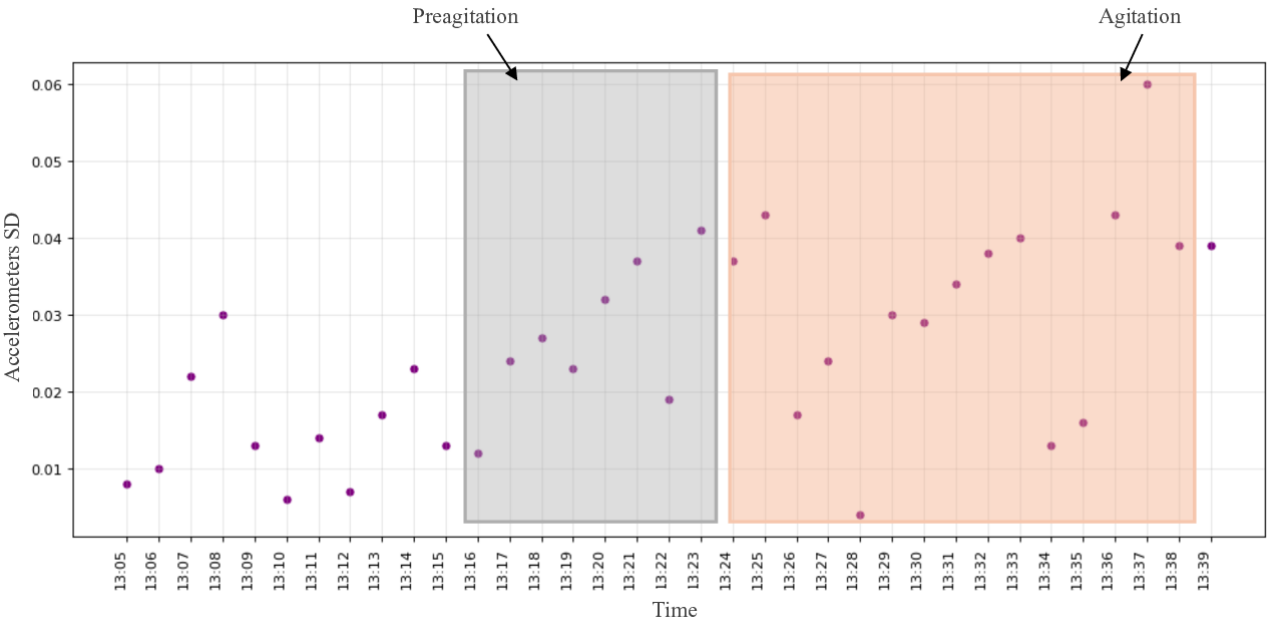
and nurse notes (highlighted in red). This event occurred during the second day and lasted for 23 minutes from 5:55 PM to 6:17 PM. This observation suggests that the patient's AA was related to the electrodermal signal connected to the emotions. We also observed an apparent change to the data before the actual AA occurred, which we manually marked as preagitation labels (highlighted in blue).

Figure 3. The EmbracePlus wristband raw data with agitation and preagitation annotation: the tonic mean plot for participant #1.



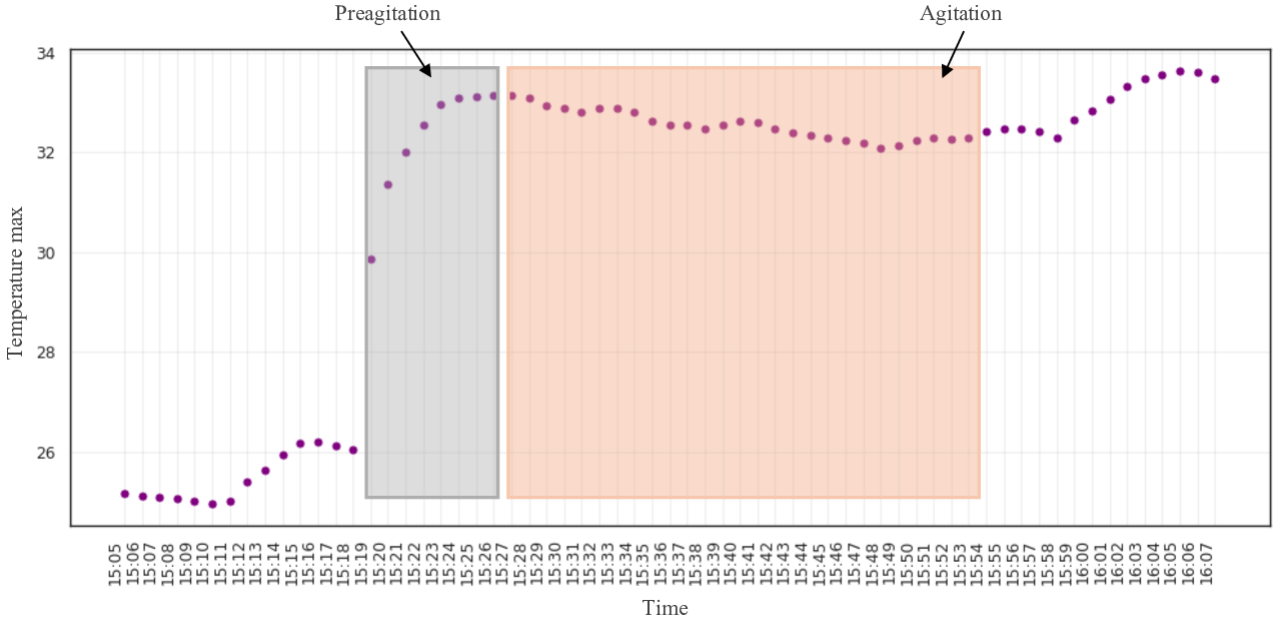
For participant #2, the acceleration features were the top features in identifying the AA event. Figure 4 shows one of the AA events for this participant occurring between 1:24 PM and 1:38 PM using the accelerometer data. Moreover, a change in the pattern of the signal 8 minutes before the event is manually labeled as preagitation.

Figure 4. The EmbracePlus wristband raw data with agitation and preagitation annotation: the accelerometer plot for participant #2.



For participant #3, the most dominant features were the temperature features, so an example of the temperature readings for an AA event is shown in Figure 5. Just as before, a change in the pattern before the observed AA event is manually labeled as preagitation. These observations suggest the potential for detecting preagitation patterns from raw data, enabling the prediction of AA before it occurs.

Figure 5. The EmbracePlus wristband raw data with agitation and preagitation annotation: the temperature plot for participant #3. max: maximum.



The Wristband EmbracePlus Digital Biomarkers

We explored all the digital biomarkers offered by EmbracePlus. Taking the first 3 participants as an example, we observed that pulse rate, activity counts, and activity class were the leading indicators for AA detection for the first 3 participants. In Figures 6-8 , the same AA events discussed in the previous subsection for the 3 participants are illustrated, and the values during labeled AA events from the camera and nurse notes are highlighted in red. Additionally, we observed a noticeable change in the data before the onset of AA, manually designated as preagitation labels and highlighted in gray. The manual labeling of the preagitation was done after reviewing all the signals for the participants and noting the same change across multiple patterns.

Figure 6. The activity counts from the digital biomarkers data for participant #2.

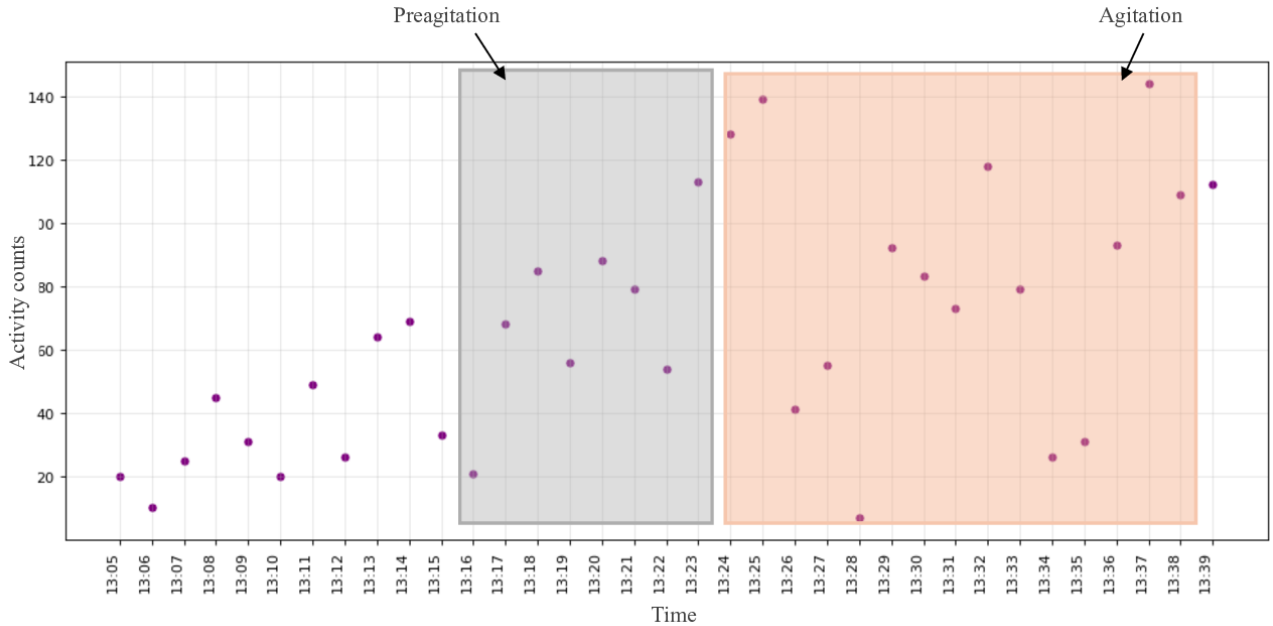


Figure 7. The pulse rate from the digital biomarkers data for participant #3.

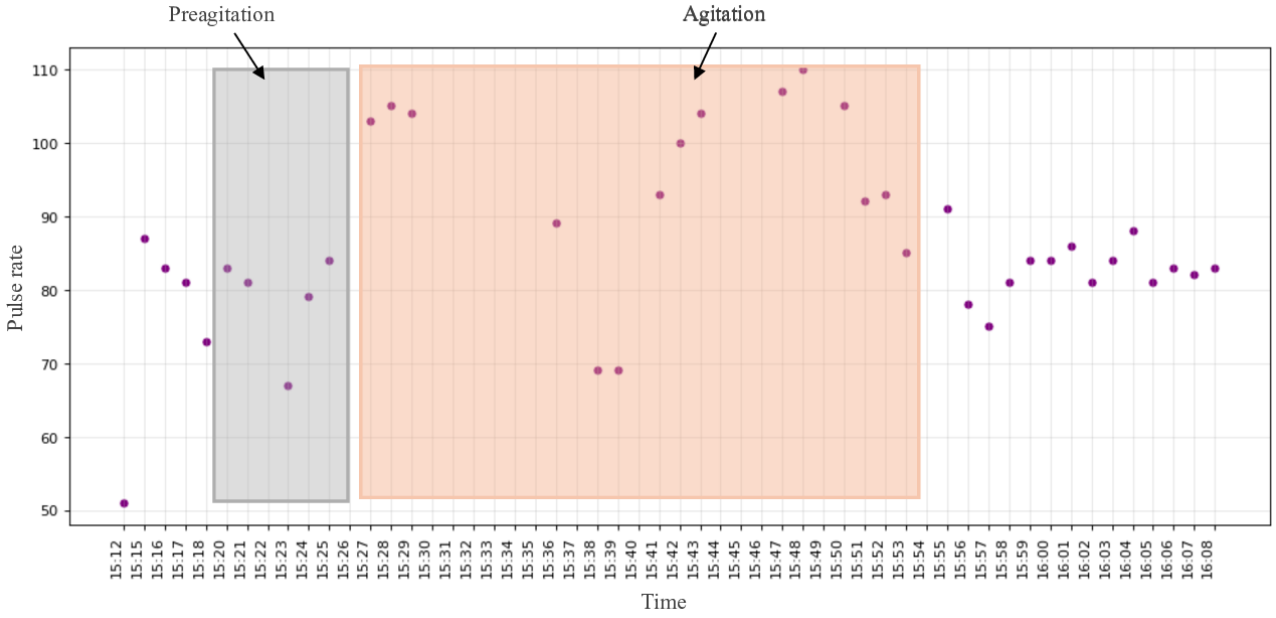

Figure 8. The activity class from the digital biomarkers data for participant #1.

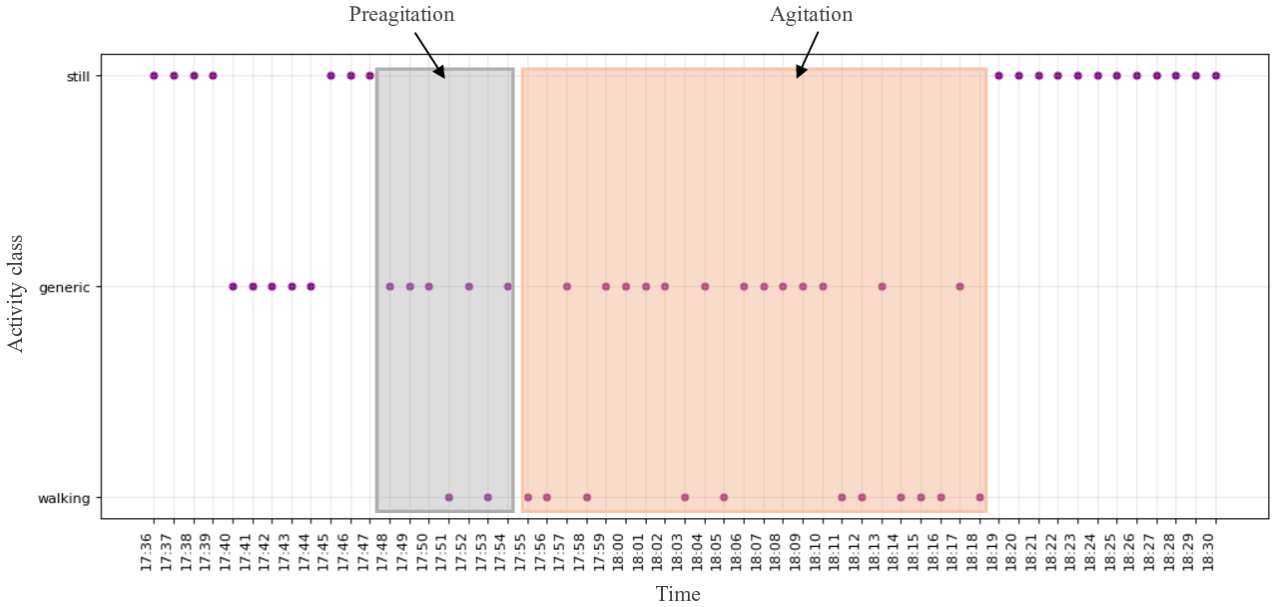

Figure 1 illustrates the activity class for participant #1, extracted from the accelerometer signal, revealing that the participant was in motion rather than stationary during AA and preagitation episodes, indicating body movement during these events. Figure 6 displays the total activity counts for participant #2 from the accelerometer signal. While the normal activity count for the participant ranged between 0 - 100 during AA and preagitation events, it surged to 50 - 140, signifying heightened activity levels during AA. Finally, Figure 7 presents the pulse rate derived from the heart rate signal for participant #3. Although the participant's average pulse rate ranged from 55 - 80 (SD 12.4) bpm, it increased to 90 - 110 (SD 11.6) bpm during AA and preagitation events. Across the raw and digital biomarkers data, we observed that the preagitation occurred from 3:20 PM to 3:27 PM. This indicates that signs of AA behavior occurred approximately 7 minutes before the actual event, suggesting the potential to predict and prevent AA events.

Performance of Video-Based Detection

We preprocessed our videos using OpenPose and performed feature extraction as described in the methodology section. As AA behaviors are repetitive in nature, we selected RNN models to capture the sequential patterns of these events. Features were extracted from 30-second windows. The window moves 1 second at a time to capture different variations of AA behaviors from the skeletal points. For the classification task, we tested 2 different network structures, which are LSTM and GRU.

In the feature analysis step, we focused on reducing the model's dimensionality without compromising its performance. Initially, 47 features were extracted based on skeletal movements,

including Euclidean distances and angles between key body parts. It is evident from the figures that more features are highly correlated in agitation events than in nonagitation events. This had a strong effect on the feature reduction as only the highly correlated features in both datasets were removed. We investigated the correlation of the features more deeply and tested the model on fewer features based on a correlation threshold. Setting the correlation threshold to 0.8 reduced the number of features to 39 features. The number of features based on the correlation threshold did not change even when the threshold was set to as low as 0.5 due to the huge difference in correlation between both types of events. Both datasets are randomly split into 70% for training and 30% for testing. The training was conducted on a Lambda server equipped with an RTX A6000 GPU, and each model was trained for 100 epochs with a batch size of 256. We used the Adam optimizer to efficiently handle sparse gradients and used a sigmoid activation function for binary classification (AA vs nonagitation). We report the results of all the tests on the testing set in Table 6.

Table . Video results comparison.

Model	Number of features	Accuracy	AUC[a]	F_1-score	Recall	Time (s)
LSTM[b]	47	0.94	0.98	0.97	0.96	16.1
LSTM	39	0.94	0.98	0.98	0.97	**14.7**[c]
GRU[d]	47	0.95[e]	0.98[e]	0.98[e]	0.97	30.2
GRU	39	0.95[e]	0.99[e]	0.98[e]	0.98[e]	29.8

[a]AUC: area under the curve.

[b]LSTM: long short-term memory.

[c]Bold text indicates the shortest inference time.

[d]GRU: gated recurrent unit.

[e]Bold text indicates the best result for each metric.

We compared metrics such as accuracy, AUC, and F_1-score. We also compared the response time, an essential factor in real-time applications, of all models. As observed in the table, the reduction in the number of features did not affect the performance of the models. The LSTM model, in both cases, achieved an accuracy of 94% and an AUC of 98%. The GRU model reached 95% accuracy and 99% AUC. Although the performance of both models is similar, the response time of the GRU model is double that of the LSTM. The response time for the LSTM was 15.9 seconds when all the features were used in training and was almost one second faster with fewer features. The GRU models, however, had a response time of 30.1 seconds for 47 features and 29.7 seconds for 39 features. The results show that the GRU model is superior across all evaluation metrics, albeit for the response time, where it lags behind the LSTM model by a huge margin. As we aim to detect AA as early as possible, the swifter response time can allow for timely interventions by health care providers in case of any AA event. The high AUC values of both models signify a strong ability to minimize the rate of false positives. This is crucial to ensure the reliability of the model in detecting real AA with lower false alarms, causing less overhead for health care providers. The faster response time posits the LSTM model as possibly the more advantageous model for real-time deployment.

Discussion

Principal Findings

The successful implementation of the system within the hospital setting, considering privacy and the positive feedback from patients and health care professionals, highlights the system's viability in a real-world clinical environment. The system used in this study integrated physiological data from the EmbracePlus wristband and video footage from CCTV cameras, allowing for a comprehensive and multimodal approach to AA detection. The EmbracePlus wristband system demonstrates promising results in detecting and classifying AA and preagitation events in individuals with severe dementia. The AA detection results are reflected in the video detection system, and the preagitation labels can be added to the system from EmbracePlus. The following discussion highlights key findings and their implications, followed by suggestions for future work.

The EmbracePlus wristband, which leverages both raw data and digital biomarkers, demonstrated its efficacy in discerning patterns associated with AA and preagitation. The personalized Extra Trees model emerged as the top-performing algorithm for the raw data, achieving high performance. Furthermore, features such as electrodermal tonic mean, accelerometer activity class, and pulse rate highlighted the significance of identifying AA. Furthermore, the outcomes of our analysis are promising and demonstrate the potential of predicting AA in dementia care settings in real time. We were able to predict preagitation events from all participants at least 6 minutes before the actual AA event. The identification of preagitation patterns in the data suggests that physiological changes precede observable AA behavior. Being the first to explore these patterns in individuals with severe dementia from the EmbracePlus wristband, this study lays the groundwork for a deeper understanding of the dynamics and physiological signatures of AA behaviors. The newfound ability to identify preagitation patterns offers a potential window for early intervention and preventive measures.

Moreover, the video detection system, incorporating CCTV footage and advanced pose estimation techniques, was used along with the EmbracePlus wristband for AA detection. The privacy preservation technique, which follows the REB

protocols in the hospital, does not exploit the patient's personal features or body image without affecting the performance of the proposed model. The LSTM neural network and the GRU networks exhibited robust performances. The high AUC of both models is particularly crucial in the context of health care to minimize the risk of false negatives and ensure that true AA events are accurately identified. During the real-time deployment stage, the model adapts and continuously improves based on the collected data. The labeled preagitation labels collected from the wristband can be fed into the training set of the video detection system to provide insight into detecting preagitation from the video footage. The outcomes of our analysis are promising and demonstrate the potential of both LSTM and GRU neural networks in detecting AA in dementia care settings in real time.

Future Work

For future work, we will focus on expanding our dataset by recruiting more participants from the hospital. We aim to validate the system over the long term, assessing its stability, generalizability, and adaptability to health care and home care environments. This step is crucial for building a database with a substantial number of AA and preagitation events, which is essential for developing a high-performance detection system using machine learning. Once our detection system is established, we plan to automate the real-time system that is capable of predicting AA. This involves receiving data in real time, classifying the data, and sending notifications to the health care providers if an AA event occurs. Additionally, we plan to improve the real-time AA detection of the video system. We also plan to use the preagitation labels from the EmbracePlus wristband to help our video detection model predict AA before they happen. During the initial stages of this study, health care providers will review and confirm all collected AA events. Their feedback is crucial in refining and enhancing the model's performance and should aid in identifying any limitations or challenges. Once the model is reliable, it will automatically detect and predict AA with no human intervention.

Conclusions

This study represents a notable step forward in developing an AA and preagitation detection system for individuals with severe dementia. It uses a comprehensive approach by integrating psychological biomarker sensing and video detection systems. The results demonstrate the feasibility and efficacy of monitoring systems that combine various data sources for AA detection. This study recruited 10 participants from the Ontario Shores Center for Mental Health Sciences Institute. We used the EmbracePlus wristband for continuous health monitoring and video footage from CCTV cameras for real-time observation of AA events. In the preliminary data analysis, the features extracted from the raw data of the EmbracePlus wristband demonstrated exceptional performance in detecting AA events, with the Extra Trees model emerging as the top-performing algorithm for all the personalized models and MLP outperforming the rest of the models for the general model and achieving an accuracy of 98%. Exploring the digital biomarkers further strengthened the system's classification of AA, preagitation, and normal events. Pulse rate, activity class, and activity counts have emerged as critical indicators for detecting AA. This study revealed the potential for detecting preagitation patterns, showcasing a 6-minute lead time before actual AA events. This early detection capability holds promise for timely intervention and preventive measures. In addition to the EmbracePlus wristband, the video-based detection demonstrated promising results in detecting AA using GRU, achieving a 95% accuracy rate and a robust AUC of 98%. The data analysis' promising results highlight the potential of the multimodal approach to enhance patient care and safety by predicting AA events. This research will provide new directions for researchers interested in technologies for dementia care and provide challenging propositions in detecting and monitoring, modeling, and evaluating patient-specific interventions for people living with dementia demonstrating NPS.

Abstract

Background: Personal support workers (PSWs) are often expected to provide ongoing support for complex conditions and have identified an increased need for training in several areas, including dementia and mental health. Web-based interventions may be helpful complements to traditional in-person continuing education and training, but their effectiveness must be explored further.

Objective: This study's objective was to evaluate the usability, usefulness, satisfaction with, and effectiveness of the web-based Dementia Foundations Program among unregulated care providers who provide care to persons living with dementia or are in training.

Methods: A cohort of 50 PSWs, PSW trainees, and paid care companions from 3 recruitment sites were invited to access the Dementia Foundations Program, a 4-hour self-paced web-based program composed of 4 courses, for up to 6 weeks. Usability, usefulness, and satisfaction were assessed using surveys after each course and following the program. Dementia knowledge and attitudes were measured using the Dementia Knowledge Assessment Scale and the Dementia Attitudes Scale, with differences between baseline and postprogram scores analyzed using repeated measures ANOVA.

Results: Participants reported high levels of satisfaction with the program. Of the 50 participants, 46 (92%) agreed that the web-based training met their expectations, 47 (94%) agreed that the training covered a broad range of topics and was not missing any important content, and 49 (98%) agreed that the web-based training would benefit them. There was a significant postprogram improvement in dementia knowledge as measured by the Dementia Knowledge Assessment Scale, with an average 30% improvement across all cohorts. Dementia Attitudes Scale scores were also significantly improved postprogram across all cohorts.

Conclusions: This pilot study in PSWs, PSW trainees, and unregulated care companions demonstrated high satisfaction levels with the web-based Dementia Foundations Program. There were substantial improvements in knowledge and small improvements in attitudes for participants, and it was perceived as a useful tool that complemented their existing education and training. The Dementia Foundations Program is a user-friendly and effective e-learning program, which can be conveniently scaled and spread to enhance unregulated care provider dementia education.

Introduction

Background

The number of older adults aged 60+ years is expected to double worldwide by 2050 [1]. In Canada specifically, the older seniors population aged 75+ years is expected to grow even sooner, possibly tripling by 2046 [2]. This has the potential to increase the prevalence of age-related health conditions such as dementia, as well as the need for adequate human health resources [3].

The Need for Unregulated Care Providers

There are estimated to be about 600,000 people in Canada living with dementia currently, with that number projected to grow to

almost a million in 2030 [4]. Unregulated care professionals who provide care to older adults play an important role in the effort to meet the growing demand for care from Canada's aging population. Several occupational titles can be used to describe these unregulated care providers, including personal support workers (PSWs), health care aides, and home care workers [5]. For the purposes of this paper, we will predominantly use the term PSWs, with the intent that this information applies to most professionals working in similar unregulated care roles.

It is estimated that there are over 1 million PSWs in Canada [6] providing support, including assisting with daily living activities, light housekeeping, meal preparation, socialization, and companionship [7], in several settings, including home, community, and clinical. In Canada, PSWs are not currently required to hold accredited qualifications and are not formally regulated by an organization or governing body. This lack of regulation of training can lead to gaps in knowledge and caregiving abilities [6]. PSWs have indicated that more training is needed, specifically in the field of dementia and mental health [8]. With over 69% of residents in long-term care (LTC) homes living with dementia and 87% with some form of cognitive impairment [9], more specific education and training about dementia are needed for PSWs.

Dementia Education Approaches

There are currently a variety of training approaches for dementia for unregulated care providers. Some PSW training programs or colleges might offer traditional didactic instruction on topics related to dementia; some of these programs have transitioned to webinar-based instruction during the pandemic. For PSWs or other unregulated care providers already in the workplace, the most common approach would be occasional on-the-job training, such as periodic "in-service" or "lunch-and-learn" sessions. These approaches tend to be synchronous, nonstandardized, and not necessarily educationally designed. Very few offer foundational knowledge content about dementia. Some approaches may also involve face-to-face instruction, which did prove to be challenging during the pandemic, concerning public health guidance as well as participant hesitance, even with the loosening of public health guidance [10]. Many of those solutions would be both challenging to scale and likely inconvenient for these care providers, who may not have flexible schedules that can accommodate synchronous instruction, especially if expected to be done on unpaid (personal) time.

For these reasons, the Dementia Foundations Program was developed in 2021 at McMaster University, aligning with several performance objectives and standards of the PSW Program Standard for Ontario Colleges from the Ministry of Training, Colleges and Universities [11]. During program development, project team members and target audience stakeholders identified the need for flexible, asynchronous solutions to best facilitate delivery to their PSW employees and students.

Program Description

The Dementia Foundations Program is a web-based, asynchronous (self-paced) series of 4 courses that takes approximately 4 hours total to complete. Each of the 4 courses includes modules on various topics related to dementia and dementia care and is described in Table 1.

Table . Dementia foundations program course descriptions.

Course number and course name	Course content
1. Foundations of Dementia	• What cognition is and how it is impacted by dementia • Difference between normal aging and mild cognitive impairment • Different types and stages of dementia • Types of treatments available
2. Responsive Behaviors and Mental Health	• Psychiatric issues such as apathy, depression, and anxiety that may affect people with dementia • Behavioral, emotional, and psychiatric symptoms of dementia • Strategies to help manage responsive behaviors
3. Home Supports and Safety	• Identifying safety risks • Strategies to reduce harm • Home and community-based supports and services available for patients and families
4. Promoting Brain Health and Caregiver Wellness	• Importance of brain health • How to make positive brain health choices • Why caregiver wellness is important and what can be done to support it

The program is intended as a complementary dementia education resource that may benefit care providers' training for several reasons. First, the modules within the courses use high-quality, evidence-based, multimedia instructional design [12,13], which has been shown to improve learning outcomes. Second, it can be delivered asynchronously for self-paced learning at any time and from any place, unlike other training programs that may use real-time training formats such as instructor-led classroom or webinar training. Third, the program has been developed using responsive web design and is compatible with any internet-connected device (smartphone, tablet, or desktop). Fourth, it is more efficient and cost-effective to scale than standardized digital or in-person training, as it does not require the presence of instructors. Lastly, the Dementia Foundations

Program offers a certificate of completion for each course and the complete program that learners can share with future employers detailing the time they have invested in learning about caring for those living with dementia.

Study Purpose

The objective of this study was to evaluate the usability, usefulness, satisfaction, and effectiveness of the Dementia Foundations Program among unregulated care providers who currently provide care to, or could provide care to, persons living with dementia.

Methods

Study Design

A pilot pre-post design was used with measures taken at baseline, after each of the 4 courses, and after program completion. Participants were able to complete the program at their own pace over a maximum of 6 weeks.

Participants and Recruitment Cohorts

A total of 50 participants were recruited through collaborative partner networks via an email campaign, keeping in line with typical pilot study sample size guidance in the literature [14,15]. Participants were organized into 3 recruitment cohorts: those working in the city of Ottawa's LTC homes, those currently a part of Durham College's PSW training program, and those recruited from the uCarenet homecare digital marketplace. Participants who fulfilled the following inclusion criteria were eligible to participate: (1) had a good command of the English language, (2) were sufficiently computer literate to use the Dementia Foundations Program, and (3) were currently an unregulated health care provider or trainee in Ontario, Canada. Interested participants were directed to a private web-based sign-up link where they were provided further study information and could submit informed consent. Once informed consent was received, a member of the research team manually added participants to the Dementia Foundations Program within the learning management system. Participants were grouped according to their recruitment cohort to allow the research team to identify and analyze patterns and trends among these 3 different settings.

The Dementia Foundations Program

Participants had access to the Dementia Foundations Program from June 1 to July 9, 2021. The program could be accessed from any internet-enabled device at any time or location. In addition to the 4 courses, participants in this pilot study had access to a "Getting to Know You" course at the beginning (which included the baseline assessments), and a "Review and Final Quiz" course at the end, which included the postprogram assessments.

Program Usability, Usefulness, and Satisfaction

To evaluate perceived usability, usefulness, and satisfaction with the training, 2 questionnaires were developed based on the Information Assessment Method for all questionnaire—a content-validated questionnaire designed to collect feedback from health information consumers based on 4 domains: situational relevance, cognitive impact, information use, and health benefits [16]. The first was administered after each course (postcourse assessment), and the second was delivered upon program completion (postprogram assessment). All questions were required, and each survey could only be submitted once; participants were able to review their responses and were asked to complete any questions they had missed before submitting.

The postcourse assessment consisted of 7 questions in total: 4 questions that could be answered on a 5-point Likert scale ranging from "strongly agree" to "strongly disagree" ("I thought the course content was very important to my professional/learning needs" [usefulness], "I understood the content in this course" [usability], "I was able to complete the course in a reasonable amount of time" [usability], and "I would recommend this course to a colleague" [usefulness and satisfaction]), 2 questions that could be answered with multiple-select answers ("What do you think about this course?" [usefulness] and "Which benefit(s) are you expecting after taking this course?" [usefulness]), and 1 open text question ("Any other comments about this course?" [usability, usefulness, or satisfaction]).

The postprogram survey consisted of 8 questions total: 4 questions that could be answered on a 5-point Likert scale ranging from "strongly agree" to "strongly disagree" ("This online training met my expectations" [satisfaction], "I felt that this training covered a broad range of topics and was not missing any important content or topics" [usefulness and satisfaction], "This online training will benefit me" [usefulness and satisfaction], and "I feel my certificate/credential related to this program will be very valuable to me with current or future employers" [usefulness and satisfaction], 1 question that could be answered with a 3-point Likert scale ranging from "too low" to "too high" (thoughts on proposed pricing structure), 1 question that could be answered with multiple-select options ("Which of the following courses would you consider paying for?"), and 2 open text questions ("How much would you be willing to pay for this program?", and "Is there anything else you would like to say about this program?" (usability, usefulness, or satisfaction).

Dementia Knowledge

To evaluate the effectiveness of the Dementia Foundations Program, change in knowledge and attitudes related to dementia was assessed. Knowledge was measured at baseline and after program completion with the Dementia Knowledge Assessment Scale (DKAS; reliability α=.85; ω_h=0.87; overall scale) [17]. The DKAS consists of 25 items on different aspects of dementia that could be answered with "true," "probably true," "false," "probably false," or "I don't know." The total scores achievable for this scale range from 0 to 50, with greater dementia-related knowledge reflected by a higher score.

Dementia Attitudes

Attitudes about dementia were measured at baseline and after program completion with the Dementia Attitudes Scale (DAS) [18]. The DAS consists of 20 items on a 7-point Likert scale that reflect the affective, behavioral, and cognitive components of the attitudes toward individuals with Alzheimer disease and

related dementias. The total scores achievable for this scale range from 20 to 140, with a more positive attitude reflected by a higher score.

Learning Management System Setup

All assessments were offered digitally within a learning management system. The baseline "Getting to Know You" course included a demographic questionnaire (age, sex, race or ethnicity, highest level of education completed, occupation, and most common workplace setting), the DKAS, and the DAS. The postcourse assessment was built directly into the end of each of the 4 courses. The postprogram "Review and Final Quiz" course included the DKAS, DAS, and postprogram assessment.

Data Analysis

Descriptive analyses were used to summarize the baseline characteristics of the study population. Differences between baseline and postintervention DKAS and DAS scores for all groups were analyzed using repeated measures ANOVA. All analyses were performed using R (version 4.4.1; R Foundation; June 14, 2024).

Ethical Considerations

The Hamilton Integrated Research Ethics Board reviewed the study protocol and granted exemption from full review on March 18, 2021, as this was considered a quality improvement initiative. Participants were required to provide informed consent. All participants were informed of the length of time of the e-learning and surveys, as well as details surrounding data collection, storage, and investigator identities. Participants' identities and confidentiality were maintained throughout the research study. All participant data were deidentified and were stored on password-protected secure servers to prevent unauthorized access. There was no known risk or harm to participating in this study or publicizing its results or findings. Upon program completion, participants were provided with a CAD $80 (US $58.22) gift card and a certificate of completion for their professional portfolio.

Results

Participant Characteristics

A total of 50 unregulated care providers enrolled and completed this study. Of these, 24 (48%) participants identified as PSWs, 16 (32%) identified as a PSW trainee or student, 1 (2%) identified as a health care aide, 1 (2%) identified as a personal care assistant, 4 (8%) identified as other front line health care workers, 1 (2%) identified as unregulated care provider manager, and 3 (6%) identified as other (while with no further details on what their role was, care settings identified were retirement home or LTC [recruited from the Durham College cohort], group home [recruited from the uCarenet cohort], and possibly for a family member [recruited from the uCarenet cohort] for these 3 participants). Participant demographics broken down by the 3 recruitment cohorts are outlined in Table 2.

Table . Participant demographics in each recruitment cohort.

Characteristics	Number of responses per recruitment cohort		
	City of Ottawa LTC[a] (n=20), n (%)	Durham College (n=17), n (%)	uCarenet (n=13), n (%)
Age (years)

Program Usability, Usefulness, and Satisfaction

Overall, the courses were positively rated, with most participants agreeing that the course was “very important” to their professional and learning needs (Table 3). Participants agreed that the training benefited them by “improving the health and well-being of the people that they care for.” Additionally, participants identified that the training allowed them to “feel more confident,” “prevent a problem,” “handle a problem or the worsening of a problem,” and “decide something with someone else.” The participants were also asked to provide any additional comments about the course; many open-text responses were very positive. Participants identified the importance and applicability of the information to their professional work.

In general, participants reported high levels of satisfaction with the program. A total of 46 of 50 (92%) of participants agreed or strongly agreed that the web-based training met their expectations, 47 (94%) agreed or strongly agreed that the training covered a broad range of topics and was not missing any important content, 49 (98%) agreed or strongly agreed that the web-based training would benefit them, and 46 (92%) agreed or strongly agreed that the program would be very valuable with current or future employers. No support inquiries were received from participants, further confirming the high usability of the program.

Table . Summary of postcourse feedback.

Question and course	Response breakdown, n (%)				
	Strongly disagree	Disagree	Neither agree nor disagree	Agree	Strongly agree
I thought the course content was very important to my profession/learning needs					
Course 1 (Foundations of Dementia)	4 (8)	0 (5)	1 (2)	18 (36)	27 (54)

Change in Dementia Knowledge

All 50 participants completed the baseline and postprogram DKAS. One participant from the City of Ottawa LTC recruitment cohort was missing data for 15/25 items on the baseline DKAS due to a technical glitch. The most conservative approach was taken where it was assumed the participant would have received 2 points for each missing answer (ie, the highest score possible). The average baseline DKAS score was 34.2 of 50 (68%, SD 10.5) and the average postprogram score was 44.2 of 50 (88.4%, SD 4.7). Scores for all participants are shown in Figure 1, with scores for each recruitment cohort shown in Figure 2.

Figure 1. Baseline and postprogram DKAS scores for all participants. Results of repeated measures ANOVA (mean with 95% CI) with time as the only predictor of DKAS, including a random effect for participant ID. *Represents statistical significance (*P*<.001). DKAS: Dementia Knowledge Assessment Scale.

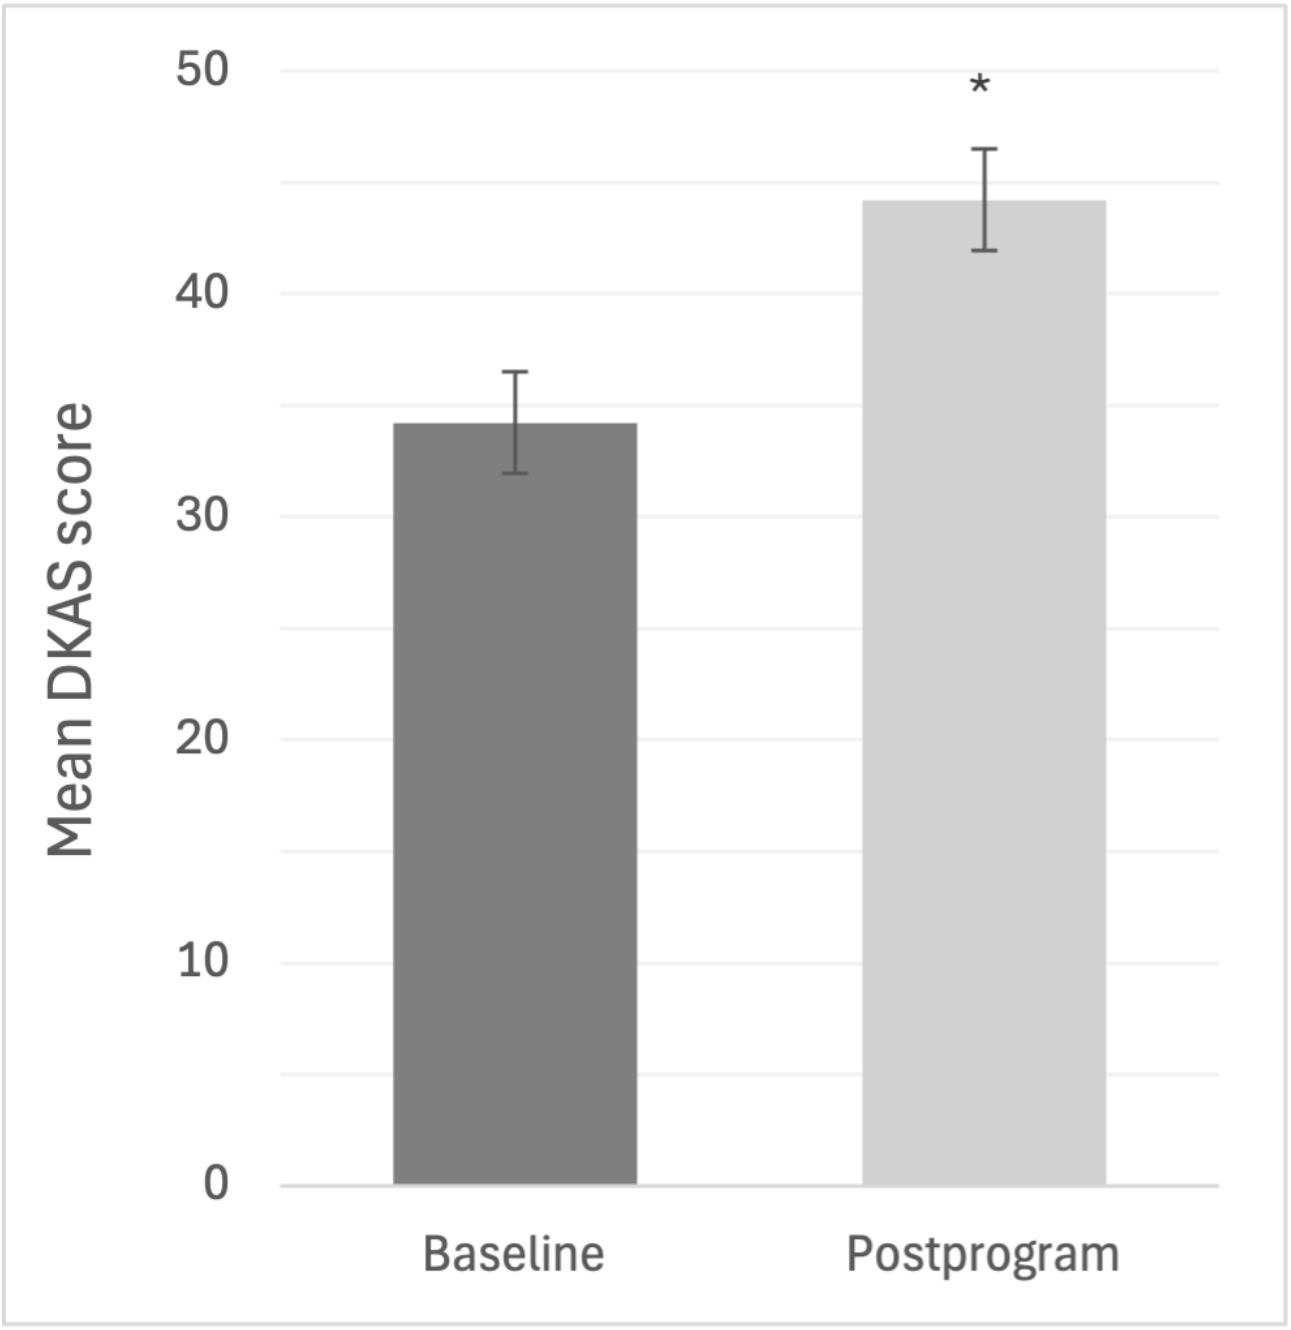

Figure 2. Baseline and postprogram DKAS by cohort and time. Results of repeated measures DKAS model (mean with 95% CI) with cohort time interaction, including a random effect for participant ID. *Represents statistical significance (P<.05). DKAS: Dementia Knowledge Assessment Scale; LTC: long-term care.

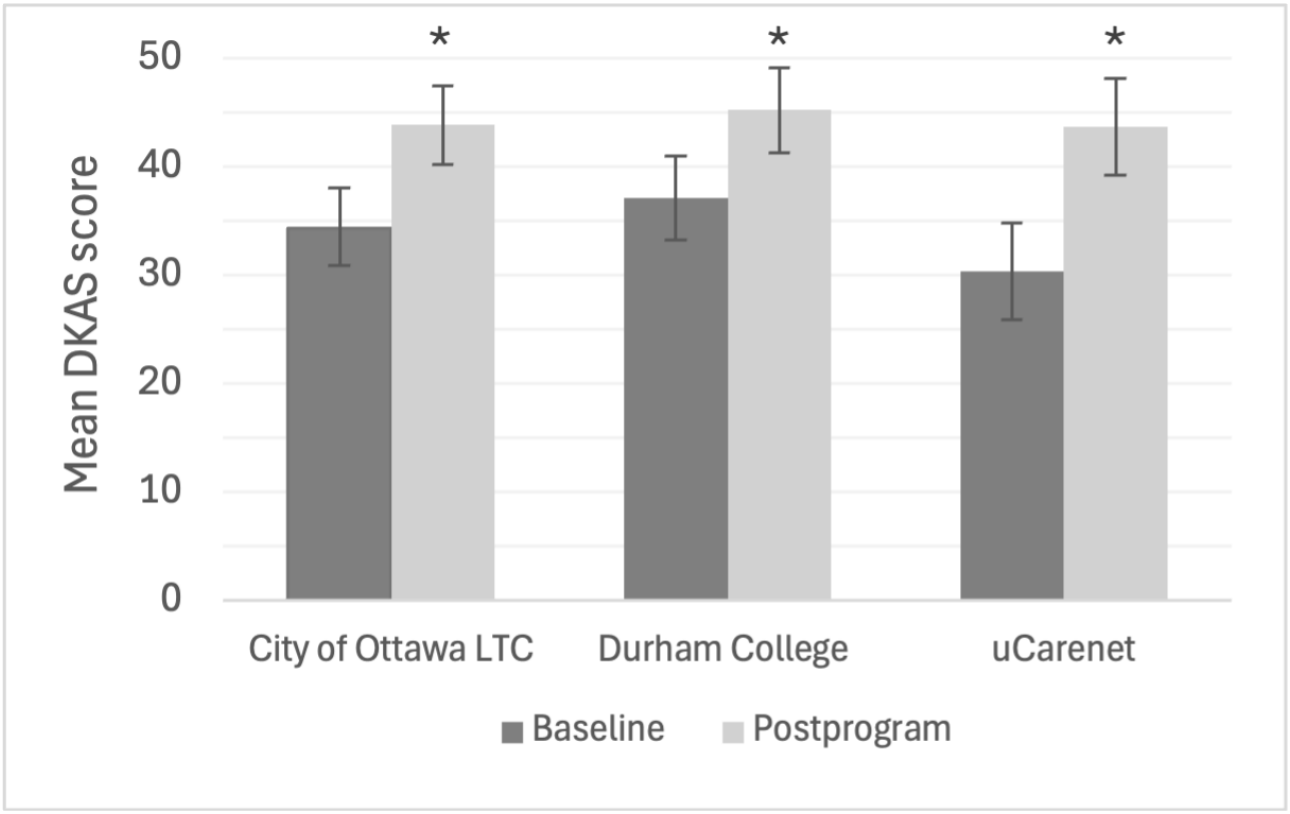
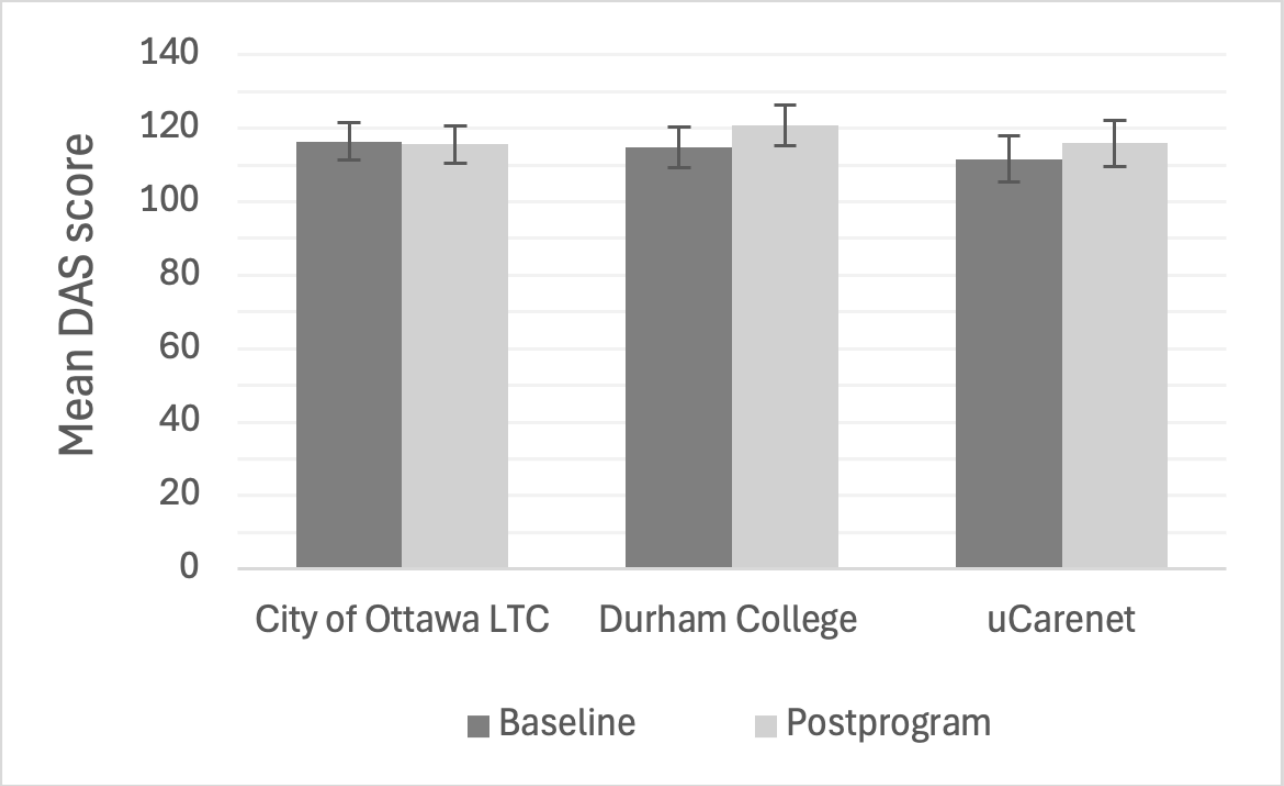


Repeated measures ANOVA showed a statistically significant effect on DKAS scores ($F_{1,49}$=58.533, P<.001), with scores increasing from baseline to postprogram across all 3 recruitment cohorts (η2=0.276). The model, including only time as a predictor and a random effect for participant ID, demonstrated that relative to baseline, there was an average 9.98-point increase on the DKAS score postintervention (95% CI 7.88-12.08; SE 1.065; P<.001). Post hoc testing did not reveal any significant differences in DKAS scores between recruitment cohorts; the model including an interaction with time and cohort, and a model with just time (not including cohort at all), were not statistically significantly different (P=.24).

Change in Dementia Attitudes

All 50 participants completed the baseline and postprogram DAS. On average across all recruitment cohorts, participants scored 114.7 of 140 (82%; SD 11.6) at baseline and 117.5 of 140 (84%; SD 11.2) postprogram. Scores for each recruitment cohort are shown in Figure 3.

Figure 3. Baseline and postprogram DAS scores among participants by cohort. Results from repeated measures DAS model (mean and 95% CI) including interaction for cohort and time. DAS: Dementia Attitudes Scale; LTC: long-term care.



Repeated measures ANOVA showed a statistically significant effect on DAS scores ($F_{1,49}$=4.383, P=.04; η2= 0.015). The model including only time as a predictor demonstrated that relative to baseline, there was an average 2.8 point increase on the DAS score postprogram (P=.04). Post hoc testing did not reveal any significant differences in DAS scores between recruitment cohorts; the model including an interaction with time and cohort, and a model with just time (not including cohort at all) were not statistically significantly different (P=.15).

Discussion

Principal Findings

The purpose of this pilot study was to evaluate the usability, usefulness, satisfaction, and effectiveness of the Dementia Foundations Program, a series of 4 web-based courses about various aspects of dementia developed for unregulated care providers such as PSWs. Three sites were recruited from slightly different populations (PSW trainees, PSWs working in LTC, and PSWs and other unregulated care providers working in community settings) who were all willing to take part in recruitment efforts due to the perceived benefit of additional dementia care training for their students, employees, and members. Overall, the program was positively valued for its usability, and participants reported a high level of satisfaction with the program. Participant knowledge, as measured by the DKAS, significantly increased after completing the program, with an average 30% improvement across all recruitment cohorts. A statistically significant increase was also seen for dementia attitudes as measured by the DAS, with a more modest average improvement of 2.5%. While scores for both the DKAS and DAS did not significantly differ between cohorts, there are a few trends worth highlighting.

PSW trainees from the Durham College cohort had higher baseline DKAS scores and slightly lower DAS scores compared to the PSWs from both the City of Ottawa LTC and uCarenet cohorts. The differences in knowledge scores could be explained by how trainees might have higher fact-based knowledge (from more recent studying) and may be more used to taking knowledge assessments, whereas practicing PSWs may have more everyday clinical knowledge and may not have taken a formal course in some time. When looking at dementia attitudes, the overall significant increase can be attributed to the Durham College and uCarenet cohorts, rather than the Ottawa LTC cohort. This conceptually makes sense, as practicing PSWs may already possess more developed attitudes toward dementia that would not be expected to change drastically after only 4 hours of knowledge-based education. Conversely, PSW trainees and PSWs not working in LTC homes who have had less exposure to working with people with dementia may be more prone to shifting their attitude in a significant way after 4 hours of education.

Comparison to Prior Work

Dementia Education

There is currently a lack of dementia-specific care training offered to unregulated care providers, leading to gaps in care [8,19]. This highlights the need for increased and enhanced training to improve education with the purpose of improving care for individuals with dementia. Research has shown that dementia education and training for health care workers improves knowledge, fosters positive attitudes, increases

confidence, and ultimately produces better outcomes for individuals living with dementia [20,21]. An extensive review by Surr et al [22] evaluated various features of dementia education programs for health care providers. Among the findings, the authors concluded that effective dementia education programs should be relevant to the workers' role and experience, include practice-based learning with theoretical content, be delivered by an experienced facilitator, and involve in-person facilitation. Although there are some existing on-the-job dementia training programs for unregulated care providers, they vary in availability, are more expensive to deliver, and are often less convenient for care providers who may not have flexible schedules to accommodate this type of instruction. The COVID-19 pandemic also imposed limitations on access to many in-person education programs. Thus, a blended knowledge approach that combines in-person training with web-based learning can deliver feasible and effective dementia education with the potential to be scaled and spread to a large population.

Furthermore, the recommendation by Surr et al [22] for in-person delivery may be influenced by several factors. For example, it is likely the case that most education and training programs about dementia have historically been delivered in person. Second, those programs delivered digitally (whether synchronously through webinar platforms or asynchronously) may not have incorporated best practices concerning the instructional design of multimedia e-learning. High-quality instructional design has been shown to improve learning transfer. The Dementia Foundations Program was created using evidence-based principles for multimedia learning outlined by Mayer [12] and Clark and Mayer [13]. The findings from the current study indicate that this entirely asynchronous web-based program is a useful and effective training modality for improving dementia-related knowledge among unregulated care providers. The high satisfaction with the program is evident in the course open-text comments, where most participants praised the program for its informativeness, user-friendliness, and usefulness to their profession as unregulated care providers.

About DKAS

Significant improvements in dementia knowledge were seen after the intervention for both PSWs and PSW trainees. As unregulated care providers in Canada have noted a lack of dementia-specific care training and education, this indicates that the Dementia Foundations Program is an effective way to impact dementia knowledge for this group. Other web-based dementia education programs have also been shown to be effective in increasing dementia knowledge. Eccleston et al [23] evaluated the efficacy of the 9-week-long Understanding Dementia Massive Open Online Course (UDMOOC) for people with varying professional and educational backgrounds. Similar to the Dementia Foundations Program, the UDMOOC aims to improve dementia knowledge by teaching a broad community audience basic neurobiology, dementia pathophysiology, medical management, and person-centered care. The median DKAS score at baseline for their study was 34.5 out of 50, which is comparable to our current pilot study's baseline median DKAS score of 35.5 out of 50, implying both groups started with similar levels of dementia knowledge before embarking on the training. The median postprogram scores for both studies were 45 of 50, both demonstrating a significant increase in dementia knowledge. These results are consistent with the current study's findings, indicating that web-based dementia education modalities are effective at increasing dementia knowledge. However, it is worth noting that the Dementia Foundations Program can be completed in a single day with only 4 hours' worth of content, whereas the UDMOOC estimates 21 hours over a 7- to 9-week period. Comparable baseline and postprogram median DKAS scores for both programs suggest the Dementia Foundations Program is more efficient for busy professionals, with similar knowledge gain in a much shorter amount of time.

When considering the mode of delivery of instruction, 1 study conducted by Parveen et al [24] also found that the most impactful dementia training programs involved a blend of both e-learning and in-person delivery, although another study conducted by Vollmar et al [25] found no significant differences between learning through in-person compared with web-based learning. With the significant increase in dementia knowledge shown by both the current study and Eccleston et al using only a web-based approach, it is reasonable to consider digital-only approaches to some aspects of dementia education, especially when considering the increased flexibility this offers to an unregulated care worker audience with potentially variable and less flexible schedules. A blended approach has been shown to be effective in other studies, and one can speculate that an efficient and effective approach might involve high-quality asynchronous web-based approaches for baseline knowledge education, complemented by in-person skills training.

About DAS

Dementia attitudes significantly increased from baseline to postprogram, with scores moving from an average of 114.7 to 117.5. While this increase is modest at 2.5%, baseline scores on the DAS started quite high compared to other studies looking at dementia attitudes in nursing students in Malta (mean DAS score of 107.9) [26] and health care professionals in China (mean DAS score of 91.3) [27]. The highest possible score on the DAS is 140, corresponding to the highest possible positive attitude toward dementia. The DAS scores from the current study indicate that this sample of participants already possesses relatively positive attitudes toward dementia compared to previous studies, therefore leaving only modest room for improvement on this measure.

Baseline DAS scores averaged 114.7 across all 3 recruitment cohorts, with uCarenet starting with the lowest score of 111.6 and the City of Ottawa LTC starting with the highest score at 116.4. After the 4-hour intervention, DAS scores were significantly higher at 117.5 across all 3 recruitment cohorts, with the Durham College PSW trainees showing the largest increase among cohorts from 114.9 to 120.9. Logically, this cohort showed the biggest increase in positive attitudes toward dementia, as trainees have very likely spent less time working with older adults and those with dementia. The experienced PSWs and other paid caregivers that comprised the Ottawa LTC and uCarenet cohorts have likely been working with people with dementia for many years and have had ample time to develop personal attitudes toward dementia, as previous research

has shown that working with and having ongoing and meaningful interactions with individuals living with dementia are key to fostering a change in attitudes [26,28]. It can therefore be reasonably assumed that 4 hours' worth of independent learning is not a sufficient intervention length to cause an attitude change in experienced workers, but remains sufficient exposure to improve attitudes toward dementia among trainees. This contrasts with a study that explored the impact of a single dementia awareness session on changing dementia attitudes among adolescents, with no significant improvements in either the intervention or control groups [29]. However, the difference may be that the Durham College PSW trainees were more accepting of a potential attitude change toward dementia given their desired career choice as a PSW.

Limitations

We acknowledge that there are limitations to this study. First, the relatively small sample size of 50 PSWs, PSW trainees, and other unregulated care professionals from Ontario who took part in this study is not necessarily representative of the diverse and large population of unregulated care providers in Canada or internationally. However, as the sample size was based on the typical large effect sizes for e-learning interventions, the results of this study remain valuable for an initial assessment of a new e-learning program for this population. This was further confirmed by the detection of statistically significant changes in both dementia knowledge and attitudes as measured by the DKAS and DAS. Second, the lack of a control group due to the pre-post study design introduces an unknown risk of bias; however, the pre-post design does alleviate intraparticipant variability and is consistent with the majority of studies in a 2019 systematic review of studies assessing technology-delivered dementia education to health care providers [30]. Lastly, not all participants had active experience working with people living with dementia, and as a result, may not have found the learning content to be relevant. However, trainees were intentionally included to be able to assess the program's suitability to incorporate into a training program, rather than continuing education once employed.

Conclusions and Future Directions

The Dementia Foundations Program was positively evaluated by a group of 50 unregulated care providers, predominantly PSWs and PSW trainees, with participants showing a significant improvement in both dementia knowledge and attitudes. Participants found the training very useful in supplementing their existing education and training, with particular relevance to the PSW trainee cohort. The findings of this study have implications for unregulated care providers who support people living with dementia, as well as trainees who may not yet interact with those living with dementia. The Dementia Foundations Program is an effective and user-friendly e-learning program that can be conveniently incorporated within existing dementia training and educational programs as part of a blended teaching and learning strategy to enhance dementia knowledge in unregulated care providers and trainees. Widespread implementation has the potential to increase training capacity and fill gaps in existing workforce training and improve dementia knowledge, attitudes, and awareness among care providers as dementia prevalence increases in Canada.

Since this pilot study was conducted, the Dementia Foundations Program has reached 1012 users from December 2021 to September 2024, with approximately 55% completing all 4 courses and receiving a certificate. Postprogram evaluations show high satisfaction with the courses from individuals who purchased the program digitally and employees and students from organizations who purchased the program for professional development.

Future work will focus on the spread and scale of this training program through advertising and partnerships with relevant organizations and institutions, and future research should use implementation science to assess organizational adoption and effectiveness. Continuous quality improvement evaluations will be conducted to determine the best approach for widespread implementation.

Acknowledgments

The authors disclose receipt of the following financial support for the research, authorship, or publication of this paper: This project received funding from the Centre for Aging & Brain Health Innovation (CABHI). AJL receives support through the John R Evans Chair in Health Sciences Educational Research and Instructional Development, Faculty of Health Sciences, McMaster University. The authors wish to thank Sheila Bauer, BScN, MHA, and the City of Ottawa LTC, Deborah Schuh, BScN, and the Durham College PSW Training Program, and Nectari Charitakis, BA, and uCarenet for their collaboration and assistance with recruitment. The authors also wish to thank Dr David Streiner for his guidance and mentorship throughout the statistical analysis.

Data Availability

The datasets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

AJL and SA designed this study and led recruitment and data collection. SA, AJL, and AS performed data analyses. SA, SC, and PG drafted this paper. AS and SC created the figures. All authors read and approved this final paper.

Conflicts of Interest

AJL and RS are co-owners of the Dementia Foundations Program. There is a fee to access the Dementia Foundations Program.

Abstract

Background: Australia's aging population is looking to age in place, accessing care alternatives external to the traditional model of residential aged care facilities. This evaluation is situated in a Social Day Program, delivered by an aged care organization. It is designed to cater for people living with dementia, located in an environment equipped with new technologies including age-specific interactive computer gaming, social robots, sensory stimulation, and virtual reality. The technologies are designed to support older adults, enabling them to stay connected and maintain physical and cognitive functioning, independence, and quality of life.

Objective: This project aimed to undertake a multifaceted evaluation of the implementation of the new technologies, including an exploration of the barriers and enablers to uptake. The key issue is how to enhance the potential for optimizing the use of these technologies in the Social Day Program environment, to help inform decision-making regarding the implementation of these technologies at the organization's other sites, and future investment in such technologies by aged care organizations generally.

Methods: Observation of technology use within the organization was conducted over a 16-week period. Surveys and semistructured interviews were used to collect information from staff related to their experiences with the technology. Thematic analysis was used to analyze the interviews. Data were triangulated across the sample.

Results: Forty-eight observation periods were completed, totaling 126.5 observation hours. Technology use by clients was observed on 24 occasions, for 22 (17.4% of the observation time) hours. Nineteen staff completed surveys. Nearly three-quarters (n=14) of the staff perceived there to be barriers to the clients' use of technology, and 18 (95%) staff reported that they assisted clients to use the technology. Ten (53%) staff reported receiving training to use the technology and feeling confident in their knowledge of the technology to assist clients in using it. Twelve staff members participated in an interview. Key themes identified from the interview data were: technology has potential but is not for everyone, incorporating the subtheme technology as a placation tool, staff knowledge and confidence, and technology functionality and support.

Conclusions: This evaluation identified that technology was not being used for the purposes of enrichment or experience enhancement, nor extensively. Multiple barriers to the implementation and sustained use of the technology items were identified. Recommendations to improve implementation and promote sustained use of technology, based on the findings of this evaluation and evidence from the literature, may apply to other organizations seeking to implement these technologies in similar programs.

Introduction

Background

With a shift to consumer-directed care, and Australia's aging population looking to age in place and access a range of supported care alternatives outside the traditional model of residential aged care facilities, there are a lot of new offerings for consumers. Often funded through the Australian government–supported Aged Care Community Packages, these offerings can include in-home care and home support services or colocated aging-specific services in centralized hubs. Services include Dietetics, Allied Health Group Programs, Exercise Physiology, Gym and Physical Activity, Massage, Music Therapy, Occupational Therapy, Physiotherapy, Podiatry, Speech Pathology, Gerontology, and Social Day Programs.

ECH Inc (hereinafter referred to as the organization) is a South Australian retirement living and in-home care services provider established in 1964 and based in the state of South Australia. The "profit for purpose" organization's mission is "helping

people to live confidently and independently, and to get more out of life" [1]. This project was situated in one of the organization's Social Day Programs, which occur at 4 centers across metropolitan South Australia. The Social Day Program involved in this evaluation is situated within a proof-of-concept Care Hotel that was purpose-designed to provide care givers respite options with 8 short-stay suites for people living with dementia or who may be recovering from surgery. These Social Day Programs, provided on weekdays between 9 AM and 3 PM, are designed to cater for community-dwelling people living with dementia or memory loss and are located in environments where the clients have space to engage socially with others or have supported, quiet alone time. Clients can be dropped off at and picked up from the Social Day Program by family members or transported to and from the Social Day Program by a bus provided by the organization. Program staff are trained to ensure that each client's interests and abilities are met, with the provision of activities that are enjoyable and meaningful. Participation in the Social Day Program is also available to Care Hotel guests, as is access to the space outside the Social Day Program hours (evenings and weekends). This space is equipped with new technologies that are designed to support older adults as they age, enabling them to stay connected and maintain physical and cognitive functioning, independence, and quality of life [2-5]. These technologies are varied and includes an age-specific interactive computer gaming console, "Obie" that projects interactive games onto a surface (table or floor) to encourage active play; a relaxation chair in a sensory stimulation room; virtual reality (VR) headsets (the Odysee system, with virtual experiences including travel, museums, and hot air ballooning); white noise bubble tubes (tubes with color changing lights, filled with bubbles, that are intended to provide visual distraction and calm); 2 robotic dolls; and a robotic sensory cat.

Systematic reviews support the effectiveness of these technologies, with interactive computer gaming improving physical and psychological functioning [6]; interactions with social robots positively affecting agitation, anxiety and loneliness, medication consumption, and quality of life [5]; and VR technology improving physical health outcomes [7] and cognition, memory, and depression [8] for older adults. The implementation of such technologies in the aged care environment is not without its challenges. Other studies have identified organizational factors, such as funding and staff engagement or knowledge, client-specific issues such as frailty, dementia, or limited prior exposure to technology, inappropriate or unsuitable technologies, or resistance from family members [9]. Similar barriers were identified in a systematic review of VR technology, with the addition of the potential for cybersickness during use also perceived to be a barrier [10]. Research focused on social and assistive robots has identified concerns around the potential for infantilization or loss of dignity for older adults who use them [11]. The items chosen by the organization were selected due to the evidence supporting their effectiveness and with the intention of supporting engagement and enrichment for their clients. Providing a variety of technologies, rather than a single type of technology, was intended to broaden the appeal of technology to clients.

This Study

The organization requested an extensive review of the use of these technologies in this unique setting. This research aimed to undertake a multifaceted evaluation of the implementation of technologies at the Social Day Program, including an exploration of the barriers and enablers to the use of technology within the Social Day Program. The key issue, and the focus of this paper, is identifying how to enhance the potential for optimizing the use of these technologies at the organization, making recommendations to help inform decision-making regarding the implementation of these technologies at other sites, and future investment in new technologies for the organization's clients.

The evaluation was intended to answer the following research questions:

1. What is the utility of these technologies?
2. What are the barriers and enablers to the uptake of these technologies?
3. What is the impact (physical, psychosocial, and quality of life) of technology use experienced by the clients, as perceived by the staff?

Methods

Study Design

Observation of technology use within the Social Day Program was conducted over 16 weeks by a research assistant (RA), with periodic support from undergraduate physiotherapy students completing a health promotion placement with the evaluation team. Surveys and semistructured interviews were used to collect information from staff related to their experiences with the technology. Data were triangulated across the sample, with observation, survey, and interview data integrated and compared to establish alignment and contrast among the findings of each method.

Participants

Participants were staff working in the organization's Care Hotel or Social Day Program. Staff provided written informed consent to participate in the evaluation. For the observation component, participants included clients of the Social Day Program and clients of the Care Hotel who were accessing the Social Day Care space.

Observation of Technology Use

Observation of the use of technology by staff, Social Day Program clients, and Care Hotel guests using the Social Day Program space was undertaken between July and November 2022. Observation periods of 4 hours each, either morning and overlapping early afternoon or late morning until the end of the day, occurred during the Social Day Program sessions across the week, but also after hours and on weekends to ensure capture of use of technology outside of typical program activity periods. An observation checklist was used to capture data related to technology-user type (ie, client, family member or carer, staff, or other), technology item, duration of use, concurrent use of an item by multiple participants, support or assistance provided, emotional impacts, communication, physical impacts, and other

notable information. This checklist was developed by the evaluation project team in consultation with the Stakeholder Advisory Group and piloted by the RA and placement student observers, with checklist items modified as required throughout piloting.

Surveys

Consenting staff completed an anonymous electronic survey (Qualtrics). Survey items were initially drafted by the evaluation team and refined using a co-design approach in collaboration with the Stakeholder Advisory Group. The Stakeholder Advisory Group was comprised of members of the organization and evaluation project team and a representative from each of the 3 stakeholder-participant groups (clients, family members or carers, and staff of the Social Day Program) and was formed to ensure consumer awareness and the suitability and feasibility of evaluation methods. The staff survey was intended to identify the perceived implications for staff involved in implementing the technology and supporting clients to use the technology.

Survey questions collected information about participant demographics, staff assistance with technology items, length of time staff assisted clients with the technology, and most- and least-assisted technology items. Perception of impact were collected across 6 domains relative to each of the items of technology: social engagement, cognitive awareness, communication, mood state, activities of daily living, and physical mobility. Responses were on a 4-point Likert scale, with responses being: don‘t know, no improvement, some improvement, and a lot of improvement. Additionally, there were questions relating to whether staff perceived that clients disliked any technology items; barriers to clients using the technology; staff training; staff confidence when supporting clients; and barriers to staff supporting clients with the technology items.

Interviews

Semistructured, once-off, one-on-one interviews were conducted by 1 of 2 University of South Australia RAs, with consenting staff. Interview questions were initially drafted by members of the evaluation project team and refined and co-designed in collaboration with the Stakeholder Advisory Group (Multimedia Appendix 1). Interviews were conducted either in person at the Social Day Program or over the phone. All interviews were recorded and then transcribed verbatim.

Data Analysis

Observation and survey data are reported as counts or counts and percentage responses as relevant. Content analysis of open-ended survey questions was intended; however, an insufficient number of responses was provided, and a descriptive approach to reporting the responses was instead used. Reflexive Thematic Analysis [12,13] was used to analyze interview data, which were coded independently by a member of the evaluation team. Semantic codes and candidate themes were reviewed and discussed among the team across multiple iterations before the final themes were decided. We applied a constructionist epistemology, with an experiential lens on the data, with the intention of highlighting the experiences and perspectives of staff related to the use of technology in the Social Day Program environment. While our approach was predominantly inductive, in that we sought to represent the meaning of the information as it was communicated by the staff, elements of a deductive approach were applied to ensure that the established themes aligned with the research questions, for example, what the staff perceived to be barriers to and enablers of technology use in this setting.

Ethical Considerations

This evaluation research was approved by University of South Australia’s Human Research Ethics Committee (204457). A waiver of consent was approved for the purpose of observing technology use in the Social Day Program. This was on the proviso that before commencing each observation period, staff and the evaluation project team announced to clients during Circle Time—an activity during which information is relayed to clients and their family members—that an observation period was about to begin. This enabled clients to leave the room if they did not wish to participate in this part of the evaluation project. Participants remained anonymous, in that information that might identify them was not recorded per their use of technology, and they were not asked to modify their behavior for the evaluation. Participants provided written informed consent for use of their survey data. Written informed consent was also provided by interview participants. Each interview participant received an honorarium (AUS $30 gift card; US $19.43) to acknowledge their contribution to the project. Data are anonymized and no information is provided that would identify participants.

Results

Participants

Thirty-one staff were approached to participate in the evaluation project; 19 based in the Care Hotel, and 12 staff based in the Social Day Program. Nineteen (61.3%) staff completed surveys (9 Care Hotel and 10 Social Day Program). Ten (32.3%) of the 31 staff approached (3 Care Hotel and 7 Social Day Program) provided written informed consent to participate in the interview; all 10 interviews were completed.

Observation of Technology Use

Forty-eight observation periods were completed, totaling 126.5 observation hours. Technology use by clients was observed on 24 occasions, for 22 (17.4% of the observation time) hours. The relaxation chair and the robotic cat were the most frequently used technology items. The relaxation chair was used 7 times for a total of 9 hours and 36 minutes, and the robotic cat was used 7 times for a total of 3 hours and 14 minutes. Conversely, the Obie interactive games table and VR headsets were the least frequently used technology items (once for 64 min and once for 39 min, respectively). When technology was used, clients were mostly observed socially engaging and communicating with staff and other clients, with some clients also observed speaking to the robotic cat and dolls.

Surveys

Of the 19 staff members who consented and responded to the staff survey, 10 (53%) worked in the Social Day Program and

9 (47%) were Care Hotel staff. Ninety-five percent (n=18) of staff reported that they helped or supported clients in using the technology items. Social Day Program staff assisted clients more than Care Hotel staff across all technology items except for the relaxation chair. Furthermore, all 9 Social Day Program staff indicated they assisted clients with the Obie interactive games table and robotic cat. Seventeen of the nineteen (89%) staff members nominated the VR headsets as the technology item they engaged with the least. Staff reported that on average, clients engaged with the technology items from 10-minutes to more than 60-minutes. This finding is reflected in the observation data, with the average time clients spent using technology items ranging from 32-minutes to 96-minutes.

Improvements in social engagement, cognitive awareness, communication, mood state, activities of daily living, and physical mobility were seen to some extent across each of the technologies, although not for all items (Table 1).

Table . Perceived improvements associated with technology use.

Technology item and domain		Don't know, n (%)	No improvement, n (%)	Some or a lot of improvement, n (%)
Obie ICG[a] table				
	Social engagement	1 (5)	3 (16)	15 (79)
	Cognitive awareness	3 (16)	4 (21)	12 (64)
	Communication	1 (5)	2 (11)	16 (84)
	Mood state	1 (5)	0 (0)	18 (95)
	Activities of daily living	2 (11)	9 (47)	8 (42)
	Physical mobility	0 (0)	8 (42)	11 (58)
VR[b] headsets				
	Social engagement	10 (53)	4 (21)	5 (26)
	Cognitive awareness	12 (63)	5 (26)	2 (11)
	Communication	12 (63)	4 (21)	3 (16)
	Mood state	10 (53)	4 (21)	5 (26)
	Activities of daily living	11 (58)	7 (37)	1 (5)
	Physical mobility	12 (63)	6 (32)	1 (5)
Robotic cats				
	Social engagement	2 (11)	1 (5)	16 (84)
	Cognitive awareness	2 (11)	5 (26)	12 (63)
	Communication	2 (11)	2 (11)	15 (79)
	Mood state	2 (11)	0 (0)	17 (90)
	Activities of daily living	3 (16)	11 (58)	5 (26)
	Physical mobility	3 (16)	8 (42)	8 (42)
Robotic dolls				
	Social engagement	1 (5)	1 (5)	17 (90)
	Cognitive awareness	1 (5)	4 (21)	14 (74)
	Communication	3 (16)	1 (5)	15 (79)
	Mood state	2 (11)	0 (0)	17 (89)
	Activities of daily living	5 (26)	8 (42)	6 (32)
	Physical mobility	4 (21)	6 (32)	9 (47)
Relaxation chair				
	Social engagement	2 (11)	7 (37)	10 (52)

	Communication	3 (16)	5 (26)	11 (58)
	Mood state	1 (5)	0 (0)	18 (95)
	Activities of daily living	3 (16)	6 (32)	10 (53)
	Physical mobility	2 (11)	6 (32)	11 (58)

[a]ICG: interactive computer gaming.

[b]VR: virtual reality.

Nearly three-quarters (n=14) of the responding staff perceived there to be barriers to the clients' use of technology, with equal numbers responding "yes" when compared by staff type. Ten (53%) of the responding staff had received training. Ten (53%) staff indicated they felt confident when assisting clients to use the technology; however, ten (53%) staff also felt that barriers existed that inhibited them from assisting the clients to use the technology (5 each from the Social Day Program and Care Hotel).

Key concepts raised by staff in their responses to the open-ended questions about their perceptions of technology use within the Social Day Program related to why clients may dislike technology, the barriers to technology use by clients, factors related to staff confidence in supporting clients to use technology, and the barriers to staff supporting clients to use technology.

Staff perceived that clients may dislike the technology because they have health or cognition issues that limit their ability to engage with technology; due to negative perceptions or stigmatization by other clients of people who use the robotic doll or cat; that clients have no interest in technology or use of technology; and that clients did not like particular items, finding them to be noisy or creepy (ie, the robotic doll). These aspects were also considered to be barriers to clients' use of technology, with the addition of staff knowledge and confidence in the use of technology, and the time impact on staff to assist clients in using the technology.

Interviews

Interviews were conducted with 12 staff members to assess the use of technology within the Social Day Program, and the enablers of and barriers to technology use. Interviews ranged between 18 and 44 minutes. The three themes developed during the analysis of the interview data: (1) technology has potential but is not for everyone, with the subtheme technology as a placation tool; (2) staff knowledge and confidence in using technology; and (3) technology functionality and support, are based on our interpretation of how staff experienced technology use in the Social Day Program and the factors that are likely to be enablers or barriers that influence the adoption of technology and sustainability of technology use in this environment. These themes address the research questions that form the basis for the evaluation. Quotes from participants are used as illustrative examples of the themes established.

Technology Has Potential but it Is not for Everyone

This theme reflects the value and appropriateness that the staff perceive in technology use for their clients, assuming who might be likely to benefit from technology use and, conversely, for whom technology is not for. This theme incorporates the safety and personal considerations that were voiced as being needed when using technology. There were conflicting perspectives related to the use of technology within the Social Day Program. The potential benefits of the technology were raised often, including increased social engagement through the use of interactive games or being able to placate agitated clients with the robotic cat or time in the relaxation chair (a subtheme). While there was some concern about the cognitive benefits of the technologies, that the clients had to sit for prolonged periods to use some of them and therefore were being sedentary just as they would be at home (staff 14), and that some items had the potential to cause "sensory overload" (staff 2), others thought that the technology promoted social interaction, could "enrich the time clients spent at the Social Day Program" (staff 24), and could benefit future clients, in particular those who were tech-savvy. For one staff member, their initial perception that technology would "not be a great idea" (staff 1) changed positively when they saw the impact of technology use for some clients, for example, the connections made with the robotic cat. Similar observations of such connections are reflected by the following comment from a staff member.

> *I wasn't sure about the babies and the cat. I thought maybe that was a bit babyish...It's funny to watch how they [clients] perceive that and how quick they are to defend the cat, whereas sometimes you wouldn't even get a couple of words out of them, but they've got to make sure the cat is okay.* [Staff 7]

Generational factors, in that the client demographic needed assistance as they were not tech-savvy, or not familiar with, or not interested in technology, situated some clients in the "technology is not for everyone" group, in the eyes of the staff. These factors were often raised as a possible barrier to greater use of the technology in the Social Day Program. Future generations were viewed to be more likely to be receptive to technology, as evidenced by the following comments:

> *I think it's a double-edged sword and it has the potential to be brilliant, however unfortunately with that particular generation, because they were not particularly technologically minded or advanced, they are somewhat overwhelmed by it perhaps.* [Staff 6]

> *Look, we do have to help them most times just because they are technologies and it's not their era. Today's kids will be great in the future for these things, but these people were not brought up with these technologies.* [Staff 4]

While there was acknowledgment of the potential benefits of technology use, it was clear that staff were wary of the possible downfalls associated with it, demonstrating concern around physical and psychological safety for clients with frailty or cognition issues, or for whom memories of past traumas were triggered by using technology. Examples of this included clients who had worked in child abuse situations and had experienced miscarriages or the death of infants being exposed to the robotic dolls.

> *Some clients are really not suitable for the dolls and some aren't suitable for the animals. It does depend, because they've got either histories of – we've got some clients that have worked in child abuse situations. They're not good with the dolls, because it really upsets them. Knowing that background as well...we do the assessments and we ask the questions. But it's good knowing those things.* [Staff 4]

The juxtaposition between the potential benefit of technology use and its appropriateness was evident in the commentary around the use of the VR equipment. There was a common thread that the VR equipment could be the most beneficial for clients of all of the technologies introduced to the Social Day Program, allowing clients to reminisce about places they may have previously lived in or visited and activities previously performed, such as flying planes. For others, the VR was a source of concern; for example, clients with frailty issues may be scared to use it due to a fear of falling, and those with cognitive issues may be confused by what they are seeing.

> *I think that the VR would definitely be useful for some clients who may enjoy it, a lot of more cognitive ones I think, because people who have low cognition may get very frightened of some of the things they see.* [Staff 1]

Ensuring the safety of clients while they were using technology by having measures in place to assess physical capacity to use the VR, for example, or having background information that enabled identification of potential trauma triggers to avoid clients being exposed to them, was raised, with some staff indicating processes were in place within the organization to accommodate this.

> *We've got a safety test before we just chuck anybody on it [VR], because some people do have the same thing as me with the nausea and dizziness and stuff. There is a possibility of falling down.* [Staff 4]

Combined, not being tech-savvy, being averse to technology, or perceived to be at risk of physical or psychological injury due to technology use cemented the concept that technology is not for everyone involved in the Social Day Program.

Technology as a Placation Tool

Incorporated within this theme is the subtheme of technology as a placation tool. We initially wrestled with whether the use of technology in this way was situated as a potential benefit of technology use or a standalone theme; however, throughout the data, the utility of technology as a method of placation for clients, and therefore, it being perceived as a potential benefit, was evident. It seemed that while this was not an intended application of technology within the Social Day Program, placating agitated clients with items such as the robotic cat or time in the relaxation chair was rationalized by staff to lead to enriched experiences for those clients, as well as other clients in the program, whose experience was no longer being impinged upon by an agitated client. As a by-product, the benefit was extended to family members of the agitated clients who did not have to pick clients up from the Social Day Program earlier than intended, as described in the following comment:

> *It makes them extend their stay here in the day program. Rather than having to be picked up at lunchtime because their day is done and they've had enough stimulation for the day, they can be in there [the sensory room] for half an hour to an hour, come back out and enjoy the rest of the day 'til 3:30 [PM].* [Staff 4]

Knowledge and Confidence in Using Technology

This theme encapsulates concepts related to staff knowledge of the capabilities of the various pieces of technology and how to use them, as well as their confidence in assisting clients to use the technology, as a key driver in the use of technology in the Social Day Program. Further, these aspects are likely to influence whether technology continues to be used in the program. It was apparent across the data that training was important to staff; however, most reported that they had received little to no training in the use and maintenance of the technology. Further, there were perceptions that some of the technology required little training, such as the robotic doll and cat, whereas other types of technology, such as the VR or Obie, required more training of staff. This may have contributed to lower usage of these technologies as evidenced through observation, survey, and interview data, as may have confidence in using the technology. Perceptions of the relationship between training and confidence to use technology are contrasted. In some cases, staff reported that more training in the use of the available technology would increase their confidence to use the technology, for example:

> *I would like more training and capacity. I can do basic things, but I'm not confident using things...Yeah, I think I don't feel really confident with it. I'd like to be. I'd like to learn to do it.* [Staff 9]

Others felt confident to use the technology, irrespective of the level of training they had received. It was suggested that increasing confidence in the use of technology may increase the enthusiasm staff have for technology use, and subsequently, increase the regularity of technology use in the programs at the organization and assist in better tailoring technology use to individual clients.

Technology Functionality and Support

This theme reflects the importance of having available technology that is functional, as well as accessible support for staff in cases when the technology was not working. This would seem obvious in any environment where technology such as that implemented was being used; however, it was frequently raised by interviewees that technical and maintenance issues with the technology were common. These are clear barriers to the use of technology in the Social Day Program and are likely to influence the willingness of staff to use the technology or assist clients to use it. An example of this related to the VR technology, which staff reported had rarely been in working condition since its introduction. While some staff reported helping other staff to use the technology, obtaining higher-level support to repair the equipment had proved problematic, as illustrated by this comment from a staff member.

> *[If] I had a problem with something over the weekend let's say, I would have absolutely no idea who to call to get that support and I don't even think that the support necessarily is available. Therefore, from that perspective those clients would simply miss out until someone was able to be contacted to fix it. It would be a too bad, so sad kind of concept, which is not cool really.* [Staff 6]

Discussion

Principal Findings

This project aimed to undertake a multifaceted evaluation of the implementation of technologies at a Social Day Program to help inform decision-making regarding their implementation at the organization's other sites. The evaluation included (1) observation of use, (2) surveys of staff members' perceptions of enablers and barriers to use of the technologies, and (3) interviews with staff to further explore their experiences in use of technology and enablers and barriers to implementation and use of the technologies. The observation, staff survey, and

interviews provide a rich dataset to enable the evaluation. Observation over an extensive period identified limited use of technology, further verified by the survey data, with potential reasons for this, including barriers to and enablers of technology use identified in survey data and thematic analysis of interview data.

When technology was used it was predominantly used during the Social Day Program and by Social Day Program clients rather than after hours by the Care Hotel guests. One reason for this may be that guests in the Care Hotel might be recuperating from medical procedures, rather than solely attending for respite purposes. As such, these guests may not be able to engage, nor be interested in engaging, in technology use at this time. Alternatively, the technology located in the guests' Care Hotel rooms, such as an interactive television and tablet, which were not the focus of this evaluation, may have negated the need to access the technology located in the Social Day Program. For example, guests could relax and listen to music in their hotel rooms, and therefore would not need to access the sensory room and relaxation chair.

While items such as the robotic cat have been shown to be popular, a large portion of the use appears to be as a means of placating clients who were agitated or were disturbing other clients. This is not to say that the potential benefits of technology use at the organization were not recognized by some staff; however, encouragement of use may not be aligned with the original intention behind the implementation of the technology. Staff highlighted occasions when the use of the robotic cat by clients enhanced interaction between those clients, other clients, and staff. While mixed findings have been reported concerning the use of robotics in other aged care environments, some studies have shown that robotic animals such as cats and dogs can be conversation starters and contribute to enhanced engagement for older adults and people living with dementia [14,15].

In other cases, staff spoke of the opportunity that the sensory room provided for clients in being able to support an extended period of attendance at the Social Day Program, and in their eyes, held this as a potential benefit of technology use. Clients who may normally need to be picked up early, as they found the activities of the Social Day Program tiring or overwhelming, could instead remove themselves from the activities and take some time-out to relax in the sensory room. Being able to do this meant that these clients could spend longer days at the Social Day Program, rather than having to go home early. This has flow on benefits for their family carers, who, as a result, have a longer period on that day for respite. Research supports a reduction in care-related stressors for the carer during respite, and that the longer the respite duration, the greater the benefit to the carer [16]. Each of these factors can be highlighted to staff as potential benefits as a means of supporting implementation and greater use of the technology.

Harnessing the staff members' own perceptions of the emotional, social, cognitive, and physical benefits of technology use that were identified through this evaluation may be one approach to facilitating successful implementation. Observational, survey, and interview data indicated that technologies were perceived to positively impact the emotional state of clients. This was not only the calming effect reported and that is acknowledged in the literature [17], but also included observed happiness and enjoyment, as well as the social engagement that occurred among groups of Social Day Program clients as they used the Obie and robotic cats, for example.

Safety—both physical and psychological—was a prominent consideration for staff. Caution was raised about the risk of falls with some of the technology, in particular VR. The use of VR has been evaluated in other aged care environments and has been shown to have both positive and negative impacts. While it has the potential to engage and enrich the experience of the organization's clients by providing them access to activities, experiences, and environments that may no longer be physically accessible to them, VR may not be acceptable to, nor appropriate for, all people living with dementia [18]. Raised in the survey and interview data, these safety concerns extended to the possibility of psychological trauma for clients exposed to technology such as the robotic cats, categorizing them as part of the "technology is not for everyone" group. Concerns were raised about the stigma associated with people who use technologies such as the robotic cat or doll, because they are "not real." "Infantilization" of older adults living with dementia and their loss of dignity through the use of robotic toys, which they perceive to be real, has been explored in other research [17], and in some cases, it is the family members of the older adult holding this perception [19]. Strategies suggested to minimize this and maintain dignity when items such as robotic toys are used to engage people include creating an obvious environment of "play" [20].

Barriers to, and Enablers of, Technology Uptake and Use

As evidenced through this evaluation, several factors act as barriers to and enablers of technology use within the Social Day Program. The key factors, reflected by the developed themes, relate to staff training in, and knowledge of, technology operation and features; technology functionality and the availability of real-time technology support for staff; and perceptions of a generational influence on technology use. All of the barriers—and subsequently the enablers—to technology use identified in this evaluation were common to another recent Australian evaluation of technology use in aged care [9], suggesting they are not specific to this particular organization, but more reflective of the aged care environment generally.

Staff awareness and understanding of the underlying purpose of technology use for this population, beyond it being used as a behavior management tool, may also act as an enabler of greater use of technology within the organization. This includes opportunities for technology to promote "meaningful engagement" and social interaction [19], particularly, the technology should facilitate social interaction among those present and not be a replacement for it [9]. However, technologies that require staff to invest more of their already limited time to support clients in using them may also be less likely to be encouraged within the Social Day Program.

"Visibility" of the technology was considered by some staff to be an enabler of technology use; however, it was not raised sufficiently to warrant inclusion as a theme. Staff suggested

that technology items that are visible and easily accessible by staff and clients are more likely to be used regularly. Further, staff members who regularly use the technology and encourage clients to do so have the potential to encourage other staff members to do the same. As such, increased visibility of the technology has the potential to encourage more use within the organization.

Other potential barriers to the use of technology relate to perceptions that the current generation of clients at the Social Day Program are not "tech-savvy," do not like technology, or just have no interest in using it. Interviews identified that the clients were perceived not to have used much technology across their lifetime and that technology is likely to be more acceptable to future generations of clients who have grown up with and are familiar with technology. Staff reported observing positive impact related to social engagement, communication, and mood state, suggesting that some clients did enjoy using the technology. Enjoyment and acceptability of technology by older adults would seem to be obvious in whether technology is used and have been shown to be perceived by older adults as relevant in the successful implementation of technology to support ageing in place [20].

Sustainability

Targeting the enablers of technology use identified in this evaluation will contribute to ongoing technology use in the organization's Social Day Program. Taking a person-centered approach to technology use, by modifying organizational approaches to understanding the interests of clients, the physical and cognitive capabilities of clients, knowledge of potential triggers for negative or trauma responses associated with technology use; as well as technology that is maintained in good working order will also be a driver of sustainability.

Limitations

A limitation of this evaluation was having little data from clients and their family members, and therefore not being able to make their voices prominent in this evaluation. To an extent, this is reflective of other evaluations that have been undertaken in the aged care environment. In some cases, family members may not be involved in the lives of their guest or client family member. In others, the only respite family members may have is when the guest or client is at the Social Day Program. This may see family members not wanting to use that time for activities such as this evaluation.

In cases where guests or clients are living with cognitive decline or dementia, it was difficult to engage them in the interview process. However, it is important to ensure that people living with cognitive decline or dementia are included in projects about them, in particular, in the consultation and co-design process [21], which we were able to achieve through having clients and family members in the stakeholder group. While there were several instances in which staff provided negative feedback related to the technology not being operational, with limited support provided, it is also possible that other staff were reluctant to provide negative perspectives, which may introduce some bias to the findings.

Recommendations

While the use of technology may benefit this population, the potential benefits have not been fully realized at the organization due to several implementation barriers: there is a lack of staff knowledge, confidence in use, and training relevant to the operation of the different technologies, the technology has not always been operational and ongoing, accessible support is not available. There is a perception that technology has benefits, although the use of technology may not always be as intended by the organization, however, this is contrasted by the expressed view that technology is not for everyone and there are physical and psychological risks involved in use of technology in the Social Day Program population, many of whom live with cognitive decline. By addressing the barriers identified in this evaluation and strengthening the enablers per the following recommendations, the potential for clients to benefit across the domains could be enhanced.

Based on the results from the evaluation and considering the evidence from the literature, the following recommendations may enhance the implementation of technology in programs similar to the one described here:

- Increase staff knowledge of technology and its potential benefits for older adults living with cognitive decline, through the provision of more structured and regular training, a summary information sheet of project findings, quick refresher sessions, instruction sheets, and time to "play" and practice with the technology. This needs to include not only how to operate the technology and trouble shoot common problems or issues, but also provide an understanding of all the features and options (to enable tailoring to client needs or capabilities) and how to use the technology to best benefit the clients.
- Develop an information technology maintenance and support process that is resourced to ensure the equipment is functional at all times and enables staff to access real-time information technology support to address operational or technical issues. This should also include the development of comprehensive but user-friendly instructions to assist with understanding the features of the technology, operating the technology, and troubleshooting.
- Ensure that appropriate measures are in place to establish client physical and psychological safety, so that they are not exposed to technology that may be inappropriate for their circumstances.
- Increase the visibility and accessibility of the technology, so that it is at the forefront of staff's, clients' and their family members' or carers' thoughts as an activity. This may be through pictural posters placed around the room as reminders that the technology is there, with simple step by step instructions placed near technology or by leaving the technology in easy-to-access locations.
- Consider the placement of technology within the space.

Conclusions

This evaluation of technology use in a Social Day Program has identified that technology is not being used extensively, nor is it being used for the purposes of enrichment or experience enhancement. Multiple barriers to implementation and sustained

use of the technology items have been identified, spanning perceptions of clients' preference or low ability, to a lack of staff training and knowledge to support adequate use of the technology. Recommendations to improve implementation and promote sustained use of technology, based on the findings of this evaluation and evidence from the literature, may apply to other organizations seeking to implement these technologies in similar programs.

Abstract

Background: Frailty syndrome increases the vulnerability of older adults. The growing proportion of older adults highlights the need to better understand the factors contributing to the prevalence of frailty. Current evidence suggests that geomatic tools integrating geolocation can provide valuable information for implementing preventive measures by enhancing the urban physical environment.

Objective: The aim of this study was to analyze the relationship between various elements of the urban physical environment and the level of frailty syndrome in older Chilean people.

Methods: A cohort of 251 adults aged 65 years or older from Talca City, Chile, underwent comprehensive medical assessments and were geographically mapped within a Geographic Information Systems database. Frailty was determined using the Fried frailty criteria. The spatial analysis of the frailty was conducted in conjunction with layers depicting urban physical facilities within the city, including vegetables and fruit shops, senior centers or communities, pharmacies, emergency health centers, main squares and parks, family or community health centers, and sports facilities such as stadiums.

Results: The studied cohort was composed of 187 women and 64 men, with no significant differences in age and BMI between genders. Frailty prevalence varied significantly across clusters, with Cluster 3 showing the highest prevalence (14/47, *P*=.01). Frail individuals resided significantly closer to emergency health centers (960 [SE 904] m vs 1352 [SE 936] m, *P*=.04), main squares/parks (1550 [SE 130] m vs. 2048 [SE 105] m, *P*=.03), and sports fields (3040 [SE 236] m vs 4457 [SE 322]m, *P*=.04) compared with nonfrail individuals. There were no significant differences in urban quality index across frailty groups, but frail individuals lived in areas with higher population density (0.013 [SE 0.001] vs 0.01 [SE 0.0007], *P*=.03).

Conclusions: Frail individuals exhibit geospatial patterns suggesting intentional proximity to health facilities, sports venues, and urban facilities, revealing associations with adaptive responses to frailty and socioeconomic factors. This highlights the crucial intersection of urban environments and frailty, which is important for geriatric medicine and public health initiatives.

KEYWORDS

aging; frailty; geospatial clustering; urban factors; neighborhood conditions.

Introduction

Understanding the aging process and the sociodemographic determinants related to enhancing the quality of life has emerged as a very relevant research area in light of the rapid aging of the global population [1-3]. Currently, 12% of the world's population is aged ≥60 years, and projections suggest that this proportion may rise to 21.5% by the mid century [4]. Similarly, the ≥80 years age group is expected to increase from 1.7% to 4.5% [4]. In this context, Chile is experiencing a pronounced aging phenomenon [4,5]. Projections indicate that the Chilean population aged ≥60 years is set to surge from 15.7% to 32.9% by 2050, with the proportion of individuals aged ≥80 years potentially reaching 10.3% [4].

According to the World Health Organization, the frailty syndrome is a crucial determinant regarding the state of dependency, the presence of chronic diseases, polypharmacy, and the quality of life in older people [6,7]. The frailty syndrome is defined as a preventable and reversible clinical state in which the capacity of older people to cope with everyday stressors is compromised by an increase in vulnerability and the physiological deterioration associated with aging [8]. Recent results show a prevalence of frailty in Chile slightly higher than 20% [9,10]. Frail persons have higher risks of mortality, cognitive impairment, fractures, and hospitalization, among other adverse health events, which, considering the increase in the population of older people, represents a challenge for public health and social welfare systems [11,12].

The built environment refers to spaces altered or created by human activities, encompassing a spectrum from homes and schools to workplaces, highways, urban expanses, accessibility to amenities, recreational areas, and pollution [13]. This environment can be delineated into 2 primary components: the microenvironment, encapsulating neighborhood and street-level attributes, and the macroenvironment, which includes the degree of urbanization and patterns of land use [14]. Enhancing our understanding of how the urban physical environment impacts older adults can significantly aid in formulating effective plans and interventions to prevent the progression and onset of frailty while promoting the well-being of this population [15]. Previous research conducted by our group has demonstrated that leveraging geomatic tools, which integrate geolocation as an additional dimension of analysis, can provide valuable insights for studying frailty as a syndrome and supporting the implementation of preventive measures [16,17].

According to reports from the World Health Organization on aging and friendly cities, enhancing the environment through improvements in physical structures and community support is an effective approach to maintaining the health of older people [18]. Recent evidence underscores the impact of neighborhood characteristics on frailty among older people. Those residing in neighborhoods with abundant green spaces exhibit a lower incidence of frailty, whereas individuals perceiving precarious conditions in their surroundings, houses, and environment face a higher risk of frailty [19-21]. A comprehensive multilevel (individual and community) cross-sectional analysis highlighted that older adults living in aesthetically pleasing and walkable neighborhoods tend to exhibit lower levels of frailty. In contrast, areas with high-traffic roads, for example, were associated with a higher prevalence of frailty [22,23]. These findings emphasize the critical role of physical environmental factors in shaping the health and well-being of older populations, highlighting the importance of designing age-friendly communities that promote active and healthy aging.

In this context, this study aims to analyze the relationship between various elements of the urban physical environment and the level of frailty syndrome in older Chilean people.

Methods

Participants and Study Design

The research adopted a cross-sectional case-control design, with a representative sample of older persons (aged ≥65 years old, both men and women) randomly selected from various Family Health Centers and community groups of older people in Talca City, Chile (n=251). All medical centers that serve older adults in the city were considered, ensuring geographical representation. The inclusion criterion was adults aged 65 years and older. Participants with self-reported or medically documented cancer, Parkinson disease, or vascular events were excluded, as were older individuals unable to walk or speak [9]. The calculation of the sample size (aged ≥65 years old, both men and women) considered a prevalence of frailty in older adults of 24.6% [9], with a 95% CI, statistical power of 80%, and a loss percentage of 20%. The proportions of women and men in the sample were determined by the relative distribution of the adult population over 65 years using data from the National Socioeconomic Characterization Survey [24]. No additional stratification was applied.

Frailty Diagnosis

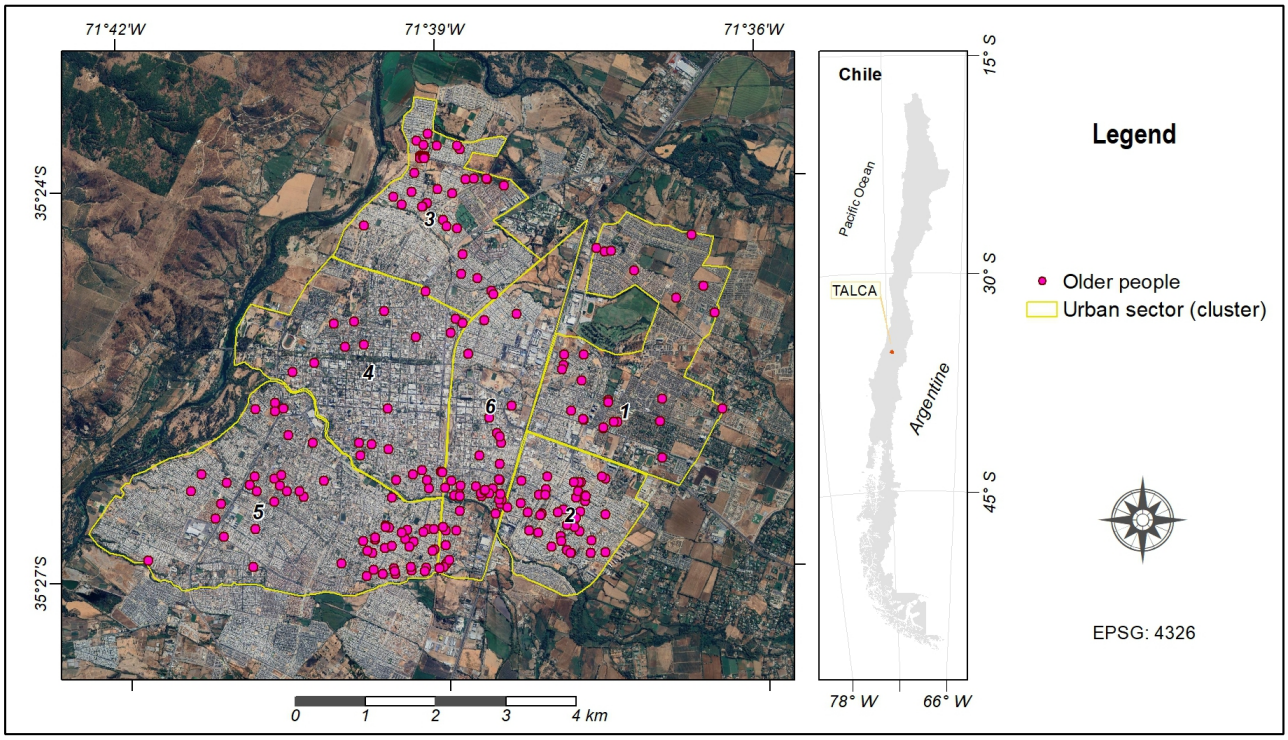
The Fried frailty phenotype criteria were used as the diagnostic tool for assessing frailty [9,25]. This method evaluates the presence or absence of the following components: slowness, weakness, weight loss, exhaustion, and low physical activity. These parameters were defined based on the criteria described previously by Palomo et al [9], which include: (1) slowness: walking velocity below a cut-off of 0.8 m/s average 3-meter walk at a usual pace, adjusted for sex and height according to the standards of the Short Physical Performance Battery, (2) weakness: handgrip strength measured using an Electronic Handgrip Dynamometer (Camry), with sex-specific cut-off (male <27 kg, female <15 kg), (3) weight loss: defined as loss of at least 5 kg in the previous 6 months, (4) exhaustion: a positive response to any of the following two questions from the Center for Epidemiological Studies Depression Scale: “I felt that anything I did was a big effort” and “I felt that I could not keep on doing things” at least 3 to 4 days a week,” (5) low physical activity: difficulty walking, assessed by the questions “Do you have difficulty walking a block?” or "Do you have difficulty climbing several flights of stairs without resting? Participants meeting 3 or more of these components were categorized as frail, those with no 1 or 2 components were considered prefrail, and individuals lacking all components were classified as non-frail or robust [9].

Geospatial Clusters

Each participant was geographically located according to the city address informed and represented as a point object based on the residence information provided during the medical evaluation. All data were organized into a point feature layer accompanied by its corresponding thematic table. This layer was integrated into a geodatabase for subsequent analysis within its geographical context, along with pertinent factors related to the urban physical environment. Figure 1 displays the individual residency positions of each older adult participating in the study within their respective geographical cluster. These geographical

areas were delimited in the city of Talca, Maule Region, Chile, based on geospatial location and sociodemographic characteristics. Cluster 1 corresponds to the northeastern sector characterized by high socioeconomic status. Cluster 2 encompasses the southeastern sector with low socioeconomic status. Cluster 3 covers the northern sector with a lower-middle socioeconomic class, and Cluster 4 represents the "historic center" area. The southern sector of medium-high socioeconomic level is covered by Cluster 5, and Cluster 6 corresponds to the "industrial center" area.

Figure 1. Location of older individuals within the 6 urban sectors.



Urban Quality Level

A georeferenced database was constructed using Geographic Information Systems (GIS) technology to represent pertinent geographical information concerning urban physical facilities within the city, encompassing: (1) vegetables and fruits shops, (2) senior centers or communities, (3) pharmacies, (4) emergency health centers, (5) main squares and parks, (6) family or community health centers, and (7) stadiums and sports fields. Each component within the study area was depicted as a GIS layer, either in point or polygon form, at the neighborhood scale. This representation (Figure 2) was derived from data sourced from OpenStreetMap [26], Google Maps [27] and Infraestructura de Datos Geospaciales de Chile (IDE Chile) [28]. Subsequently, each GIS layer underwent analysis using the Euclidean distance method, providing insights into the proximity of every location within the city to the considered infrastructure. The resulting distance layers were subsequently classified to delineate 3 distinct zones encircling the urban facilities, categorizing their proximity as either close, medium, or distant. Next, each proximity class for every layer was assessed on a scale ranging from 1 to 3, wherein the closest proximity received a score of 3, and the more distant areas were assigned a score of 1. The distance ranges, and the corresponding values assigned to each urban facility were defined according to local context and are presented in Table 1. A general criterion for evaluation was that the closer the facility, the higher the value assigned. A raster calculator was used to aggregate all layers, yielding a summary index where a higher numerical value signifies enhanced urban quality in the depicted area. Afterward, the values derived from the distance analyses and the corresponding summary index for each participant were integrated into the point feature layer. Management, processing, and analyzing data were performed using ArcGIS software, version 10 (ESRI, Redlands, USA).

Figure 2. Geographical distribution of urban physical facilities within Talca City.

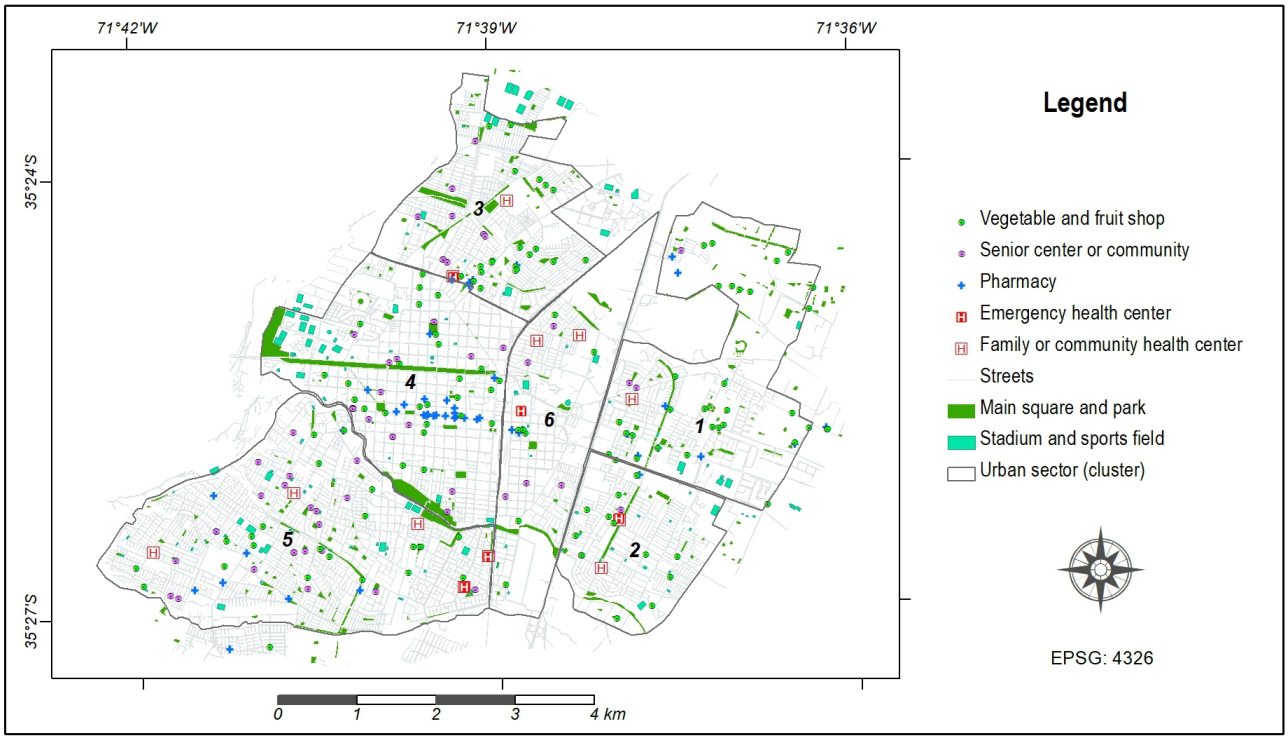


Table . Distance ranges and values for each urban physical facility.

Facility and distance ranges	Value
Vegetables and fruit shops (m)

Statistical Analysis

Statistical analyses were conducted using GraphPad Prism 9. Continuous variables were expressed as mean (SD) or median (95% CI). Categorical variables were expressed as percentages with a 95% CI. In the evaluation of differences between groups, the chi-square test with Yate correction was used to assess proportions, while ANOVA or the Kruskall-Wallis test, as appropriate, was applied to assess differences in means or medians. Statistical significance was considered at *P* values below .05.

Ethical Considerations

The institutional board review approval for this study was obtained from the Comité de Ética Científica (CEC) of Universidad de Talca (reference number 06 - 2021). All procedures followed adhered to the ethical standards of the CEC and the World Medical Association's Declaration of Helsinki. All study participants provided written informed consent.

Results

Sociodemographic Characteristics and Cluster Distribution

Table 2 presents the sociodemographic characteristics of the analyzed cohort of older people. The sample comprised 74.5% women and 25.2% men, with no significant differences observed in age and BMI between the 2 genders. In addition, Table 2 illustrates the distribution of the geospatial clusters established during the study. Analysis indicated no significant difference in the distribution of the 6 designated clusters between men and women.

Table . Sociodemographic description and geospatial distribution of the studied sample of older people.

Variable	Women (n=187)	Men (n=64)	*P* value
Gender, % (95% CI)	74.5 (68.7-79.4)	25.5 (20.5-31.2)	—[a]
Age (years), mean (SD)	73.8 (5.9)	75 (5)	.152
BMI (kg/m^2), mean (SD)	33.6 (33.5)	28.4 (6.5)	.243
Spatial cluster showing percentage of prevalence, % (95% CI)			
Cluster 1	10.2 (6.6-15.3)	15.6 (8.7-26.4)	.260
Cluster 2	18.7 (13.7-24.9)	14.1 (7.6-24.6)	.452
Cluster 3	16.6 (11.9-22.5)	25 (16-36.8)	.142
Cluster 4	11.2 (7.5-16.6)	9.4 (4.4-18.9)	.817
Cluster 5	26.2 (20.4-32.9)	17.2 (9.8-28.2)	.176
Cluster 6	17.1 (12.4-23.2)	18.8 (11.1-29.9)	.845

[a] —: not applicable.

Analysis of Urban Quality

Figure 3 shows the different levels of urban quality [3] obtained from the cumulative assessment of physical environmental elements considered in this study. These elements mainly encompass basic urban services and infrastructures essential for the local population, with particular importance for the cohort of older people under study. The quality level is closely related to the accessibility of the various facilities from each location within the city. In addition, Figure 3 also shows the individual distribution of older adults, each denoted by their frailty status, which is subsequently analyzed in Table 3. This table displays the distribution of the frailty status through the different geospatial clusters. The prevalence of frailty varies between 7.3% and 34.1% among these clusters. Notably, cluster 3 exhibits a significantly high prevalence of frail people (34.1%, *P*=.006), followed by cluster 5 (21.9%, *P*=.417); however, this last prevalence is not significantly high.

Figure 3. Frailty status of older individuals over summary index within the geospatial clusters defined for Talca city.

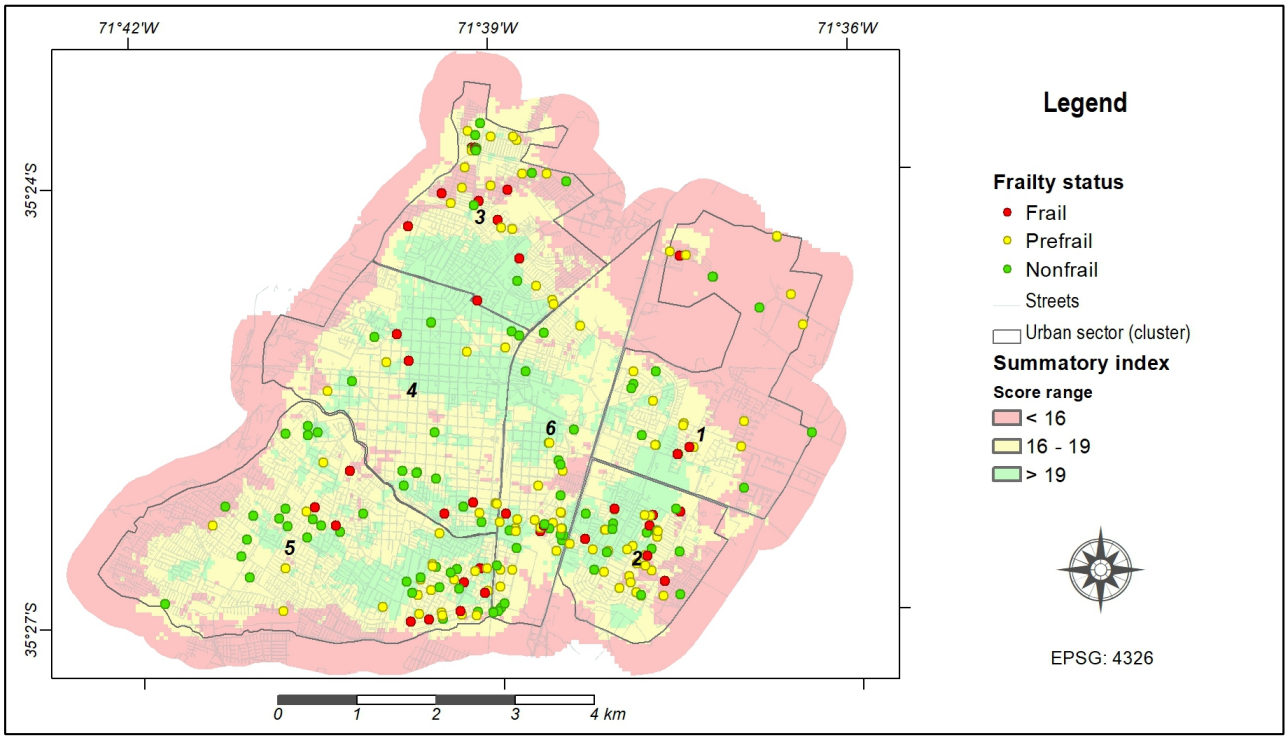

Table . Distribution of older people by frailty status and geospatial clustering.

Spatial cluster	Frailty status considering the percentage of prevalence			*P* value
	Nonfrail (%, 95% CI)	Prefrail (%, 95% CI)	Frail (%, 95% CI)	
Cluster 1	14.3 (8.5 - 22.9)	11.7 (6.9 - 19)	7.3 (2.5 - 19.4)	.620
Cluster 2	14.3 (8.5 - 22.9)	21.6 (14.9 - 30.2)	17.7 (8.5 - 31.3)	.270
Cluster 3	12.1 (6.8 - 20.4)	19.8 (13.5 - 28.2)	34.1 (21.5 - 49.5)	.006
Cluster 4	14.3 (8.5 - 22.9)	8.1 (4.3 - 14.6)	12.2 (5.3 - 25.5)	.477
Cluster 5	30.7 (22.2 - 40.9)	20.7 (14.2 - 29.2)	21.9 (12 - 36.7)	.417
Cluster 6	14.3 (8.5 - 22.9)	18 (11.9 - 26.2)	7.3 (2.5 - 19.4)	.225
Total	100	100	100	—[a]

[a] —: not applicable.

Analysis of Distances to Urban Facilities, Summary Index, and Population Density

Figure 4 illustrates the variation in average distance between old persons (categorized by their frailty status) and relevant urban facilities. For the facilities of vegetable and fruit shops (A), senior centers or communities (B), pharmacies (C), and family and community health centers (F), there were no significant differences in the average distance across different frailty status groups. However, a clear linear trend is observed between the groups, where frail people tend to reside further from vegetable and fruit shops (frail: 335.6 [SE 31.2] vs nonfrail: 275.9 [SE 16.5]) and closer to the senior centers or communities (frail: 368.2 [SE 38.6] vs nonfrail: 435.9 [SE 35.9]) than the nonfrail people. On the other hand, the facilities of emergency health centers (D), main squares and parks (E), and stadiums and sports fields (G) present significant differences in the average distance across different frailty status groups, where frail people resided significantly closer to emergency health centers (frail: 960.4 [SE 90.4] vs nonfrail: 1352 [SE 93.6], *P*=.04), main squares and parks (frail: 155 [SE 13] vs prefrail: 204.8 [SE 10.5], *P*=.03), and stadiums and sports fields (frail: 304 [SE 23.6] vs prefrail: 445.7 [SE 32.2], *P*=.04), than both nonfrail and prefrail people, respectively. Finally, Figure 5 shows the variations in the summary index and population density between the frailty status groups. While the summary index (A) shows no significant differences between groups, there is a significant difference in population density (B) between the frail and nonfrail status groups, being higher for frail people (frail: 0.013 [SE 0.001] vs nonfrail: 0.01 [SE 0.0007], *P*=.03).

Figure 4. Comparison of the mean distance for different frailty status diagnosed using the Fried phenotype criteria with respect to relevant urban facilities of (A) vegetables and fruits shops; (B) senior centers or communities; (C) pharmacies; (D) emergency health centers; (E) main squares and parks; (F) family or community health centers; (G) stadiums and sports fields. The data presented are the mean (SE). Statistical analysis was performed using the ANOVA test with the Tukey pos-hoc test. *P<.05.

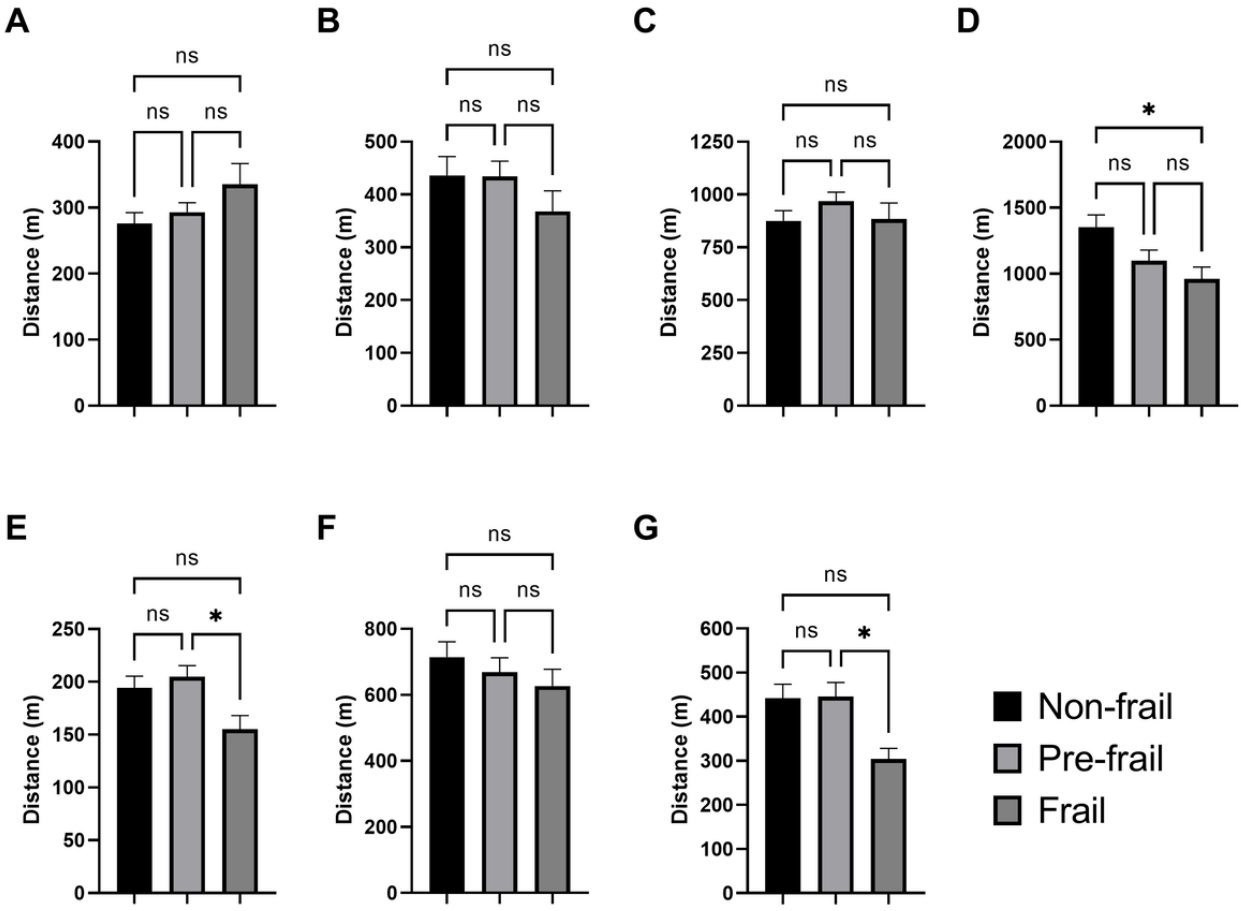

Figure 5. Comparison of mean values for different frailty status diagnosed according to the Fried phenotype criteria for the (A) summary index, (B) population density. The data presented are mean (SE). Statistical analysis was performed using the ANOVA test with the Tukey post-hoc test. *P<.05.

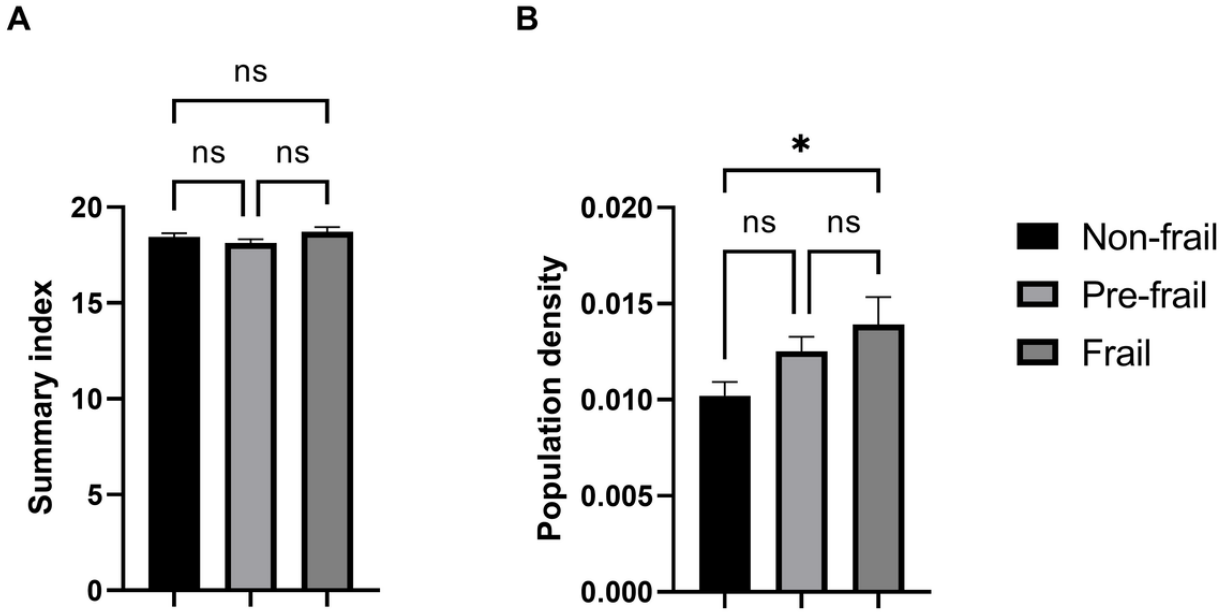

Discussion

Principal Findings

This study explores the relationship between urban physical environment factors and frailty syndrome, with a particular focus on its diagnostic criteria. The results mentioned above indicate that frail individuals tend to live closer to emergency health centers, stadiums, sports fields, and senior centers, suggesting efforts to improve their health and social engagement. In addition, frail individuals primarily reside in densely populated areas, which are associated with limited physical activity and higher mortality rates. Given the relevance of the Fried frailty phenotype as a standard frailty assessment tool in various studies involving older adults, it was selected for frailty characterization [11,29,30]. Investigating the link between frailty and urban environment is innovative and can provide invaluable insights for government programs aimed at enhancing the well-being of older people [31,32]. However, this emerging topic remains underdeveloped, limiting opportunities for comparisons specific to frailty. The incorporation of geomatics tools enables the use of geolocation as an additional analytical dimension, offering valuable insights into the study of frailty as a syndrome. This is especially important when the primary focus is on understanding the impact of the urban physical environment on the frail condition of older individuals [16,17]. Currently, the use of information and communication technologies among older persons is increasing, and different benefits have been developed about frailty with respect to predicting the risk, assisting in identifying changes in frailty parameters, enhancing adherence to a healthy diet, and distinguishing older rehabilitation patients who need to be readmitted to the hospital from those who can remain in the community which could facilitate this key process [33-37].

The data from Table 2 indicate homogeneity within the cohort, with no significant influences in the study parameters when stratified by gender. Participants had an average age range of 73 - 75 years old and exhibited a high BMI. This trend of elevated BMI is consistent with findings from other studies focused on older Chilean people, wherein a significant prevalence of obesity (BMI >25 kg/m^2) has been documented [8,9,38]. Gender did not appear to influence the distribution prevalence within the identified clusters. However, it is necessary to account for gender in geospatial clustering analyses involving older people, given its potential impact on various health outcomes, as recently evidenced in COVID-19 studies [39].

The findings presented in Table 3 suggest that geospatial distribution significantly impacts the prevalence of frailty syndrome. Notably, clusters 3 and 5, which are associated with middle to low socioeconomic classes, concentrate more than half of the frail people. This evidence is consistent with studies where low socioeconomic groups have been associated with a higher risk of developing frailty [31]. Furthermore, previous research indicates that frailty condition among older people tends to exhibit spatial clustering, wherein certain areas within and outside the city display localized concentrations of both high and low prevalence of frail people [16,40]. These clustering patterns can be attributed to the diverse urban infrastructures and socioeconomic disparities observed across different sectors within the city [16].

In this study, the outcomes depicted in Figure 3 reveal a geospatial clustering concentrated in the southern part of the city, primarily associated with clusters 3 and 5. However, when considering the general condition of the urban physical environment, characterized by the summary index, the group of frail people does not show significant differences compared with the other groups (Figure 5A). This fact suggests that, despite various groups of adults residing in environments characterized by comparable habitability conditions, distinctions in certain factors, as evidenced in Figure 4, can exert relevant positive or negative influences. Thus, the urban physical environment is likely connected with concurrent factors associated with the frailty syndrome, serving either as causal factors or as responses to such influences.

Frailty is acknowledged as a critical factor influencing the health and well-being of older people [11-18]. It stands out as the primary risk factor and indicator for the initiation of dependency, as well as the occurrence of chronic diseases, hospitalizations, falls, fractures, and mortality. The extensive array of health-related challenges observed in frail people may be associated with their proximity to emergency health centers, as well as family or community health centers [15-20]. Likewise, frailty has exhibited strong associations with obesity, sarcopenia, and low physical activity. Consequently, the proximity identified between the frail group and stadiums and sports fields may suggest a purposeful endeavor to improve body composition and address underlying clinical conditions [41,42].

Simultaneously, the frail group exhibited greater proximity to main squares and parks and to senior centers or communities renowned for fostering social activities among older people [43]. Given the well-established associations between frailty and social isolation, depression, and loneliness [44], the observed significant trend might signify a proactive response to enhance community engagement. This trend could also be indicative of the city government's concerted efforts to provide these facilities to a population in need. By strategically situating frail individuals near these spaces, urban planners and policymakers may be aiming to reduce the adverse effects of isolation and encourage greater social participation. Engaging in recreational activities and interacting with peers in accessible public spaces can help mitigate the mental health challenges often faced by frail older adults. Furthermore, these spaces serve as venues for both physical and mental stimulation, which are critical to maintaining functional independence and improving overall well-being.

Conversely, the robust association between frailty and obesity might elucidate the trend observed trend of increased distance from the frail group to fruit and vegetable shops. Nevertheless, validation of this hypothesis necessitates examination within a more extensive cohort. While elevated intake of fruits and vegetables has been linked to a diminished frailty risk, the impact of the proximity of these food supply points on frailty remains ambiguous [45]. Furthermore, greater distances to pharmacies may indicate challenges in accessing essential drugs

and medications, a factor that should be taken into account in health programs tailored to support the frailty group.

The findings depicted in Figure 5B indicate that the frail group tends to inhabit regions characterized by elevated population density. Older adults tend to live in densely populated marginalized areas due to economic, social, and structural factors. Financial limitations, the lack of adequate housing options, access to family support networks, and mobility barriers are some of the key factors influencing their stay in these areas. This circumstance poses an increased risk to this group, as current scientific understanding suggests a positive correlation between population density in a given neighborhood and increased susceptibility of middle-aged and older adults to overweight conditions [46]. This association can be ascribed to the proclivity of individuals residing in densely populated areas to adopt a sedentary lifestyle, marked by limited physical activity and diminished energy expenditure [20,46]. Notably, low physical activity and sedentarism are integral components of the frailty phenotype observed across diverse cohorts of older adults [11,12,26]. Furthermore, elevated population density has been lined to increased mortality rates across all causes in older people [11,12,47,48].

Initiatives aimed at preventing frailty underscore the imperative to advocate for physical activity, nutrition, and social engagement as primary and efficacious interventions. These interventions can be effectively implemented through a health education program tailored to inspire and engage older people [49,50]. Our findings underscore the importance of taking urban factors into account when examining the frailty condition of older people. This evidence aligns with previous research emphasizing the importance of these factors in the well-being and social engagement of older adults, as well as their association with frailty [16,51]. These results emphasize the imperative to investigate further and enhance our comprehension of the role played by urban factors in shaping frailty among older people. Regardless, it is imperative to consider the complex interrelationship between the urban physical environment and frailty condition when devising structural preventive measures aimed at improving the well-being of older people [16,47].

Conclusions

Contemporary evidence underscores the relevance of urban factors in influencing the onset of frailty and the diverse health factors linked to this syndrome. Frailty stands as a highly prevalent geriatric syndrome in the elderly, elevating the susceptibility to a range of adverse health and social outcomes. Addressing this challenge necessitates the development of age-friendly cities tailored to the needs of older populations. Our findings suggest that individuals classified as frail tend to reside in closer proximity to emergency health centers, as well as family or community health centers, which may be indicative of adaptive responses to the features associated with frailty, such as elevated mortality risk and diminished levels of physical activity. Likewise, frail people tend to reside closer to stadiums and sports fields, which may imply a deliberate endeavor to enhance body composition and address underlying clinical conditions. On its part, the closer proximity of frail people to urban infrastructures such as main squares and parks, and senior centers or communities may be indicative of the concerted effort by the municipal government to provide these facilities to a population in need. However, it is important to highlight that the frail group predominantly inhabits areas characterized by elevated population density, aligning with earlier research associating higher mortality rates with increased population density among older adults. Likewise, the geospatial clustering highlights the relevance of both socioeconomic status and geographic location in relation to frailty prevalence, unveiling an elevated occurrence of this syndrome in sectors characterized by a lower-middle socioeconomic class. This finding aligns with and reinforces previously established evidence. Ultimately, the existing body of evidence, coupled with our study findings, underscores the significance of investigating frailty and its associations with the urban environment and related factors. This emerging field of research holds groundbreaking potential, offering substantial implications for geriatric medicine. Furthermore, it provides invaluable insights that can inform the development of governmental initiatives aimed at promoting healthy aging and proactively preventing frailty.

Abstract

Background: Hospital discharge for older adult patients carries risks. Effective patient-provider communication is crucial for postacute care. Technology-based communication tools are promising in improving patient experience and outcomes. However, there is limited evidence comparing patient and provider user experiences on a large-scale basis, hindering the exploration of true patient-provider shared understanding.

Objective: This study aimed to evaluate an electronic health record–based discharge communication tool by examining and comparing patient and provider perspectives.

Methods: This study comprised a cross-sectional self-administered staff survey and a pre-post cross-sectional patient survey. Physicians, nurses, and older adult patients aged 65 years and older discharged from 4 public hospitals were included. Patient-provider comparison items focused on 3 aspects of the design quality of the tool (information clarity, adequacy, and usefulness) and overall satisfaction with the tool. In addition, patients' experience of discharge information and their medication-taking behaviors before and after the program implementation were compared based on a validated local patient experience survey instrument. Providers' perceived usefulness of this tool to their work and implementation intentions were measured based on the technology acceptance model to enhance understanding of their experiences by conducting structural equation modeling analysis.

Results: A total of 1375 and 2353 valid responses were received from providers and patients, respectively. Patients' overall satisfaction with this communication tool is significantly higher than providers', and patients rated the information clarity and usefulness presented by this tool higher as well (P<.001). However, patients rated information adequacy significantly lower than providers (P<.001). Meanwhile, patients reported a significant improvement in their experience of discharge medication information, and fewer patients reported side effects encounters after the program implementation (126/1083, 11.6% vs 111/1235, 9%; P=.04). However, providers showed inconsistent implementation fidelity. Providers' perceived quality of the tool design (β coefficient=0.24, 95% CI 0.08-0.40) and perceived usefulness to their work (β coefficient=0.57, 95% CI 0.43-0.71) significantly impacted their satisfaction. Satisfaction can significantly impact implementation intentions (β coefficient=0.40, 95% CI 0.17-0.64), which further impacts implementation behaviors (β coefficient=0.16, 95% CI 0.10-0.23).

Conclusions: A notable disparity exists between patients and health care providers. This may hinder the achievement of the tool's benefits. Future research should aim for a comprehensive overview of implementation barriers and corresponding strategies to enhance staff performance and facilitate patient-provider shared understanding.

Introduction

At hospital discharge, health care providers play a crucial role in delivering comprehensive medication information, including side effects and warnings, to ensure safe medication therapy during patients' postacute care [1]. However, previous literature has reported that older adult patients often lack awareness or understanding of their medication regimen after being discharged home [2-4]. Insufficient knowledge is associated with their suboptimal adherence to treatment [5,6], an elevated likelihood of adverse events [7], increased readmissions and emergency department visits [8], and burden on the health care system [9].

A wide array of communication strategies has been documented in the literature with the aim of facilitating information provision by health care providers and enhancing patient awareness and understanding of health-related information [10]. Their effectiveness in reducing readmissions and enhancing patient satisfaction was supported by a recent meta-analysis [1]. Notably, information technology–based communication practices have emerged as a prominent and preferred mode for delivering discharge information, as highlighted in literature reviews [11]. In addition, a systematic review concluded that computer-enabled discharge communication interventions improve both patient and provider satisfaction and reduce perceived adverse events [12]. A Cochrane review further indicated that computer-generated reminders presented on paper can enhance the quality of care [13]. However, there is a scarcity of research comparing the perspectives of older adult patients and health care providers with concordance measures for a large-scale technology-based discharge communication tool. Measuring and comparing the alignment between patient and provider perspectives enables the unveiling of true shared understanding in terms of discharge education [14].

In Hong Kong, the provision of discharge medication information, particularly regarding side effects and warnings, was found to be suboptimal, according to a regular patient experience survey [15]. In 2017, the Hospital Authority developed a computer-generated written medication reminder called the postdischarge information summary (PDIS) to address this issue [16]. The key components of the PDIS were co-designed by a multidisciplinary program team consisting of government officials, clinicians, quality and safety representatives, and technology experts. The first component includes a salient medication reminder, a computer-based drug database encompassing 58 prescribed medications for local older adult patients, and 235 most pertinent side effects and warning items. This database underwent validation through 3 rounds of Delphi expert consensus meetings [17]. The second component comprises a list of follow-up appointments across all Hong Kong public hospitals. The PDIS system generates personalized information by integrating into the electronic health record (EHR). During discharge, physicians or nurses are required to print the written summary through the PDIS system and distribute it to discharged patients or their caregivers, along with a detailed explanation of its contents. No teach-back was required at the moment of program introduction. A comparison of the discharge communication workflow between usual practice and PDIS-incorporated practice is shown in Multimedia Appendix 1.

The objective of this study is to evaluate this EHR-based discharge communication tool by examining and contrasting the perspectives of both older adult patients and health care providers.

Methods

Study Design

This study comprises a self-administered cross-sectional staff survey and a pre-post cross-sectional patient survey. The pre-post patient surveys were conducted among 2 different patient groups. The STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guideline [18] was used to strengthen the reporting process (Checklist 1).

Setting and Sampling

The study involved 4 piloting public tertiary hospitals representing 3 out of 7 geographical clusters of Hong Kong. The PDIS was introduced in a phased manner within the geriatric and medicine department in January 2018 [16]. For the staff survey, all physicians and nurses involved in the PDIS implementation were invited to participate in the study. The surveys were conducted at least 6 months after the PDIS implementation, which spanned from August 2018 to June 2019. Paper-based promotion leaflets, invitation letters, and questionnaires were distributed through designated coordinators in each hospital. This survey was conducted anonymously and on a voluntary basis.

For the patient survey, the sample size was determined based on the inpatient discharge statistics for patients aged 65 years or older in 2015, as provided by the Hospital Authority. In order to achieve a precision level of ±4% with a 95% CI, a minimum of 1450 respondents was required for pre-post rounds. Assuming a 50% response rate, at least 2900 patients were randomly selected from the discharge records for each round. Responses from caregivers acting as surrogates were accepted if patients were unable to respond independently. Readmitted cases and day patients were excluded. Within 14 days of their discharge, patients were contacted by telephone. The pre-post survey was conducted from June to December 2017 and May to December 2018, accordingly.

The staff survey used English and the patient version used Chinese. We used English in staff survey because English is their working language and they are proficient in English. Furthermore, staff surveys are typically conducted in English in Hong Kong, so it was assumed that participants would feel comfortable with this language. To ensure language did not pose a barrier to participation or affect the responses collected, we decided to use Chinese for the patient survey. We do not anticipate any language concordance issues because the researchers who were responsible for collecting patient responses were well-trained before the survey to ensure they can correctly convey the meaning of the questions.

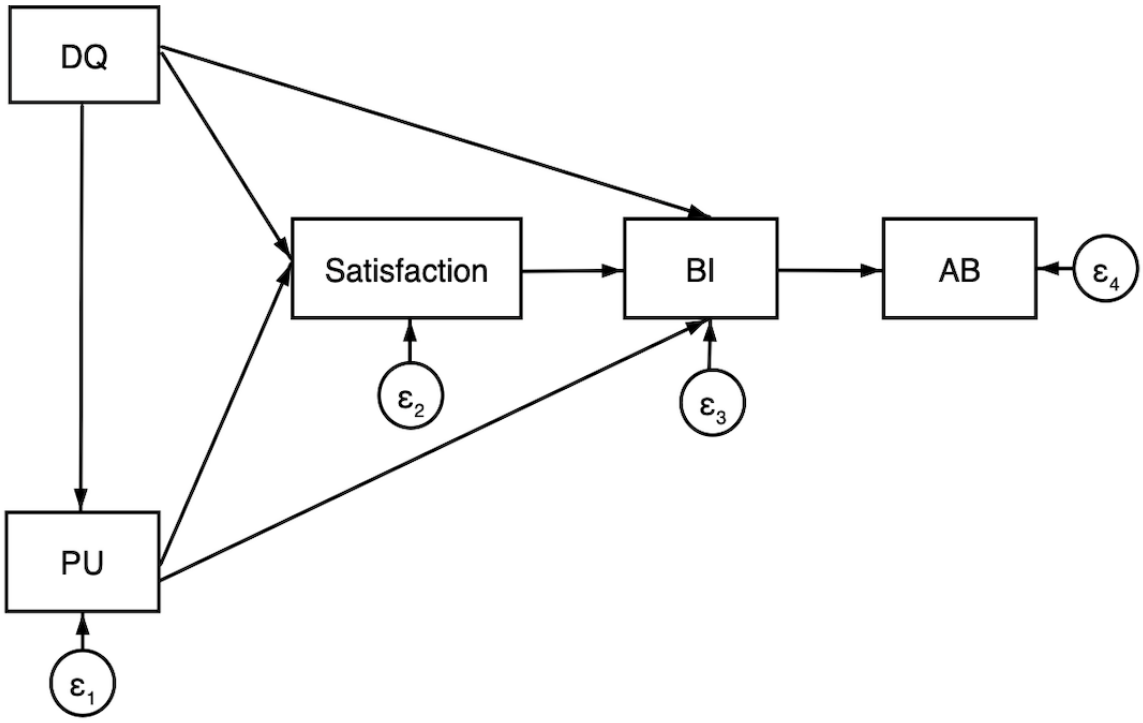
Theoretical Framework

The staff survey collected information on providers' practicing behaviors and user experience, adapted by the technology acceptance model (TAM) [19]. TAM has been designed to investigate why individuals adopt a specific technology and has been widely used in different settings [20].

According to the TAM, the perceived usefulness of the technology can impact users' behavior intention, which can be a determinant of users' actual behaviors. We added another domain named design quality to capture providers' perceived information quality of the tool. We also measured the overall satisfaction of the PDIS experience. Existing literature suggests that design quality can significantly influence staff adoption and implementation of the technologies [21]. The traditional TAM component of "Perceived Ease of Use" was not fully applicable in this context, as our primary aim was to compare the perceptions of patients and staff regarding their user experiences and perceptions of the PDIS. However, "Perceived Ease of Use" tends to be more relevant to staff, given that staff interact with the information system while patients interact with a paper-based version rather than a technology. Consequently, we adopted "Design Quality" as a domain to facilitate a meaningful comparison of perspectives between these 2 groups. In addition, we sought to streamline our survey to enhance response rates, particularly among staff who may have limited time to participate. Thus, we decided to use design quality as a domain in place of perceived ease of use.

We hypothesized that (1) design quality would have an impact on perceived usefulness, satisfaction, and behavior intention; (2) perceived usefulness would impact satisfaction and behavior intention; (3) satisfaction would impact behavior intention; and (4) behavior intention would impact actual behavior (Figure 1).

Figure 1. Conceptual framework of the factors impacting implementation fidelity. AB: actual behavior; BI: behavior intention; DQ: design quality; PU: perceived usefulness; "ε1", "ε2", "ε3", and "ε4" were the residual errors.



Measurements

The Staff Survey

Perceived Usefulness

In total, 4 items were used to measure perceived usefulness: (1) "PDIS supports my medication education," (2) "PDIS enhances my communication with patients or caregivers," (3) "PDIS enhances my job efficiency," and (4) "I find PDIS useful in my job." The Cronbach α for this domain was 0.97, indicating the good reliability. A Likert scale ranging from 0 ("strongly disagree") to 10 ("strongly agree") was used for these 4 items.

Design Quality

Design quality was measured using 3 items developed by the research team: (1) "The information provided by the PDIS is clear," (2) "The information provided by the PDIS is sufficient," and (3) "The information provided by the PDIS is useful to your patients or caregivers." The Cronbach α for this domain was 0.92, indicating good reliability. A 10-point Likert scale was used to measure these three items ranging from 0 ("strongly disagree") to 10 ("strongly agree").

Behavior Intention

One item, which was investigator team constructed, was adopted to measure behavior intention: "I am willing to use PDIS to deliver patient discharge information in the future." The 10-point

Likert scale was used (0: strongly disagree to 10: strongly agree) for this item.

Satisfaction

Satisfaction was measured using a single item: "How would you rate your experience of delivering patient discharge information using PDIS?" A 10-point Likert scale ranging from 0 ("very poor") to 10 ("very good") was used for this question.

Actual Behaviors

The actual behavior was defined as the implementation fidelity and measured by the frequency of distributing, reading, and explaining the PDIS to patients and caregivers with a 3-level ordinal scale (never, sometimes, and always). A composite score for actual behavior was created by converting the ordinal scale for each behavior into to a 0, 1, and 2 scale and summing it up across the 3 practicing behaviors (distribution, read, and explanation) to generate a total score.

Qualitative Comments

Free-text fields were provided to solicit provides' comments on their PDIS experiences. Respondents were prompted with the following question: "Is there anything you would like to tell us about the PDIS (eg, things that were particularly good, areas for improvement, or any other comments)?"

Demographic Information

Demographic information was collected in the final section of the survey. For example, we asked their self-reported gender, age, working experience in years, and professional role (eg, interns, residents, specialists, associate consultants, and consultants for physicians; enrolled nurses, registered nurses, advanced practice nurses, and ward managers for nurses).

The Patient Survey

The pre-post patient surveys consist of the following sections.

The Patient Experience

The items were drawn from the validated local assessment tool, the Short-form Hong Kong Inpatient Experience Questionnaire (SF-HKIEQ) [22], soliciting patient agreement on the clarity, adequacy, and usefulness of discharge medication information, including side effects and warnings, using an ordinal scale (yes, to some extent, or no) or Likert scale of 0 - 10 from strongly disagree to strongly agree; the Cronbach α is 0.87, indicating good reliability. The overall satisfaction of the PDIS experience was also solicited. A 0 - 10 Likert scale of strongly disagree/very bad to strongly agree/very good was applied to measure the items. In the patient survey, consistent with the previous analysis approach for the SF-HKIEQ, questions with an ordinal scale were converted to a 0, 5, and 10 scale and aggregated to calculate the mean and SD.

Self-Reported Medication-Taking Behavior

This section was developed based on the 4-item Morisky, Green, Levine (MGL) scale [23] and relevant studies [24]. Furthermore, 1 item was adopted from the MGL scale: "Ever forget to take medicines?" In addition, 2 items were investigator-constructed: "Whether you were compliant with their medication regimen" and "Whether you have ever experienced medication side effects." These 3 items were measured by binary responses (yes or no).

Design Quality

The patient postsurvey includes the same question of the design quality domain of the staff survey, allowing comparative analysis: (1) "The PDIS information is clear to me or patients," (2) "The PDIS information is enough to me or patients," and (3) "The PDIS information is useful to self-care or care for patients." A 10-point Likert scale was used (0: "strongly disagree" to 10: "strongly agree"). The Cronbach α was 0.94, indicating a high reliability.

Free-Text Field

A free-text section was added to solicit patients' comments on the PDIS experiences. Similarly with staff survey, we asked patients "what information do you need that was not provided by the PDIS, and any other comments?"

Patient Characteristics

Patient characteristics, such as their age, self-reported gender, education level (primary, secondary, college, and above), whether received the government subsidy, the comprehensive social security assistance designed for people whose income is not sufficient to meet basic needs), living arrangements (living alone or living with others), chronic conditions (including heart disease, hypertension, type 2 diabetes, and cancer), and self-reported quality of life using visual analog scale of the EQ-5D-5L Hong Kong [25], were also asked.

Data Analysis

The statistical analysis was performed utilizing R version 4.0.5 (R Project for Statistical Computing) and Stata version 18 for Mac (StataCorp). Provider and patient demographic information were summarized as means and percentages using descriptive statistical analysis. The staff survey and patient survey were analyzed separately. For the staff survey, subgroup analysis was conducted to evaluate the differences among physicians and nurses. The practicing behavior frequency and PDIS experiences were compared using the Pearson chi-square test and Mann-Whitney *U* test. The Mann-Whitney *U* test was used due to the outcome variables were skewed. In order to understand the relationship between the determinants of the behaviors like design quality, perceived usefulness, behavior intention, satisfaction of the PDIS, and the actual behavior, as well as the relationship between different determinants, the covariance-based structural equation modeling (CB-SEM) was applied. The goodness of fit index, comparative fit index (CFI), root mean square error approximation (RMSEA), Tucker-Lewis index (TLI), and standard root mean squared residual (SRMSR) were used to evaluate the goodness-of-fit of the model. The direct effects, indirect effects, and total effects between the core variables were assessed using a bootstrapping approach (n=2000). Standardized path coefficients (β) were used to estimate the path relationships. Statistical significance was set at P=.05.

For the patient survey, changes in patient experience regarding medication information before and after PDIS implementation were compared using the Mann-Whitney *U* test due to the

outcome variables were skewed. The difference between self-reported side effects encounters and compliance was assessed using the Pearson chi-square test.

To identify the disparity between staff and patient. the shared questions related to PDIS experience (eg, information clarity, adequacy, and usefulness, and the overall experience of the PDIS) in the staff and patient postsurveys were compared using the Mann-Whitney *U* test. For the qualitative comments from both staff and patient, thematic synthesis [26] was applied to identify and compare the common themes in free-text comments for the PDIS program between patients and providers. Furthermore, 2 coders independently coded all the utterances of patients and staffs to generate the initial codes to achieve consensus on coding. The disagreement were formally resolved through several discussions with a senior researcher experienced in qualitative study. After that, the inductive analysis was performed by one coder to generalize initial codes into overarching themes. The initial summary themes were developed and discussed with the senior research to reach consensus. The final list of themes was reviewed and consented by the research team. The theme list were identical for patient and staff and the frequency of each theme were counted in order to compare the pattern for patients and staffs.

Ethical Considerations

Ethical approval has been provided by the Joint Chinese University of Hong Kong – New Territories East Cluster Clinical Research Ethics Committee in compliance with the Declaration of Helsinki (CREC 2019.436). For the staff survey, implied consent was applied as participating staff members returned the completed questionnaires to the research team. For the patient survey, verbal consent was obtained from patients over the phone before the survey. All data were deidentified to protect participants' privacy and confidentiality.

Results

Comparative Analysis

A total of 1375 providers completed the survey with a 76% response rate, comprising 966 (72%) female participants, 650 (50%) participants aged 18 - 29 years old, 595 (50%) participants with 0 - 5 years of working experience, and 1216 (88%) nurses (Table 1).

From the patient side, we received 2353 valid responses, including 1109 (47%) and 1244 (53%) responses collected through the pre- and postsurveys, respectively. The response rate was 55.5% for the presurvey and 59.4% for the postsurvey. The demographic composition was similar between the pre- and postsurvey groups, except that 6.4% (presurvey group: 853/1106; postsurvey group: 1023/1226) more participants were receiving the government subsidy in the postsurvey group (P<.001) (Table 2).

The comparative evaluation showed that patients consistently provided significantly higher ratings for their overall PDIS satisfaction compared with providers (mean 8.28, SD 1.60 vs mean 6.29, SD 1.88, respectively; *P*<.001) (Figure 2). Specifically, patients reported higher ratings for information clarity (mean 8.58, SD 2.50 vs mean 6.54, SD 1.86, respectively; *P*<.001) and usefulness of the PDIS (mean 8.14, SD 2.46 vs mean 6.50, SD 2.02, respectively; *P*<.001). On the contrary, patients were inclined to receive more information through the PDIS (mean 5.33, SD 1.35 vs mean 6.14, SD 2.08, respectively; *P*<.001).

Figure 2. Comparison of patient and health care providers' postdischarge information summary experiences. *P* value was obtained from the Mann-Whitney *U* test. **P*<.001.

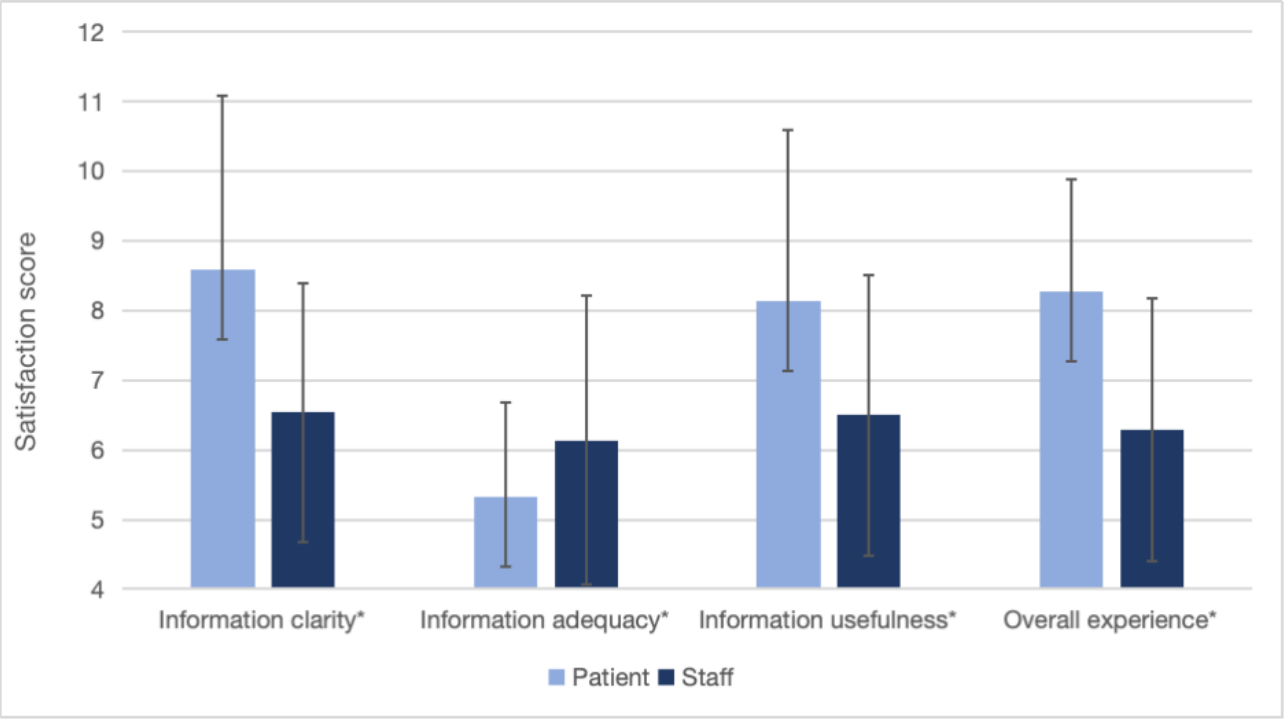

Figure 3 displays the similarities and differences between patients and providers regarding their comments on PDIS experiences. A total of 538 comments were received (421 were from providers and 117 were from patients). The most frequently commented aspect was PDIS features for both providers (147/421, 35%) and patients (73/117, 62%). However, the specific area of the feature was different. Providers emphasized the need for broader coverage of the drug databases (60/147, 41%) and the lack of multiple language versions (59/147, 40%), while patients' concerns revolve around the inconvenience of medication names and follow-up information being in English (45/73, 61%), the discomfort with medical jargon (9/73, 13%), and font size (7/73, 10%). In addition, providers frequently commented on the content of the PDIS form. For example, 27% (114/421) of the comments were related to the medication listed on the PDIS and emphasized the need for additional medication details such as medication changes, indications, and instructions.

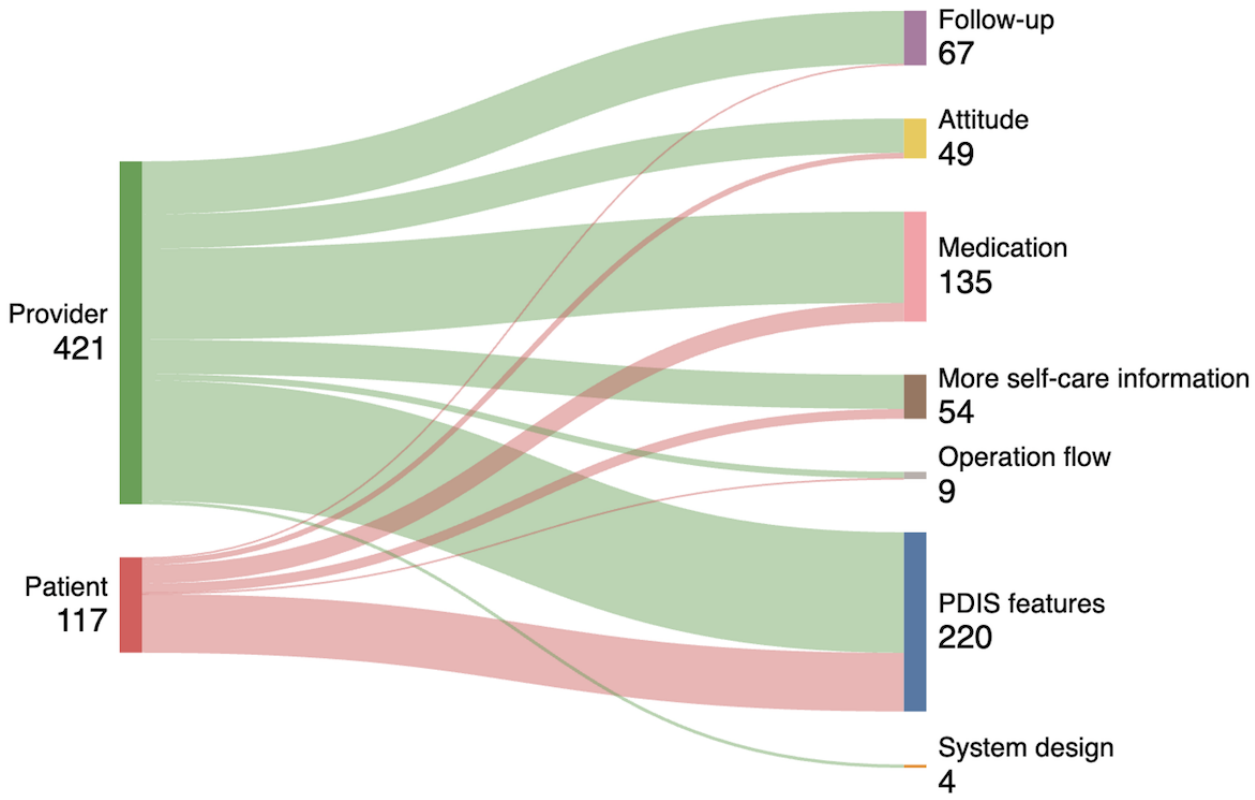
Figure 3. Comparison of the qualitative comments on the postdischarge information summary between patients and health care providers. PDIS: postdischarge information summary.



Staff Survey

Analysis of the practicing behaviors (Table 3) revealed that 72.1% (n=922) of the providers reported being able to consistently distribute the PDIS form to patients or caregivers, whereas 56% (n=667) stated they could consistently explain its content. Subgroup analysis demonstrated significant variations across different roles. Regarding distribution, 78% (n=915) of nurses reported always doing so, compared with 6.4% (n=7) of doctors (P<.001). Similarly, 57% (n=666) of nurses reported always explaining the content, compared with 4% (n=1) of doctors (P<.001).

Table . Health care providers' practicing behaviors and experience of the postdischarge information summary.

Items		Total (N=1375)	Doctors (n=159)	Nurses (n=1216)	*P* value[a]
PDIS[b] implementation behavior, n (%)					
Distribute		1234 (89.7)	109 (68.6)	1170 (96.2)	<.001
	Always	922 (72)	7 (6.4)	915 (78)

Perceptions of PDIS experiences, mean (SD)					
Perceived design quality					
	PDIS information is clear to your patients or careers	6.54 (1.86)	6.50 (1.61)	6.54 (1.86)	.67
	PDIS information is adequate to your patients or careers	6.14 (2.07)	6.24 (1.61)	6.14 (2.08)	.93
	PDIS information is useful for patients or careers	6.50 (2.02)	6.69 (1.81)	6.50 (2.02)	.70
Perceived usefulness					
	PDIS supports my medication education to patients or careers	6.35 (2.07)	6.08 (1.81)	6.36 (2.07)	.32
	Patient-provider communication becomes more effective with PDIS	6.21 (2.05)	6.00 (1.55)	6.21 (2.06)	.34
	PDIS enhances my job efficiency	5.97 (2.20)	6.08 (1.72)	5.97 (2.21)	.83
	PDIS is useful in my job	6.03 (2.16)	6.12 (1.68)	6.02 (2.17)	.97
Behavior intention					
	I am willing to use PDIS	6.09 (2.18)	6.12 (1.63)	6.09 (2.19)	.72
Overall satisfaction					
	Overall rating of PDIS user experiences	6.29 (1.88)	6.56 (1.51)	6.28 (1.88)	.75

[a]*P* value was obtained from the chi-square test and Mann-Whitney *U* test.

[b]PDIS: postdischarge information summary.

Physicians and nurses indicated moderate satisfaction with the design quality and perceived usefulness of the PDIS to their work, as reflected by mean agreement scores ranging between 5.96 and 6.54 (Table 3). The subgroup analysis did not identify

any differences between professional roles regarding user experiences. The CB-SEM analysis (Figure 4) showed that design quality significantly impacted their perceived usefulness (β coefficient=0.96, 95% CI 0.90-1.01) and behavior intention (β coefficient=0.14, 95% CI 0.06-0.21). In addition, perceived usefulness had a significant impact on behavior intention (β coefficient=0.48, 95% CI 0.26-0.70). Furthermore, behavior intention had a significant impact on the actual behavior (β coefficient=0.16, 95% CI 0.10-0.23). In addition, satisfaction can be significantly impacted by the design quality (β coefficient=0.24, 95% CI 0.08-0.40) and perceived usefulness (β coefficient=0.57, 95% CI 0.43-0.71). The structural equation modeling (SEM) model presents a good fit overall, with all indicators exceeding the recommended thresholds (Table 4). The results of the indirect effects and total effects can be found in Multimedia Appendices 2 and 3. In total, 3 mediating pathways were identified: (1) an indirect pathway from design quality through satisfaction to behavior intention (β coefficient=0.770, 95% CI 0.700 - 0.841, proportion mediated=15.1%); (2) an indirect pathway from perceived usefulness through satisfaction to behavior intention (β coefficient=0.228, 95% CI 0.185 - 0.272, proportion mediated=32.5%); and (3) an indirect pathway from design quality through perceived usefulness to satisfaction (β coefficient=0.544, 95% CI 0.482 - 0.605, proportion mediated=30.8%).

Figure 4. Structural equation modeling for factors impacting the providers' implementation fidelity. AB: actual behavior; BI: behavior intention; DQ: design quality; PU: perceived usefulness; "ε1", "ε2", "ε3", and "ε4" were the residual errors.

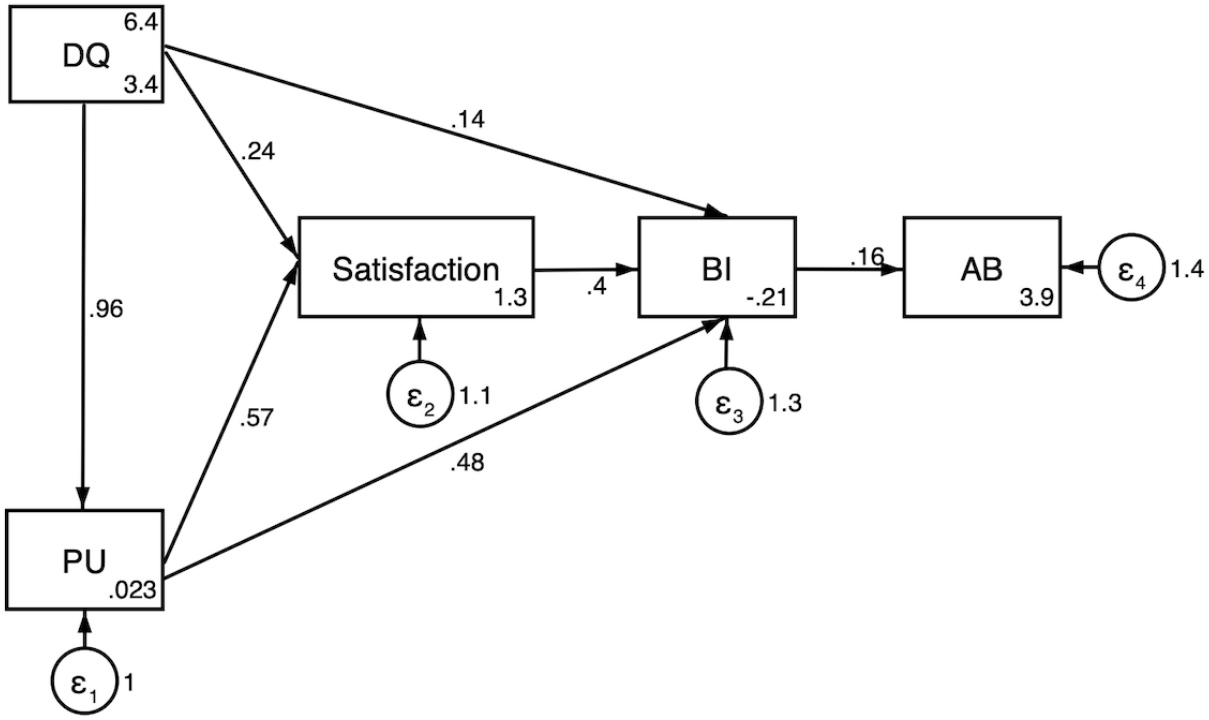

Table . Direct effects for the model[a].

Relationship	Standardized estimates (95% CI)	Remarks
Design quality → Perceived usefulness	0.955 (0.923-0.987)	Supported
Design quality → Satisfaction	0.242 (0.151 - 0.333)	Supported
Perceived usefulness → Satisfaction	0.569 (0.487-0.651)	Supported
Design quality → Behavior intention	0.137 (0.031-0.242)	Supported
Perceived usefulness → Behavior intention	0.476 (0.371-0.582)	Supported
Satisfaction → Behavior intention	0.402 (0.288-0.515)	Supported
Behavior intention → Actual behavior	0.164 (0.131-0.197)	Supported

[a]Model fit: χ_{441}^2=3088.344, *P*<.001; root mean square error approximation=0.052; comparative fit index=0.997; Tucker-Lewis index=0.990; standard root mean squared residual=0.021.

Patient Survey

Table 5 showed significant improvements in patient experience related to overall discharge information clarity (mean 8.18, SD 1.69 vs mean 7.93, SD 1.84, respectively; *P*=.002), adequacy (mean 8.15, SD 1.76 vs mean 7.92, SD 1.93, respectively; *P*=.01), and usefulness (mean 8.26, SD 1.70 vs mean 8.06, SD 1.80, respectively; *P*=.02). In addition, a significant increase was found in information adequacy for both side effects (mean 9.6, SD 2.0 vs mean 8.6, SD 3.4, respectively; *P*<.001) and warnings (mean 9.7, SD 1.8 vs mean 9.2, SD 2.7, respectively; *P*=.004). Only warning information reached statistically significant improvement in clarity (mean 8.77, SD 2.32 vs mean 8.45, SD 2.45, respectively; *P*=.03) and usefulness (mean 8.7, SD 2.45 vs mean 8.44, SD 2.39, respectively; *P*=.03).

Table . Older adult patients' or caregivers' perceptions of discharge medication information and medication-taking behavior between pre- and postsurvey groups.

Items		Total (N=2353)	Presurvey (n=1109)	Postsurvey (n=1244)	*P* value[a]
Perspectives of the discharge medication information					
Clarity, mean (SD)					
	Side effects	8.47 (2.50)	8.31 (2.63)	8.60 (2.39)	.10
	Warning signs	8.61 (2.39)	8.45 (2.45)	8.77 (2.32)	.03
	Overall	8.06 (1.77)	7.93 (1.84)	8.18 (1.69)	.003
Adequacy, mean (SD)					
	Side effects	9.2 (2.8)	8.6 (3.4)	9.6 (2.0)	<.001
	Warning signs	9.4 (2.3)	9.2 (2.7)	9.7 (1.8)	.004
	Overall	8.04 (1.85)	7.92 (1.93)	8.15 (1.76)	.02
Usefulness, mean (SD)					
	Side effects	8.47 (2.46)	8.34 (2.51)	8.57 (2.42)	.12
	Warning signs	8.57 (2.42)	8.44 (2.39)	8.70 (2.45)	.03
	Overall	8.17 (1.75)	8.06 (1.80)	8.26 (1.70)	.01
Medication-taking behaviors					
Self-reported side effects encounter, n (%)		2318 (86.1)	1083 (85.6)	1235 (86.6)	.04
	Yes	237 (10.2)	126 (11.6)	111 (9)	
	No	2081 (89.8)	957 (88.4)	1124 (91)	
Self-reported medication compliance, n (%)		2325 (86.4)	1085 (85.8)	1240 (87)	.39
	Yes	2226 (95.7)	1043 (96.1)	1183 (95.4)	
	No	99 (4.3)	42 (3.9)	57 (4.6)	

[a]*P* value was obtained from the Mann-Whitney *U* test and chi-square test.

No statistically significant difference was found between pre- and postsurvey groups in the percentage of self-reported medication compliance. Notably, the postsurvey group had a significantly lower percentage of self-reported side effects encounters (126/1083, 11.6% vs 111/1235, 9%, respectively; *P*=.04). Among participants who reported encountering side effects, the majority (96/111, 86.4%) still followed the medication instructions as prescribed.

Discussion

Principal Results

This is the first study to compare the perceptions of older adult patients and health care providers regarding the use of large-scale EHR-based discharge communication tools with concordance measures. There was a noticeable difference in ratings between patients and providers, with patients giving higher ratings in terms of design quality and overall experience of this tool. Qualitative comments indicated that patients and providers have different areas of concern regarding this communication tool. Furthermore, from the health care providers' side, inconsistent practicing behaviors were found, which were significantly influenced by the implementation intentions (represented as behavioral intentions in the SEM model), overall satisfaction, design quality, and perceived usefulness of the program. However, from the patients' side, older adults who received the written summary reported improved experiences with discharge information, including information clarity, adequacy, and usefulness.

Comparison With Previous Work

Providers assigned significantly lower scores to the perceived information clarity of the PDIS to their patients than patients themselves. This difference may be due to the providers' concern about the challenges associated with older adults' health literacy [27] and the potential negative consequences of sharing information on side effects, such as patients' anxiety and non-compliance [28-30]. However, the improved patient-reported ratings of information clarity on medication warnings and overall medication information, significantly fewer side effects encounters, and no evidence of patient noncompliance found by our study and others [31] suggested that taking action is no worse than inaction but yields better outcomes, contrary to the biased perception held by staff members [32]. In order to address staff concerns, facilitate their implementation, and fulfill patients' needs, rephrasing risk information by using lay language, shorter sentences, supplementing verbal descriptions with visual aids, and presenting medication benefits along with side effects can be considered [33-35].

Providers rated information usefulness for patients or caregivers lower than patients in this study, further impacting their implementation. The lower beliefs on the value of the communication tool for patient care from the provider side may be due to the beliefs that patients may not effectively follow the advice due to a lack of skills or inability to recall, despite clinicians appropriately delivering the instructions [36]. Therefore, it is suggested that using cognitive aid strategies such as teach-back techniques, repetition, demonstration, and reducing the complexity of the information to enhance patients' capacity to perform self-care tasks and recall of information [10]. The discrepancy can also be attributed to providers' lack of awareness regarding patient needs, which was also reported by previous studies [37]. Our study results, as well as other research [38], suggest that patients view information about medication side effects and warnings as crucial when making decisions about seeking professional assistance. Patient-provider information gap may not only lead to patient dissatisfaction but also levy stress on providers [37]. Therefore, it is important to leverage patient voices as credible sources and build long-term patient-provider relationships to address this gap.

It is important to note that older adults tend to rely more on health care providers and perceive them as trustworthy sources of information, as reflected in higher satisfaction with received medication information among older adults than younger individuals in a previous study [39]. Therefore, it is crucial to address provider-reported barriers in PDIS implementation to ensure a higher level of program satisfaction and implementation fidelity. Our study found that the design quality and perceived usefulness to providers' work can hinder their implementation, which is in accordance with previous studies [40,41]. This can be attributed to the low compatibility of the service with providers' existing workflow [21]. Our study found that providers expressed a preference for enriching the PDIS content with additional medication elements, such as medication changes, indications, and instructions, indicating their priorities for discharge education are not fully met. This suggested that involving frontline implementers as program designers and developers is crucial for program fit, staff self-efficacy, capacity, and commitment [21]. Other than the perceived usefulness and design quality of the program reported in our study, a comprehensive understanding of the complex elements involved in implementation, including context, stakeholders, and organizational factors, is needed [42]. This knowledge facilitates the creation of customized strategies and policies that have a higher likelihood of achieving success [43]. Therefore, conducting implementation research is essential in identifying the barriers and facilitators linked to the implementation of the PDIS to ensure providers' user experiences are optimized, leading to improved patient access to high-quality care and maintaining a high level of patient experiences among the older adult population.

Limitations

This study has several limitations. First, self-reported data may be subject to inaccuracies due to social desirability bias. However, including participants from diverse backgrounds may mitigate this limitation to some extent. Second, patient outcomes were not measured in this study, as our focus was on exploring and comparing patient and provider experiences with technology-based communication tools. Given the positive experiences reported by patients, future research could investigate clinical outcomes to further enhance the evidence base. Third, the pre-post survey design for a patient survey without a control group limits our ability to determine whether the observed changes are directly attributable to the PDIS. The cross-sectional design for the staff survey can limit our ability to establish causal inferences regarding factors influencing providers' inconsistent implementation. Subsequent studies using longitudinal or experimental designs are warranted to understand the causal mechanisms and develop effective strategies to enhance staff performance. Finally, as we did not impose a strict designation of specific professional roles (doctor or nurse) for the tasks involved in PDIS implementation, there may be an underestimation of the effects of the determinants on behavioral intention and actual behaviors.

Conclusions

EHR-based discharge communication tools have the potential to improve the patient experience with discharge information. However, there is a notable difference in user perceptions between patients and providers. This difference may hinder the full benefits of the program for patients. These findings have implications for future research, particularly in implementation research, where barriers and strategies to enhance staff performance can be investigated. In addition, the study provides valuable insights for organizations seeking to improve patient-provider shared understanding of postacute care plans among older adult patients during hospitalization, particularly through technology-based interventions.

Acknowledgments

We are grateful to the steering committee members for their professional advice regarding the implementation of the postdischarge information summary. We acknowledge the assistance of Ms Tang PF. We would also like to thank the HA Head Office and the cluster coordinators for their kind assistance in the logistics for conducting the study.

Authors' Contributions

ELYW, EKY, and KST were involved in the conception and design of the study. DYXW is the lead author and prepared the article. AWLC was involved in data collection. DYXW, ELYW, and AWLC were involved in data analysis. All the authors were involved in the critical revision and the final approval of the article.

Abstract

Background: Subjective cognitive concerns (SCCs) may be among the earliest clinical symptoms of dementia. There is growing interest in applying a mobile app–based cognitive assessment to remotely screen for cognitive status in preclinical dementia, but the relationship between SCC and relevant mobile assessment metrics is uncertain.

Objective: This study aimed to characterize the relationship between SCC and adherence, satisfaction, and performance on mobile app assessments in cognitively unimpaired older adults.

Methods: Participants (N=122; $Mean_{age}$=68.85 [SD 4.93] years; $Mean_{education}$=16.85 [SD 2.39] years; female: n=82, 66.7%; White:n=106, 86.2%) completed 8 assessment days using Mobile Monitoring of Cognitive Change (M2C2), an app-based testing platform, with brief daily sessions within morning, afternoon, and evening time windows (24 total testing sessions). M2C2 includes digital working memory, processing speed, and episodic memory tasks. Participants provided feedback about their satisfaction and motivation related to M2C2 upon study completion. SCC was assessed using the Cognitive Function Instrument. Regression analyses evaluated the association between SCC and adherence, satisfaction, and performance on M2C2, controlling for age, sex, depression, and loneliness. Linear-mixed effects models evaluated whether SCC predicted M2C2 subtest performance over the 8-day testing period, controlling for covariates.

Results: SCC was not associated with app satisfaction or protocol motivation, but it was significantly associated with lower rates of protocol adherence (ß=−.20, *P*=.37, 95% CI −.65 to −.02). Higher SCC endorsement significantly predicted worse overall episodic memory performance (ß=−.20, *P*=.02, 95% CI −.02 to −.01), but not working memory or processing speed. There was a main effect of SCC on working memory performance at day 1 (estimate=−1.05, SE=0.47, *P*=.03) and a significant interaction between SCC and working memory over the 8-day period (estimate=0.05, SE=0.02, *P*=.03), such that SCC was associated with initially worse, then progressively better working memory performance.

Conclusions: SCCs are associated with worse overall memory performance on mobile app assessments, patterns of cognitive inefficiency (variable working memory), and mildly diminished adherence across an 8-day assessment period. Findings suggest that mobile app assessments may be sensitive to subtle cognitive changes, with important implications for early detection and treatment for individuals at risk for dementia.

Introduction

Subjective cognitive decline (SCD) refers to self-perceived changes in cognitive functioning in the setting of normative performance on objective cognitive measures [1]. Older adults with SCD are more likely to demonstrate cognitive decline over time compared with their peers who do not endorse significant cognitive concerns [1-6]. This association has led many to posit that SCD may be one of the earliest clinical manifestations of Alzheimer disease and related dementias (ADRD) [1,3]. SCD has been linked with critical ADRD neural substrates and biomarkers, including structural [7-9] and functional [4,10] alterations, white matter dysfunction [11-13], and the presence of amyloid (Aβ) and tau [14-17]. However, it is important to acknowledge that most individuals notice changes in cognition as they age (up to 80% of people over the age of 70 years), and that many individuals with SCD do not ultimately progress to dementia [2]. As such, investigating novel markers within SCD may enhance early risk detection in this preclinical population.

Disentangling the relationship between SCD and performance on traditional neuropsychological measures is inherently complex. By definition, individuals with SCD perform in the normal range on objective cognitive tasks [3]. However, some studies have demonstrated that SCD is not without mild cognitive deficits. For example, there is evidence of mild reductions in processing speed, executive functioning, language, and memory in SCD [18-22], and such minor deficits have been correlated with concurrent Alzheimer disease (AD) biomarkers and future clinical progression [23]. There is presently a multitude of approaches in the field and widespread debate about how to best assess SCD, and measure selection may directly impact the association of SCD with concurrent cognition and risk for future cognitive decline [24-27]. It is also essential to recognize that SCD intrinsically reflects a longitudinal change over time [28]; however, traditional neuropsychological evaluations only capture a snapshot of in-the-moment cognitive status. Furthemore, for individuals with a high cognitive baseline, normative performance on objective testing may actually represent a decline in cognitive performance [1]. Novel and highly sensitive cognitive tools are needed to characterize more subtle deficits experienced by individuals with SCD [28].

There is growing interest in using smartphone-based, digital technology to remotely screen and track cognitive functioning in older adults at risk for dementia or those along the AD continuum. Smartphone usage among older Americans is highly prevalent (62% - 81% of people over the age of 60 use a smartphone) [29], and a number of smartphone-based cognitive assessment apps have been developed [30,31]. Such approaches are not only more accessible, convenient, time-effective, and scalable [31-33], but also may be more sensitive to subtle cognitive changes not captured by traditional paper and pencil cognitive assessments [31,32]. Smartphone-based cognitive assessments may also demonstrate superior ecological validity when completed in the individual's lived context with a familiar piece of technology [30,31,34]. Smartphone technology also facilitates high-frequency, repeated cognitive assessment, which allows for the quantification of subtle markers of decline in older adults, such as intraindividual variability and patterns in cognition over time [30-32,35,36]. However, the self-administered, unsupervised nature of smartphone-based cognitive assessments raises concerns related to task adherence, engagement, and potentially confounding factors that may occur within an uncontrolled environment [32].

Particularly relevant to aging research is the limited understanding of how subjective cognitive concerns (SCCs), the core feature of SCD, may be associated with engagement, satisfaction, and performance on such smartphone-based cognitive assessments. Preliminary evidence suggests that smartphone use may be associated with fewer SCCs in older adulthood and possibly constitute a protective factor against cognitive decline [37]; hence, smartphones may represent a promising tool for novel assessments and potential interventions for at-risk populations with self-perceived cognitive decline. Emerging literature suggests that smartphone-based cognitive testing generally has adequate adherence rates (>70%) [32], but little is understood about factors (such as SCC) which may impact engagement or motivation on unsupervised digital tests [38]. These are especially important relationships to disentangle, given the ubiquity of SCC in aging populations [2], high rates of smartphone usage [29], and growing interest in remote assessment to enhance accessibility to cognitive screening. In addition, the relationships between digital cognitive testing and AD biomarkers [39-41], as well as SCC and AD biomarkers [15,17,42], is supported by emerging research, but no studies to date have directly investigated the relationship between SCC, AD biomarkers, and digital smartphone cognitive tasks.

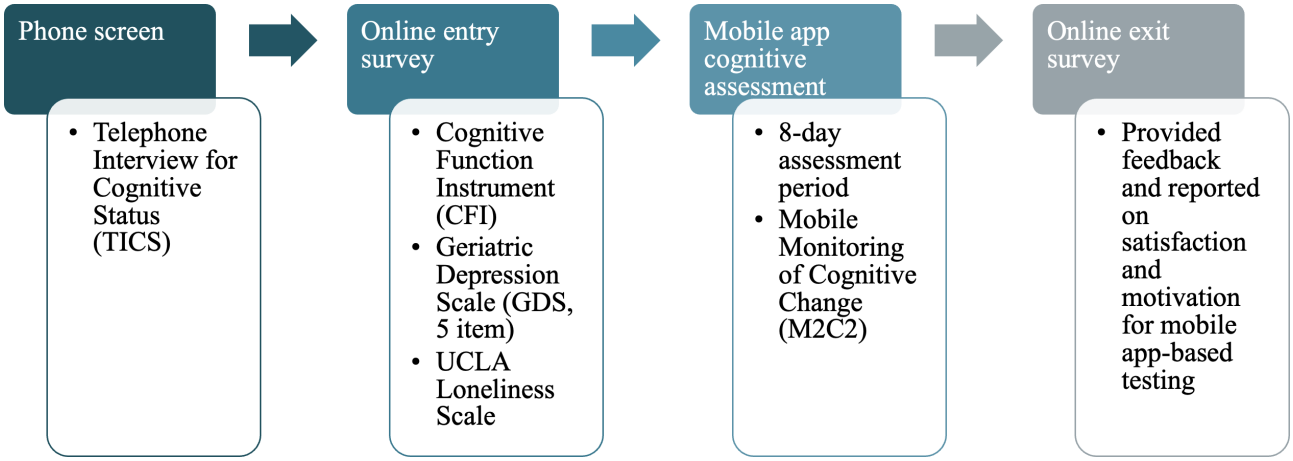
In light of the need to better understand the role of SCC in smartphone-based cognitive assessments in aging populations at risk for AD, the present analysis sought to characterize the relationship between SCC and adherence (aim 1), satisfaction and motivation (aim 2), and performance (aim 3) on a mobile app–based digital cognitive assessment in a sample of cognitively unimpaired older adults. Given the established association between SCC, cerebral Aβ positivity (eg, the hallmark biomarker of AD), and risk for cognitive decline [14-16,23], a secondary aim sought to understand if Aβ positivity moderated the relationship between SCC and performance on the mobile app–based cognitive assessment. Results represent the first step toward quantifying the impact of SCC on smartphone-based cognitive testing in older adult populations, with crucial implications for early detection in those at risk for cognitive decline and dementia.

Methods

Participants, Recruitment, and Procedures

Participants consisted of 122 cognitively unimpaired older adults, between the ages of 60 and 80 years of age, recruited from the Butler Alzheimer's Prevention Registry, a local database of older adults interested in AD research at the Butler Hospital Memory and Aging Program (MAP) [43]. All study procedures were carried out remotely, and detailed recruitment and procedural information has been described previously [38,41,44]. Study procedures are presented in Figure 1.

Figure 1. Study procedures. UCLA: University of California, Los Angeles.



We used a targeted recruitment to enroll individuals with previous amyloid positron emission tomography (PET) data (elevated [Aß+] or nonelevated [Aß-] determined by clinical read by a radiologist) (final n=73) [41] as well as those without PET data. PET results were available if recorded in our Registry as part of previous research participation at the MAP. Individuals (n=256) were invited to participate in the study through an email or phone call. Individuals who consented (n=146) completed an online survey before the initiation of the remote testing protocol, which included various screening measures, including the Cognitive Functioning Index (CFI) [45] (subjective cognitive concern screen), Geriatric Depression Scale 5-item version (GDS-5) [46] (depressive symptoms screen; score range 0 - 5, with higher scores indicating worse depressive symptoms), and the University of California, Los Angeles (UCLA) 3-Item Loneliness Scale [47] (loneliness screen; score range 0 - 6, with higher scores indicating worse loneliness). The modified Telephone Interview for Cognitive Status (TICSm) [48] (objective cognition screen; score range 0 - 50, with lower scores indicating worse cognitive functioning) was also completed before the remote testing protocol by phone, administered by a research assistant. During screening, 23 participants were excluded, and 1 participant was lost to follow up. After the completion of the 8 day remote study protocol, participants (final n=122) were invited to provide feedback (including study satisfaction and motivation) on their experience through an online survey, and a US $20 gift card was provided for compensation.

Inclusion criteria involved unimpaired cognition, daily use of a smartphone, and familiarity with smartphone features. Unimpaired cognition was defined as a TICSm cutoff score of ≥34 [48]. Exclusion criteria included self-reported history of cognitive impairment or dementia, history of neurologic disease or severe mental illness, and physical inability to complete smartphone-based testing.

Subjective Cognitive Concerns

The CFI is a 14-item self-report measure which probes changes in cognitive and functional domains over the past year. The CFI was selected for inclusion in this study as it is a widely used, briefly administered measure of SCC that has been well-validated for used in cognitively healthy and preclinical dementia populations [42,45,49,50]. Items reflect memory concerns, increased use of compensatory strategies, changes in driving, or difficulty managing instrumental activities of daily living. Participants respond with yes (1 point), no (0 points), or maybe (0.5 points), with total scores ranging from 0 to 14 (continuous variable). Higher scores reflect greater SCC. As a sensitivity analysis, we also created a SCC variable that included CFI items that solely assessed cognition (CFI-Cog), by removing the functioning related items to create a refined examination of SCC. CFI-Cog included CFI items 1, 2, 3, 4, 5, 6, 8, 11, and 13. This approach is consistent with a recent study which identified that cognitively focused CFI items, rather than functionally related CFI items, were endorsed at a higher rate and more likely to be associated with Aß+ in cognitively unimpaired older adults [42].

Mobile App–Based Cognitive Assessment

Overview

Remote cognitive tasks were completed using the Mobile Monitoring of Cognitive Change (M2C2) app [51] (more details in Figure 2), a cognitive testing platform developed as part of the National Institute of Aging Mobile Toolbox initiative, with strong previous theoretical, empirical, and psychometric support, including evidence of sensitivity to age and age-related neuropathology [34,38,44]. Android smartphones preloaded with the cognitive assessment app were mailed to participants along with a detailed use guide. Phone functions were locked to prevent the use of features such as web browsing and the camera. Participants completed 3, brief (ie, 3 - 4 minutes) M2C2 sessions each day during morning, afternoon, and evening time windows for 8 consecutive days. Additional sessions could be completed on day 9 as optional or make-up sessions. Staff provided support through phone or email as needed, as described previously [41]. During each M2C2 session, participants completed 3 previously characterized cognitive measures assessing visual working memory (Color Shapes), processing speed (Symbol Match), and episodic memory (Prices). Each task took approximately 60 seconds to complete.

Figure 2. Mobile Monitoring of Cognitive Change (M2C2) app subtests.

Color Shapes

The Color Shapes visual working memory task is a visual array change detection test measuring intraitem feature binding. Participants determine if shapes change color across 2 sequential presentations in which the shape locations change. Performance was measured by discriminability (d-prime) performance calculated from the proportion of correct identifications and proportion of misidentified stimuli [51].

Symbol Match

The Symbol Match processing speed task is a speeded continuous performance test of conjunctive feature search. Participants are asked to identify matching symbol pairs. Performance was measured by the median reaction time to complete the task across all trials (in milliseconds) [51].

Prices

The Prices episodic memory task uses an immediate delayed forced-choice recognition paradigm. Participants incidentally encode 10 grocery item-price pairs for later recall while judging whether or not the item's price is "good." Recall trials begin immediately after the learning trials. Performance was measured by the proportion of correct responses on the 10 recall trials [51].

Study Adherence, Satisfaction, and Motivation

Adherence was quantified as the number of testing sessions completed across the 8-day ambulatory protocol (out of 24 sessions).

Participants' feedback covered various aspects, including their satisfaction with the protocols and their level of motivation to engage with the study tasks. Feedback related to satisfaction was measured with 2 items: "Completing the brain games was fun" and "I became bored with the brain games." Participants rated their responses on a 6-point Likert scale (1=strongly disagree to 6=strongly agree). For the purposes of this study, responses were dichotomized by those who agreed (Likert scale responses 4, 5, and 6) or those who disagreed (Likert scale responses 1, 2, and 3) on these items due to a largely positive response bias (most individuals found the tasks to be fun and not boring).

Feedback regarding motivation was measured on the item: "It was hard to motivate myself to complete the games each time." Participants rated their response on a 5-point Likert scale (1=Agree to 5=Disagree). As above, responses were dichotomized into those who agreed or were neutral (Likert scale responses 1, 2, and 3) and those who disagreed (Likert scale responses 4 and 5) for the purpose of this analysis due to a largely positive response bias (most individuals found themselves to be easily motivated to complete the tasks).

Statistical Analysis

Descriptive statistics were conducted to characterize the sample in terms of demographics (self-reported biological sex, race, ethnicity, and years of education), self-reported symptoms of depression (by the Geriatric Depression Scale 5-item version [46]), loneliness (by the UCLA Loneliness Scale [47]), and SCC (CFI total and CFI-Cog), relevant app-based metrics (ie, adherence, satisfaction and motivation), and objective cognitive performance (ie, visual working memory, processing speed, and episodic memory). Pearson correlation coefficient (for continuous variables) and point biserial correlation (for binary variables) were implemented as appropriate to assess the relationship between SCC and demographic variables, depression, loneliness, and outcomes of interest (eg, adherence, satisfaction, motivation, and performance on app-based cognitive assessment). To address aims 1 - 3 and secondary analyses, SCC (continuous variable) was the main predictor of interest and we adjusted for covariates, including age, sex, depression, and loneliness, in all models. Covariates were selected based on significant association with independent and dependent variables of interest. A priori significance threshold (α) was set at $P \leq .05$. For our moderation analyses, we examined α levels up to $P \leq .10$.

To test aim 1, linear regression models were used to evaluate the association between SCC and adherence (continuous variable) over the 8-day protocol. For the purposes of this analysis, the CFI total score was the main SCC predictor of interest. We present results for CFI-Cog only when they differ from the CFI total score. To test aim 2, logistic regression models were conducted to evaluate the association between SCC and satisfaction (dichotomized self-report items related to level of fun and boredom), and SCC and motivation (dichotomized self-report items related to motivation). Individual regression models were implemented for each motivation and satisfaction outcome of interest. To test aim 3, separate linear regression models were constructed to evaluate the association between SCC and performance on each M2C2 based cognitive assessment (Prices, Color Shapes, and Symbol Search, all continuous variables). Linear-mixed effects models were used to evaluate whether SCC predicted M2C2 subtest performance over time while controlling for age, sex, and loneliness. Finally, as a secondary analysis in a subsample of participants with Aβ PET data, we fit linear regression models with SCC and the interaction of SCC and Aβ PET positivity as predictors, to test the moderation effect of Aβ PET positivity on the association between SCC and study adherence and performance on M2C2 tasks, adjusting for covariates. All descriptive and regression analyses were conducted using SPSS version 28.0.1.1 (IBM Corp). Linear mixed-effects models were conducted using the *nlme* R package.

Ethical Considerations

The project received approval from the Butler Hospital Institutional Review Board (#1882523), and all the participants provided informed consent. All data was de-identified. Participants were compensated for their time with a $20 gift card.

Results

Participant Characteristics and Correlates of Subjective Cognitive Concerns

Overall sample demographics and SCC, adherence, satisfaction, motivation, and performance variables are presented in Table 1. The sample (N=122) was 68.85 (SD 4.93) years old

(range=60 - 81 y) with 16.52 (SD 2.39) years of formal education. The majority of the sample identified as female (n=82, 66.7%), White (n=106, 86.2%), and non-Hispanic (n=109, 88.6%). In the subset of individuals with Aβ PET scans, there were 25 Aβ positive participants and 48 Aβ negative participants. Subjective cognitive concerns, as measured on the CFI, were fairly minimal in this sample. On average, the sample scored 1.8 (SD 1.7) out of 14 possible points on the overall CFI ; however, the most common score on the CFI was 0 (mode=0), with 18% of the sample expressing no concerns about their cognition on the CFI.

Table . Sample demographic, subjective cognitive concerns, and mobile app protocol metrics.

	Total sample (N=122)	Subsample with Aβ[a] PET[b] (n=73)
Demographic characteristics		
Age (years), mean (SD)	68.85 (4.93)	69.25 (4.48)
Education (years), mean (SD)	16.52 (2.39)	16.45 (2.60)
Female, n (%)	82 (66.7)	52 (71.2)
White, n (%)	106 (86.2)	65 (89)
Non-Hispanic, n (%)	109 (88.6)	64 (87.7)
Depression (GDS[c]), mean (SD)	0.27 (0.54)	0.24 (0.46)
Loneliness (UCLA[d]), mean (SD)	0.70 (1.15)	0.56 (0.98)
Cognitive status (TICSm[e]), mean (SD)	39.32 (3.33)	39.01 (3.03)
Subjective cognitive concerns		
CFI[f] total score, mean (SD)	1.86 (1.70)	1.96 (1.80)
CFI-Cog[g], mean (SD)	1.39 (1.35)	1.96 (1.80)
Protocol adherence, mean (SD)	22.45 (2.58)	21.86 (2.30)
Protocol satisfaction		
Who had fun, n (%)	102 (85)	59 (83.1)

Aim 1: Subjective Cognitive Concerns and Adherence to Mobile App–Based Cognitive Assessment Protocol

Overall, remote assessment protocol adherence was high in the sample, with participants completing on average 93.5% of the 24 testing sessions over the 8-day period. CFI-Cog endorsement significantly predicted overall remote testing adherence over 8 days. This suggests that higher levels of SCC were associated with worse adherence (a diminished number of test sessions completed across the protocol) (ß=−.197, *P*=.04, 95% CI −.647 to −.021). However, this association was not observed when using the CFI total score as the predictor (Table 3).

Aim 2: Subjective Cognitive Concerns, Satisfaction, and Motivation on Mobile App–Based Cognitive Assessment

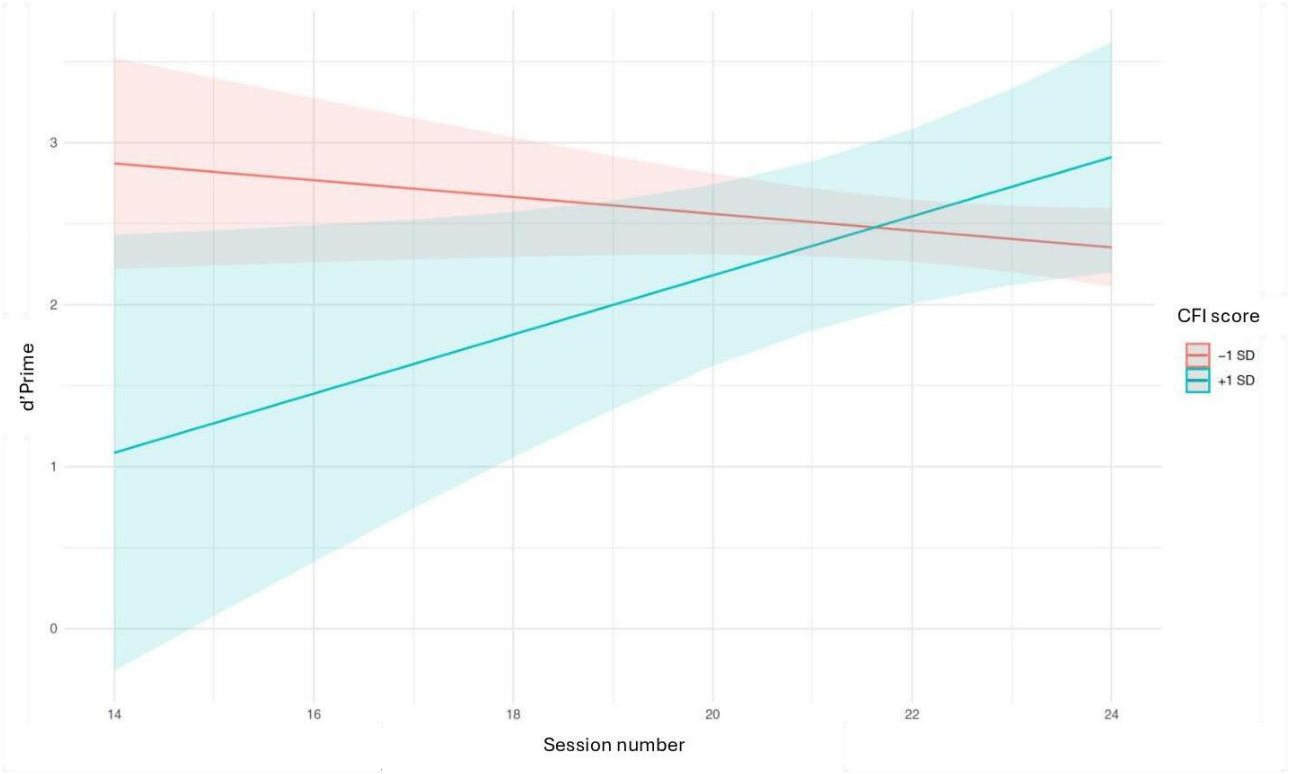
In terms of overall protocol satisfaction, participants endorsed that completing the assessments was fun (n=102, 85%) and not boring (n=92, 75.2%). Participants also reported that they did not encounter difficulties in motivating themselves to give their best performance (n=93, 77.5%). CFI total score was not associated with metrics of study satisfaction in the adjusted models, including how fun or boring participants found the protocol to be. In terms of motivation, CFI total score was not predictive of self-reported effort across the protocol period (more details in Table 3).

Aim 3: Subjective Cognitive Concerns and Performance on Mobile App–Based Cognitive Assessment

SCCs and their association with overall objective cognitive performances on digital cognitive tests was also investigated (more details in Table 3). High SCC endorsement on the CFI total score was significantly predictive of poorer overall performance on the Prices task (ß=−.200, *P*=.02, 95% CI −.020, to −.002). There were no significant associations between the CFI and performance metrics for Color Shapes (*P*=.86) or Symbol Search (*P*=.94).

We also investigated the association of SCC and longitudinal trends of cognitive performance over the 8-day testing period (M2C2 app performance descriptives for each study day have been previously reported) [38]. There was a main effect of the CFI total score suggesting that higher levels of SCC were associated with worse performance on Color Shapes (working memory) at day 1 (unstandardized estimate [b]=−1.047, SE=0.47, *P*=.03). Furthermore, there was a significant interaction between SCCs and Color Shapes performance (b=0.048, SE=0.02, *P*=.03), such that higher CFI total scores were associated with improved performance on this subtest over time. In other words, although high SCC was associated with worse working memory performance initially, individuals seemed to benefit from repeated practice and ultimately performed better (more details in Figure 3). There were no significant associations between SCC and intraindividual variability in Prices or Symbol Match performances over the protocol period.

Figure 3. Subjective cognitive concerns association with working memory longitudinally over the 8-day mobile-appmobile app protocoll. CFI: Cognitive Function Instrument.



Secondary Aim: Moderating Effect of Amyloid Status on the Relationship Between Subjective Cognitive Concerns and Mobile App–Based Cognitive Assessment

The moderation of Aβ positivity on the relationship between CFI and app-based metrics, as well as CFI and cognitive performance (ie, Prices, Color Shapes, and Symbol Search) was investigated in a subset of individuals with Aβ PET scans (n=73). The presence of Aβ did not moderate the relationship between CFI total score and adherence. There was evidence for moderation at the $P<.10$ level of Aβ positivity on the relationship between CFI total score and Prices was observed, but did not fall within the $\alpha=.05$ threshold (ß=.179, $P=.09$, 95% CI −.003 to .036). Aβ status did not moderate the association between SCC and Color Shapes or Symbol Search.

Discussion

Principal Findings

This study sought to characterize the relationship between SCC and mobile app–based protocol engagement (adherence, satisfaction, and motivation) and performance on cognitive tasks in a cohort of cognitively healthy older adults. While protocol satisfaction and motivation were not impacted by SCCs, overall adherence was associated, such that higher levels of SCCs predicted lower rates of adherence. Overall, we show that SCCs were associated with worse objective performance on mobile app–based assessments. Our findings suggest that mobile app–based assessments hold promise as sensitive tools to detect subtle neurodegenerative changes in individuals at risk for dementia, with potential application for early detection, diagnosis, and treatment.

We observed an association between SCCs, as measured on the Cognitive Function Index (CFI), and overall worse performance on a test of episodic memory (Prices). A significant association was not observed between SCC and overall performance on tasks of processing speed or working memory. Findings in the broader SCD literature are quite mixed as to whether SCCs are or are not associated with concurrent cognitive functioning abilities [52]; as such, our results may indicate that the use of sensitive digital cognitive tools could enhance the association between SCC and objective cognitive metrics. Our result reflecting a unique association with episodic memory is perhaps clinically meaningful, as memory concerns specifically are frequently considered to be the hallmark presenting symptom of AD [2,53], particularly in individuals over the age of 65 [53]. This observation is underscored by our finding of a moderating effect of cerebral Aβ positivity (at the $P<.10$ level) on the relationship between SCC and episodic memory (Prices) in a subsample of participants with biomarkers available for analysis (secondary aim), such that the association of SCC with episodic memory was stronger in the presence of Aβ. This result adds to the growing evidence base for an association between SCC and higher Aβ [52]. Replication of this analysis in a larger sample may clarify the interplay between SCC, AD biomarkers, and subtle memory deficits observed on mobile app–based assessment in otherwise cognitively and clinically normal older adults. That being said, it is worth considering that the unique association between SCC and episodic memory in our sample may be at least somewhat secondary to the way the CFI is constructed, as this instrument mostly focuses on episodic memory-related cognitive concerns [45]. Previous studies have

demonstrated the importance of querying beyond just memory concerns to most sensitively detect dementia risk [54,55]. Indeed, SCC can be sampled by a multitude of techniques and approaches (eg, memory only vs multiple cognitive domains; traditional paper and pencil vs digital assessments; self vs informant report; capturing current ability vs change in ability, etc) [24,25], all of which may impact the sensitivity of the SCC measures to detect current and risk for future cognitive impairment. Future research should carefully weigh SCC assessment approaches, and consider incorporating a more comprehensive SCC screener which queries across a broader range of cognitive domains, as this may be valuable for detecting more meaningful associations between SCC and mobile app–based cognitive performances.

We also evaluated patterns of cognitive performance across the 8-day assessment period. Analyses revealed that more SCC was associated with initially worse working memory (Color Shapes) performance on day one. However, individuals with higher SCC showed progressively improving working memory performance over the assessment period, and by day 8 were performing in a similar range with those with lower SCC. This pattern was not observed on the episodic memory or processing speed subtests. This finding is consistent with recent results from Aschenbrenner et al [56], which showed variability over high frequency app-based assessments in attention and working memory-based skills, but not in episodic memory, in older adults who were at increased genetic risk for AD [56]. Our finding of an initial relative weakness in working memory skills could reflect the presence of mild cognitive inefficiencies in older adults with SCC, which may be compensated for with repeated exposure to the task over time. This may be due to early dysfunction in working memory processes, which have been characterized in preclinical AD [57,58]. Subjectively, this may be experienced by these individuals as thinking which requires increased concentration, that is punctuated by occasional lapses, and is associated perhaps with a sense of being cognitively overwhelmed, all of which may be driving the report SCC in daily life, but may be subtle enough that it may not be detected on traditional neuropsychological tests. Hence, this type of unique marker of cognitive inefficiency would only be afforded through high frequency, mobile app–based cognitive assessment in this population. The plausible role of performance anxiety may also explain variability in cognitive performance overtime. Although beyond the scope of the present analysis, research which comprehensively measures the role of in-the-moment psychological and physiological states by ecological momentary assessment techniques in relation to in the moment SCC and objective cognition will be critical next steps.

Our findings related to SCC and metrics of protocol engagement and satisfaction with unsupervised, high frequency digital cognitive assessments have potentially broad implications for aging research, especially in light of increasing interest in using these techniques to remotely assess cognitive functioning in this population [31,32]. Indeed, whether or not a study is directly examining SCC or includes SCD as a clinical group of interest, aging studies must contend with the fact that SCCs are widespread and may be clinically meaningful feature among the older adults in their sample [2]. We show that SCC was not associated with protocol satisfaction (including how fun or how boring the experience was) nor did SCC effect how motivated a participant was to engage and put forth their best effort. However, higher levels of SCC did impact protocol adherence in our sample, with mildly worse compliance those with higher SCC observed. For context, protocol adherence was overall quite high in our population (93.5%) and similarly high compliance rates have been described in several other recent smartphone-based studies [32], yet no previous studies have directly explored the impact of SCCs on protocol adherence. It may be that high frequency, mobile assessments are able to detect mild patterns of forgetfulness (manifested in slightly worse adherence rates) in older adults with SCC, so future research should be attuned to this possibility. Replication of this association between SCC and adherence to remote protocols in larger, more demographically diverse samples is warranted.

Limitations

Some limitations of this study, as well as potential future directions of this research, warrant acknowledgment. Our sample was largely White, disproportionally female, and highly educated. This limits the generalizability of the study findings to broader demographic groups. Our sample was from a relatively small single cohort and only a subset had AD biomarkers available for analysis, restricting study power and may have impeded our ability to obtain significant findings. A measure of anxiety symptomology was not available in the present sample, limiting our ability to understand the plausible role of anxiety, SCC, and performance on digital assessments [32,59]. The main predictor of interest in this study, the CFI, shows adequate evidence for validity and reliability [42], but is somewhat limited in the domains of cognitive concerns it measures (eg, memory and daily functioning). Research has shown that comprehensive assessment of concerns across a broad range of cognitive domains may be most sensitive to risk in aging populations [60], so future smartphone-based research may consider including a broader range of cognitive concern items to better understand this relationship. We were unable to assess informant-report of SCC in this sample, which has been demonstrated to be optimized to predict risk above and beyond self-report [25], and this should be addressed in future smartphone studies. Although such metrics were not available in this study, there is also a small but growing literature which has examined the use of smartphones to assess SCC in a digital remote format in tandem with cognitive tests and relevant clinical outcomes in older adult samples [61-63]. Future research on SCC and smartphone-based digital cognitive assessments should investigate the relative value of traditional in person reported SCC (eg, the CFI) versus smartphone based digital SCC assessments. Finally, this cross-sectional study was not able to investigate the relationship between SCC and longitudinal decline on smartphone-based cognitive performance in individuals with positive AD biomarkers. It will be essential for future studies to follow participants over time to understand if SCC at baseline may predict incident decline on these novel cognitive metrics. Due to the limited nature of this pilot study, we cannot provide specific recommendations about optimal SCC assessment approach for use in future digital cognitive studies.

Conclusions

SCCs are frequently one of the earliest clinical symptoms of dementia [2]. However, clinical interpretations of SCCs are complicated by the ubiquitous endorsement of these concerns [2], their potential for non-neurodegenerative etiology (eg, psychiatric, medical, or sociodemographic factors) [2,3], and frequent lack of association with traditional objective cognitive testing [1]. Smartphone-based, digital cognitive assessments, which are increasingly used in aging research, may offer potential for improved ecological validity and sensitivity to subtle markers of cognitive decline [30-32,35]. Hence, such smartphone-based digital tools may be able to capture quite mild deficits in individuals with SCC who perform within normal limits on traditional neuropsychological tests. Results from the current study showed that SCCs are associated with worse overall memory performance on mobile app assessment, and patterns of cognitive inefficiency (variable working memory) and mild forgetfulness (diminished adherence) across an 8-day assessment period in cognitively intact older adults. Findings indicate that mobile app assessments may be uniquely sensitive to very subtle neurodegenerative changes in at risk older adults, with critical implications for early detection and timely intervention.

Abstract

Background: Horticultural therapy (HT) has been proposed to be an effective intervention for improving the psychosocial well-being of people with dementia and their caregivers. However, constraints such as limited land space in high-density cities, unstable weather, and lack of gardening experience may hamper the delivery of HT to people with dementia and their caregivers.

Objective: This pilot study aimed to examine the feasibility and preliminary effects of a technology-enhanced home-based HT for people with dementia and their caregivers using a hydroponic indoor growing system.

Methods: A single-group pre-post design was adopted. A total of 37 dyads of people with dementia and their caregivers participated in 3 weekly face-to-face sessions, followed by 8 weeks of home-based horticultural activities. Outcomes were measured at baseline and postintervention (at week 11), including feasibility outcomes, cognitive function, neuropsychiatric symptoms, and happiness levels of people with dementia. Caregivers' outcomes included positive aspects of caregiving, perceived stress levels, depressive symptoms, caregiver distress, and happiness levels. Semistructured focus group interviews were conducted with the caregivers to further explore their horticultural experience.

Results: Intervention feasibility was established with a completion rate of 83.78% and an attrition rate of 2.63% (n=1). Significant improvements were detected in caregiver distress (P<.05) and the happiness level of people with dementia (P<.01). The qualitative findings indicated that HT improved the psychological well-being of both people with dementia and caregivers, enhanced the relationships between caregivers and people with dementia, expanded the caregivers' social networks, and enhanced the autobiographical memory of people with dementia.

Conclusions: This pilot study provides evidence on the feasibility of using a hydroponic indoor grower to conduct home-based HT for people with dementia and their caregivers. The findings suggest positive effects on the psychological well-being of both people with dementia and their caregivers. Caregivers reported potential positive effects of HT on the autobiographical memory retrieval of people with dementia. Due to the pilot nature of this study, a control group was not employed. Therefore, large-scale randomized controlled trials are encouraged to further confirm the effectiveness of the intervention.

horticultural activity; dementia; caregivers; dyadic intervention; technology–enhanced intervention

Introduction

With the global aging population, dementia has become a significant public health concern. The World Health Organization estimates that the number of people with dementia worldwide is approximately 55 million, with this figure expected to rise to about 78 million by 2030 and 139 million by 2050 [1]. The global cost of dementia saw a substantial increase of 62% between 2010 and 2019, with the economic burden projected to reach an estimated US $1313.4 billion in 2019. Notably, informal care significantly contributes to roughly half of the total global costs [2]. People with dementia often exhibit behavioral and psychological symptoms of dementia (BPSD), including agitation, anxiety, irritability, depression, apathy, disinhibition, and changes in sleep or appetite [3]. More than 80% of people with dementia were affected by aggression, apathy, agitation, and depression, while around 30% experienced hallucinations and delusions [3,4]. Conceivably, BPSD adversely impacts the capacity to perform activities of daily living (ADL) and the maintenance of interpersonal relationships. This in turn results in significant stress and negative emotions for their family caregivers. For instance, caring for people with dementia has been associated with elevated levels of psychological distress and stress, as well as lower levels of self-efficacy, subjective well-being, and physical health [5]. Due to the significant level of psychological distress and stress involved in caregiving activities, approximately 50% of caregivers of people with dementia are susceptible to major depressive disorder [6]. A high level of caregiver stress is a risk factor for unhealthy behaviors, such as a sedentary lifestyle, inadequate dietary habits, and substance abuse, leading to an increased vulnerability to chronic illnesses among caregivers [7,8]. Caregiver burden is also linked to an increased risk of engaging in abusive behavior towards the care recipient [9]. It is therefore important to develop psychosocial interventions to promote the psychological well-being of both caregivers and people with dementia, as well as to alleviate the BPSD experienced by people with dementia.

Horticultural therapy (HT) has been proposed to be an effective intervention for improving the psychosocial well-being of people with dementia and their caregivers. HT is grounded in the Biophilia Hypothesis, which emphasizes the healing effects of human-plant interactions on physical, mental, and emotional domains [10]. According to the Attention Restoration Theory (ART), engaging with natural environments can restore cognitive fatigue by automatically capturing attention, thereby allowing the replenishment of directed attention capacity [11]. The Stress Recovery Theory (SRT) also proposes that interacting with nature can trigger physiological and psychological stress reduction and elicit positive affect, which in turn facilitates the replenishment of depleted psychological resources after stressful events [12,13]. For instance, HT establishes a sense of control, empowerment, and cooperation, which in turn can facilitate emotional stability when under a state of cognitive overload [14]. The physiological effects of HT on stress reduction in older adults are characterized by lower cortisol, heart rate, and blood pressure [15,16]. It has also been found that increased high α and low α wave activities after a single treatment [17]. Increasing α and theta activity in the brain's occipital lobes helped decrease anxiety and improve functioning in those with generalized anxiety disorder [18]. In addition, the social interactive nature of HT can facilitate social support for vulnerable groups [19].

More recently, HT has been extended in its application to people with dementia and demonstrated positive effects on BPSD, as well as enhancing physical and cognitive abilities, including memory and orientation, among people with dementia [20]. In the context of caregiving for people with dementia, HT can foster meaningful contact and social interaction between people with dementia and their caregivers [21,22]. A randomized controlled trial (RCT) demonstrated that HT can effectively reduce caregiving burden and promote the quality of life among caregivers of people with dementia [23]. Another RCT reported evidence of the protective effects of HT on the immune system and cognitive functioning, as well as its positive effects on reducing anxiety and promoting social interactions among older adults [24]. Several systematic reviews and meta-analyses have shown reliable effects of HT in improving cognitive functioning in people with dementia [25,26]. For instance, an improved capacity for autobiographical memory retrieval is often observed through engaging in horticultural activities [27]. In addition, HT also demonstrated benefits in alleviating BPSD in people with dementia, as suggested in multiple systematic reviews and meta-analyses [25,27-29].

Traditionally, HT is led by a registered therapist to achieve tailored rehabilitative or vocational goals. HT commonly includes participatory tasks such as cultivating, pruning, weeding, and planting flowers. Ornamental HT may also involve garden tours and nature viewing [16,22]. However, in densely populated areas, HT may not have the luxury of spaces to engage in home-based horticultural activities. The extreme climate in certain areas may create additional difficulties in engaging in outdoor horticultural activities. In addition, for caregivers who may be occupied with caregiving tasks, horticultural activities that require a significant amount of skills and time, such as monitoring the condition of various plants, may pose additional challenges for them [30].

While HT is promising in managing BPSD in people with dementia and improving the quality of life in both people with dementia and their caregivers, it is important to consider the environmental and spatial conditions in which HT is implemented, as these factors may inadvertently impact its

effectiveness. In this study, we proposed a novel approach to take advantage of technology to overcome the above limitations and to make horticultural activities more accessible for people with dementia and their caregivers, especially in densely populated areas. In recent years, there has been a growing body of research on the application of technology-assisted HT, such as using virtual reality to deliver HT (eg, VR Garden) [31]. However, there are certain limitations. One of the main drawbacks is the lack of real-world sensory experiences, such as smells and tactile sensations, which are inherent to traditional HT. Additionally, the use of virtual reality may lead to cybersickness, a condition characterized by symptoms similar to motion sickness, which can negatively impact the user experience and therapeutic outcomes [32]. To address these limitations, a hydroponic indoor grower can create a controllable, optimized environment for engaging in horticultural activities in a home-based HT for people with dementia and their caregivers. The hydroponic indoor grower also allows mobile app connectivity to track the progress of plant growth, which can guide people with dementia and their caregivers to engage in horticultural activities. Therefore, this pilot study aimed to address the following research objectives:

1. To examine the feasibility and acceptability of conducting a technology-enhanced home-based HT among people with dementia and their caregivers.
2. To investigate the preliminary effects of the intervention in (1) improving cognitive function and BPSD of people with dementia, (2) promoting positive caregiving experiences in family caregivers, and (3) reducing the caregivers' level of stress and depressive symptoms.

Methods

Study Design

To examine the feasibility and preliminary effects of the technology-enhanced home-based HT on improving the psychological well-being of people with dementia and their caregivers, we used an explanatory sequential multimethods approach. A single-group pre-post design is used for our quantitative assessment. The entire intervention lasted for 11 weeks, with outcome measures taken at baseline (T0) and post intervention (T1). A qualitative approach was used to explore the participants' experiences in-depth in the HT. Semistructured focus group interviews were conducted with participants after the intervention, with the aim of identifying the strengths, limitations, and difficulties experienced during the program.

Participants

Participants were recruited from a convenience sample of people with dementia and their caregivers in collaboration with 4 community centers operated by the nongovernmental organization (NGO) that provide gerontology services. Promotional posters were used to advertise the program in NGOs. The program allowed interested participants to enroll independently, while NGO staff reached out to interested individuals to provide further information and assistance. The Hong Kong version of the Montreal Cognitive Assessment-5-Minute (MoCA-5-min) [33] was administered by a research assistant in screening for stages of dementia in potential participants. Eligible participants were then enrolled based on the following inclusion and exclusion criteria. The inclusion criteria for people with dementia were as follows: (1) 65 years or above, (2) diagnosed with any type of dementia at the early to moderate stage, and (3) community-dwelling and living with family caregivers (ie, noninstitutionalized). The criteria for caregivers included the following: (1) at least 18 years old; (2) blood or by-marriage relatives (eg, spouses, siblings, children, and grandchildren) of a person who has been clinically diagnosed with dementia, regardless of its type; and (3) take up caring responsibilities ranging from physical aids (eg, transportation, financial assistance, personal hygiene, and decision-making) to emotional support, and provided most of the daily care and support for the people with dementia (daily contact of at least 4 hours). Participants were deemed ineligible if they had a current medical diagnosis with any acute mental illnesses that would otherwise prevent them from engaging in HT.

An a priori power analysis was performed using G*Power 3.1 [34], based on effect sizes in literature related to the effects of HT on psychological outcomes. A meta-analysis reported an effect size of 0.55 [35], the power analysis was formulated using a 1-tailed *t* test to detect a medium effect size with a power of 0.80 at a *P* value of .05, which resulted in a target sample size of 23. Considering an attrition rate of approximately 15% [36], it was necessary to include more than 27 dyads in the study.

Ethics Approval

Ethical approval for the study was obtained from the Institutional Review Board of The Hong Kong Polytechnic University (approval number HSEARS20220801002), and the trial was registered in ClinicalTrials.gov (NCT05577975). Prior to participation, all participants (both people with dementia and their caregivers) were required to provide informed consent. The process of obtaining informed consent from people with dementia adhered to the guidelines outlined by the Alzheimer's Society. A demonstration session was set up to explain the study's purpose, procedures, risks, benefits, and voluntary nature clearly to both people with dementia and their caregivers. During this session, the research assistant explained the consent form, demonstrated the equipment, and provided an overview of the participation process. People with dementia and their caregivers were allowed to try out some parts of the HT before signing the consent form. Only those people with dementia who were still willing to participate after this experience were allowed to sign the consent form. Ongoing assent was also obtained from participants with dementia throughout the study, and their willingness to participate was regularly monitored and respected.

Intervention

In the technology-enhanced home-based HT, the activities were also designed based on the Biophilia Hypothesis, with an emphasis on human-plant interactions. We further incorporated interactive components between people with dementia and their caregivers, in which people with dementia participated in the planting process alongside their caregivers. The caregivers assumed responsibility for decision-making and progress monitoring for the planting process, while people with dementia followed directions from caregivers and provided assistance

throughout the process. Examples of horticultural tasks performed by caregivers included formulating planting plans, adjusting optimal light conditions, strategizing fruit harvesting schedules, and devising culinary techniques for the harvest. Meanwhile, people with dementia executed tasks such as observation, flower watering, active participation in planting light regulation, and assisting caregivers with harvesting. According to the SRT and ART, these activities are posited to have cognitive and stress restoration effects. Based on the Sensory Integration Theory, these activities can mobilize the 5 senses through multisensory stimulation, tactile input, and olfactory and gustatory experiences [37,38], which can further enhance the cognitive functioning of people with dementia. Furthermore, the interactive components may enhance the dyadic relationship between people with dementia and their caregivers.

The technology-enhanced home-based HT was facilitated by a hydroponic indoor smart grower, which is a smart device that provides a greenhouse environment with adjustable LED grow lights and smart sensors (Figure 1). Features of the device include automatic watering and a removable water reservoir, as well as built-in smart sensors to detect nutrients, air temperature, humidity, light intensity, water temperature, and water level. The mobile app connectivity via Wi-Fi allows participants to monitor the growth conditions with notifications when water and nutrients need to be replenished, minimizing the probability of plant growing failure. The app can also customize planting plans for each type of plant and automatically adjust to suitable light intensity, resulting in faster plant growth and harvest. Additionally, the app can track the progress of plant growth and guide users to conduct horticultural activities.

Figure 1. Hydroponic indoor smart grower.

Upon the project's commencement, the hydroponic indoor smart grower was delivered to the enrolled participants. With reference to the optimal therapeutic dose between 100 and 500 minutes of HT for stress reduction [39], the intervention consisted of 3 weekly face-to-face (F-T-F) training sessions, each lasting 90 minutes. This was followed by 8 weeks of home-based horticultural activities (Table 1), with a total weekly time commitment of 1 hour. The program activities are presented in Table 2. A biweekly telephone call schedule was established to follow up on progress and program adherence. Additionally, a social media platform group was created for the participants to ask questions and share their horticultural experiences. The social media platform provided additional insight into participants' adherence to home-based horticultural activities.

Table 1. Intervention schedule of the technology-enhanced home-based horticultural therapy.

	F-T-F[a] sessions			Home-based horticultural activities with biweekly telephone follow-up							
	Week 1	Week 2	Week 3	Week 4	Week 5	Week 6	Week 7	Week 8	Week 9	Week 10	Week 11
Duration (minutes)	90	90	90	60	60	60	60	60	60	60	60

[a]F-T-F: face-to-face.

Table 2. Program content of the technology-enhanced home-based horticultural therapy.

Week	Theme	Objectives	Reality orientation contents
4	Vision; Hearing; Smell	Stimulating the senses of vision, hearing, and smell; focusing on the appearance of the smart grower; encouraging people with dementia-caregiver interaction.	Focusing on LED[a] light differences according to certain modes of the smart grower; focusing on the water sound when the smart grower performs auto-watering system; smelling the seeds to see if different seeds have different smells; and sharing their sensory information to each other.
5	Smell; Touch; Motor	Stimulating the senses of smell and touch; enhancing visual-spatial skills and executive; promoting motor skills.	Smelling the leaves at the beginning stage of the plants; touching the plants (To see the texture, eg, hard/soft/smooth/rough/solid/fluid); trimming plants; taking photos to record plant growth.
6	Vision; Touch	Stimulating the senses of vision and touch; enhancing visual-spatial skills and executive functioning; enhancing cognitive ability through comparison.	Examining the pattern, shape, size, or height of the vegetables (eg, bok choy vs tomato) in day and night; touching different types of vegetables to see if the textures are different; sharing their sensory information to each other; taking photos to record plant growth.
7	Smell; Vision; Motor; Memory	Stimulating the senses of smell and touch; promoting motor functioning; enhancing visual-spatial skills and executive; enhancing cognitive functioning (memory) through comparison; encouraging people with dementia-caregiver interaction.	Comparing the shape, size, and height of different vegetables to see the differences in the growing process; smelling the leaves or stem of vegetables; pruning the vegetables; sharing and discussing what are the differences from the beginning; taking photos to record plant growth.
8	Motor; Touch; Decision making	Stimulating the senses of touch; promoting motor functioning; stimulating cognitive functioning through decision-making process; enhancing visual-spatial skills and executive.	Touching the leaves or stem of the plants or vegetables to see if the textures are different from the beginning to mid-late stage of planting; planning and discussing which plants to cut; taking photos to record plant growth.
9	Vision; Motor; Decision making	Stimulating the senses of vision; promoting motor functioning; stimulating cognitive functioning through decision-making process; enhancing visual-spatial skills and executive.	Counting the number of vegetables (eg, how many bak choy/tomato?); deciding which vegetables to cut; cutting suitable vegetables; taking photos to record plant growth.
10	Smell; Vision; Motor; Memory	Stimulating the senses of smell and touch; promoting motor functioning; enhancing visual-spatial skills and executive; enhancing cognitive functioning (memory) through comparison; encouraging people with dementia-caregiver interaction.	Comparing the shape, size, and height of different vegetables to see the differences in the growing process; smelling the leaves or stem of vegetables; pruning the vegetables; sharing and discussing what are the differences from the beginning; taking photos to record plant growth.
11	Motor; Vision; Decision-making	Stimulating the senses of vision; promoting motor functioning; stimulating cognitive functioning through decision-making process.	Deciding what type of dishes to cook (salads or pasta); cooking the decided dishes based on the vegetable; recording the odor and color of the dishes; taking photos to record plant growth.

[a]LED: light-emitting diode.

Measures

Overview

Measurements were taken at T0 and T1. The feasibility of the intervention was evaluated by means of attrition rate, attendance rate, and completion rate. The outcome measures for people with dementia included self-care abilities, cognitive function, behavioral symptoms, and happiness levels. Caregivers' outcomes consisted of positive caregiving experiences, perceived stress levels, depressive symptomatology, caregiver distress, and happiness levels.

People With Dementia Outcomes

The Barthel Index was used to measure the capacity to perform ADLs. Barthel Index comprised 10 ADLs, including feeding, bathing, grooming, dressing, using the toilet, transferring (moving from the bed to the chair and back), mobility (on level surfaces), climbing stairs, and controlling bowel and bladder functions [40]. Items are rated based on whether individuals can perform activities independently, with some assistance, or

are dependent (scored as 10, 5, or 0). The index yields a total score out of 100, with higher scores indicating greater levels of functional independence [40]. We categorized the Barthel Index scores as follows: 0-20 (total dependence), 21-60 (severe dependence), 61-90 (moderate dependence), 91-99 (mild dependence), and 100 (total independence) [41]. The Barthel Index had excellent test-retest reliability (intraclass correlation coefficient [ICC]≥0.962) [42].

The MoCA-5-min was used to measure the cognitive functions of people with dementia over the telephone, administered by social workers [33]. It comprises 4 domains: attention (immediate recall of 5 words), executive function/language (1-minute verbal fluency), orientation (6-item date and geographic orientation), and memory (delayed recall and recognition of 5 words learned in item 1). The total scores of the MoCA-5-min range from 0 to 30, with higher scores representing a higher level of cognitive function. The MoCA-5-min had an excellent test-retest reliability (ICC=0.89) [33].

BPSD of people with dementia was measured using the Neuropsychiatric Inventory Questionnaire (NPI-Q) [43]. The NPI-Q consisted of 12 neuropsychiatric symptoms, including delusions, hallucinations, agitation/aggression, irritability/depression, anxiety, euphoria/exuberance, apathy/indifference, disinhibition, irritability/instability, abnormal motor behavior, nocturnal behavioral disorders, and appetite/eating disorders. Each symptom is evaluated based on frequency (1=rarely to 4=very often, once or more per day) and severity (1=mild [causing little distress in the patient] to 3=severe [very disturbing to the patient and challenging to redirect]). A total score for each domain is calculated by multiplying the frequency and severity ratings. The overall NPI score is derived by summing the scores across all domains, with a higher score indicating more severe neuropsychiatric symptoms. The NPI-Q has demonstrated satisfactory psychometric properties [43].

The Visual Analogue Scale of Happiness was used to measure the happiness level of people with dementia [44]. The Visual Analogue Scale of Happiness is an analog scale containing 6 faces expressing emotions ranging from great happiness to deep sadness, and people with dementia need to identify which face best represents their mood. Subjects that chose the faces “Little Unhappy,” “Unhappy,” or “Very Unhappy” were prone to exhibit depressive symptoms [45]. The reliability and validity of the scale have been validated [46].

Caregivers Outcomes

The Positive Aspects of Caregiving Scale was used to measure caregivers’ positive caregiving experience [47]. It consists of 11 items with 2 subscales: enriching life and affirming self. Participants answered on a 5-point scale ranging from 0 (strongly disagree) to 4 (strongly agree). Scores range from 0 to 44, with higher scores indicating more positive self-perceptions of caregiving. The Positive Aspects of Caregiving Scale demonstrates high levels of internal consistency, with a Cronbach α of 0.89 among the family caregivers of people with dementia in Hong Kong [47].

The Chinese version of the Perceived Stress Scale was used to measure the stress level in caregivers [48]. It is a 10-item measurement rated on a 5-point Likert-type scale, ranging from 0 (never) to 4 (very often). The total score ranges from 0 to 40, with higher scores indicating higher levels of perceived stress. The Perceived Stress Scale showed acceptable levels of psychometric properties, which included an internal consistency reliability of Cronbach α of 0.85 and a test-retest reliability coefficient of 0.85 [49].

The Center for Epidemiological Studies Depression Scale was used to measure depressive symptoms in caregivers over a 1-week recall period [50]. It consists of 20 items and is rated on a 4-point Likert scale, ranging from 0 (rarely or none of the time) to 3 (most or almost all the time). Scores range from 0 to 60, with higher scores indicating greater depressive symptoms. The Center for Epidemiological Studies Depression Scale has demonstrated acceptable psychometric properties, including a test-retest reliability of 0.91 and an internal consistency of 0.86 [51].

The Neuropsychiatric Inventory-Distress Scale (NPI-D) was used to measure caregiving distress [52]. It assesses the psychological distress levels caused by neuropsychiatric symptoms, as reported in the NPI-Q, to the caregivers [43]. Participants rated their distress levels according to the severity of symptoms in people with dementia using a 6-point Likert scale, which ranges from 0 (not at all distressing) to 5 (very severely or extremely distressing). The Cronbach α coefficient for the Chinese version of the NPI-D was 0.72 [53].

Perceived happiness was measured using the Subjective Happiness Scale (SHS) [54]. The SHS consists of 4 items; 2 of these assess the current state of happiness, including absolute happiness ratings and relative happiness ratings compared with peers. The remaining 2 items measure trait happiness by asking participants to indicate the extent to which they identify with descriptions of both happy and unhappy individuals. The SHS is rated on a 7-point Likert-type scale, ranging from negative to positive. Responses to the 4 items are averaged, yielding a range from 1 to 7. A higher score indicates greater levels of happiness. The Cronbach α for the Chinese version of the SHS was 0.82, and the test-retest reliability was 0.70 [55].

Feasibility Outcomes

Intervention feasibility was assessed using the completion rate, attendance rate, and attrition rate. The attrition rate was calculated by dividing the number of dropouts by the total number of enrolled subjects. The attendance rate was determined by averaging the individual attendance rates, which were calculated by dividing the number of F-T-F sessions attended by the total number of F-T-F sessions. The completion rate was defined as the percentage of participants who attended more than 80% of the sessions, which included home-based horticultural activities and totaled more than 600 minutes.

Quantitative Analysis

Data analysis was performed using IBM SPSS (version 23). We first explored patterns of sociodemographic characteristics of the participants. Then, paired-sample *t* tests were used to compare the outcomes before and after the intervention. Unless

otherwise specified, the statistical analyses performed did not exceed a 2-tailed α level of 0.05.

Qualitative Analysis

Given that caregivers of people with dementia experience varying levels of distress and may respond differently to the intervention, we adopted stratified purposive sampling based on this criterion to enhance the representativeness of the data. The caregiver's level of distress was assessed using NPI-D, with mild distress categorized as 0-13 points (77.78%), moderate distress as 14-26 points (16.67%), and severe distress as >27 points (5.56%) [52]. Participants for the qualitative study were selected through stratified sampling based on these different levels of distress. A total of 4 semistructured focus groups were conducted with 18 participants. A trained research assistant led the focus groups, asking participants to share their experiences using the smart growers, as well as their interactions with people with dementia during the program. A probing question—"What is your experience related to the use of the device in interacting with your relative?"—was used to facilitate the discussions. The focus group interviews were recorded and transcribed with the participants' consent.

Thematic analysis was used to analyze the transcribed verbatim; the authors read the texts, generated initial codes, and developed potential themes [56]. The process concluded with data saturation, when no new findings were discovered. Emergent themes were discussed and agreed upon by the researchers. The comprehensiveness of the content analysis was ensured through digital recordings and verbatim transcriptions, which were independently completed and then discussed by 2 researchers. The emergent themes, validated through researcher consensus after thorough discussion, exemplify the methodological rigor underlying the study's credibility.

Results

Quantitative Findings

A total of 50 dyads of people with dementia and their family caregivers were invited to participate in the study, and 38 dyads met the selection criteria and joined the study. The attrition rate was 2.63%, with 1 participant dropping out due to behavioral issues after the first F-T-F training session. The attendance rate for F-T-F sessions was 94.64%. A total of 36 out of 38 dyads attended the first session, while 35 out of 37 dyads attended both the second and third sessions. The completion rate was 83.78%, as 31 out of 37 participants achieved a participation rate of 80% or higher (>600 minutes).

Sample characteristics of people with dementia are presented in Table 3. The majority of participants were male (21/38, 55.3%), with a mean age of 81.8 (SD 8.4) years. Regarding the self-care abilities of the participants, only 21.1% (n=8) exhibited no dependence, while the majority displayed mild to moderate dependence.

Table 3. Sociodemographic characteristics of people with dementia (N=38).

Variables	Values
Age (in years), mean (SD)	81.8 (8.4)
Age (in years), range	60-102
Sex , n (%)	
Male	21 (55.3)
Female	17 (44.7)
Marital status , n (%)	
Married	23 (60.5)
Divorced/Widowed	15 (39.5)
Self-care abilities , n (%)	
Total independence	8 (21.1)
Mild dependence	25 (65.8)
Moderate dependence	5 (13.2)
Severe dependence	0 (0.0)
Total dependence	0 (0.0)

Demographic characteristics of caregivers are summarized in Table 4. Female caregivers accounted for 73.7%, with a mean age of 58.4 (SD 8.8) years. The average duration of care provided to people with dementia was 4.7 (SD 0.3) hours per day.

Table 4. Sociodemographic characteristics of caregivers (N=38).

Variables	Values

Duration of care provided to people with dementia, in hours/day (hours), mean (SD)	4.7 (0.3)

[a]HKD: Hong Kong Dollar (1 HKD=US $ 0.13).

For people with dementia, there were significant pre-post improvements in cognitive functions and behavioral and BPSD, although the results did not reach statistical significance. Furthermore, we observed a significant improvement in the happiness level of people with dementia from T0 (mean 7.67, SD 1.40) to T1 (mean 8.79, SD 1.02; P<.01; Table 5).

Table 5. Outcome measures of the technology-enhanced home-based horticultural therapy for people with dementia (N=37, one participant dropped out).

Variables	T0[a], mean (SD)	T1[b], mean (SD)	*P* value	95% CI
Happiness	7.67 (1.40)	8.79 (1.02)	<.01	–1.75 to –0.46
Cognitive functions	14.07 (6.58)	14.36 (6.55)	.61	–1.41 to 0.84
BPSD[c]	10.03 (8.26)	7.72 (5.22)	.20	–1.29 to 5.91

[a]T0: preintervention.

[b]T1: postintervention.

[c]BPSD: behavioral and psychological symptoms of dementia.

Regarding caregivers, at a descriptive level, we observed pre-post improvements in perceived stress, depressive symptoms, and happiness, although the differences did not reach a statistically significant level. Specifically, we observed significant improvements in caregiver distress from T0 (mean 12.93, SD 9.40) to T1 (mean 7.83, SD 8.01; $P<.05$; Table 6).

Table 6. Outcome measures of the technology-enhanced home-based horticultural therapy for caregivers (N=37, one participant dropped out).

Variables	T0[a], mean (SD)	T1[b], mean (SD)	*P* value	95% CI
Stress	25.72 (6.17)	25.66 (6.00)	.96	–2.89 to 3.03
Depressive symptoms	16.79 (10.70)	17.03 (9.73)	.92	–5.28 to 4.80
Positive aspects of caregiving	31.34 (8.23)	31.00 (10.29)	.89	–4.86 to 5.55
Caregiver distress	12.93 (9.40)[c]	7.83 (8.01)[c]	<.05[c]	0.16 to 10.05[c]
Happiness	6.74 (3.93)	7.08 (4.37)	.41	–1.42 to 3.35

[a]T0: preintervention.

[b]T1: postintervention.

[c]Significant effects.

Qualitative Findings

Overview

A total of 18 caregivers joined the focus group. The majority of them were either children (n=12) or spouses (n=6) of the care recipients. Overall, the qualitative findings from the focus interviews can be summarized under the themes of (1) perceived benefits and (2) perceived challenges of the technology-enhanced home-based HT.

Perceived Benefits

Under the theme of perceived benefits, we further identified four subthemes: (1) improved emotional well-being, (2) improved relationship with people with dementia, (3) increased social network among caregivers, and (4) reinforced autobiographical memory retrieval and storytelling abilities.

Improved Emotional Well-Being

Caregivers positively recalled how they had enjoyed engaging in horticultural activities at home using the smart grower. They shared their excitement at witnessing the growing process of the vegetables. One participant shared that growing vegetables alleviated her stress, as it had become a meaningful goal in her life. Additionally, she appreciated the colorful lighting of the machine, which they found to be a decorative element in their homes.

> *Seeing the growth of vegetables is like looking after a baby. The first thing I do every day is to take photos of the vegetables… I also feel happy when I see the attractive symbols on the machine, such as the stars and mountain symbols.* [P3]

The caregivers were pleased that they could enjoy the fruits of their labor. The vegetables they grew, such as carrots and lettuce, were used to create delicious dishes. They felt a sense of pride and satisfaction after receiving compliments from friends and family members who saw photos of their harvest.

Similar perspectives were also evident in people with dementia. They felt happiness and excitement about the growing process, especially during the harvest. As one caregiver shared,

> *My father was also involved in the growing of lettuce…He looked at the smart grower and watered the plant every day. He felt happy when he saw the harvest in the smart grower…He could feel the nature at home.* [P10]

Another caregiver noted that while her husband could not actively participate in the growing process, he enjoyed watching it, particularly the colorful lighting on the smart growing machine.

Improved Relationship With People With Dementia

Caregivers found that their relationship with people with dementia improved through home-based horticultural activities. As one caregiver explained,

> *I put the smart grower near the window, and my husband (people with dementia) will help to water the plant…We are taking care of the plant together…It is just like a toy for us.* [P4]

These activities offered a way for them to collaborate and grow the vegetables together.

Increase Social Network Among Caregivers

Caregivers also reported increased interaction with other caregivers through the home horticultural activities. They were able to ask questions about the smart grower and share photos of their harvest in WhatsApp groups. This facilitated the formation of new friendships, as they had a common topic to discuss.

I uploaded photos to the WhatsApp group and others posted pictures on the group. So, I see how other people's plants are growing and talk to people.(P1) We have set a WhatsApp groups. When I don't understand sometimes, I will ask in the group. The student assistants will help me in the group and other caregivers will also answer and we will discuss together in the group. [P9]

The increased social interactions were corroborated by our WhatsApp group records. Participants actively shared recipes for their harvests with each other. Some caregivers displayed their stir-fried Chinese cabbage, while others shared recipes for garlic Chinese cabbage and methods for cooking baby turnip

with chieh-qua. More noteworthy was how caregivers enthusiastically shared their planting progress and complimented each other's growing vegetables. These positive interactions led to the formation of new friendships among participants.

Reinforced Autobiographical Memory Retrieval and Storytelling Abilities

One caregiver noted that the smart grower offered an opportunity for people with dementia to reminisce about the past. The people with dementia had experience growing crops in their homeland during childhood, and the home horticultural activities revived those childhood memories. This opportunity facilitated the sharing of historical anecdotes and the exercise of cognitive abilities, such as autobiographical memory retrieval.

> *Dad is interested in gardening, as growing vegetables with this machine reminded him of his country gardening days, and every now and then he would tell us about his previous experiences.* [P13]

Difficulties

While the horticultural activities generally had positive impacts on people with dementia and their caregivers, there were also some perceived challenges. These challenges can be summarized into two subthemes: (1) operational difficulties in using the smart grower, and (2) light disturbance from the smart grower.

Operational Difficulties in Using the Smart Grower

Some caregivers found the smart grower not easy to operate due to its sophisticated design featuring many high-tech components. Issues such as Wi-Fi connection problems were encountered during use. For people with dementia with mild to moderate dependence, the complexity of the operations seemed to diminish their patience and motivation, presenting a barrier to their active participation in the entire growth process.

> *Sometimes, the elder have no caregivers to help them. So, they can't do it by themselves because they don't understand English very well. For example, the word 'reset' they can't understand. Also, they would not know what to do if the Wi-Fi disconnected.* [P13]

Light Disturbance from the Smart Grower. Additionally, other caregivers expressed concerns about the lighting emitted by the smart grower. They reported using covers or towels to minimize light disturbance at night, indicating a need for better light management features in the device.

> *The machine emits light and is very disruptive to sleep. Sleeping in a very small house is really affected. When sleeping in the living room, the light turns red and is a little scary. It may have some effect on plants, but not sure. The next day it gives off normal light again.* [P14]

Discussion

Principal Findings

This pilot study aimed to investigate the feasibility of technology-enhanced home-based HT in improving the psychological well-being of people with dementia and their caregivers. Overall, our quantitative results suggested that technology-enhanced home-based HT is a feasible dyadic intervention for both people with dementia and their caregivers. The overall attrition rate was low (2.63%), with a satisfactory completion rate (83.78%). These findings indicate that caregivers and people with dementia are receptive to using technology for engaging in horticultural activities. Further qualitative findings revealed that both people with dementia and their caregivers were excited about using the smart growing machine, as it provided a novel experience for them. They also welcomed the interactive horticultural activities and found that their relationship with each other improved as a result.

The use of technology-enhanced HT has progressively become an increasingly popular approach to delivering HT. For example, virtual reality–based HT has recently been demonstrated as a viable and effective approach in promoting positive psychological outcomes in older adults, such as enhancing self-esteem and mastery [57]. Technology-enhanced HT can mitigate limitations posed by factors such as venue and weather conditions, offering a more flexible and convenient therapeutic approach. In contrast to a virtual reality–based HT, our technology-enhanced home-based HT not only exhibits the benefits of using technologies but also allows participants to touch and feel plants in reality, which can be more relatable to the feeling of nurturing life. According to the Biophilic Hypothesis, actual human-plant interactions play a vital role in exerting the therapeutic effects of HT [58].

Our quantitative results suggested a significant reduction in caregiver distress, aligning with previous studies that used a traditional delivery mode of HT. Previous research has demonstrated that horticultural activities can alleviate the caregiving burden [23]. Our qualitative findings further suggested that home-based horticultural activities may simultaneously enable people with dementia to engage in meaningful and socially interactive experiences with their caregivers, potentially improving their relationships and alleviating caregiver distress. Moreover, our findings indicated a significant increase in happiness levels among people with dementia. These findings also corroborated previous studies using traditional HT that reported a positive emotional impact on people with dementia [59]. Our qualitative findings provided further insights that the heightened levels of subjective well-being could be attributed to participants' enthusiasm for observing plant growth and acquiring a sense of satisfaction through harvesting activities.

Overall, our findings are in line with the ART, in that perceiving plants in their natural environment has the potential to enhance attention restoration and increase persuasive effects [11,60]. Our findings are also in line with SRT, suggesting that HT is associated with positive affect, which in turn facilitates stress recovery [12,61]. Although we did not observe a significant decrease in perceived stress levels, we found an overall improvement in emotional well-being among caregivers. For example, an increase in emotional well-being is inversely correlated with elevated levels of stress and anger [62]. Consistently, HTs can reduce cortisol levels through engagement in horticultural activities, such as self-harvesting processes, and the consumption of harvested fruits and vegetables [15]. The use of social media groups also facilitated social interactions

among caregivers and provided a source of support. The mutual encouragement and compliments about each other's vegetables, along with sharing recipes for their harvest created positive interactions that extended beyond the initial horticultural activities, offering an additional benefit of alleviating caregiving stress [63-65].

Our qualitative findings suggested that some participants reminisced about their past experiences in farming during the activities. Reminiscing about past events requires the recall of autobiographical memory [66,67], and actively externalizing autobiographical memory for later retrieval (ie, reminiscing about past events) can enhance memory performance and afford greater control over memory encoding processes [68]. While previous studies have suggested that engagement in horticultural activities can enhance the cognitive abilities of people with dementia [21,22], we did not detect a significant pre-post improvement in the cognitive functions of people with dementia. It is plausible that because the MoCA is a global measure of cognition, it may partially explain why we did not detect a significant pre-post improvement in MoCA scores, despite an increasing trend descriptively, as people with dementia primarily improved in memory abilities. However, this interpretation should be made cautiously due to our small sample size. Future studies should incorporate a larger-scale RCT to further investigate the cognitive benefits of the technology-enhanced home-based HT.

Limitations

This study had several limitations. Due to the pilot nature of the research to establish the feasibility of a technology-enhanced home-based HT, a control group was not employed. Therefore, a full-scale RCT is encouraged to provide further confirmatory evidence about the effectiveness of this intervention. Furthermore, there were only 3 F-T-F sessions provided to offer training and support to the participants. This dosage may have been insufficient. In the qualitative findings, caregivers reported having technical difficulties in using the smart grower at home, such as Wi-Fi connection issues. Previous studies have found similar observations that the older population may have a lower level of readiness for home technology [69]. Therefore, the complexity of the device use may be a significant barrier to the engagement of the older population, particularly for people with dementia [70]. Consequently, it is conceivable that the program outcomes could be further enhanced with more F-T-F sessions and better integrated technical support for people with dementia and their caregivers. A more comprehensive training and support system may help address the operational difficulties encountered with the smart grower technology.

Conclusion

The findings of this pilot study support the feasibility and offer preliminary evidence of using a hydroponic indoor grower to conduct technology-enhanced home-based HT to improve the psychological well-being of people with dementia and their caregivers. There were positive effects on the emotional well-being of people with dementia and a decrease in caregiver distress. The qualitative findings further suggested improved relationships between people with dementia and caregivers. Additionally, there were potential benefits of this intervention in improving the autobiographical memory retrieval capacity of people with dementia, indicating the cognitive benefits of this intervention. Future studies are encouraged to incorporate a larger and more diverse sample to further evaluate the sustainability of the positive psychological benefits of the technology-enhanced home-based HT for people with dementia and their caregivers.

Abstract

Background: The growing aging population faces increasing mobility limitations, highlighting the need for assistive technologies as potential solutions. These technologies support the independence and well-being of older adults and individuals with mobility challenges. Indoor mobility is essential for daily activities and significantly impacts their lives. Limited indoor mobility can reduce quality of life and heighten the risk of falls.

Objective: This study explores how positive aging perceptions, quality-of-life enhancements, and social support influence the acceptance and readiness of indoor assistive technologies among older adults.

Methods: A cross-sectional study was conducted at a gerontechnology laboratory, requiring participants to visit the facility in person. Each 60-minute session included demonstrations of various indoor assistive technologies and the completion of a questionnaire. The assistive technologies showcased encompassed a wide range of devices. Participants' positive aging perceptions, quality-of-life enhancements, social support, technology acceptance, and readiness were measured using validated scales. Data were analyzed with AMOS (version 28; IBM Corp) and SPSS (version 28; IBM Corp), using structural equation modeling and multivariate analysis of covariance to assess the effects of predictors while controlling for demographic factors.

Results: A total of 104 older adults aged 60 years and older participated, with a mean age of 67.92 (SD 5.68) years. Structural equation modeling indicated that positive aging perception has a significant influence on older adults' control beliefs (P=.095), comfort (P=.047), and confidence (P<.001) in gerontechnology. Multivariate analysis revealed significant combined effects of quality-of-life enhancement (P=.01) and social support (P=.03) on technology acceptance and readiness, wherein quality-of-life enhancement (P=.001) and social support (P=.008) negatively impacted security perception. Among demographic variables, educational level significantly impacted gerontechnology confidence (P=.004) while ethnicity influenced optimism (P=.003).

Conclusions: This study sheds light on key factors affecting older adults' acceptance and readiness to adopt indoor assistive technologies. Findings highlight the importance of fostering positive aging perceptions through these technologies. Addressing issues related to control beliefs, comfort, and confidence in gerontechnology is essential to enhance technology acceptance and readiness among older adults. Future research should investigate the underlying mechanisms and create targeted interventions to support successful technology adoption in this population.

Introduction

Background

Recent years have seen an increased focus on addressing the needs of older adults and individuals with mobility challenges [1]. As the global population ages, the prevalence of mobility challenges has become a significant societal concern [2]. The World Health Organization (WHO) projects that by 2050, the number of people aged 60 years and older will reach 2 billion, with a substantial portion experiencing mobility limitations [3]. This demographic shift has intensified efforts to develop innovative solutions that support the independence and well-being of older adults and those with mobility challenges [4].

Indoor mobility, which includes activities such as sitting, standing, and walking, is essential for maintaining independence and overall well-being, especially among older adults and individuals with mobility difficulties [5,6]. Limited indoor mobility can lead to serious consequences, including an increased risk of falls and a diminished quality of life [5]. Therefore, enhancing indoor mobility is crucial for enabling these individuals to participate actively in daily activities and sustain their independence [7]. Assistive technologies, such as commodes, home care beds, and reclining wheelchairs, have emerged as solutions to address the specific needs of this population. These technologies help overcome mobility limitations and improve functional abilities [8], potentially transforming how older adults and individuals with mobility challenges interact with their living environments. Successful integration of assistive technologies requires careful selection and personalization to match the unique capabilities, needs, and preferences of each user [9].

Indoor assistive technologies encompass a wide range of tools, devices, and equipment designed to enhance and support the independence and mobility of older adults and individuals with functional limitations within indoor settings [10]. These technologies include mobility aids (eg, scooters, walkers, and wheelchairs), transfer and positioning devices (eg, grab bars, patient lifts, and reclining chairs), smart home systems (eg, automated lighting and voice-controlled appliances), and various adaptive equipment (eg, bed rails, shower chairs, and toilet risers). Tailored to address the specific challenges faced by older adults and those with mobility challenges, these technologies facilitate daily activities and help maintain independence at home and in other indoor environments [11]. Through targeted support to increase functional capacity, indoor assistive technologies empower older adults and individuals with mobility challenges, enhancing their daily lives [12] and improving overall quality of life and well-being [13,14].

Gerontechnology, the intersection of gerontology and advanced technology, aims to enhance the health, independence, and quality of life of older adults [15]. Incorporating gerontechnological advancements into indoor assistive technologies addresses the unique challenges faced by this population, fostering greater independence and well-being [15]. Examples of gerontechnology applications include advanced mobility aids such as smart walkers and wheelchairs, cognitive support tools such as memory aids and smart home systems, and social engagement platforms such as web-based communication tools [16]. These technologies assist older adults in maintaining physical movement, performing daily activities, and reducing social isolation, thereby creating an environment where they can live independently and with dignity. Acceptance and readiness to adopt these technologies are influenced by positive aging perceptions, enhanced quality of life, and social support systems. This study examines how these factors drive technology acceptance and readiness among older adults, ultimately improving their lives through indoor assistive technologies.

Theoretical Background

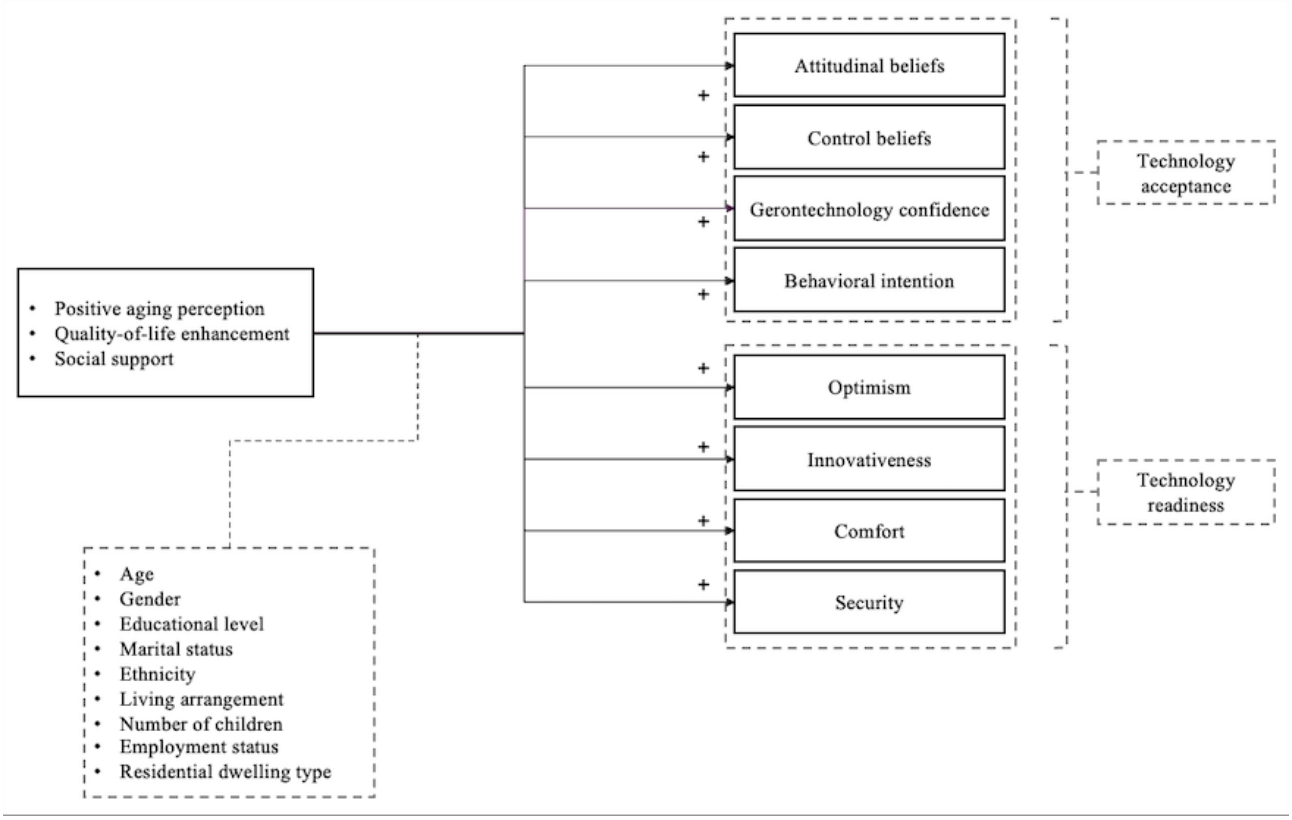
This study is grounded in the Theory of Planned Behavior (TPB) [17]. The TPB posits that individuals' behavioral intentions are influenced by 3 primary constructs: attitudes, subjective norms, and perceived behavioral control. In the context of this study, attitudes represent older adults' overall evaluation and perception of indoor assistive technologies. This study investigates whether older adults who hold a positive aging perception and believe that assistive technologies enhance their quality of life are more likely to adopt and use these technologies [18,19].

Subjective norms within the TPB refer to the social influences and societal expectations that shape an individual's behavior [20]. In this study, subjective norms are assessed through the role of social support—specifically, the assistance provided by family and friends—in influencing the acceptance and readiness to adopt indoor assistive technologies among older adults.

Perceived behavioral control is another critical construct of the TPB, encompassing individuals' beliefs and perceptions about their ability to perform a specific behavior [21,22]. This study measures perceived behavioral control by evaluating older adults' perceptions of their confidence and readiness to adopt and use indoor assistive technologies.

Applying the TPB enables this study to identify the factors that drive various aspects of older adults' acceptance and readiness to embrace indoor assistive technologies. Such insights are valuable for developing interventions and strategies aimed at promoting engagement, well-being, and overall quality of life among older adults [23]. The study's conceptual model is illustrated in Figure 1.

Figure 1. Study conceptual model.



Recognizing the needs of older adults with diminished mobility highlights the importance of creating innovative strategies to enhance their independence and physical and psychological well-being [1]. Although existing studies have examined the perceptions of technologies among older adults with and without disabilities or impairments, there remains a need for more evidence-based research focused on the specific factors that influence the acceptance and readiness to adopt indoor assistive technologies. Understanding these factors can provide promising pathways for improving indoor mobility and enhancing the quality of life for this population [13,22].

Previous research has explored various dimensions of indoor assistive technologies. For example, Gitlin et al [24] discovered that assistive devices and home modifications significantly improved functional abilities and reduced the risk of falls among older adults, indicating positive attitudes toward these technologies. Similarly, several studies have shown that the use of assistive devices in home environments leads to increased independence and reduced caregiver burden [15,25], underscoring the role of social support in technology acceptance. In addition, Demiris et al [26] and Liu et al [27] examined older adults' perceptions of their ability to use smart home technologies, aligning with the concept of perceived behavioral control in the TPB [17]. More recent studies, such as Peek et al [19], have identified key factors influencing the acceptance of technology for aging in place, including perceived ease of use, usefulness, and social influence, while Mitzner et al [28] highlighted the importance of user experience in technology acceptance among older adults. These studies provide empirical evidence supporting the benefits of indoor assistive technologies and emphasize the necessity of understanding user acceptance and readiness.

The global demographic shift toward an aging population and the rising prevalence of mobility limitations present urgent challenges that must be addressed. With the projected increase in the number of older adults, developing interventions and strategies that effectively cater to their unique needs and preferences becomes crucial [4]. To achieve a comprehensive understanding of older adults' needs regarding assistive technologies, targeted strategies must investigate their perspectives, acceptance, and readiness of aging in relation to indoor assistive technologies. Conducting such research can bridge existing knowledge gaps and inform the creation of strategies tailored to the specific needs of older adults, ultimately enhancing their overall independence and well-being [5].

This study aims to explore the influences of positive aging perception, quality-of-life enhancement through assistive technologies, and social support on technology acceptance and readiness among older adults in an indoor setting. Specifically, this study seeks to understand how these factors interact and contribute to older adults' attitudes and readiness to adopt and use indoor assistive technologies. The hypothesis posits that a positive aging perception, improved quality of life, and supportive social relationships positively affect older adults' technology acceptance, including attitudinal beliefs, control beliefs, confidence in gerontechnology, and behavioral intention. It is further hypothesized that these factors also positively impact older adults' readiness, which encompasses comfort, innovativeness, optimism, and security.

Methods

Study Setting

This study used a cross-sectional experiential design conducted at a gerontechnology laboratory located at an Australian university's international branch campus in Malaysia. Participants were required to visit the laboratory in person to take part in the study. Each session lasted approximately 60 minutes and included active participation in demonstrations of various indoor assistive technologies, followed by the completion of a questionnaire. The assistive technology demonstrations encompassed a wide range of devices tailored to support mobility.

Participants Recruitment

Recruitment efforts targeted individuals through advertisements placed across multiple social media platforms and in universities. Interested participants registered their interest by completing an online registration form through Google Forms or by contacting the provided phone number. Eligibility criteria were established to ensure suitable participation, including being aged 60 years or older; not having severe mobility challenges that would prevent full engagement in the experiential session; the ability to attend the demonstration session; and the capacity to provide written informed consent. These criteria ensured that participants could actively engage in the study activities and provide meaningful feedback on the assistive technologies demonstrated.

Study Design

Participants engaged in an experiential session featuring various indoor assistive technologies (given in Figure 2A-J). Each demonstrated device is specifically designed to support older adults and individuals with mobility challenges within their living environments [29]. The session included the following technologies: The SafeFree handling side guard and home care bed (Figure 2A) provide safe and comfortable support for resting, sleeping, and transferring activities within the home. The transfer roller kit board (Figure 2B) assists with safe transfers from beds, chairs, or the floor, enhancing indoor mobility. The tilt and reclining wheelchair (Figure 2C) allows users to adjust their position and posture to perform different activities at home. The shower commode chair (Figure 2D) enables individuals to bathe and use the toilet safely within their living spaces. The commode with a mobile pan (Figure 2E) offers discreet and convenient toileting support indoors. The recliner and stand-up sofa (Figure 2F) incorporate features that aid in sitting, standing, and repositioning for those with mobility challenges. The antislip seating mat (Figure 2G) enhances stability and safety on various seating surfaces within the home. The carbon fiber quad cane (Figure 2H) provides additional support and stability for individuals with limited mobility. The 3-in-1 stand assist walker (Figure 2I) supports users in performing various daily activities safely indoors. Finally, the nonintrusive activity-based sensor monitoring system (Figure 2J) offers remote monitoring and support for individuals in their living spaces.

Figure 2. Assistive technologies demonstrated in the experiential session: (A) handling side guard and home care bed; (B) transfer roller kit board; (C) tilt and reclining wheelchair; (D) shower commode chair; (E) commode with mobile pan; (F) recliner and stand-up sofa; (G) antislip seating mat; (H) carbon fiber quad cane; (I) 3-in-1 stand assist walker; and (J) nonintrusive activity-based sensor monitoring system.

A trained research assistant conducted the demonstrations to ensure consistency and quality throughout the session. Each participant received personalized attention from a single research assistant to maintain fidelity. The research team reviewed and approved all demonstration materials to ensure accuracy and effectiveness. Before the study, the research assistant conducted a trial demonstration for the research team, evaluating the clarity and conveyance of the content. In addition, a research team member conducted random visits to demonstration sessions to verify that the content remained consistent and adhered to the predetermined standards.

Outcome Measures

Participants were assessed after the demonstration session using a questionnaire divided into 5 main sections: positive aging

perception, quality-of-life enhancement, social support, technology acceptance, and technology readiness.

Positive Aging Perception

The Awareness of Age-Related Change (AARC) questionnaire [30] was used to assess participants' positive aging perception. A total of 10 items were selected for this study, using a 5-point Likert scale ranging from 1 (not at all) to 5 (very much). The internal consistency reliability demonstrated strong results for both AARC-Gains (α=.82) and AARC-Losses (α=.78) [31].

Quality-of-Life Enhancement

Quality-of-life enhancement was measured based on Moxley et al [32]. This section comprised 5 items evaluated using a 7-point Likert scale, from 1 (Not at all) to 7 (A lot). The items specifically addressed the extent to which assistive technologies can improve the quality of life for older adults. This scale has been widely adopted in gerontechnology research including studies by Dale et al [33].

Social Support

Social support was assessed using a 5-item scale adapted from Moxley et al [32]. This scale evaluated the level of assistance required from family and friends in becoming proficient with the presented technologies. Responses were measured on a 7-point Likert scale, ranging from 1 (Not at all) to 7 (A lot). The scale's widespread use in gerontechnology research, as demonstrated by its application in Dale et al [33], underscores its validity and reliability.

Technology Acceptance

Technology acceptance was evaluated using the Senior Technology Acceptance Model questionnaire, adapted from Chen and Lou [34] and Venkatesh et al [35]. This instrument included 4 variables: attitudinal beliefs (3 items), control beliefs (4 items), gerontechnology confidence (gerontechnology anxiety; 2 items), and behavioral intention (3 items). Participants responded on a 7-point Likert scale, from 1 (Strongly disagree) to 7 (Strongly agree). The questionnaire demonstrated strong internal consistency, with α values ranging from 0.96 to 0.97 [36]. Its widespread adoption across various fields highlights its effectiveness in assessing users' perceptions and attitudes toward technology adoption and utilization [37].

Technology Readiness

The Technology Readiness Questionnaire (TRQ) developed by Parasuraman and Colby [38] was used to measure participants' readiness and willingness to embrace technology. The TRQ includes 4 dimensions: comfort, innovativeness, optimism, and security, with 4 items assigned to each dimension. Participants rated each item on a 5-point Likert scale, where higher scores indicated a greater inclination to adopt and use technology. The TRQ's extensive application in aging-related research emphasizes its relevance in evaluating individuals' attitudes and preparedness for technology adoption [39].

Analytical Techniques

The measurement model was validated using confirmatory factor analysis (CFA) with SPSS (version 28.0; IBM Corp) and AMOS (version 28; IBM Corp). CFA evaluated the validity of the measurement model by examining the relationships between observed variables and their underlying latent constructs. A total of 8 key goodness-of-fit indices, recommended by Hu and Bentler [40], were used to assess the model fit. These indices included Cronbach α, chi-square and its respective degrees of freedom (χ^2/df), goodness-of-fit index (GFI), incremental fit index (IFI), comparative fit index (CFI), Tucker-Lewis index (TLI), root mean square error of approximation (RMSEA), and parsimony goodness-of-fit index (PGFI).

Descriptive statistics summarized the demographic variables, providing the mean and SD for each measure to offer an overview of the sample characteristics. Correlation analysis was performed to provide a preliminary assessment of the relationships between variables, while structural equation modeling explored the main relationships between predictor and outcome variables. Multivariate analysis of covariance (MANCOVA) was used as a post hoc analysis to scrutinize the effects of predictor variables on outcome variables while controlling for demographic characteristics such as age, gender, education level, and ethnicity. Wilks lambda (λ) was used to assess multivariate effects, followed by univariate analyses to identify specific between-subjects effects. Effect sizes were reported using partial eta squared (η^2). Statistical significance was set at $P<.05$, with marginal significance noted at $P<.10$.

Ethical Considerations

The research protocol was developed by Monash University Malaysia, and study approval was granted by the Monash University Human Research Ethics Committee (project ID: 39857; review reference: 2023-39857-98651) in September 2023. All participants provided written informed consent and received a token of appreciation of RM 50 (approximately US $11.2) for their participation. To ensure participant confidentiality, all collected data will be anonymized. In instances where full anonymization is not possible, strict protective measures will be implemented, including secure data storage and restricted access to authorized personnel only, to safeguard participant information.

Results

Participant Characteristics

A total of 104 older adults participated in the study, with an average mean age of 67.92 (SD 5.68) years. The sample comprised 58.7% (61/104) women and 41.3% (43/104) men. Educational levels varied, including 2.9% (3/104) with primary education and below, 24% (25/104) with secondary education, 27.9% (29/104) holding a diploma or preuniversity qualification, 29.8% (31/104) possessing a degree or professional certification, and 15.4% (16/104) with postgraduate degrees. Most participants were married (73/104, 70.2%), followed by those who were never married (5.8%, 6/104), divorced (9/104, 8.7%), widowed or widowers (10/104, 9.6%), separated (5/104, 4.8%), and others (1/104, 1%). Ethnically, the majority identified as Chinese (86/104, 82.7%), with smaller representations of Indian (16/104, 15.4%), Malay (1/104, 1%), and other ethnicities (1/104, 1%). Regarding living arrangements, 78.8% (82/104) resided with household members, 17.3% (18/104) lived alone, and 3.8% (4/104) had other living situations. Participants reported having

varying numbers of children, with 14.4% (15/104) having none, 14.4% (15/104) having 1 child, 32.7% (34/104) having 2 children, 32.7% (34/104) having 3 children, 1.9% (2/104) having 4 children, and 2.9% (3/104) having 5 children. In terms of employment status, 57.7% (60/104) were private retirees, 11.5% (12/104) were government retirees (including pensioners), 8.7% (9/104) were self-employed, 5.8% (6/104) were private sector employees, 7.7% (8/104) were homemakers, 5.8% (6/104) were unemployed, and 2.9% (3/104) were in other categories. The majority of participants lived in terraced, linked houses, or semidetached homes (60/104, 57.7%), followed by flats, apartments, condominiums, or townhouses (34/104, 32.7%); detached houses (9/104, 8.7%); and other dwelling types (1/104, 1%). Statistical analysis revealed that living arrangements significantly varied within the sample (P=.002), while other demographic variables did not show significant differences (Table 1).

Table 1. Demographic information (N=104).

Demographics	Values	*P* value
Age (years), mean (SD)	67.92 (5.68)	.22
Gender, n (%)		.08
Men	43 (41.3)	
Women	61 (58.7)	
Educational level, n (%)		.97
Primary school and below	3 (2.9)	
Secondary school	25 (24)	
Diploma or preuniversity	29 (27.9)	
Degree or professional	31 (29.8)	
Postgraduate	16 (15.4)	
Marital status, n (%)		.16
Never married	6 (5.8)	
Married	73 (70.2)

Demographics	Values	*P* value
Flat, apartment, condominium, or townhouse	34 (32.7)	
Detached house (bungalow or traditional house)	9 (8.7)	
Terrace, link house, or semidetached	60 (57.7)	
Others	1 (1)	

Correlations

The correlation analysis in Table 2 identified several significant relationships among the study variables. Age positively correlated with marital status (r= 0.278; P=.004), indicating that older participants were more likely to be married. Gender exhibited a significant negative correlation with living arrangements (r=–0.309; P=.001), suggesting that women were more likely to live with household members compared with men. Educational level was negatively associated with employment status (r=–0.233; P=.02). Residential dwelling type showed a positive correlation with living arrangements (r=0.397; P<.001) and the number of children (r=0.207; P=.04), indicating that certain housing types were more common among those living with more children. Quality-of-life enhancement was negatively related to age (r=–0.220; P=.02) and educational level (r=–0.201; P=.04). Social support positively correlated with quality-of-life enhancement (r=0.223; P=.02) and negatively correlated with gerontechnology confidence (r=–0.317; P=.001). Behavioral intention was positively associated with quality-of-life enhancement (r=0.246; P=.01), attitudinal beliefs (r=0.275; P=.005), control beliefs (r=0.396; P<.001), gerontechnology confidence (r=0.206; P=.04), optimism (r=0.428; P<.001), and innovativeness (r=0.204; P=.04). These correlations offer preliminary insights on how demographic factors and positive perceptions of aging, quality of life, and social support influence technology acceptance and readiness among older adults.

[a]Not applicable.

[b]Gender: 1=men and 2=women.

[c]Educational level: 1=primary school and below, 2=secondary school, 3=diploma or preuniversity, 4=degree or professional, and 5=postgraduate.

[d]Marital status: 1=never married, 2=married, 3=separated, 4=divorcee, 5=widow or widower, and 6=others.

[e]Ethnicity: 1=Malay, 2=Chinese, 3=Indian, 4=others.

[f]Living arrangement: 1=living alone, 2=living with household members, and 3=others.

[g]Employment status: 1=private sector employee, 2=self-employed, 3=government retiree (includes pensioners), 4=private retiree, 5=homemaker, 6=unemployed, and 7=others.

[h]Residential dwelling type: 1=flat, apartment, condominium, or townhouse; 2=detached house (bungalow or traditional house); 3=terrace, link house, or semidetached; 4=others.

Measurement Model

The measurement model was validated via CFA. The Cronbach α values for positive aging perception, quality-of-life enhancement, social support, technology acceptance, and technology readiness were 0.736, 0.855, 0.815, 0.740, and 0.731, respectively, demonstrating acceptable internal consistency.

Model fit indices were as follows: χ^2_{752}=1069.140, *P*<.001; GFI=0.703; IFI=0.858; CFI=0.850; TLI=0.829; RMSEA=0.064; and PGFI=0.585. These values met the recommended thresholds, indicating a moderately acceptable model fit [40].

Structural Model

The structural model was tested via structural equation modeling (Table 3), illustrating how positive aging perception, quality-of-life enhancement, and social support relate to various aspects of technology acceptance and readiness among older adults. Positive aging perception significantly enhanced gerontechnology confidence (β=.462; *P*<.001) and comfort (β=.323; *P*=.047) and exhibited a marginally significant positive relationship with control beliefs (β=.228; *P*=.095). In contrast, quality-of-life enhancement and social support did not show significant effects on any of the technology acceptance or readiness components. These findings suggest that positive aging perception plays a crucial role in fostering confidence and comfort with gerontechnology, whereas quality-of-life enhancement and social support have limited impacts on technology acceptance and readiness within this population.

Table 3. Structural equation modeling results.

Path	Standardized coefficient (β)	Unstandardized coefficient (B)	SE	*t* value	*P* value

Post hoc Observations

The MANCOVA assessed the combined effects of independent variables and demographic factors on technology acceptance and readiness among older adults (Tables 4 and 5). The analysis revealed that positive aging perception did not significantly influence the various aspects of technology acceptance and readiness when controlling for demographic characteristics (Wilks λ=0.897, $F_{8,61}$=0.877, *P*=.54, partial η^2=0.103). This consistency reinforces the structural model findings, indicating that the relationships between positive aging perception and factors such as control beliefs, comfort, and gerontechnology confidence remain stable across different demographic groups. Conversely, quality-of-life enhancement (Wilks λ=0.737, $F_{8,61}$=2.717, *P*=.01, partial η^2=0.263) and social support (Wilks

λ=0.762, $F_{8,61}$=2.387, *P*=.03, partial η²=0.238) significantly impacted technology acceptance and readiness. A closer examination showed that both quality-of-life enhancement (*P*=.001) and social support (*P*=.008) negatively influenced security perceptions, suggesting that improvements in these areas are associated with reduced concerns about the security of assistive technologies. In addition, demographic factors played a notable role: educational level significantly predicted gerontechnology confidence (β=29.548, *P*=.004, partial η²=0.201) and ethnicity was a significant predictor of optimism (β=3.373, *P*=.003, partial η²=0.187). These findings indicate that while positive aging perceptions consistently affect certain aspects of technology acceptance, quality-of-life enhancements and social support are crucial in shaping specific perceptions such as security. Furthermore, educational attainment and ethnic background influence confidence and optimism regarding technology use. These granular insights highlight the importance of addressing both demographic and psychological factors to foster effective adoption and readiness for indoor assistive technologies among older adults. Further explanation is provided in the Discussion section.

Table 4. Multivariate analysis of covariance on the effects of predictor variables while controlling for demographic characteristics.

Variables	Wilks λ	*F* value (*df*)	*P* value	Partial η²
Predictor variables				
Positive aging perception	0.897	0.877 (8, 61)	.54	0.103

Security	0.401	0.101	1.339 (7, 95)	.15

Discussion

Principal Findings

This study explored the relationships between positive aging perception, quality-of-life enhancement, social support, and various factors related to technology acceptance and readiness among older adults.

The preliminary analysis using correlation analysis revealed significant associations between demographic factors and key variables, such as age being positively related to marital status and negatively associated with quality-of-life enhancement and gerontechnology confidence; educational level being negatively correlated with living arrangements and gerontechnology confidence; and social support being positively correlated with quality-of-life enhancement. These insights suggest that the older adults who participated in this study predominantly consisted of married individuals with varying educational backgrounds, most of whom lived with household members and received substantial social support, which in turn influenced their perceptions and confidence regarding assistive technologies.

The primary analysis using structural equation modeling indicated that a positive perception of aging significantly enhances gerontechnology confidence and comfort, with a marginal positive relationship with control beliefs. These findings suggest that older adults who maintain a positive outlook on aging are more confident and comfortable with using gerontechnology, which aligns with existing literature emphasizing the role of positive aging attitudes in technology adoption [41,42]. However, quality-of-life enhancement and social support did not exhibit significant direct effects on most components of technology acceptance and readiness within the structural model. This contrasts with some previous studies that highlighted the importance of these factors in technology adoption [43,44], indicating that their influence may be more complex or mediated by other variables not captured in this model.

The post hoc analysis using MANCOVA further revealed that quality-of-life enhancement and social support significantly impact technology acceptance and readiness when controlling for demographic characteristics. Specifically, both quality-of-life enhancement and social support were found to negatively influence security perceptions, suggesting that as these factors increase, concerns about the security of assistive technologies decrease. This negative influence on security perceptions could be explained by demographic factors such as educational level and ethnicity. Educational level significantly predicted gerontechnology confidence, indicating that individuals with higher education may feel more confident in using technology, thereby reducing their security concerns. Similarly, ethnicity emerged as a significant predictor of optimism, suggesting that cultural or social backgrounds influence positive expectations toward technology, which can also alleviate security apprehensions. These findings highlight that while quality-of-life enhancements and social support do not directly influence the larger set of technology acceptance factors, they play a crucial role in alleviating security-related concerns, which are vital for the overall readiness to adopt assistive technologies.

Interestingly, social support showed negative associations with gerontechnology confidence and security perceptions in the structural model, although these were not statistically significant. This counterintuitive finding, if significant, may indicate that excessive reliance on social support could undermine individuals' confidence in using technology independently or heighten concerns about privacy and security. Such dynamics, which contrast past observations [45-48], warrant further investigation to understand the complex role of social support in technology adoption among older adults. One possible explanation is the influence of social norms, where older adults may experience expectations or pressures from their social networks that discourage full technological engagement [49]. An overreliance on assistance from others might also reduce the perceived need for technology, leading to decreased confidence and increased security concerns. Privacy and trust issues related to technology could also contribute to these negative relationships, as older adults may fear privacy breaches or distrust the reliability of assistive technologies [50,51].

The significant influence of demographic characteristics, particularly educational level and ethnicity, emphasizes the importance of considering sociodemographic factors in technology acceptance models. Higher educational levels were associated with greater confidence in using gerontechnology, likely due to better technological literacy and problem-solving skills acquired through education. Ethnic background influencing optimism suggests that cultural factors play a role in shaping positive attitudes toward technology adoption. These findings extend previous research [43,52] by quantifying the impact of these demographic factors and highlighting their specific effects on different aspects of technology acceptance.

Contrary to initial expectations, this study did not find significant associations between positive aging perception and several factors, including attitudinal beliefs, behavioral intention, innovativeness, optimism, and security, whereas quality-of-life enhancement and social support did not produce significant relationships. This may suggest that older adults' attitudes toward indoor assistive technologies may be more complex or mediated by other factors such as perceived need, technology complexity, or previous experience with similar devices that were not considered in this study [19,49]. While the lack of significant associations may seem surprising, it is important to acknowledge that the adoption and acceptance of assistive technologies among older adults are influenced by multifaceted factors [53]. The variables examined herein might be influenced by additional variables or interact with each other in ways that were not captured in this particular study. Future studies could explore other variables or contextual factors, such as cognitive abilities, physical health, technological literacy, or specific characteristics of the assistive technologies themselves, to develop more comprehensive models of technology acceptance among older adults [54].

Implications and Recommendations

This study underscores the importance of fostering positive aging perceptions to enhance gerontechnology confidence and

comfort among older adults. To achieve this, stakeholders should develop and implement educational programs and workshops that clearly demonstrate the benefits and practical applications of assistive technologies. These initiatives can help older adults build a more optimistic outlook on aging and increase their confidence in using these devices effectively.

Integrating quality-of-life enhancements and social support into the design and implementation of assistive technologies is crucial for addressing security concerns. Assistive devices should incorporate features that directly improve users' daily living experiences, such as intuitive user interfaces and robust safety mechanisms. These enhancements can help reduce apprehensions about the reliability and security of the technologies, making them more acceptable and trustworthy for older adults.

Demographic factors, including educational level and ethnicity, significantly influence technology confidence and optimism. To accommodate varying educational backgrounds, assistive technology solutions should offer clear instructions, accessible interfaces, and comprehensive training materials. Technologies should also be culturally tailored to respect and integrate the diverse cultural preferences of different ethnic groups. This cultural sensitivity can promote greater acceptance and positive attitudes toward the use of assistive technologies among ethnically diverse populations.

The negative associations observed between social support and gerontechnology confidence and security perceptions indicate that excessive reliance on social networks might undermine independent technology use and heighten security concerns. To address this, support systems should be designed to empower older adults to use assistive technologies independently. Training programs for caregivers and family members should focus on encouraging autonomous use of technology rather than providing constant assistance. Addressing privacy and trust issues through transparent data handling practices and robust security features should further help alleviate security concerns, thereby enhancing older adults' readiness to adopt assistive technologies.

To this end, enhancing technology acceptance and readiness among older adults requires a comprehensive approach that includes promoting positive aging attitudes, improving quality of life through targeted technology features, tailoring solutions to meet diverse educational and cultural backgrounds, and structuring social support to foster independence. Implementing these strategies should facilitate the effective adoption of indoor assistive technologies, ultimately improving the independence and well-being of older adults.

Limitations and Future Directions

This study presents several limitations that should be considered when interpreting the findings. First, the sample comprised older adults aged 60 years and older who participated in an indoor setting, predominantly Chinese and married, with most living with household members. While this demographic reflects typical patterns in urban Malaysian environments, it may limit the generalizability of the results to wider populations, including those in rural areas or living in assisted living facilities. Future research should use stratified sampling techniques to include a more diverse range of settings and demographics, enhancing the applicability of the findings across different contexts.

Second, the cross-sectional design of the study restricts the ability to establish causal relationships between variables. The associations identified provide a snapshot at a specific point in time but do not account for changes and developments over time. Longitudinal studies or experimental designs would be beneficial in examining the causal effects and temporal dynamics between positive aging perception, quality-of-life enhancement, social support, and technology acceptance and readiness.

Third, reliance on self-report measures to assess constructs such as positive aging perception, quality-of-life enhancement, social support, and technology acceptance introduces potential biases, including social desirability and recall bias. These biases may affect the accuracy of the data collected. Future studies could incorporate objective measures or combine self-report instruments with other assessment methods to achieve a more comprehensive understanding of these constructs.

Fourth, this study focused on specific variables—positive aging perception, quality-of-life enhancement, and social support—to explore their influence on technology acceptance and readiness. Other relevant factors, such as cognitive abilities, physical health, technological literacy, and specific characteristics of assistive technologies, were not included in the analysis. Incorporating a wider range of variables in future research would provide a more comprehensive view of the factors influencing older adults' technology acceptance and readiness. Using a multidimensional framework could capture the complex interactions among various factors more effectively.

Finally, the sample primarily consisted of Malaysian participants living in urban areas, which limits the diversity and generalizability of the findings to other cultural or demographic groups. Future studies should endeavor to include a more varied sample to examine potential cultural or contextual differences in the relationships between the variables. Using cross-cultural research designs or multisite studies can help identify and account for cultural and contextual variations, thereby enhancing the relevance and applicability of the findings across different populations.

Conclusion

Understanding the factors that influence older adults' acceptance and readiness to adopt indoor assistive technologies is essential for enhancing their independence and well-being. This study demonstrates that a positive perception of aging significantly increases gerontechnology confidence and comfort among older adults, while quality-of-life enhancements and social support play crucial roles in reducing security concerns related to technology use. Demographic factors, particularly educational level and ethnicity, also significantly influence confidence and optimism toward technology adoption. These insights highlight the need for targeted strategies to effectively promote the adoption of assistive technologies. Future research should explore the underlying mechanisms that drive these relationships and develop customized interventions to support successful technology integration among older adults.

Acknowledgments

This study was supported by the AGELESS research program funded by the Malaysian Ministry of Higher Education Long Term Research Grant Scheme (LRGS/1/2019/UM/01/1/1, LR005-2019, GOV-000047). We also extend our gratitude to Asian Integrated Medical Sdn Bhd for the loan of assistive technologies, which were used solely for demonstration purposes within the scope of this study.

Abstract

Background: Despite their potential, the use of serious games within immersive virtual reality (iVR) for enhancing motor skills in older adults remains relatively unexplored. In this study, we developed a self-adaptive serious game in iVR called REAsmash-iVR. This game involves swiftly locating and striking a digital mole presented with various distractors.

Objective: This short-term longitudinal pre-post study aims to evaluate REAsmash-iVR's efficacy in promoting motor learning in older adults. Specifically, we seek to determine the transfer and retention of motor learning achieved through REAsmash-iVR to other iVR tasks.

Methods: A total of 20 older adults participated in the study, engaging with REAsmash-iVR over 7 consecutive days. The evaluation included iVR tests such as KinematicsVR and a VR adaptation of the Box and Block Test (BBT-VR). KinematicsVR tasks included drawing straight lines and circles as fast and as accurately as possible, while BBT-VR required participants to move digital cubes as quickly as possible within 60 seconds. Assessments were conducted before and after the intervention, with a follow-up at 1 week post intervention. The primary outcome focused on evaluating the impact of REAsmash-iVR on speed-accuracy trade-off during KinematicsVR tasks. Secondary outcomes included analyzing movement smoothness, measured by spectral arc length, and BBT-VR scores.

Results: Results revealed significant improvements in speed-accuracy trade-off post intervention compared to that before the intervention, with notable retention of skills for straight lines (t_{19}=5.46; P<.001; Cohen d=1.13) and circle drawing (t_{19}=3.84; P=.001; Cohen d=0.787). Likewise, there was a significant enhancement in spectral arc length, particularly for circle drawing (χ^2_2=11.2; P=.004; ε^2=0.23), but not for straight-line drawing (χ^2_2=2.1; P=.35; ε^2=0.003). Additionally, participants demonstrated transfer with significant improvement (q=5.26; P<.001; Cohen r=0.678) and retention (q=6.82; P<.001; Cohen r=0.880) in BBT-VR skills.

Conclusions: These findings provide perspectives for the use of iVR to improve motor learning in older adults through delivering self-adaptive serious games targeting motor and cognitive functions.

Introduction

By 2050, the proportion of older adults (older than 65 years) worldwide will nearly reach 22% [1,2]. Within the population, some older adults experience progressive functional decline, encompassing both motor and cognitive aspects [3]. This decline exacerbates issues of inactivity and sedentariness [4] contributing to increased prevalence of age-related diseases [5,6]. As an illustration, it is projected that by the year 2050, the number of individuals affected by major neurocognitive disorders will surge from 50 to 152 million worldwide, marking a 3-fold increase in cases [7].

Older adults' functional decline is typically associated with lower motor functions [8] and reduced quality of life [9,10]. Consequently, older adults tend to adopt compensatory behaviors that mitigate the impact of these reduced functions on their daily living activities [11]. These behavioral compensations include making slower, less accurate, less linear, and less smooth movements [12,13].

Motor learning refers to any experience-dependent improvement of a skill and typically involves both motor and cognitive processes [14]. Once learned, motor skills can be retained for an extended duration, resulting in sustained enhancements in performance [14]. A skill is not deemed fully acquired until the ability to retain or apply it in different contexts is demonstrated [15]. Research suggests that both healthy older adults and those with neurocognitive disorders can improve their motor performance through motor learning, exhibiting enhancements in movement speed, smoothness, coordination, and accuracy [16,17]. However, current motor learning programs mainly focus on gait and balance and therefore, demand time and availability from caregivers [18]. In response to these demands, new portable devices with cost-saving potential such as virtual reality (VR) might be of interest to promote motor learning in older adults.

VR can be defined as a computerized technological system that allows users to interact with a simulated multisensorial environment while providing real-time performance feedback [19]. Two main types of VR experience exist. Nonimmersive VR (niVR) is where users maintain awareness of their physical surroundings and receive visual feedback via a 2D display. Immersive VR (iVR) facilitates total immersion in the digital environment (using a head-mounted display or a large, curved screen with a panoramic view), with a comprehensive panoramic perspective [20]. Recent research suggests that VR programs may enhance participants' level of physical activity [21] and cognitive skills such as reaction time [22].

In rehabilitation, VR devices are often combined with serious games. Serious games refer to any game-based initiative that primarily focuses on learning objectives (such as education or rehabilitation) rather than simple entertainment [23]. Serious games have the capability to fulfill motor learning principles [24-26], as they motivate participants to make numerous practice repetitions through the use of multisensory feedback, personalized challenges, and through use of compelling and enriched environments [27,28]. After a certain period of familiarization, VR devices may allow participants to follow self-directed interventions and complete remote assessment of objective motor and cognitive performance (eg, analysis of kinematics and reaction time) during interventions [29]. However, despite the potential, the use of serious games in VR to promote motor learning in older adults remains underexplored [30]. In addition, the generalization of skills acquired in iVR to other skills in iVR remains debated.

A recent review has proposed intriguing methods to enhance the comprehension of motor learning in VR, including tracking participants' kinematics, manipulating sensorial feedback and difficulty parameters, and precisely simulating VR physics [27]. Prior work showed that kinematic indexes acquired in iVR (eg, movement linearity) were reliable and could possibly differentiate hand movements between healthy older adults and those with major neurocognitive disorders [31]. Additionally, several studies have provided evidence to support the idea that the provisioning of haptic and visual feedback in VR positively influenced movement smoothness, accuracy, and rapidity, thereby contributing to the improvement of motor learning in VR [32-35]. Recent evidence also highlights the efficacy of incorporating bimanual tasks in VR for promoting unimanual motor learning, aligning with the notion that the acquisition of motor skills in a digital environment can be optimized when the tasks closely mimic the complexities of everyday activities [36-38]. In line with the Yerkes-Dodson law, there is also evidence indicating that to maintain participants' motivation, the level of difficulty should be optimally balanced, neither too hard nor too easy [39]. To achieve this optimal balance, research suggests that game difficulty should be adjustable and tailored to individual participants' motor and cognitive performance [29,40,41]. Research supports the idea that self-adaptive training, where the difficulty is adjusted based on real-time performance, can optimize learning [42]. For instance, 1 study has highlighted that individualized VR training for driving led to more effective learning and retention of performance compared to traditional VR, video, and manual training [43]. The literature indicates success rates ranging from 60% to 80% as ideal for effectively enhancing participants' motivation [40,44].

Regarding older adults, several studies have demonstrated that motor learning in VR can be effective, resulting in improvements in motor performance along with the retention of learned skills over time. For example, a longitudinal study found that both healthy older adults and those with Parkinson disease were able to achieve learning and retention of skills

across 10 different niVR games, with effective transfer of these skills to similar untrained tasks [45]. While these results are promising for niVR, the retention of iVR skills and transfer to other tasks remains underexplored. A recent multicentric large parallel randomized controlled trial (n=293) has nevertheless produced encouraging results, demonstrating that progressive cognitive-motor training in iVR was effective in older adults, with greater improvements in global cognition and physical frailty compared to traditional interventions [46].

Following current recommendations aiming at improving motor learning in older adults, we developed a self-adaptive serious game in iVR (REAsmash-iVR) [47]. This game consists of finding and hitting a digital mole as fast as possible when presented with different types of distractors. In this version, we use a regulator to continuously adapt exercise difficulty according to participants' performance. As this version has not yet been tested among older adults, this work aims to test the feasibility and effectiveness of REAsmash-iVR in promoting motor learning within this population. Specifically, we sought to determine the transfer and retention of motor learning achieved through REAsmash-iVR to other iVR tasks. We hypothesized that REAsmash-iVR would significantly improve participants' unimanual reaching velocity and accuracy in other iVR tasks. We also aimed to assess the effect of REAsmash-iVR on participants' simple reaction time.

Methods

Study Design

This study used a short-term longitudinal pre-post design, with data collected at 3 time points: baseline (T0), immediate postintervention (T1), and 1-week follow-up (T2). This design allowed us to assess both immediate and retained motor learning effects, aligning with established motor learning literature for intermediate-term retention and transfer [39].

Ethical Considerations

The study was conducted in adherence to the principles of the Helsinki Declaration and received approval from the Hospital-Faculty Ethics Committee of Saint-Luc-UCLouvain in Belgium (B403201524184) and the Recherche Sectorielle en Réadaptation et Intégration Sociale Ethics Committee in Canada (#2020-1909). Prior to commencing the trial, all participants provided written informed consent. The study adhered to Transparent Reporting of Evaluations with Nonrandomized Designs (TREND) guidelines. Participation was voluntary and uncompensated, and all data was collected, stored, and analyzed in a manner that ensured participant anonymity.

Participants

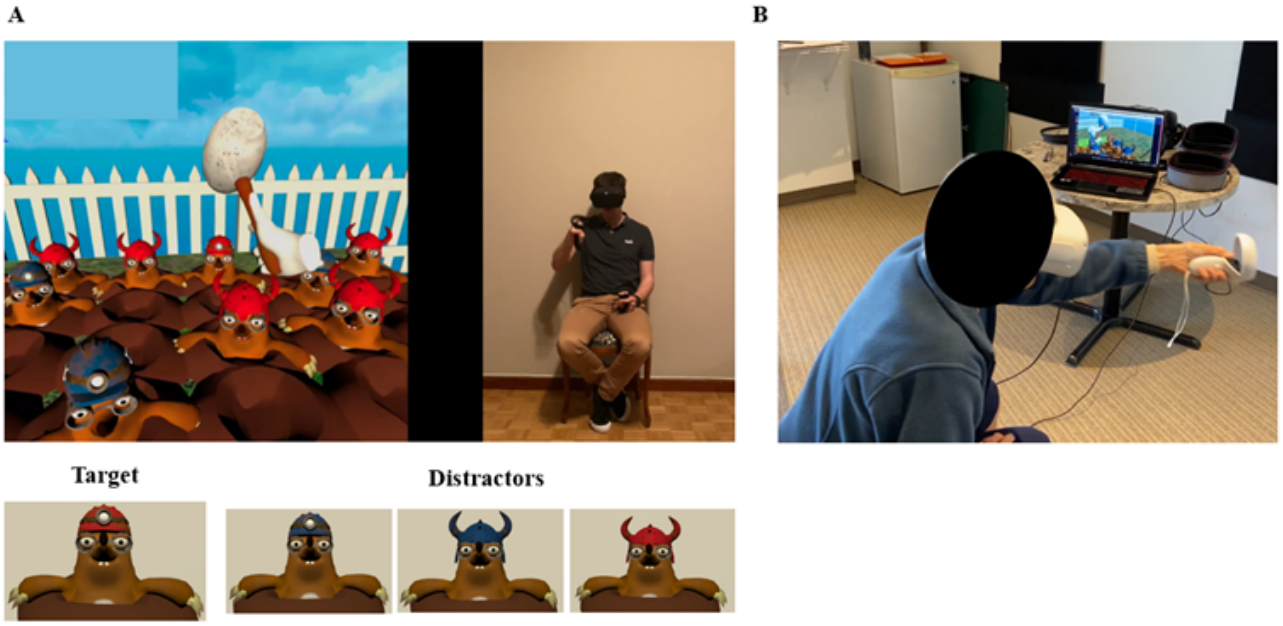
The study recruited participants from the Belgian and Canadian populations between October 2022 and December 2023 using convenient sampling, leveraging word of mouth, and community outreach strategies. Inclusion criteria were individuals aged 65 years and older, possessing corrected-to-normal vision, and demonstrating the ability to comprehend simple instructions. Older adults with orthopedic or neurological disorders that might have impacted their capacity to handle a controller or that could alter upper extremity movements were excluded from the study. Participants' cognition was screened using the Montreal Cognitive Assessment [48].

A flowchart diagram illustrating the participant flow through each stage of the study is presented in the Results section, as recommended by reporting guidelines such as TREND and CONSORT (Consolidated Standards of Reporting Trials) to ensure transparency and clarity in reporting [49,50].

Materials

The self-adaptive serious game REAsmash-iVR was developed using Unity 2019.3.15 software on the Oculus Quest 2 (Meta). This headset provides a high-resolution display (1832×1920 pixels per eye) and up to 90 Hz refresh rate, which ensures smooth and immersive interaction. The system includes 6 degrees of freedom tracking through integrated sensors, which allows participants to move freely within the digital environment. The device is equipped with 2 handheld controllers with motion tracking, which participants use to interact with the game, particularly for striking the target with a digital hammer. The controllers are equipped with motion sensors and buttons for precise input. As presented in Figure 1, Sidequest software was used to facilitate synchronization and video sharing from the headset to a laptop during the experiment.

Figure 1. Illustration of the REAsmash-iVR. (A) The upper part of the panel simultaneously depicts the REAsmash-iVR environment as seen through the VR headset (left) and the corresponding movements performed by a participant while interacting with the system (right). The lower part of the panel shows the target (a mole wearing a red miner helmet) and the distractors (moles wearing blue miner helmets, blue-horned helmets, and red-horned helmets). (B) Experimental setup: This panel illustrates a participant playing REAsmash-iVR using an immersive VR headset connected to a computer, which streams the application. iVR: immersive virtual reality; VR: virtual reality.

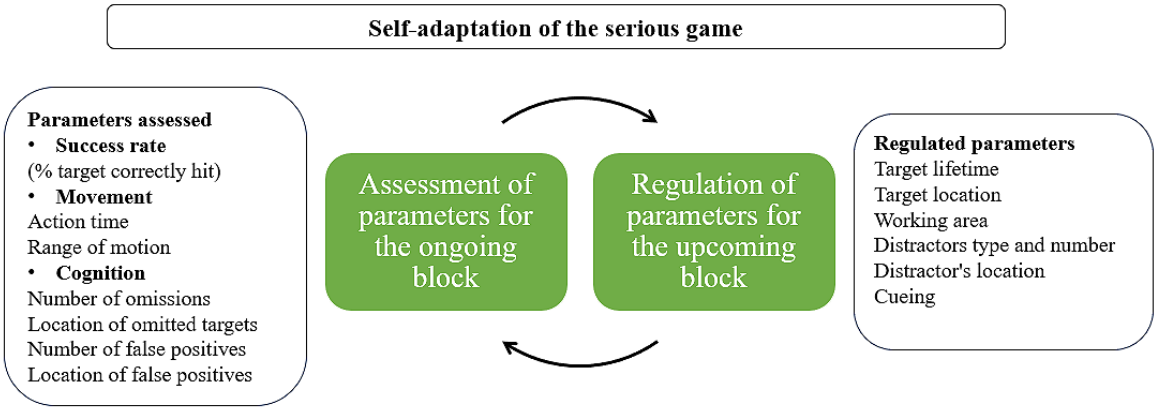


In the REAsmash-iVR serious game, the participant is asked to locate a target as quickly as possible. The target consists of a mole wearing a red miner's helmet and is presented among distractors (moles wearing helmets of different shapes and colors: a blue miner's helmet, a horned blue helmet, and a horned red helmet). These distractors manipulate cognitive difficulty by competing for attention during the task, requiring participants to focus and filter out irrelevant stimuli while searching for the target. To enhance cognitive engagement, distractors were designed to vary in salience, with some mimicking the target more closely in shape and color. Throughout the game, participants were instructed to only hit the target mole with the red miner's helmet, a task that requires both attention and precise motor action. To this end, participants used digital hammers, operated by the game controllers [47]. Motor function difficulty was manipulated through iterative practice of upper extremity reaching motions in different directions and with different levels of velocity.

In the version used here, the REAsmash-iVR used a regulator to adjust difficulty automatically and progressively based on the participants' motor and cognitive performance. The regulator of REAsmash-iVR difficulty aims to have the participant an average 75% successful performance. As the user improved and learned, the game progressively became more difficult, thereby maintaining the 75% optimal success rate. From a motor learning perspective, as the game escalated in difficulty, participants were compelled to execute a greater number of reaching movements toward the moles, spanning further distances, and within shorter timeframes, necessitating more efficient and precise upper extremity actions.

To ensure a continuous and progressive adaptation of the game difficulty, we used a dynamic regulation, with an infinite number of trial blocks. Each block involved finding and hitting a total of 1 to 24 target mole (trials), depending on the participant's level of performance. Between each block, the algorithm moderates the difficulty of the game based on the overall success rate (the ratio between the number of target moles accurately hit and the number of trials) of the prior block. If the success rate was superior to 75%, the game was considered too easy by the algorithm. If the success rate ranged between 50% and 75%, the game was considered difficult. If the success rate was below 50%, the game was considered excessively difficult. Depending on the success rate of the prior block (>75% vs 50%-75% vs <50%), the parameters that were considered responsible for the observed success rate were adjusted by the algorithm. More specifically, as presented in Figure 2, during each block, in addition to the overall success rate, the algorithm evaluated the proportion of omissions (instances when the target mole is not hit vs hit), the location of omitted moles, the number of false positives (distractor moles that were hit), and the location of distractor moles hit. These outcomes were used as indicators by the algorithm to see which of the following parameters had to be adjusted for the next block: the timing and location of the target appearance, the quantity (number) and types of distractors (high vs low salience contrast), the working area (where target and distractors appeared) and the delivery of cues that helped the participant to find the target (no cues, spatial auditive cue, and visual cues).

Figure 2. Self-adaptation of REAsmash-iVR. The system assesses performance parameters (success rate, movement, and cognition) after each block and regulates the task difficulty for the subsequent block by adjusting target and distractor characteristics, working area, and cueing to maintain an optimal challenge level for the participant. iVR: immersive virtual reality.



Experimental Protocol

Participants were tasked with engaging in REAsmash-iVR for 7 consecutive days for at least 15 minutes per day at their home. They were required to maintain a seated position throughout the gameplay and were asked to use both hands during the game. The feasibility of using REAsmash-iVR in older adults encompassed the documentation of adverse events, intervention duration (measured by the total minutes of active interaction with REAsmash-iVR, excluding pauses and time spent on menus and settings), and the evaluation of the game regulation efficacy.

To investigate whether participants' motor learning in REAsmash-iVR transferred to other iVR tasks and demonstrate retention of this transfer, the following measures were performed before the intervention (T0), immediately after (T1), and 7 days later (T2). We assessed motor learning transfer using 2 distinct tools: the KinematicsVR and the iVR version of the Box and Block Test (BBT-VR). These tests were administered by assessors with a background in physiotherapy and experience in using VR. Motor learning transfer refers to the ability to apply skills and improvements acquired during training to new, untrained tasks or contexts. Effective transfer indicates that participants have not only improved performance in the trained task (eg, REAsmash-iVR) but also developed adaptable motor strategies that can be used in other scenarios (eg, KinematicsVR and BBT-VR).

The 1-week duration was chosen as it is commonly used in motor learning literature to assess intermediate-term retention and transfer [39,51]. This timeframe is long enough to observe whether improvements persist beyond the immediate training environment but avoids confounding factors associated with longer intervals, such as unrelated learning or natural recovery. Prior studies have similarly used 1-week retention tests to evaluate skill stabilization and generalization in both laboratory and applied contexts [39,51].

We used the KinematicsVR to assess motor learning transfer in terms of unilateral reaching performance in a novel visuo-motor task [31]. The KinematicsVR requires using one of the VR headset controllers to swiftly and precisely draw 3D shapes (straight lines and a circle) visually presented in an iVR environment. The 3D positions of the controller were registered as an export file (.csv) in the hardware of the headset and analyzed offline. This test was deemed reliable and usable to assess upper extremity kinematics (especially during the drawing of straight lines and circles) in older adults with and without major neurocognitive disorder [31]. For this protocol, participants were asked to perform the movements with their dominant hand. All participants underwent familiarization trials before the assessment. To ensure that the differences between T0 and T1 primarily resulted from the REAsmash-iVR intervention rather than a general learning effect across trials, we contrasted the changes in our sample with those observed in a previous study [31] where an equal sample of older adults underwent the test twice consecutively (with no intervention in between). Transfer in this context indicates that the REAsmash-iVR intervention contributed to general improvements in unilateral reaching performance in a novel task (KinematicsVR). The performance in Kinematics-VR was analyzed based on metrics such as movement velocity, accuracy, and smoothness, allowing us to determine the extent to which the trained skills carried over to this analytic task.

We also used the BBT-VR to evaluate motor learning transfer in terms of gross unilateral manual dexterity [52,53]. This test involved moving digital cubes one at a time from 1 side of a box to the other within a 60-second timeframe. During the test, participants were required to grasp the cubes using their thumb, index, and middle fingers while pressing corresponding buttons on the controller. The BBT-VR was found to be valid, reliable, and usable to assess manual dexterity in healthy adults and individuals with stroke [52,53]. Transfer in this context indicates that the REAsmash-iVR intervention contributed to general improvements in fine motor control and hand-eye coordination. The performance in BBT-VR was analyzed based on metrics such as the number of blocks transferred, allowing us to determine the extent to which the trained skills carried over to this dexterity-focused task.

We also evaluated the participants' motor learning transfer to simple reaction time. The task involved detecting, as quickly as possible, a stimulus presented on a computer screen. Participants were instructed to click as quickly as possible on the touchpad when the stimuli were presented [54].

Kinematic Analyses

By analyzing the kinematic features of movements in KinematicsVR, we could assess whether the movement strategies developed during REAsmash-iVR translated into improved performance in a new visuomotor task.

The 3D positions of the controller obtained during the Kinematics-VR test were extracted from export files (.csv) at a sampling rate of 60 Hz. The analysis of kinematic data was then conducted using a program internally developed in Python (Python Software Foundation). For each participant, a preliminary visual analysis of the data was performed (to ensure that the data were correctly acquired) and signal smoothing was applied using a Butterworth filter (sampling frequency=60 Hz; cutoff frequency=10 Hz). The following kinematic indexes were calculated: the speed-accuracy trade-off (SAT) and the spectral arc length (SPARC).

The SAT, measured in arbitrary units, is a fundamental motor learning metric that quantifies the balance between movement speed and precision, often reflecting the extent to which participants prioritize speed over accuracy or vice versa during task execution. It is widely used to assess training-induced improvements in motor performance, as optimized performance behavior tends to achieve a more favorable balance between these competing demands [55]. In this study, we computed SAT as a ratio between speed and error, using the following equation.

Velocity refers to the first derivative of controller position. Error is measured based on movement linearity, which involves comparing the displacement of the controller with the ideal path. A higher SAT thus reflects a more efficient balance of speed and accuracy, indicating potential motor learning gains.

SPARC is a measure of movement smoothness, which is a key aspect of movement quality and skillful performance. Smoothness, as computed with SPARC, provides critical insights into whether a movement is natural and healthy or involves compensatory strategies. Natural and healthy movements are generally smoother, reflecting efficient neuromotor control, while compensatory movements tend to be less smooth and more erratic. SPARC is computed as the arc length of the instantaneous speed spectrum (ie, the length of the curve depicting the normalized amplitude of the "speed" signal  as a function of its frequency [ω]) [56]. A smoother movement involves less intermittency (alternance of acceleration and deceleration) typically resulting in a more compact and less erratic speed spectrum, leading to a small arc length. A negative sign is added to the computed arc length such a more negative SPARC value corresponds to a less smooth movement. This convention ensures that higher (less negative) SPARC values indicate smoother and more skillful motor performance.

Data Analysis

We performed statistical analyses using Sigmaplot (version; 13.0, Systat Software Inc) with α=.05. For each analysis, we explicitly tested the normality of the data using the Shapiro-Wilk test, and the results informed the selection of appropriate statistical methods (parametric or nonparametric). As this study is the first to test the feasibility and effectiveness of REAsmash-iVR in promoting motor learning, a convenience sample of 20 participants was determined.

To evaluate the efficacy of REAsmash-iVR self-regulation, we reported the percentage of instances where participants achieved a median success rate falling within the range of 60%-80% (a range deemed acceptable for enhancing motivation in a gamified learning context [40,44]). This evaluation was performed across the initial 55 blocks (which represented the minimum number of blocks observed in all participants).

Our primary outcome was to assess participants' motor learning transfer (and retention) to unilateral reaching performance in iVR. To analyze this, we used separate 1-way repeated measure ANOVA (or Friedman test for nonnormal data) for each shape used in the KinematicsVR assessment, comparing participants' SAT across 3 time points: before the intervention (T0), immediately after (T1), and at follow-up (T2). Post hoc pairwise comparisons were performed to detect changes between T0, T1, and T2. We used Bonferroni or Tukey adjustments (depending on the normality of the data) to control for the increased risk of type I error due to multiple comparisons. To ensure that the observed changes in KinematicsVR metrics between T0 and T1 were predominantly attributable to the REAsmash-iVR intervention and not merely a general learning effect over trials, we compared these changes with data from a previous study [31] where older adult participants underwent the test twice consecutively without any intervention in between [31]. To compare the T1-T0 changes between this study and our prior one, we used either the Mann-Whitney rank sum test (for nonnormal data) or the 2-tailed *t* test (for normally distributed data), depending on the distribution of the data.

Secondary outcomes included the assessment of REAsmash-iVR motor learning transfer to movement smoothness, manual dexterity performance in iVR, and simple reaction time. These outcomes were analyzed using 1-way repeated measures ANOVAs (or Friedman tests), with post-hoc pairwise comparisons. We also used Bonferroni or Tukey adjustments, depending on the normality of the data.

The effect size was computed using η^2 for ANOVAs, ε^2 for the Friedman test, and adjusted Cohen *d* for parametric post-hoc pairwise comparisons and 2-tailed *t* tests. For nonparametric tests, Cohen *r* was used. η^2 for ANOVAs and ε^2 for the Friedman test provide an estimate of the effect's magnitude relative to the total variance, with values of 0.01, 0.06, and 0.14 indicating small, medium, and large effects, respectively. Cohen *d* was used to quantify the standardized mean difference between conditions, with values of 0.2, 0.5, and 0.8 representing small, medium, and large effect sizes. For pairwise comparisons following the Friedman test and between-group comparisons with the Mann-Whitney *U* test, Cohen *r* was interpreted as small ($r\approx0.1$), medium ($r\approx0.3$), and large ($r\approx0.5$).

Results

Overview

A total of 20 older adults (of which 9 were women) with a mean age of 77.4 (SD 6.51) years participated in the study. Most of them were right-handed (n=17; 85%). A flowchart diagram is presented in Figure 3. Complementary information on participants' characteristics is provided in Table 1.

Figure 3. The flowchart diagram outlines the study process, including the assessment of 36 older adults for eligibility. Of these, 16 were excluded (7 did not meet the criteria, 7 declined, and 2 for other reasons). Twenty participants received the intervention, completed it, and were analyzed for feasibility, motor learning transfer, and other outcomes. Data were also compared with 20 older adult participants of a previous study.

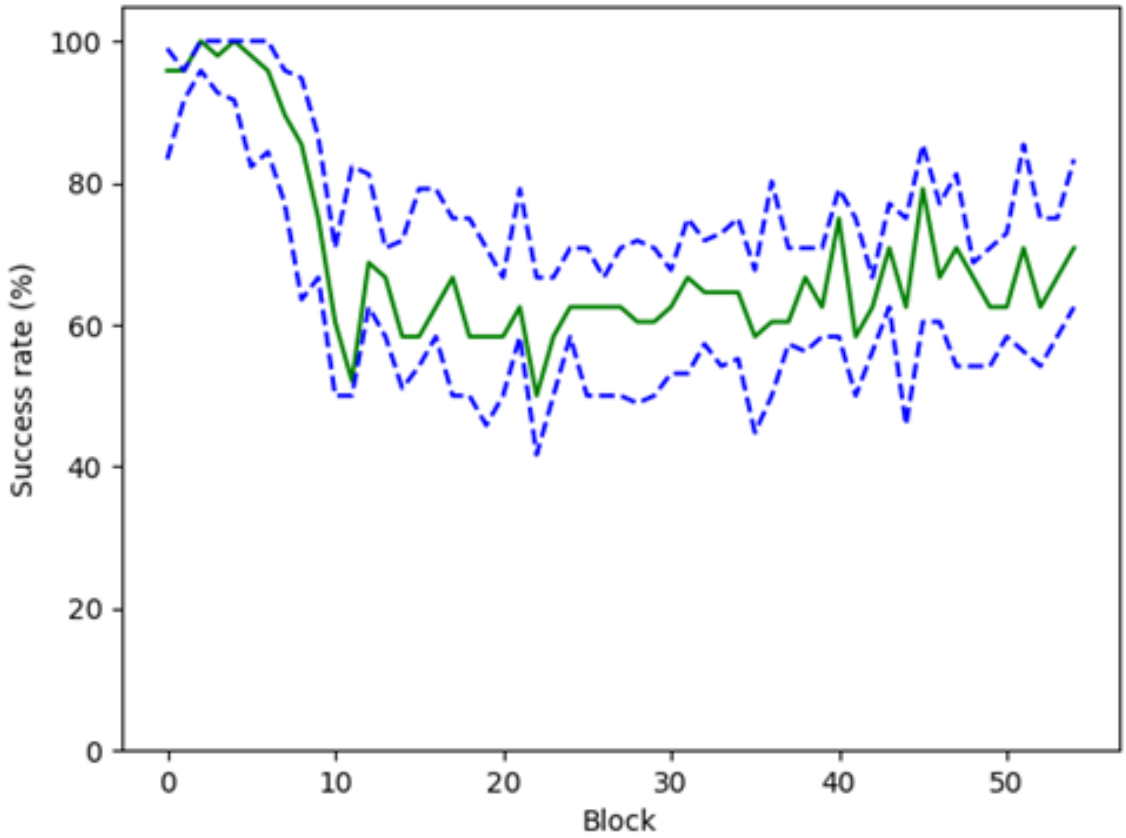
Feasibility

All participants finalized the study, and no adverse event occurred during the intervention. Participants actively played with REAsmash-iVR for 7 consecutive days for a median duration of 15.8 (IQR 9.73-15.12) minutes per day.

As illustrated in Figure 4, participants' median success rate reached a satisfactory value (60%-80%) after completing 11 blocks. Between the 11th and the 55th blocks, participants maintained a median success rate within the 60 to 80% range for 74% of the time (33 out of 44 blocks). Notably, during the final 11 blocks, participants consistently upheld a median success rate between 60% to 80%, reaching 100% coverage.

Figure 4. Evolution of success rate over the blocks. The x-axis represents the block number of the REAsmash-iVR intervention. The y-axis represents the participants' motor success rate. The green line represents the median and the blue lines the 1st and 3rd quartiles issued from all participants. iVR: immersive virtual reality; VR: virtual reality.



Primary Outcome: REAsmash-iVR Motor Learning Transfer to iVR Unilateral Speed-Accuracy Performance

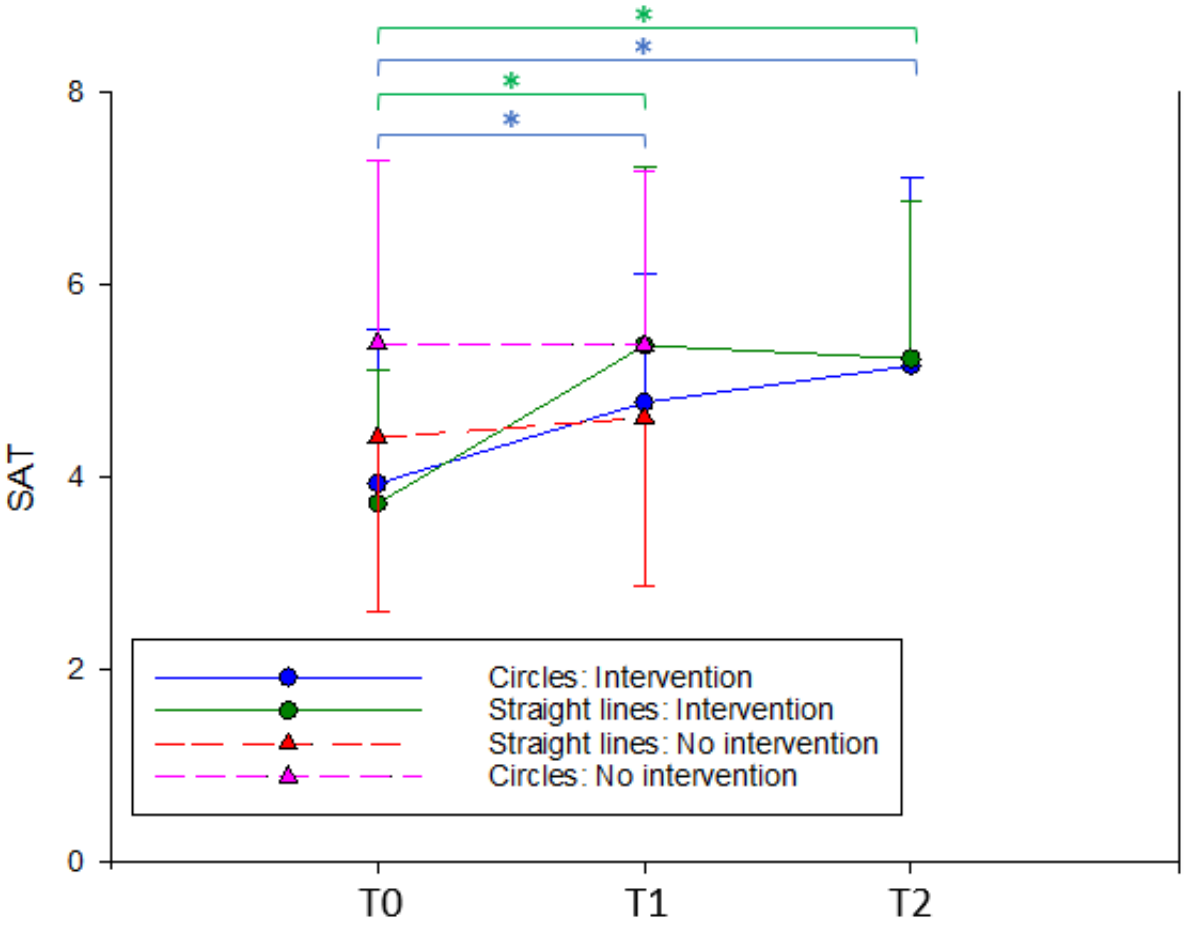
As presented in Table 2 and Figure 5, separate repeated measures ANOVA ($F_{2,38}$=21.9; P<.001; η^2=0.535) and pairwise comparison revealed that directly after the REAsmash-iVR intervention, participants significantly improved their SAT in drawing straight lines (t_{19}=5.97; P<.001; Cohen d=1.20) with retention at T2 (T0 vs T2: t_{19}=5.46; P<.001; Cohen d=1.13). Regarding the drawing of circles, participants showed significant SAT improvements ($F_{2,38}$=7.7; P=.002; η^2=0.290) between T0 and T1 (T0 vs T1: t_{19}=2.64; P=.036; Cohen d=0.613) with retention at T2 (T0 vs T2: t_{19}=3.84; P=.001; Cohen d=0.787; Table 2 and Figure 5).

Table 2. Speed-accuracy trade-off changes over time.

Separate ANOVAs	T0	T1	T2	*F* test (*df*)	RM[a] ANOVA *P* value	Post hoc T0 versus T1 *P* value	Post hoc T0 versus T2 *P* value
Straight lines, mean (SD)	3.7 (1.38)	5.4 (1.85)	5.2 (1.63)	21.9 (2,38)	<.001	<.001	<.001
Circles, mean (SD)	3.9 (1.60)	4.8 (1.34)	5.2 (1.95)	7.7 (2,38)	.002	.036	.001

[a]RM: repeated measures.

Figure 5. Evolution of SAT over time. The * indicates the statistical significance of the ANOVA pairwise comparisons; Results are presented as mean and SDs. SAT: speed-accuracy trade-off.



When drawing straight lines, participants' SAT improvements between T0 and T1 were found to be significantly greater than those observed in participants who did not follow any intervention between the tests (t_{19}=3.0; *P*=.005; Cohen *d*=0.487). Contrastingly, when drawing circles, participants' SAT improvements between T0 and T1 were not significantly greater than those observed in participants who did not follow any intervention between the tests (t_{19}=1.96; *P*=.060; Cohen *d*=0.318).

Secondary Outcomes: REAsmash Motor Learning Transfer to iVR Movement Smoothness

As presented in Table 3, the Friedman test and pairwise comparisons showed that for the drawing of straight lines, participants did not observe significant SPARC changes between T0, T1, and T2 (χ^2_2=2.1; *P*=.35; ε^2=0.003; Table 3).

Table 3. Movement smoothness changes over time.

Separate ANOVAs	T0	T1	T2	Chi-square (*df*)	Friedman test *P* value	Post hoc T0 versus T1 *P* value	Post hoc T0 versus T2 *P* value
Straight lines, median (IQR)	–1.97 (–2.027 to –1.896)	–1.92 (–1.978 to –1.783)	–1.91 (–2.016 to –1.811)	2.1 (2)	.35	N/A[a]	N/A
Circles, median (IQR)	–3.77 (–5.876 to –2.517)	–2.67 (–4.000 to –2.359)	–2.44 (–3.287 to –2.273)	11.2 (2)	.004	.03	.004

[a]N/A: not applicable.

Contrastingly, for the drawing of circles, participants showed significant SPARC improvements (χ^2_2=11.20; *P*=.004; ε^2=0.23) between T0 and T1 (*q*=3.58; *P*=.03; Cohen *r*=0.8), with retention at T2 (T0 vs T2: *q*=4.47; *P*=.004; Cohen *r*=1.0; Table 3). Moreover, improvements between T0 and T1 were significantly greater than those observed in participants who did not follow any intervention between the tests (t_{19}=2.41; *P*=0.010; Cohen *d*=0.381).

Secondary Outcomes: REAsmash Motor Learning Transfer to Manual Dexterity Performance

As presented in Table 4, the Friedman test (χ^2_2=25.9; df=2; *P*<.001; ε^2=0.532) and pairwise comparison revealed that participants significantly improved their overall BBT-VR score

between T0 and T1 (q=5.26; P<.001; Cohen r=0.678) with significant retention at T2 (T0 vs T2: q=6.82; P<.001; Cohen r=0.880).

Table 4. BBT-VR[a] scores and reaction times change over time.

	T0	T1	T2	Statistics	RM[b] ANOVA or Friedman test P value	Post hoc T0 versus T1 P value	Post hoc T0 versus T2 P value
BBT-VR score (blocks), median (IQR)	27 (20.1 to 36.4)	36 (29.8 to 45.1)	38 (29.7 to 50.5)	χ^2_2=25.9	<.001	<.001	<.001
Simple reaction time (ms), mean (SD)	398.1 (116.89)	399.9 (94.12)	379.6 (80.31)	$F_{2,38}$=0.5	.64	N/A[c]	N/A

[a]BBT-VR: immersive virtual reality version of the Box and Block Test.

[b]RM: repeated measures.

[c]N/A: not applicable.

Secondary Outcomes: REAsmash Effect on Simple Reaction Time

Participants did not show significant simple reaction time changes ($F_{2,38}$=0.5; P=.64; η^2=0.024) between T0, T1, and T2 (Table 4).

Discussion

Principal Findings

This short-term longitudinal pre-post study aimed to evaluate the feasibility and effectiveness of using a self-adaptive serious game, REAsmash-iVR, to enhance motor learning and simple reaction time in older adults. Our results suggest that, on average, participants required 10 to 40 blocks to benefit from an acceptable-to-optimal level of success rate when starting from the easiest level of difficulty (block 0). Moreover, outcomes indicated that a 7-day intervention with REAsmash-iVR resulted in improved performance in other iVR tasks, as evidenced by enhanced SAT metrics in drawing straight lines and circles, and increased score in displacing digital blocks postintervention. Notably, significant retention of speed/accuracy improvement was observed at the 1-week follow-up for the drawing of straight lines and circles, and for the displacement of digital blocks. Similarly, secondary analyses revealed that the REAsmash-iVR intervention led to improved movement smoothness in drawing circles but not straight lines. Finally, we did not observe any significant effect of REAsmash-iVR on simple reaction time.

REAsmash-iVR Impact on Motor Learning

Our findings seem to indicate that older adults effectively achieved motor learning. After undergoing the REAsmash-iVR intervention, participants exhibited the ability to apply their skills in various contexts, as evidenced by enhanced speed and accuracy in KinematicsVR and improved performance in BBT-VR. Notably, certain improvements persisted even 1 week after the intervention, suggesting intermediate-term retention of learned skills and their potential transfer to other tasks. These findings may highlight a meaningful step in motor learning within this time frame.

On the one hand, our results [31] may indicate that the notable enhancements in speed-accuracy when drawing straight lines postintervention could be credited to the REAsmash-iVR intervention, rather than being merely a result of general learning or increased familiarity with the device and setup. In fact, in our prior study [31], where no intervention occurred between assessments, we observed no significant changes in SAT in KinematicsVR tasks, further supporting the conclusion that the improvements in this study are specifically attributable to the REAsmash-iVR intervention. The self-adaptive nature of REAsmash-iVR, which allowed for tailored and optimized adjustments to accommodate each participant's unique needs and capacities, likely played a role in optimizing engagement and facilitating skill acquisition, ultimately leading to the observed enhancements in motor performance. Previous research has demonstrated that older adults achieved significant motor learning and skill acquisition when provided with appropriate optimized interventions tailored to their specific needs and abilities. For instance, a study comparing a group who practiced a square-stepping task with enhanced feedback, autonomy-supportive choices, and optimized instructions to a control group practicing without these elements, found that the experimental group exhibited faster movement times during both practice and retention phases [57]. Similarly, feedback from participants in our study overwhelmingly attested to their enjoyment of the game. Many remarked on the engaging nature of the REAsmash-iVR intervention, highlighting its immersive qualities and the satisfaction derived from mastering new skills within the digital environment. Furthermore, studies have emphasized the importance of leveraging technological advancements to develop innovative interventions that cater to the unique challenges and preferences of older adults [58,59]. In a prior study, researchers showed that an adaptive video game training intervention led to generalized positive effects on cognitive control abilities in older adults [59]. Our findings also align with [45] a longitudinal, controlled clinical study investigating motor learning, retention, and transfer in older adults using VR-based training, specifically focusing on individuals with Parkinson disease [45]. Their results demonstrated that older adults with Parkinson disease could effectively learn new motor skills through VR-based interventions. Importantly, the study observed improvements not only in motor performance but also in the retention and transfer of learned skills to real-world tasks.

The greater performance improvement here, relative to our previous study [31] could be attributed to the participants

exhibiting lower baseline performance levels in this study, potentially allowing for a greater margin of improvement. This difference becomes particularly apparent when considering circle drawing tasks, where participants had similar baseline performance levels, and improvements in speed and accuracy did not exceed those seen in our prior study [31]. However, this divergence in outcomes could also stem from the inherent differences between drawing straight lines and circles (straight vs cyclic movements). Notably, it could be hypothesized that due to the similarity in movement nature (discrete reaching movements) between drawing straight lines and hitting digital moles, REAsmash-iVR likely played a significant role in augmenting speed and accuracy outcomes in straight-line drawing tasks.

Disparities in Transfer to Movement Smoothness and Manual Dexterity in iVR

Secondary analyses revealed that participants demonstrated enhanced movement smoothness in drawing circles but not straight lines. In a prior study, researchers have recently indicated that the intermittency of movement, as evidenced by the number of velocity peaks, is influenced by the specific task being performed in older adults [60]. In our study, the lack of significant changes observed in the drawing of straight lines could potentially be attributed to the 2D and discrete nature of these movements within the KinematicsVR application. This limitation may have restricted the scope for enhancement. Conversely, when considering the drawing of circles in KinematicsVR, the continuous and 3D nature of the movements offers potential for improvement in an additional dimension (compared to the drawing of straight lines where only 2 dimensions are considered in the KinematicsVR assessment). These hypotheses are supported by the baseline results, wherein participants demonstrated a median SPARC score of –1.97 (IQR –2.027 to –1.896) for straight lines, compared to a median SPARC score of –3.77 (IQR –5.876 to –2.517) for circles. Due to the tendency for smoother movements to be indicated by SPARC values closer to 0, these results underscore a heightened potential for enhancement in circle drawing tasks.

REAsmash-iVR Effect on Simple Reaction Time

The study did not observe any significant effect of REAsmash-iVR on simple reaction time. Although these findings could have been expected, they may reflect the specific design limitations of the intervention and assessment or the need for longer intervention durations to detect changes in these outcomes. The task in iVR involved locating and responding to digital moles as quickly as possible, suggesting the potential for improvements in simple reaction times. Especially since our sample had a mean reaction time (mean 398.1, SD 116.89 ms) more than the normal in equally aged standards [54]. In comparison, in a prior study [54], researchers observed that the average mean reaction time of individuals aged between 61 and 80 years for the same task was 296.1 (SD 63.9) milliseconds. However, REAsmash-iVR engages spatial attention and distractor inhibition, aspects that cannot be adequately assessed solely through simple reaction time measurements, as the latter primarily evaluates alertness levels. Moreover, it is important to consider that reaction time improvements tend to be modest in older adults due to age-related declines in neurological processing speed [61]. Several studies have documented a decline in reaction times with increasing age, reflecting changes in neurological networks and cognitive processing abilities [62-64]. A recent study assessing 861 participants aged 70-90 years also observed that an increase in intraindividual variability of reaction time, considered as a cognitive marker of neurobiological disturbance, was associated with dementia and mortality [65]. Therefore, longer intervention periods and more comprehensive assessments may be necessary to capture subtle improvements in reaction times among older adults participating in VR-based interventions.

Limitations

We acknowledge the following limitations. First, the study's sample size (n=20) and design (pre-post), while appropriate for initial exploration, pose limitations to the generalizability and robustness of the findings. Although a retrospective comparison was used to evaluate the effect of REAsmash-iVR on motor learning, using a randomized controlled trial design would provide stronger evidence for drawing conclusions regarding the intervention's efficacy.

Second, the length of the intervention period may have been too short to observe significant improvements in certain outcomes (eg, reaction time), particularly among healthy participants. A longer study duration would be beneficial for capturing more substantial changes. Future investigations involving healthy older adults and individuals with major neurocognitive conditions could provide valuable insights into the effects of REAsmash-iVR on a broader range of participants.

Third, for the BBT-VR, retrospective comparisons between participants who received the REAsmash-iVR intervention and those who did not were possible. As a result, it remains challenging to definitively attribute observed improvements solely to the intervention itself, as opposed to potential learning effects or mere familiarization with the VR device and testing procedures. Especially since the minimal detectable change of the BBT-VR in healthy adults is relatively high (14.06 for the dominant hand and 18.23 for the nondominant hand) [52]. Therefore, future studies incorporating appropriate control groups are essential to establish the causal relationship between the REAsmash-iVR intervention and the observed transfer of performance.

Implications

The results of this study carry significant clinical and research implications. Clinically, they underscore the potential of VR technology as a novel and engaging approach to promote motor learning and rehabilitation in older adults. Previous research has demonstrated that VR-based interventions can improve motor function and engagement in rehabilitation through gamified experiences, particularly in older populations with age-related declines [66-69]. Health care practitioners working in rehabilitation settings may consider integrating VR-based interventions into their programs targeting motor impairments and age-related declines in physical function. More importantly, the use of self-adaptive serious games such as REAsmash-iVR may offer participants the opportunity for self-rehabilitation

through tailored interventions. These interventions can be specifically designed to target individual motor and cognitive deficits, providing a personalized approach to rehabilitation. Personalization in VR rehabilitation has been shown to improve outcomes by adapting difficulty levels based on real-time performance data [43]. Furthermore, the diverse range of applications available within the VR headset may enable participants to receive real-time feedback on their performance, allowing for continuous monitoring of progress and identifying areas for improvement. Several studies have highlighted the potential of iVR to assess relevant quantitative outcomes, such as hand kinematics, gaze tracking, and reaction time, in a valid and reliable manner [47,70-72]. While traditional assessments may suffer from ceiling or floor effects, limiting their sensitivity to subtle changes in performance, these quantitative metrics provide precise, objective insights into how participants behave during the task [72,73]. This allows clinicians and researchers to track nuanced motor and cognitive responses, facilitating more tailored rehabilitation strategies. Such feedback mechanisms could enhance motivation and engagement, facilitating more effective rehabilitation outcomes. VR may boost motivation by providing immersive environments that promote goal-oriented tasks, immediate feedback, and a sense of achievement through gamified elements [74]. These features not only increase adherence to rehabilitation programs but also foster a positive emotional response, which is critical for sustaining long-term engagement and improving functional recovery [75,76]. Additionally, with advancements in VR and mixed-reality headset technologies, iVR devices hold promise for promoting social interaction and connectivity among older adults [77,78]. Research has shown that digital environments can foster social engagement, reducing isolation and improving mental well-being [79,80]. Digital conferences, collaborative gaming experiences, and social environments can be facilitated through VR platforms, fostering social engagement and reducing feelings of isolation, which are particularly relevant in the context of aging populations and social distancing measures. Incorporating these social aspects into VR-based interventions could not only enhance the overall user experience but would also contribute to the holistic well-being of older adults.

From a research perspective, the study highlights the importance of exploring optimal parameters and mechanisms underlying VR interventions to maximize their therapeutic benefits, eventually using regulators of difficulty. Larger controlled studies are needed to elucidate the long-term effects, optimal dosage, and generalizability of VR interventions across different populations and settings.

Conclusions

This study provides valuable insights into the feasibility and potential effectiveness of using a self-adaptive serious game to enhance motor learning in older adults. While the intervention demonstrated promising results in improving reaching accuracy and velocity balance, and movement smoothness, future research is warranted to elucidate its broader impact on physical and cognitive function in aging populations.

Acknowledgments

The authors thank Stéphane Grade, Camille Ganci, and Anthony Garcia for their technical support in the development of the game. This work was supported by postdoctoral grants of the Centre Interdisciplinaire de recherche en réadaptation et intégration sociale (Cirris), the Réseau provincial de recherche en adaptation-réadaptation, and Wallonie-Bruxelles International (all awarded to GE). The authors also thank the Région Wallonne, the SPW-Economie-Emploi-Recherche, and the Win2Wal Program (convention 1810108) for their support.

Abstract

Background: Older adults living with HIV face challenges accessing regular geriatric care, and while virtual care services could offer a solution, they may come with limitations.

Objective: This study aimed to co-design a culturally appropriate virtual care model tailored to older adults' needs using the experience-based co-design methodology.

Methods: We used a qualitative, experience-based co-design approach with 19 older adults living with HIV. The process involved 3 phases: identifying needs through interviews and questionnaires, codeveloping a care model prototype through focus groups and a workshop, and refining the model using feedback from a world café format. Data were analyzed using thematic content analysis.

Results: The co-design process led to a virtual care model prototype that directly addressed participants' key needs. These included personalized communication methods, simplified technology interfaces for easier access, and culturally responsive care practices. Participants emphasized the importance of privacy in virtual consultations, flexible scheduling to accommodate health fluctuations, and ongoing support for managing both HIV and aging-related conditions. Their feedback shaped a model designed to bridge service gaps, offering a more inclusive, accessible, and patient-centered approach to virtual geriatric care.

Conclusions: This study co-designed a potential virtual geriatric care model grounded in the experiences of older adults living with HIV. By integrating participants' insights throughout the design process, the model offers a promising approach to improving care for this vulnerable population. Future directions for research to test this model are proposed.

older adults; HIV; virtual care; co-design; qualitative research

Introduction

Background

The global population is aging, with the number of people aged ≥50 years projected to double by 2050, reaching approximately 2 billion individuals worldwide [1]. The aging global population also includes a growing number of older adults living with HIV [2]. Due to advancements in combination antiretroviral therapy, the life expectancy of people living with HIV has significantly increased [3], leading to the first generation of people living with HIV now reaching geriatric age [4]. This demographic shift brings unique challenges as older adults living with HIV experience a complex interplay of age-related comorbidities and HIV-related health issues [5-7].

Older adults living with HIV encounter a myriad of challenges that significantly impact their geriatric care. Medically, these individuals are more likely to experience comorbid conditions, including cardiovascular disease [6,8,9], diabetes [6,10], and osteoporosis [11-13], which can complicate HIV management and treatment [14]. These comorbidities complicate treatment regimens and require coordinated care, which may not always be available [15,16]. The specialization of health care often leads to fragmented care, where health care providers focus solely on HIV management without considering the broader geriatric care needs of the patient, such as mobility, nutrition, and mental health [17,18]. Furthermore, the physiological changes associated with aging, combined with the long-term effects of HIV and its treatment, can exacerbate these comorbidities, leading to a higher burden of illness and increased health care use [19]. Psychologically, older adults living with HIV may experience higher rates of depression [20-22], anxiety [23,24], and cognitive impairment [25-27] than their younger counterparts living with HIV. The stigma associated with both aging and HIV can combine and contribute to social isolation, discrimination in health care settings, and declines in mental health and overall well-being [28-30]. In addition, older adults may encounter ageism within health care settings, which can negatively affect the quality of care they receive and their willingness to seek further treatment [31-33]. Thus, the increase in older people living with HIV underscores the increasing need for comprehensive geriatric care that addresses the complex health needs of older adults [34,35].

HIV is highly stigmatized, and this can exacerbate other experiences of stigma and discrimination [32,36,37]. Notably, geriatric care (ie, care delivered specifically for older adults) is most effective when it meets the sociocultural needs of its patients [38,39]. Socioculturally appropriate care refers to health care that respects and responds to the cultural and social needs of patients, integrating their backgrounds, beliefs, and values into their care plans [40-43]. This approach is crucial for improving patient outcomes, enhancing satisfaction with care, and reducing health disparities [44-46]. However, delivering socioculturally appropriate care, particularly in the intersection of geriatrics and HIV, presents unique challenges [43]. These include a lack of cultural competency training [47,48], insufficient resources [49-51], language barriers [52,53], and implicit biases among health care providers [54-56], which can lead to misunderstandings and suboptimal care [57]. Moreover, individuals aging with HIV may come from diverse countries and have varying sexual identities and unique histories of trauma, discrimination, and stigma that differ from those of the general population [36,37,58]. Cultural mismatches such as failing to address the stigma associated with HIV in certain cultures can result in reduced patient engagement, lower treatment adherence, and worse health outcomes [36,59]. Therefore, addressing these challenges is essential to provide effective geriatric care to diverse people living with HIV.

Virtual care holds significant potential to address some of the challenges faced by older people living with HIV [60-63]. For instance, virtual care can help facilitate regular check-ins and monitoring without the need for frequent in-person clinic visits, which is particularly beneficial for those with mobility issues or transportation obstacles or for those living in remote areas [64-66]. As one example, virtual interventions for rural older veterans living with HIV have been shown to improve access to care and patient health outcomes, including quality of life, medication adherence, depressive symptoms, internalized stigma, and loneliness [67]. Virtual platforms can also provide a discrete way for patients to access care, potentially reducing stigma-related barriers to seeking health care in person [68-70].

While virtual care has revolutionized health care delivery, it also presents several challenges that need to be addressed for effective implementation [71,72]. One major issue is the digital divide, where limited access to technology and reliable internet connectivity, especially in rural and underserved areas, hampers the ability of patients to engage in virtual care [73-75]. In

addition, digital literacy poses a significant barrier as many patients, particularly older adults, may lack the knowledge and skills to navigate digital health platforms effectively [17,73,76]. There is a need to develop specialized socioculturally appropriate virtual geriatric care models tailored to the unique needs of diverse older people, including those living with HIV. Geriatric care refers to the specialized medical and supportive care tailored to meet the complex health and social needs of older adults, encompassing chronic disease management, functional support, and holistic well-being [50].

Delivering geriatric care virtually for people living with HIV presents both opportunities and significant challenges. While virtual care can enhance access to health care for older adults living with HIV, particularly in underserved or rural areas, it also requires careful consideration of various factors. One of the primary challenges is the complexity of managing multimorbidity, a hallmark of aging in people living with HIV, which often involves the treatment of multiple chronic conditions, including cardiovascular disease, diabetes, and mental health disorders [77,78]. Virtual care platforms may struggle to capture the full range of physical and cognitive assessments needed to effectively manage these conditions. In addition, older adults with HIV may face difficulties with digital literacy, which can hinder their ability to use virtual care tools effectively [79]. This is particularly true for older adults who may already experience cognitive decline or sensory impairments. The quality of the therapeutic relationship can also be affected in virtual settings as the absence of in-person interactions may reduce the ability of health care providers to observe subtle nonverbal cues and create a trusting environment [79]. Moreover, people living with HIV may have unique psychosocial challenges, such as stigma and social isolation, which can be exacerbated by virtual care [79]. Addressing these challenges requires the development of specialized, culturally competent virtual care models that incorporate both technological solutions and social support structures to ensure holistic, patient-centered care for older adults living with HIV [43].

Co-design is a valuable approach in developing and refining health interventions and services as it actively involves key players in the design process to ensure that the resulting solutions are highly relevant and effective for end users [80]. By engaging those who will ultimately benefit from these interventions, co-design fosters a deeper understanding of their needs, preferences, and sociocultural contexts, leading to more tailored and impactful outcomes [80,81]. By involving older adults in the design process, the resulting solutions will be more relevant and effective in addressing their unique health challenges and sociocultural contexts. *Co-design* promotes cultural sensitivity by incorporating the perspectives and experiences of diverse patient populations into the design and delivery of health services [82]. This is particularly important for older people living with HIV, who may face additional stigma and barriers underpinned by the intersection of sociocultural considerations and demographic factors such as age [83]. Addressing the gaps in the literature will ensure that the unique health challenges and sociocultural contexts of older people living with HIV are considered, leading to more effective and inclusive geriatric-HIV health care interventions [43].

Objectives

This paper reports on the co-design of a culturally appropriate virtual care model for older adults living with HIV using an experience-based co-design (EBCD) approach [84]. By involving older people living with HIV, this study sought to create a person-centered care model that enhances their health care experience and outcomes [85].

Methods

Study Design

In this community-based participatory research (CBPR), we used a qualitative EBCD methodology [84] that integrated participants as co-designers (details can be found in a published protocol [43]). CBPR is an approach that emphasizes collaboration between researchers and community members throughout the research process [86,87]. It aims to address community-identified needs and promote social change by integrating knowledge and action for social justice [86,88]. Co-design involves meaningful engagement of end users in the research design process, encompassing participation at every stage of the research and varying in intensity from passive involvement to highly active participation [84,89-91]. To achieve our research objective of co-designing a geriatric-HIV virtual care model, we adapted and used a variety of participatory EBCD methods, including interviews, focus groups, scenario design, and world cafés [84,92]. We briefly describe our methods in the following sections.

Ethical Considerations

Ethical considerations in CBPR include ensuring informed consent, where community members fully understand the research process and its implications [93]. This study was approved by the Sinai Health Research Ethics Board (approval 23-0106-E). All participants provided written informed consent to take part in the study, be audio recorded, and have anonymous quotations published. The participants were given the opportunity to have access to a translator and ask to clarify any concerns before signing the consent form. Participants in the focus groups and workshop were provided with refreshments and lunch and were reimbursed for their travel expenses. Participants in all phases also received an honorarium of $43 USD for their time, compensated at an hourly rate. Our study also emphasized community ownership of research findings, allowing the advisory committee to make decisions about how results are disseminated. All data shared with the advisory committee were anonymous.

Researcher Positionality

The research team (n=18) consisted of Canadian experts in co-design methodologies with diverse backgrounds and expertise in HIV research, equity-informed health care, health service research, and implementation science. This interdisciplinary team included PhD-trained researchers and clinicians specializing in geriatrics, family medicine, and infectious diseases, as well as occupational therapists, social workers,

health service administrators, and peer researchers with lived experience.

A community-based advisory team (n=10) was established before protocol development to ensure ongoing engagement throughout the project. This advisory team comprised knowledge users such as administrators from nonprofit organizations serving older persons living with HIV, including shelter staff, health care providers, charity organizations, and community centers. In addition, the advisory team included older individuals living with HIV and clinicians specializing in geriatric care. Regular individual meetings with principal investigators were conducted throughout the research process.

Recruitment and Participants

Our study sample was distinct from our advisory committee and included older individuals who self-identified as HIV positive; were aged ≥50 years; and resided in Ontario, Canada. We purposively sought diversity across various dimensions: (1) sex and gender, (2) age, (3) ethnicity and race, (4) socioeconomic status, (5) previous use of virtual geriatric care (ie, yes or no), (6) geographical location (rural vs urban), (7) time living with HIV, (8) non-English first language, and (9) level of educational attainment.

We used quota and purposive sampling to ensure a representative sample [94,95]. Our advisory team engaged in community outreach at relevant meetings and events to assist with recruitment, leveraging their networks and organizations. We also posted study flyers at community-based organizations, religious institutions, and culturally oriented events. Finally, our advisory team's websites and social media platforms were used to promote the study. All participants contacted the research coordinator to learn more about the study, and eligibility was confirmed based on the demographic characteristics to ensure alignment with our purposeful sampling technique.

Data Collection

Data collection occurred in 3 phases, which are outlined in this section and published in a previous protocol [43]. No deviations were made, aside from the fact that no focus groups occurred in phase 1. Phase 1 focused on understanding participants' needs and perspectives through semistructured interviews. The interviews were conducted by a trained research assistant with support from the primary author. The interviews focused on participants' experiences throughout their illness trajectory, current and anticipated needs for geriatric care, and priorities for virtual care. To ensure effective purposive quota sampling, demographic information was collected from participants at the time of recruitment, allowing us to determine whether they met the specific criteria for inclusion in the study. This demographic questionnaire captured diverse lived experiences and socioeconomic data relevant to this study's aims. Once participants were recruited, all interviews were audio recorded, professionally transcribed, and reviewed for accuracy by a research assistant. The narrative summaries of the interviews were created by the first author based on both the interviewer's notes and recollections and the transcripts of the interviews. These summaries were developed to provide a comprehensive overview of each interview, highlighting key themes, insights, and participant perspectives. Following their creation, the narrative summaries were shared with the research team and the advisory team via email and team meetings. The narrative summaries were included in the dataset for analysis and were considered part of the field and meeting notes, providing a synthesized account of key themes and insights from the interviews to support the interpretation and development of findings.

Before initiating the co-design process, we prioritized trust building to create a comfortable and inclusive environment for participants. To minimize power imbalances, we limited the number of researchers present, ensuring that the space felt less formal and more participant driven. In addition, we asked participants whom they wanted involved in the process, allowing them to shape the composition of the sessions. These efforts fostered a sense of ownership, encouraged open dialogue, and reinforced the collaborative nature of the co-design approach.

Phase 2 involved 2 focus groups and a workshop, all drawing on the same participants to apply an EBCD approach to develop a prototype for a culturally appropriate HIV virtual care model. The focus groups primarily aimed to gather in-depth qualitative data through structured discussions that allowed participants to share their experiences and insights about virtual care. In contrast, the workshop was more interactive and aimed at synthesizing the findings from the focus groups, where participants worked collaboratively to co-design and refine the elements of the HIV virtual care model. In preparation for phase 2, participants in the focus groups were provided with a detailed presentation summarizing the main needs identified in phase 1 before the workshop formally began. This presentation, based on comprehensive data collected during the initial phase, highlighted key insights into the unique challenges faced by older adults living with HIV. By sharing this information with the participants, we informed them about critical areas to address in the design process, ensuring that their feedback in the focus groups was grounded in the context of the identified needs. The focus groups and workshop were jointly led by a trained neutral facilitator and peer researcher who was trained through a structured program designed to build both facilitation and research skills. The training included an overview of the research objectives, ethical considerations, and techniques for creating a supportive and nonjudgmental environment for participants. The peer researcher was also trained in active listening, group dynamics, and how to manage sensitive topics, particularly those related to the experiences of older adults living with HIV. The workshop, guided by a modified 4D cycle of Appreciative Inquiry [96], aimed to identify strengths in existing care models and design principles for improved virtual care, accommodating both in-person and virtual attendance [97]. The modified 4D cycle of Appreciative Inquiry involves the phases of *Discovery*, *Dream*, *Design*, and *Destiny*, focusing on identifying strengths, envisioning an ideal future, cocreating actionable plans, and implementing sustained changes [96]. The *Definition* phase was also included for greater adaptability to specific contexts and goals. Discussions used visual tools such as concept mapping and word clouds [98] that were kept for analysis. All verbal focus group data were audio recorded and professionally

transcribed. Postworkshop reflections with the research and advisory teams guided phase 3.

In phase 3, there were 10 returning participants from phase 2 and 2 participants new to the study. The design principles for the culturally appropriate HIV virtual care model were developed using a world café format [99]. Small group discussions fostered dynamic exchanges, integrating feedback on proposed solutions and outlining recommendations for implementation and uptake. Facilitated by a peer researcher and supported by research team members, these sessions aimed to ensure participant engagement and generate robust data for ongoing project development [99]. Memos and reflexive notes were taken by the research team throughout the study. Transcripts and notes were anonymized by removing details that could lead to participant identification. No names of participants were used in the analysis or reporting of the results.

Data Analysis

The dataset comprised audio recordings, transcripts, field and meeting notes, reflexive notes, and physical artifacts designed by participants. The analysis team, consisting of research team members and select advisory committee members, conducted thematic content analysis [100,101]. The field and meeting notes were reviewed as part of the data analysis process, contributing to the identification of key themes. In phase 1, data analysis occurred concurrently with data collection to determine thematic saturation [102]. Thematic saturation was established when no new codes or concepts emerged from the data, indicating that additional interviews were unlikely to yield novel insights. Transcripts were coded using the NVivo software (version 14; QSR International) by the principal investigator and the research assistant. A codebook developed through inductive and deductive processes informed by the knowledge-to-action framework was used and refined iteratively through team meetings [103,104]. Physical artifacts created by participants during the workshop, including Post-it notes, drawings, and summary sheets, were also systematically analyzed and integrated into the overall data analysis process to enrich and deepen the understanding of participants' perspectives. Once scanned, the images were categorized based on themes and topics that emerged from the discussions. This allowed the research team to examine not only the content of the physical artifacts but also the ways in which participants visually expressed their ideas and emotions. The drawings and Post-it notes, for example, provided additional insights into participants' cognitive and emotional responses, offering a layer of qualitative data that complemented the verbal responses collected during the sessions. The images were analyzed using a thematic approach, identifying recurring patterns, symbols, and motifs that reflected key aspects of participants' experiences. Peer researchers were sent the preliminary findings 1 week ahead of the focus groups and workshop to enable thorough review and reflection before the subsequent phases. Themes were identified through comparative analysis and refined through team discussions, with a thematic map aiding in refining final themes to inform phase 2. Phase 2 and phase 3 continued with reflexive thematic content analysis to consolidate findings from the co-design workshop and refine themes for subsequent phases [101], including the world café discussions. The analysis refined the themes that emerged during these sessions and ensured that the feedback from the world café format was directly incorporated into the final design recommendations for the virtual care model. All researchers reviewed and endorsed the final version of the manuscript as coauthors to ensure the accuracy and completeness of the findings presented. A lay version of the manuscript was also sent to all members of the advisory team and participants of the study. Participants were invited to provide their feedback via email up to the point of manuscript submission.

Validation and Reliability Strategies

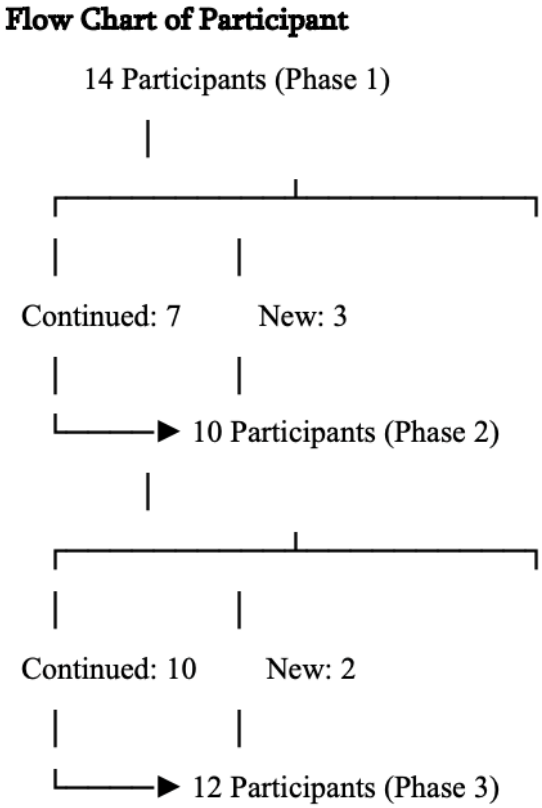
Rigor and trustworthiness in this study were ensured through several methodological strategies. First, we used a qualitative EBCD methodology, integrating participants as co-designers throughout the research process, which facilitated meaningful end-user engagement and ensured that participant perspectives were central to the study's design and outcomes. This approach was consistent with established principles of CBPR [86,105]. Second, we maintained methodological rigor by adhering strictly to our published protocol [43], which detailed the study procedures and ensured consistency in data collection and analysis methods. Our adherence to the protocol provided a structured framework for data collection and interpretation while remaining adaptable to participant and advisory committee input and emerging insights. This balance ensured that, while following a predefined approach, we also responded to and incorporated collaborators' feedback, thus enhancing the relevance and responsiveness of the methodology. Third, the study design included diverse methods that enhanced the richness and depth of the data collected and contributed to the triangulation of data sources [106,107]. The analysis team, consisting of research team members and selected advisory committee members, engaged in iterative coding and theme development supported by regular team meetings and peer review processes. This collaborative approach enhanced the reliability and credibility of the findings by ensuring that interpretations were grounded in the data and reflective of diverse perspectives [108]. Finally, transparency and reflexivity were maintained throughout the research process. That is, reflexive notes, memos, and detailed documentation of methodological decisions were kept, providing transparency in data interpretation and analysis. Regular interactions with the advisory team and participants, including sharing preliminary findings and seeking feedback, further strengthened the trustworthiness of this study by ensuring that the findings resonated with participant experiences and priorities [108].

Results

Overview

The research team conducted the co-design process between June 2023 and June 2024. In total, 19 unique participants took part in this study, with 14 (74%) participants in phase 1, a total of 10 (53%) participants in phase 2 (n=7, 70% from phase 1), and 12 (63%) participants in phase 3 (n=10, 83% from phases 1 and 2). Multimedia Appendix 1 outlines the participant characteristics, and Figure 1 shows a flowchart of the participants.

Figure 1. Flowchart of participants.



Participants co-designed a culturally appropriate and flexible HIV virtual care model that was rooted in empathy and addressed both the clinical, psychological, and social elements and the emotional aspects of aging with HIV. Phase 1 aimed to understand participants' needs regarding virtual care, revealing four key findings: (1) the desire for accessible and integrated health care; (2) the complications caused by sociocultural and demographic factors; (3) the benefits of peer support without replacing formal care; and (4) the potential of virtual care to address some barriers, although with caveats related to access and technology. Participants expressed a strong need for easily accessible, coordinated care, particularly for older adults living with HIV who face complex, overlapping health and social challenges. They highlighted the difficulties of navigating the health care system, noting that virtual care could reduce barriers but only if it accounts for digital literacy and technology access. In addition, while peer support was valued, participants cautioned against overreliance on it, emphasizing that virtual care should supplement, not replace, formal services. They also pointed out that virtual care could improve access, especially for individuals facing logistical barriers, but it must be designed with flexibility and continuity in mind. In phase 2, the focus shifted to ideating solutions for the virtual geriatric-HIV care model. Participants suggested a multimodal care approach encompassing various forms of care delivery (eg, in-person and virtual visits and digital health records). They also stressed the importance of education and clear communication regarding technology use, ensuring that older adults are informed and confident in using virtual platforms. Privacy and data security were significant concerns, with participants requesting transparency about who accesses their information and how it is used. In addition, participants emphasized the need for reminder systems to help maintain continuity of care and reduce missed appointments. These solutions were aimed at improving both the practicality and trustworthiness of virtual care for older adults living with HIV. Phase 3 focused on co-designing actionable plans, with participants emphasizing the importance of linguistic and cultural equity in virtual care. They stressed that care models should be inclusive of diverse populations, particularly those who face language barriers. Participants highlighted the need for culturally appropriate services to ensure equitable care, pointing out that older adults from different cultural backgrounds often experience compounded difficulties when accessing health care services. The plans developed during this phase aimed to refine and prioritize these solutions to create a more inclusive and effective virtual care model for older adults living with HIV. Throughout the following sections, we illustrate the findings using quotes labeled with participant ID, race or ethnicity, gender, and age.

Phase 1: Understanding Participants' Needs Regarding Virtual Care

We identified the following key and interrelated insights: (1) older adults living with HIV want accessible and integrated care, (2) intersecting sociocultural and demographic factors complicate receipt of care for older adults living with HIV, (3) peer support is beneficial but should not replace formal health care services and supports, and (4) virtual care can address barriers to care with access caveats.

Older Adults Living With HIV Want Accessible and Integrated Care

Participants emphasized the need for health care systems to prioritize services that are easily accessible and tailored to the unique health challenges faced by older individuals living with HIV. Participants noted that they often had complex, overlapping medical and social needs that required coordinated care across multiple disciplines. While most participants described positive experiences with previous care, they also discussed challenges obtaining information and reaching the appropriate care provider. Several participants specifically recounted situations in which accessing services and support felt very difficult. One participant shared the following:

> *You can go to a family doc[tor] if you have one and that is so great—again, if you have one. But the issue becomes when the doc refers you to one specialist who refers you to another then back to your family doc and you repeat because no one knows how to care for you.* [Interview participant 11; man; White individual; aged 52 years]

Therefore, participants described desiring a health care system with the ability to easily access services from care providers.

Intersecting Sociocultural and Demographic Factors Complicate Receipt of Care for Older Adults Living With HIV

Participants highlighted that they often faced systemic barriers that hindered their ability to access health care services. These challenges were exacerbated by age-related biases within the system, which was not designed to fully address or accommodate their unique needs. Participants highlighted that those with lower incomes may experience additional obstacles, including lower access to resources; heightened stigma; and greater socioeconomic disadvantages that impact their health, such as the inability to purchase both food and medication. Participants agreed that virtual care has the potential to alleviate some of these systemic barriers by providing more accessible and flexible health care options. However, for virtual care to be an effective solution, it must address the challenges associated with digital literacy and technology access. One participant pointed out the following:

> *The level that we're to access the services at, is a bit crazy and some might have challenges. Like this morning, I tried to go on the touch screen, and I can't get it on to use my phone. And then I'm seeing that there is no Internet service.* [Interview participant 5; man; Black individual; aged 56 years]

Moreover, to ensure that virtual care is equitable, it is crucial that health care providers are aware of and address the specific needs and preferences of older adults. For instance, participants noted that they preferred a larger screen for virtual consultations, such as a tablet, over smaller devices such as phones.

Peer Support Is Beneficial but Should Not Replace Formal Health Care Services and Supports

Support systems among peers were noted as critical in the management of chronic conditions among older people living with HIV. Peer support groups offered participants emotional and practical guidance from individuals who shared similar experiences, fostering a sense of community and reducing feelings of isolation. Peer interactions were also thought to provide valuable insights into managing HIV and navigating the health care system as an older person as they offered lived experiences and practical advice that complemented professional care. One participant noted the positive impact of peer support, stating the following:

> *I found that connecting with others who are dealing with the same condition really helped me cope better and stay informed about my health.* [Interview participant 3; man; South Asian individual; aged 82 years]

In the context of peer support, health management and the pursuit of independence emerged as critical themes in the experiences of older adults living with HIV, particularly within a virtual care framework. Participants relied heavily on peer support to navigate the health care system, highlighting the need for virtual care models that offer tailored resources and programs to address their unique needs. One participant emphasized the value of community-based programs, noting the following:

> *First of all, it's a safe place for LGBTQ members. And it's a positive place for me because it's 50 plus. Basically, it focuses on age and being gay and what more can we want. Canada is great—it won't discriminate by colour in medical settings, but sometimes we can't find what we need.* [Interview participant 11; man; White individual; aged 52 years]

Despite the availability of such programs, challenges remained, particularly in accessing mental health services. The participants wished for more targeted online resources for aging, stress, or depression beyond medication. Furthermore, virtual care could enhance independence in health management by facilitating regular interactions with health care providers through digital platforms. Participants expressed a need for frequent virtual check-ins, such as weekly phone calls, to better monitor and manage their health conditions and maintain a sense of connection and support.

Participants noted that, while peer support was invaluable, they were cautious that their reliance on individuals with lived experience was due to systemic gaps in health care provision and the lack of formal support structures for addressing the complex interplay of health and social circumstances affecting older adults living with HIV. One participant remarked the following:

> *If I get sick, then I lose my job, and then the chance of losing my housing rise exponentially and so basically I have to have friends who have a house or know someone who is hiring to pay for medicine.* [Interview participant 1; woman; White individual; aged 57 years]

The same participant shared the following:

> *If you have money, you'll get the healthcare in the time that you need it. And if you don't, well, then good luck.*

Another participant shared the following:

> *When you're first diagnosed, all you're focused on is survival. You aren't trying to find services; you meet people who tell you what services exist. But the healthcare system, the focus isn't on us, who've been around for a long time, and now we need different supports in place than we did 20 years ago. So, we're stuck with the same services.* [Interview participant 2; woman; First Nations individual; aged 57 years]

Virtual Care Can Address Barriers to Care With Access Caveats

Participants noted that the integration of virtual care has the potential to alleviate some of these challenges by offering more flexible and accessible health care options, thereby significantly reducing the logistical challenges associated with in-person visits, as noted by a participant who appreciated the time savings:

> *I had a bone density scan...when I had it, he wanted to make an appointment, and I had the choice between virtual or going down to the office. I saved like 4 hours.* [Interview participant 12; man; First Nations individual; aged 51 years]

Another participant shared the following:

> *When the place is very cold and you got to catch two bus, three busses to meet your doctor, and pay for it each time, we can do virtual. Then when it's nice outside whether we don't mind going and spending the time and go out and see.* [Interview participant 10; woman; mixed heritage; aged 54 years]

However, one participant wisely pointed out the following:

> *But it has to be only when minor consultation is required...it should [not] replace the face-to-face consultation.* [Interview participant 9; man; White individual; aged 59 years]

Participants emphasized the importance of effective communication and continuity of care within the virtual geriatric-HIV care model. They expressed a strong desire for seamless interactions among care providers to prevent disruptions in their treatment and communication. This continuity was described as crucial for maintaining the stability of their HIV management, including regular blood work and medication adjustments. Although participants generally reported positive interactions with health care providers, challenges arose in distinguishing between symptoms related to HIV and those associated with normal aging. One participant remarked the following:

> *Sometimes it's hard to tell whether a symptom is due to the HIV or just getting older. Clear communication and understanding from my healthcare provider are essential to figuring out what's really going on.* [Interview participant 9; man; White individual; aged 59 years]

To address these complexities, participants recommended that novel care models integrate mechanisms for clear, ongoing communication and coordination among health care providers, ensuring that specialized care is tailored to meet the intricate needs of older adults living with HIV.

Phase 2: Ideating Solutions

Participants suggested improvements to current care models for older adults living with HIV and proposed their wishes regarding virtual care through a series of activities.

Importance of Flexible Care Delivery

Participants highlighted the importance of a multimodal care approach to enhance coordinated care and access to health information for older adults living with HIV. One participant explained the following:

> *...we need it [virtual care] to be offered in a lot of ways, so not just phones because not everyone has one, not everyone has a cell phone, maybe computer, so offer a lot of ways like a phone, cellphone, tablet, computer.* [Phase-2 participant 1; man; White individual; aged 56 years]

Participants also noted that the approach should integrate various modes of care delivery, such as in-person consultations, virtual visits, and digital health records, to create a more seamless, continuous, and comprehensive health care experience. One participant shared the following:

> *...you can't just have it be one approach, sometimes you need to come in, sometimes I might need a virtual visit, sometimes I might want to send information, we need options.* [Phase-2 participant 4; woman; Black individual; aged 71 years]

Education and Communication Regarding Technology Use and Privacy

The need for clear communication regarding new technologies was a recurring theme among participants. They emphasized that educational demonstrations are essential in helping patients understand and effectively use new technological tools. One participant said the following:

> *...the worst thing someone can do is if you assume we know what we are doing with technology, so it doesn't have to be a doctor but some instructions. I sometimes use Zoom but then they say go online and upload, I have no idea how to do that.* [Phase-2 participant 6; man; White individual; aged 62 years]

Transparency regarding technology use in virtual care emerged as a crucial concern for participants. Participants emphasized the need for clear communication about who accesses patient information, how it is used, and the procedures for withdrawing consent. In the context of virtual care, the digital environment can heighten concerns about privacy and confidentiality, making it imperative to establish transparent practices in data privacy and security. Participants indicated that, in virtual settings, where information is often shared and stored electronically, patients may feel more vulnerable and uncertain about their data. Therefore, ensuring that patients are well informed about the handling of their health information is essential for building trust and fostering a sense of comfort with using virtual care services. One participant explained the following:

> *...sometimes they think we are old, so we don't understand, but I know about technology and so I want to know who is going to look at my stuff in order to trust you. If I don't know, I won't trust this [virtual care].* [Phase-2 participant 8; woman; Indian-Caribbean individual; aged 54 years]

Participants also underscored the need for transparency regarding the environment in which virtual care appointments are conducted. They expressed concerns about ensuring that these appointments occur in private and secure settings to protect patient confidentiality. Specifically, participants highlighted the importance of knowing whether providers are conducting virtual appointments from locations that guarantee privacy and maintain the integrity of sensitive health information:

> *I don't want the doctor to be like talking about HIV with their friends in the background or at Starbucks.* [Phase-2 participant 8; woman; Southeast Asian individual; aged 70 years]

Reminder Systems

Participants suggested the implementation of reminder systems for appointments and follow-ups to ensure continuity of care and reduce missed appointments. Such systems can play a crucial role in maintaining regular contact between patients and health care providers, thereby improving adherence to treatment plans and enhancing health outcomes. By leveraging technology to provide timely reminders, health care systems can support patients in managing their care more effectively and reduce the risk of lapses in treatment. One participant shared the following:

> *...maybe it's age, maybe it's life, but anything to make it easier is good. Remind me when to log in, when to book an appointment, what to do, who to see, even the name, just anything to make life easier when it comes to doctors because sometimes, I see so many and now maybe a geriatrician.* [Phase-2 participant 4; woman; Black individual; aged 71 years]

Phase 3: Designing the Action Plan

Overview

Phase 3 entailed participants co-designing and planning the necessary actions and initiatives to achieve the desired future for virtual geriatric-HIV care as outlined in phase 2. Participants concluded phase 3 by refining the ideas and virtual geriatric care models co-designed in phase 2 and phase 3. This involved prioritizing linguistic and cultural equity.

Linguistic and Cultural Equity

Participants highlighted the need for the virtual geriatric care model to incorporate linguistic and cultural considerations to ensure equitable care for the population of older adults living with HIV. Participants shared stories exemplifying the diversity of the geriatric-HIV community (inclusive of several underserved populations) and emphasized the importance of increasing services to these populations. One participant stated the following:

> *...not everyone speaks English, especially when they come here and so we need to give back and help them. It's like if you dropped someone in their countries, it's like worse than a maze.* [Phase-3 participant 11; man; White individual; aged 69 years]

Participants noted that there needs to be health- and technology-related information in multiple languages and that service providers should make translation services known to their patients. Participants also suggested that health care providers offer education that addresses many of the culturally related myths and concerns of individuals about aging with HIV. One participant said the following:

> *...doctors and nurses need to look at who they are serving that is different than them. Not everyone understands HIV is not a life sentence so tell certain people that. Or maybe someone eats food that is different, not everyone understands quinoa. Maybe recommend cultural food.* [Phase-3 participant 1; woman; Black individual; aged 51 years]

Consider Affordability

Participants were broadly aware of the fact that the cost of technology could be a barrier to many older adults living with HIV. Participants highly recommended that geriatric-HIV virtual care models be made more accessible by offering subsidized internet access or technological devices. Participants also shared that some patients may have never used technology before virtual care due to high costs and, therefore, may need training on how to best use the technology for care. Participants recognized that health care providers may not have the capacity to teach their clients, and as such, someone else in the health care organization should. For instance, participants suggested that perhaps calling a patient on a landline or inviting the patient to in-person training could help support their use of virtual modalities for health care in the future. One participant described the following:

> *...maybe invite someone to a place in person just even once or call them and walk them through something like how to turn their video on or how to send a text to a doctor.* [Phase-3 participant 17; woman; Black individual; aged 54 years]

Participants emphasized the importance of early education on technology, as previously underscored in the other phases of the study.

Participants expressed significant concern about the high cost of HIV-related medications, particularly for those aged <65 years, who are ineligible for government-funded drug coverage in Ontario. Some participants felt that health care providers were not advocating enough for the use of lower-cost alternatives such as generic medications, which could be just as effective as brand-name drugs. For instance, one patient mentioned the following:

> *It [medication] can be the choice between food, rent or medications at times, so I want someone who maybe says a cheaper supplement or maybe what medication I can maybe take a different type of. Anything to keep the cost low.* [Phase-3 participant 9; woman; Asian individual; aged 70 years]

Participants indicated that a more proactive stance from providers in promoting cost-effective treatment options, both for HIV and age-related conditions, would improve their overall care experience.

Person-Centered Care for Age-Related Health Issues

Participants highlighted the importance of having health care providers who understood the dual challenges of aging and living with HIV. They emphasized that a key feature of an effective geriatric virtual care program would be the integration of expertise in both areas. This holistic approach was seen as essential for managing the complexities of age-related conditions alongside HIV, with many noting that current segmented specialist care often leads to fragmented treatment, polypharmacy, and inconsistent care coordination. An integrated model was viewed as a potential solution to improve care continuity and reduce these challenges.

Participants emphasized the importance of incorporating cognitive health screening and related support services into the virtual care model. This integration would address current gaps in HIV care by ensuring that the program not only focuses on medical treatment but also considers the emotional aspects of aging with HIV. Current gaps within HIV care were re-emphasized, and participants noted that, for uptake of the geriatric-HIV virtual care model to occur, participants needed to "feel as if the doctor or care professionals care of us as a person, not just a billable code or something, but to really understand how much [older adults living with HIV] struggle" (phase-3 participant 8; man; White individual; aged 67 years).

Patient Resilience and Support

Participants emphasized a virtual geriatric-HIV model of care that incorporates support networks to enhance patient resilience to living with HIV in older age. The involvement of trusted individuals such as existing care providers, friends, or service agencies was deemed essential to care by participants. This holistic support system helps patients navigate the challenges of their health journey, promotes a sense of connection and belonging, and strengthens their overall well-being. By embedding these peer support networks within the virtual care model, the program can provide a more robust and empathetic approach to patient care. One participant described the following:

> *I'd trust anything that [Community Agency] recommended, so if you bring your services to them so that they encourage them, I'll trust that it would help me.* [Phase-3 participant 4; woman; White individual; aged 58 years]

Moreover, participants emphasized that a virtual geriatric-HIV model of care should include features such as virtual support groups, peer mentoring programs, and online forums where individuals with similar experiences can connect and share insights. In addition, incorporating the peer mentorship system could allow patients to receive guidance and encouragement from those who have successfully managed similar health conditions.

Discussion

Principal Findings

This study was conducted to co-design a geriatric-HIV virtual care model for older adults living with HIV. The lack of tailored interventions that consider this population's specific needs and preferences necessitated a co-design approach. Using EBCD methodology [84,85,92], we engaged older adults living with HIV to collaboratively codevelop a virtual care model. Through interviews, focus groups, and a co-design workshop, participants identified key needs such as robust support systems, health management resources, and effective communication strategies. They cocreated and refined solutions including multimodal care options, technology transparency recommendations, and reminder systems.

Using co-design methodologies ensured that the voices and experiences of older adults living with HIV were central to the development and evaluation of the virtual care models. This inclusive, user-centered approach fosters solutions that are more likely to be accepted and effective as they are directly informed by the end users' needs and preferences. Engaging participants in the research process empowers them and enhances the relevance and applicability of the findings. A strength of this study was the inclusion of many English-as-a-second-language individuals and immigrants to Canada, who are typically underrepresented in research [109]. This diverse participant pool enhanced the transferability of the findings, ensuring that the developed virtual care models were relevant and accessible to a broader range of older adults living with HIV. By actively including these often-excluded groups, this study addresses potential disparities in health care access and provides insights into the unique needs and challenges faced by these populations. Thus, this research provides practical insights into the real-world application and potential barriers to adoption of virtual care models. This dual focus ensures that this study not only explores the theoretical potential of the interventions but also addresses the pragmatic challenges that might arise during implementation. As a result, the findings are highly relevant for informing policy and practice, ultimately contributing to the advancement of care for older adults living with HIV.

The findings presented in this paper have been echoed in various other studies with other populations. Research among rural and urban adults has shown high satisfaction with virtual care [110]. In addition, studies on virtual care for substance use indicate its ability to bridge service gaps, particularly in rural areas, reinforcing the importance of multimodal care options and effective communication [111]. Canadian case studies further demonstrate the necessity of involving users in the development of virtual care tools to ensure their effectiveness and transparency [112].

Our findings underscore the importance of integrating cultural and linguistic equity into virtual care models, which has substantial implications for enhancing health care accessibility and outcomes for older adults living with HIV. Research has shown that sociocultural stigma can severely impact health care engagement and access [36,113], highlighting the importance of designing solutions that are sensitive to these issues.

Involving older adults living with HIV in co-designing care solutions is essential to ensure that their needs are met [90]. Engaging older adults living with HIV in the development process ensures that the solutions are tailored to their specific needs and the challenges they face, thus enhancing their effectiveness and acceptance [90]. This study's findings have important implications for health policy, particularly regarding the integration of virtual care models for older persons living with HIV. Existing reviews have found that virtual geriatric-HIV programs are limited [17] despite their proposed benefits. Policy makers should consider the advantages of virtual care in addressing the unique needs of this population, especially in contexts in which traditional health care access is limited. Our study highlights that participants perceive virtual care to be feasible and acceptable for meeting their geriatric-HIV care needs, suggesting that policies should support the expansion of telehealth services and funding for technological infrastructure. In addition, policies should focus on inclusivity by ensuring that virtual care models are accessible to non-English speakers and diverse cultural groups who may have differing views on HIV care [50,114]. This could involve implementing language support services and cultural competency training for health care providers to enhance the effectiveness of virtual interventions. This could also involve funding geriatric health care settings such that they can hire multilingual staff, partner with translation services, and provide localized materials.

In practice, this study underscores the importance of adopting virtual care models as a viable alternative or complement to traditional in-person geriatric consultations for older persons living with HIV [67]. Health care providers should be encouraged to incorporate these models into their service offerings, with attention to user feedback and the co-design process highlighted in this study. Research emphasizes the need for health care professionals to collaborate with patients in co-design methodologies [115] to enhance patient participation in health care services. Projects involving creative workshops have shown that health care professionals can gain valuable insights and training through active participation in co-design processes [116]. In addition, discussions on EBCD underscore the necessity of equipping health care professionals with the tools and knowledge to effectively engage in patient-centered design and improvement initiatives [117]. Overall, training health care providers in these collaborative approaches is essential for fostering meaningful partnerships with patients in health care settings. For example, health care settings could employ staff trained in the use of virtual platforms and equipped with resources to support patients in navigating these technologies. Optimal methods for training older adults to use technology involve a combination of hands-on practice, clear instructions, and personalized support tailored to individual needs and cognitive abilities [118]. Effective approaches often include guided action and attention training, addressing fears, building confidence, and providing ongoing support, with a focus on practical, relevant applications that motivate learners [118,119]. Moreover, the integration of language support and culturally sensitive practices is crucial to ensure that virtual care is accessible to diverse populations. Other studies of virtual care have found that features such as multilingual support, screen readers, and voice commands can make virtual care more accessible to diverse patient populations [120]. Moreover, integrating peers into virtual care models can be achieved through comprehensive support, training, and collaboration across various providers [121].

To test the virtual geriatric care model, future research should use randomized controlled trials comparing virtual geriatric-HIV care with traditional care in terms of patient satisfaction, health outcomes, and cost-effectiveness. Specific technological platforms and features should also be evaluated to determine their effectiveness in addressing the unique needs of culturally diverse older adults living with HIV. In addition, implementation studies should examine barriers and facilitators in various care settings to optimize and scale the model effectively. Future research should build on the findings of this study by exploring the long-term impacts of virtual care models on health outcomes and quality of life for older persons living with HIV. Longitudinal studies could provide insights into the sustainability and efficacy of these interventions over time. In addition, research should investigate the effectiveness of different technological platforms and features in meeting the needs of culturally diverse older persons living with HIV. Existing comparative studies have not assessed virtual care against traditional models in the context of HIV. In addition, issues of equity and access must be addressed to avoid further disadvantaging vulnerable individuals who may lack access to necessary technology or resources. Furthermore, exploring the barriers to and facilitators of implementation in various settings, such as acute and community care, can offer valuable information for refining and scaling virtual geriatric-HIV care models. Finally, future research should continue to address the needs of non-English speakers and other underserved groups, ensuring that virtual care remains inclusive and equitable.

Limitations

This study, while innovative in its co-design approach to developing a virtual care model for older adults living with HIV, has noted limitations. First, the sample size was relatively small and geographically limited to a dense urban center, which may impact the transferability of the findings. Most participants were already engaged with technology, which may not accurately represent the broader population of older adults living with HIV who have varying levels of technological proficiency. This existing familiarity could have positively biased the feedback on virtual care models as these participants, who were actively seeking health care services, might be more comfortable and adept with digital tools. This may not be representative of others who avoid health care and may struggle more with virtual care platforms. Consequently, the findings may overestimate the acceptability of such interventions for the entire demographic, potentially overlooking significant barriers experienced by those less familiar or comfortable with technology. Future research should aim to include a more diverse sample in terms of technological experience to ensure that the developed care models are inclusive and accessible to all older adults living with HIV. Finally, geriatric-HIV care providers and community agencies were not engaged as formal participants in the co-design phases. Their exclusion may have limited insights into the clinical and service delivery perspectives necessary for developing a more holistic and integrated care model. Engaging

these stakeholders could have addressed gaps related to continuity of care and support services. Future iterations of this model would benefit from the involvement of health care providers and community organizations to ensure that the virtual care system is aligned with existing services and adequately meets the needs of older adults living with HIV.

Conclusions

This study highlights the crucial need for socioculturally appropriate virtual care models for older persons living with HIV. Using an EBCD approach, we engaged older persons living with HIV in co-designing a virtual care model that addresses their unique needs and challenges. The findings reveal several key areas for improvement in virtual geriatric-HIV care, including the necessity for robust support systems, effective communication strategies, and tailored health management resources. Participants identified critical needs such as the integration of multimodal care options, transparency in technology use, and the implementation of reminder systems to enhance patient engagement and continuity of care. They also emphasized the importance of linguistic and cultural equity, recommending that virtual care models incorporate diverse language options and cultural considerations to ensure accessibility and relevance. In addition, affordability was highlighted as a significant barrier, with participants advocating for subsidized technology and training to overcome economic challenges. Policy makers should consider the advantages of virtual care for older persons living with HIV and support the expansion of telehealth services and technological infrastructure. Future research should explore the long-term impacts of virtual care on health outcomes and quality of life on older persons living with HIV as well as evaluating different technological platforms and features. By embracing the diverse voices of older persons living with HIV, this study paves the way for a more inclusive, innovative, and equitable virtual future of care.

Abstract

Background: Sleep holds promise as a modifiable risk factor for neurodegenerative diseases and dementia. Clinical trials to modify sleep in people at risk of or in the early stages of dementia are needed. Monitoring natural sleep from home could support pragmatic and decentralized large-scale clinical trials. However, whether longitudinal sleep research can be successfully delivered remotely in this population has not been established yet.

Objective: We investigated the feasibility of remote longitudinal research using wearable devices, web-based cognitive tasks, and a smartphone app to record sleep and cognition in older adults with mild cognitive impairment (MCI) or dementia.

Methods: Older adults with MCI or dementia due to Alzheimer disease or Lewy body disease and cognitively healthy participants completed at-home sleep and circadian monitoring (digital sleep diaries, actigraphy, wearable sleep electroencephalography, and saliva samples) and digital cognitive assessments for 8 weeks. Feasibility outcomes included recruitment, retention, and data completeness.

Results: In total, 41 participants consented (n=10, 24% participants with Alzheimer disease; n=11, 27% participants with Lewy body disease; and n=20, 49% controls). There were predominantly male and White British participants, with a mean age of 70.9

(SD 5.9) years. Retention was very high, with 40 (98%) participants completing 8 weeks of remote monitoring. Data completeness for sleep electroencephalography was 91% and ranged from 79% to 97% for all remote tasks and was overall high across all participant subgroups. In total, 30% (12/40) of participants reported receiving external support with completing study tasks.

Conclusions: High rates of retention, data completeness, and data quality suggested that longitudinal multimodal sleep and cognitive profiling using novel and remote monitoring technology is feasible in older adults with MCI and dementia and healthy older adults, even without study partner support. Remote monitoring should be considered for mechanistic and interventional trials. Careful consideration should be given to how to ensure remote monitoring technologies reduce burden and enhance inclusivity, particularly in communities traditionally underserved by research and those with lower digital literacy.

Introduction

Background

Sleep disturbances such as insomnia, fragmented sleep, daytime sleepiness, and sleep-disordered breathing are common features of Alzheimer disease (AD) and Lewy body disease (LBD) and often appear early in the disease course and before clinical diagnosis [1,2]. Short and fragmented sleep are associated with processes linked to neurodegeneration, including reduced glymphatic clearance of waste [3], increased amyloid beta (Aβ) and tau burden [4], increased neuroinflammation [5], and impaired cardiovascular health [6]. Several small studies of sleep apnea treatment have demonstrated improvement in cognitive outcomes and blood biomarkers of Aβ and tau, suggesting that sleep interventions could improve prognosis in mild cognitive impairment (MCI) and dementia [7-9]. Poor quality or insufficient sleep in midlife increases the risk of all-cause dementia and MCI [10,11], indicating that improving sleep may also protect against dementia. Large-scale clinical studies are needed to enhance our mechanistic understanding of sleep, confirm the most promising therapeutic targets, and monitor the effectiveness and safety profile of sleep interventions [12,13].

However, selecting sleep assessment tools is challenging, particularly in populations with cognitive impairment. Self-report is convenient, inexpensive, and scalable, and has often been used to examine sleep in people with dementia and MCI [14]; however, it is potentially prone to recall bias due to memory deficits or anosognosia. Self-report also correlates poorly with objective sleep measures, particularly in participants with MCI or dementia [15,16] and those with subjectively poor sleep [17], and cannot inform on key components of sleep such as sleep staging or microarchitecture. Polysomnography (PSG) is typically considered the gold standard for sleep measurement, as it provides rich objective sleep data. However, PSG typically requires expert setup, analysis, and a controlled clinic environment, meaning it is expensive, not easily scalable, and therefore typically used for 1 or a few nights [18,19]. PSG setup, especially in an artificial environment, may also not reflect natural sleep [19] as it disrupts usual routines. Longitudinal data collection in sleep research would be beneficial for monitoring clinical trials and disease progression and could account for variation in sleep from external factors such as acute illness or stress, as well as natural intraindividual sleep variation [19].

Wearable devices, smartphone apps, and telemedicine, apart from actigraphy devices, have rarely been used in MCI or dementia research [20], but offer an opportunity to collect objective and subjective data longitudinally in a natural setting [21], often at relatively low cost. Detailed and accurate sleep analysis can now be achieved through wireless technology, including electroencephalography (EEG) headbands and overnight pulse oximetry [21,22]. While actigraphy has been used in dementia research, EEG headbands and pulse oximetry are less well tested, especially in the earlier stages of impairment [23-25]. There is also increasing interest in remote cognitive testing and digital biomarkers for diagnosis and monitoring progression [26]. Despite this, the adoption of digital health technologies into neurology clinical trials, particularly in older people, has been slow [27].

Remote sleep and cognitive data collection has the potential to decentralize clinical trials, making research more convenient for participants and reducing the costs, participant burden, and carbon footprint associated with study visits, while enabling real-time longitudinal data collection of treatment effects. Improved digital access and literacy among older adults [28] and the use of technology among patients living with MCI or dementia to support independent living and for recreation indicate increasing acceptance of technology [29]. However, not all older adults are comfortable using technology, and changes in cognition, sensory processing, and communication might negatively impact the usability and acceptability of novel devices for research purposes in people with cognitive impairment [29,30]. The few studies that have tested wearable devices and digital health technologies for sleep and dementia research in the home have predominantly collected feasibility data for a single device across only a few nights [31] and required support from a study partner or care home staff [32-34]. Before trials invest in digital health technologies and remote study designs, it is important to know whether participants can and are willing to engage and provide data in such studies over a longer period and how much support might be required.

Objectives

This study aimed to establish the feasibility of predominantly technology-based longitudinal sleep and cognitive assessments from home in older adults with and without MCI or dementia.

Methods

Overview

The Remote Evaluation of Sleep to Enhance Understanding of Early Dementia (RESTED) study was a prospective longitudinal observational cohort study involving remote sleep and cognitive monitoring of participants with MCI or dementia and age-matched cognitively healthy controls. The full study protocol has been previously published [35]. The study has been reported in line with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines [36] (Multimedia Appendix 1).

Ethical Considerations

This study was approved by the Health Research Authority (Yorkshire and the Humber-Bradford Leeds Research Ethics Committee, reference 21/YH/0177). This study was conducted in accordance with the principles of the Declaration of Helsinki. All participants provided written informed consent before engaging in any study activities and were reminded of their right to withdrawal without giving a reason and that withdrawal would not affect their health care. Following consent, data were pseudonymized with participants allocated a participant identifier code to maintain privacy. Participants were not compensated for their involvement in the study; however, travel expenses for research visits outside of usual clinic visits were reimbursed. All researchers engaging with participants were trained in good clinical practice.

Study Population

The RESTED study recruited community-dwelling adults aged ≥50 years with internet access at home. Participants were recruited to 1 of 3 participant subgroups according to clinical diagnosis meeting standardized diagnostic criteria [37-40]. Participants with MCI or mild dementia due to probable AD were recruited to the AD group, participants with MCI or mild dementia due to probable LBD or Parkinson disease (PD) were recruited to the LBD group, and sex- and age-matched individuals with no known neurodegenerative conditions or cognitive impairment were recruited as controls. Exclusion criteria included advanced dementia, acute or terminal illness, and significant unrelated comorbidities that might interfere with sleep, except for obstructive sleep apnea (OSA) if participants were already undergoing treatment.

Participants were recruited from the city of Bristol, United Kingdom, and the surrounding areas via cognitive and movement disorders clinics and research volunteer databases, including Join Dementia Research. Our original target sample size was 75 participants [41]. Due to the COVID-19 pandemic, the study was delayed, and the budget was partially reallocated to studies that required no patient contact [12,13,42]. Therefore, we revised the target sample size to 40 participants and recruited from a single site (North Bristol NHS Trust).

We did not recruit or require participants to have a study partner. Participants were welcome to invite someone to support them, and study support was recorded.

Study Procedures

Screening

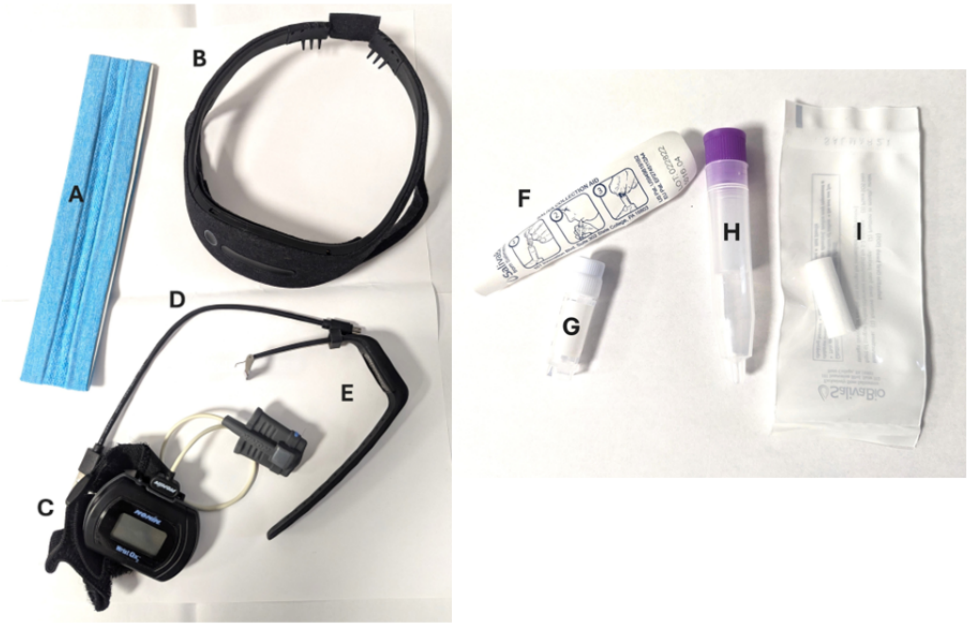
Participants were prescreened for eligibility over the telephone and invited to complete consent and screening in person. Participants who scored less than 11 out of 30 on the Montreal Cognitive Assessment (MoCA) [43] at screening were considered too clinically impaired to participate and were withdrawn.

Baseline Assessments

Eligible participants completed baseline questionnaires with a researcher to assess sleep quality (Pittsburgh Sleep Quality Index [PSQI]) [44]; daytime sleepiness (Epworth Sleepiness Scale) [45]; OSA risk (STOP-Bang) [46]; symptoms of depression (Geriatric Depression Scale-15 item) [47]; anxiety (Generalized Anxiety Disorder-7 item) [48]; and apathy (Apathy Evaluation Scale-Self) [49]. Demographic information and medical histories were also recorded.

Participants were provided with a study kit (Figure 1) consisting of an Axivity AX3 actigraphy watch (Axivity Ltd); Dreem 2 wireless sleep EEG headband (Dreem) [23]; a USB charger; a home saliva collection kit for passive drool (for a dim-light melatonin onset assay); oral swabs (for a cortisol awakening response assay); and an overnight pulse oximeter. Participants who requested a study device were provided with a tablet. Details on devices and the study kit are provided in Multimedia Appendix 2. All participants were provided with a printed participant guide with instructions for each remote study task and research team contact details.

Figure 1. The study kit provided to the Remote Evaluation of Sleep to Enhance Understanding of Early Dementia (RESTED) participants. Participants were additionally required to use a smartphone or tablet to complete digital assessments. A: Sweatband to ensure tight fitting of Dreem 2; B: Dreem 2 electroencephalography (EEG) headband; C: Nonin 3150 WristOx 2 oximeter; D: USB-C charging cable (for Dreem 2 and AX3); E: Axivity AX3 actigraph and wrist strap; F: Saliva collection aid for passive drool; G: Collection tube for passive drool; H: Storage tube for oral swab; I: Oral swab.



At baseline, participants were provided with support to download and use the MyDignio (Dignio AS) app, a telemedicine cloud-based software tool that was used to deliver digital sleep diaries, questionnaires, and reminders to complete study tasks. Participants were also familiarized with the study schedule and tasks and offered support and training ad hoc throughout the study.

Main Study Period

Participants completed 56 days of continuous sleep and regular cognitive monitoring in their own home using an Axivity AX3 actigraphy watch and daily sleep diaries [50] delivered via the MyDignio app. Participants were scheduled to complete a set of 3 web-based cognitive tests (choice reaction time, forward digit span, and self-ordered search) twice weekly on a bespoke study version of the web-based assessment platform Cognitron [51].

For 7 days during the 8-week period, participants also completed an "intensive week," consisting of daily cognitive tasks on Cognitron and nighttime sleep recordings using Dreem 2, a wireless sleep EEG headband. The Dreem sleep staging algorithm has comparable accuracy to manual sleep expert scoring of PSG [23], including in cognitively healthy older adults as well as patients with AD [52] and PD [53]. Sleep recordings were initiated by the participant at their natural bedtime each night and terminated after natural awakening each morning. Data were uploaded via Bluetooth and Wi-Fi to a server accessible to the research team. Additional study tasks during the intensive week included 4 verbal memory assessments involving immediate and delayed free recall and a target-distractor recognition task with a researcher via videoconferencing software and serial saliva samples across 1 evening to assess dim-light melatonin onset and 1 morning to assess cortisol awakening response.

Participants were also invited to undergo 2 nights of pulse oximetry for sleep apnea screening and a blood test for plasma biomarker analysis of Aβ42:40, phosphorylated-tau 181 and 217, neurofilament light chain, and glial fibrillary acidic protein. A protocol amendment approved partway through the study introduced bespoke questionnaires probing study expectations, reasons for participation, experience with technology, and how acceptable they found the intensive week study tasks. Participants were also invited to attend a remote end-of-study interview to share their experiences and asked to return for a 6-month follow-up to complete an MoCA and any outstanding study tasks (eg, missed blood test). Participant feedback from qualitative interviews and questionnaires as well as sleep characteristics for the cohort will be analyzed and presented separately.

Feasibility and Acceptability Outcomes

Recruitment and Retention

Consent, recruitment, and retention rates were recorded and are summarized in a flowchart, alongside reasons for nonparticipation at each stage of the recruitment process.

Data Quality and Completeness

For each remote study task, data completeness was assessed by the average number and percentage of completed tasks or nights' use per participant per participant group (data completeness rate). The number and percentage of individuals who completed the maximum number of data points for a given study task (eg, completed all requested 7 nights of EEG) is also provided. For

EEG, signal quality is reported based on Dreem's automated algorithm. Optimal signal quality is considered ≥85% and good quality is considered ≥70%.

Associations Between Participant Characteristics and Adherence

To explore potential associations between key clinical and demographic variables and adherence, we examined the correlation between 2 continuous measures of adherence (number of sleep diaries completed and mean record quality of Dreem EEG data) and 4 continuous variables which might impact digital literacy or engagement (age at consent, apathy, subjective sleep quality as assessed by the PSQI total score, and baseline cognitive impairment as assessed by MoCA total score).

Study Support and Resource Use

The number of participants who attended study visits with someone to support them, reported having a partner or relative who could support study tasks, and reported receiving support on at least 1 study task were recorded and are summarized descriptively.

Data Analysis

Unless otherwise stated, descriptive statistics are provided as mean (SD) for continuous variables, and frequency and percentage for categorical variables, and provided for the full cohort as well as by participant subgroup (AD vs LBD vs controls). Data analysis was performed using R (version 4.3.1; R Foundation for Statistical Computing) and R Studio software (version 2023.6.0.421; R Foundation for Statistical Computing). Actigraphy data were processed using the open-source AX3/AX6 OMGUI application and analyzed in R using the *GGIR* package [54]. Where available, sleep timing was adjusted using participants' sleep diaries; otherwise, *GGIR* uses the heuristic algorithm looking at distribution of change in z-angle [55] to estimate sleep timing. All files were also visually inspected to check for the accuracy of sleep timing. The quality of the Dreem 2 recordings was assessed by inspecting Dreem's automated record quality index in the sleep report for each night, which indicates the percentage of the recording that is of scorable quality for sleep analysis. Associations between participant characteristics and adherence were calculated using Spearman rank correlation with α set to $P<.05$. Reasons for nonparticipation and missing data are provided where known and mapped to the Capability, Opportunity, Motivation model of behavior change [56]. Where additional data were collected on any outcome (eg, participants completed an additional night of EEG than instructed), additional data points were removed before analysis to avoid biasing feasibility metrics.

Patient and Public Involvement

Patient and public involvement (PPI) was sought from individuals with lived experience of MCI and dementia before and throughout the study. PPI contributors reviewed and improved study documents and advised on the acceptability of adding blood biomarker testing. The PPI group strongly endorsed our additional recruitment materials (including an advertisement poster and a plain English participant information sheet) that we introduced partway through the study, after we received feedback from a prospective participant that standard participant information sheets are too long and use inaccessible language for people with cognitive impairment. We also introduced a reduced study protocol, which involved use of a paper (rather than digital) sleep diary, actigraphy, and EEG, to encourage recruitment of participants who may be more comfortable with less frequent use of technology; however, nobody chose the reduced protocol, they either declined altogether or participated in the full study.

Results

Participant Characteristics and Enrollment

Recruitment

Participant flow through the study is shown in Figure 2. Recruitment was open for 17 months from February 2022 to July 2023, with an average recruitment rate of 3 participants per month. Of 129 individuals identified as potentially eligible before screening, 44 individuals consented to take part, giving a consent rate of 34%. Participants described different motivations for taking part, including wanting to support dementia research, perceiving the study as helpful for themselves or others, and because the study sounded interesting or novel. Reasons for declining to take part in the study are described in Figure 3 and mapped to the Capability, Opportunity, Motivation model of behavior change [56].

Figure 2. Participant flow through the Remote Evaluation of Sleep to Enhance Understanding of Early Dementia (RESTED) study. MCI: mild cognitive impairment; MoCA: Montreal Cognitive Assessment.

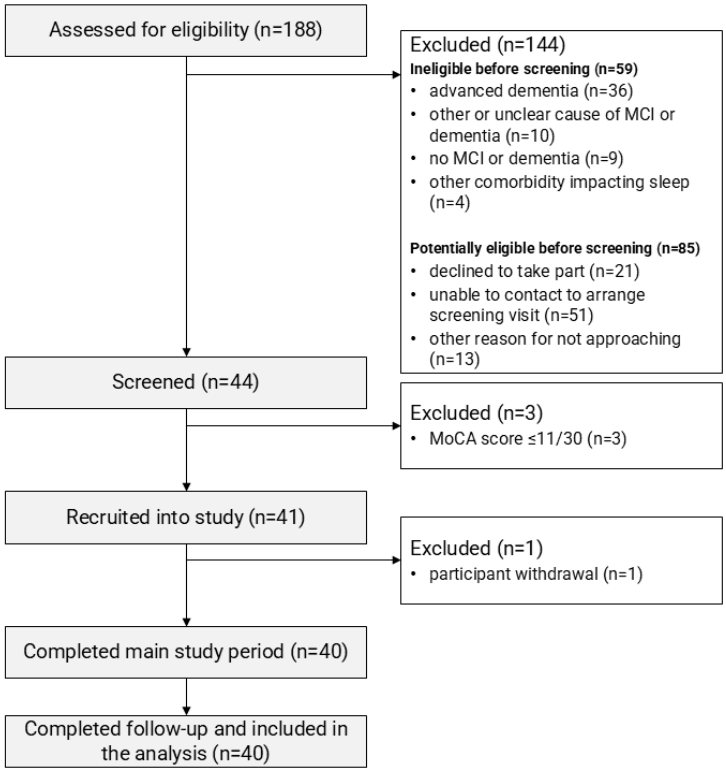


Figure 3. Reasons for declining to participate in the study could be categorized according to the capability, opportunity motivation, behavior (COM-B) model of behavior change in blue. Opportunities to increase capability, opportunity, and motivation to take part in the research are outlined in gray.

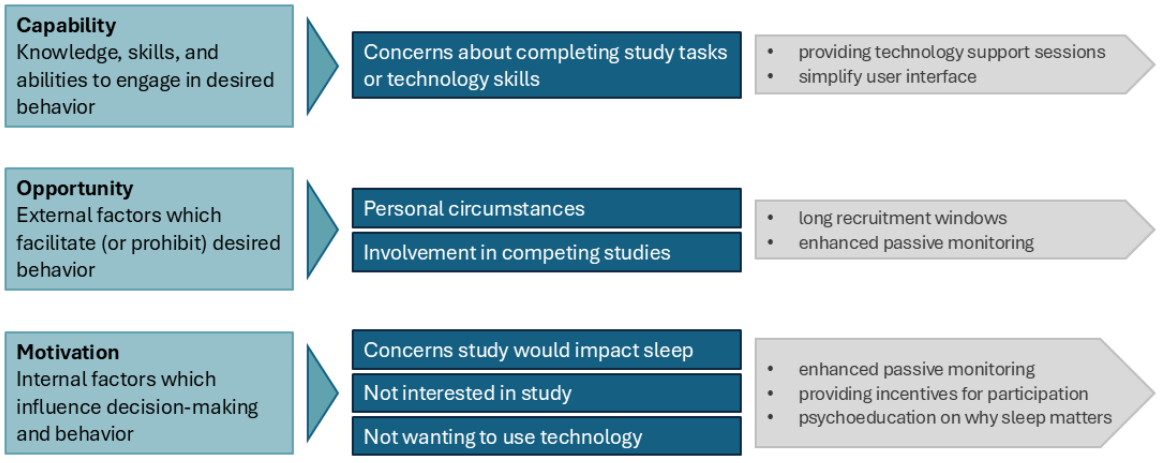

Retention

Of 44 individuals who completed screening, 3 scored less than 11 on the MoCA and were withdrawn. 41 participants were eligible and completed all baseline assessments and training in the at-home study tasks. Of the eligible participants, 1 withdrew before starting the at-home study tasks due to personal circumstances and perceived study burden. All remaining 40 participants completed the main 8-week study period and 6-month follow-up and were included in the analysis, giving a retention rate of 98%.

Participant Characteristics

Participant demographics and baseline variables are presented in Table 1. The sample was predominantly made up of male participants with a mean age at consent of 70.9 (SD 5.9, range 57-81) years. Most participants (33/40, 83%) were retired and all identified as White British. In total, 63% (25/40) of participants completed a questionnaire on experiences of digital technology and expectations of the study, which was introduced via an amendment partway through the recruitment period. Of these, most participants reported frequent use of smartphones or other smart technology (18/25, 72%), however only 12% (3/25) of participants had previously used a wearable to monitor their sleep.

Table 1. Participant characteristics for the study cohort.

Characteristics	AD[a] group (n=10)	LBD[b] group (n=10)	Control group (n=20)
Diagnosis at consent, n (%)			
Mild cognitive impairment	4 (40)	6 (60)	0 (0)
Dementia	6 (60)	4 (40)	0 (0)

Self-reported apathy: AES-S[k,l]; mean (SD)	62.2 (6.0)	53.8 (9.9)	62.8 (8.6)

[a]AD: Alzheimer disease.

[b]LBD: Lewy body disease.

[c]Aβ: amyloid beta.

[d]GFAP: glial fibrillary acidic protein.

[e]NFL: neurofilament light chain.

[f]Participants with obstructive sleep apnea were included only if they were being treated with continuous positive airway pressure.

[g]MoCA: Montreal Cognitive Assessment. Higher scores indicate better overall cognition.

[h]PSQI: Pittsburgh Sleep Quality Index. Higher scores indicate worse sleep quality.

[i]GAD-7: Generalized Anxiety Disorder-7. Higher scores indicate more symptoms of anxiety.

[j]GDS-15: Geriatric Depression Scale-15 item scale. Higher scores indicate more symptoms of depression.

[k]AES-S: Apathy Evaluation Scale-Self. Higher scores indicate more apathy.

[l]One participant had a missing value for an item, so this score was imputed using simple imputation.

Data Quality and Completeness (Adherence)

Overview

Adherence to the sleep and cognitive tasks is shown in Table 2. Adherence was very high across all study groups and tasks.

Reasons for missing data are summarized in Figure 4 with additional detail provided in Multimedia Appendix 3.

Figure 4. Reasons for missing data are mapped according to the capability, opportunity motivation, behavior (COM-B) model of behavior change.

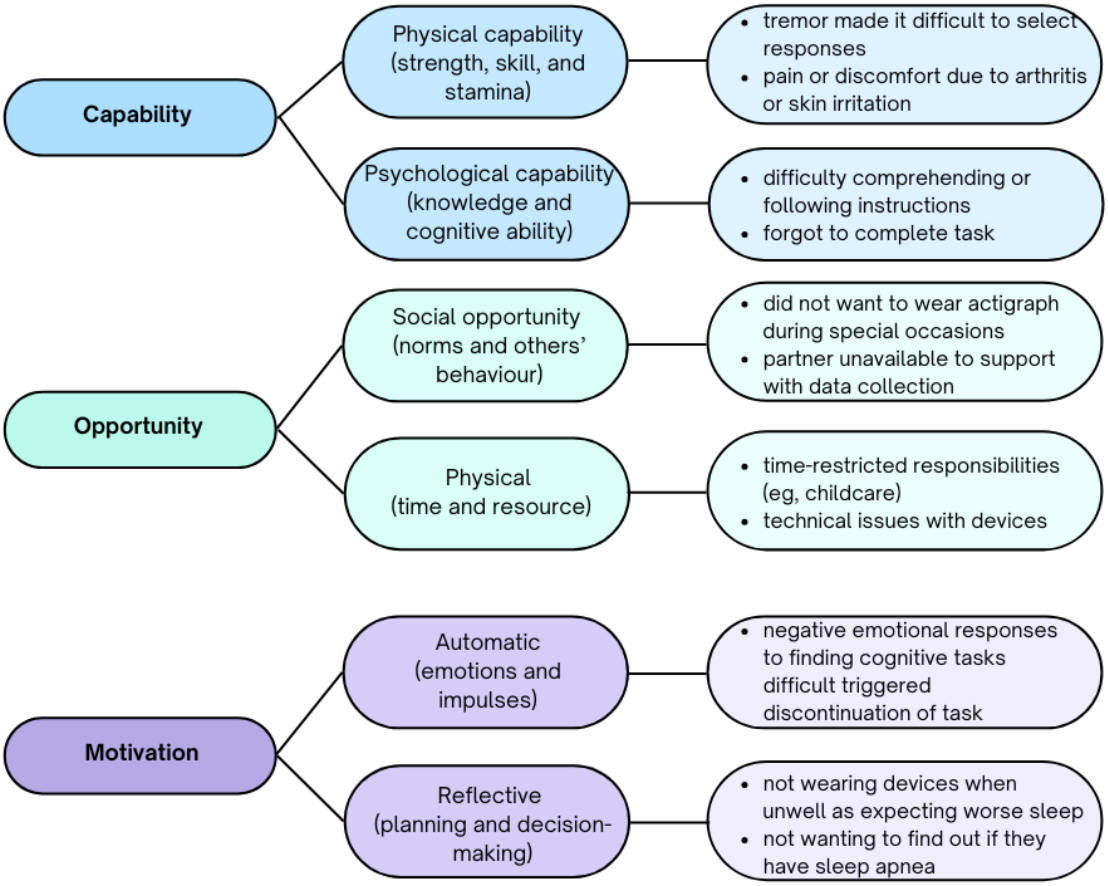

Table 2. A summary of feasibility outcomes relating to data quality and adherence for wearable devices and remote or web-based cognitive assessments.

Study task (device or software); description; and adherence or data quality metric	AD[a] (n=10)	LBD[b] (n=10)	Controls (n=20)	Total (n=40)

[a]AD: Alzheimer disease.

[b]LBD: Lewy body dementia.

[c]EEG: electroencephalography.

[d]Mean first calculated for each participant across all available recordings.

[e]Three participants who already had a diagnosis of sleep apnea were not invited to complete the pulse oximetry.

[f]CRT: Choice Reaction Time.

[g]SOS: Self-ordered search.

Sleep EEG

In total, 257 recordings were made using Dreem 2. One participant accidentally completed an eighth recording, which was removed from subsequent analyses to reduce bias.

All participants successfully recorded at least 1 night of sleep, with an average of 6.4 (1.2) nights across the cohort or a 91.4% data completeness rate (Table 2). In total, 73% (29/40) of participants provided data for all 7 nights. Average record quality was also high at 84.4% (15.8), indicating nearly optimal record quality on average across the cohort. One participant wore the Dreem 2 but did not successfully initiate the recording during the intensive week but completed 7 successful nights of recording on a second attempt later in the study. Record quality for individual EEG channels is provided in Multimedia Appendix 4.

Actigraphy

In total, 2332 nights of data across the full cohort were collected. A total of 189 of these nights contained no data, either at the

beginning or the end of the actigraphy file and were removed from sleep analyses. Following visual inspection, a further 9 nights were removed due to sustained nonwear. Therefore, 2134 nights were of sufficient quality for sleep analysis.

Across the cohort, participants provided an average of 52.8 (7.6) out of 56 analyzable nights, giving a data completeness rate of 94.3%. In total, 60% (24/40) of participants provided 56 analyzable nights. All participants recorded at least 14 days of actigraphy. Unexpected battery failure outside of participants' control (due to long-term storage without use during the COVID-19 pandemic) affected 2 participants' recordings and was identified during data check at the midpoint study visit. No participants refused to wear or discontinued use of the actigraphy device, although several reported forgetting or choosing not to wear it on certain days or taking brief breaks due to minor skin irritation.

In total, 37 diary entries were manually entered based on visual analysis of the actigraphy data due to missing sleep diaries and poor heuristic algorithm looking at distribution of change in z-angle algorithm detection of the sleep period. Finally, the sleep analysis software was instructed to solely rely on sleep diary information for 166 nights due to a clear misclassification of sleep period.

Overnight Pulse Oximetry

As 3 (8%) out of 40 participants were already being treated for established OSA, 37 (93%) participants were offered overnight pulse oximetry. In total, 3 (8%) participants declined, and 1 (3%) participant was unable to tolerate wearing the device. The remaining 33 (89%) participants completed at least 1 successful overnight recording, with 26 (70%) recording successful oximetry traces on both nights. The data completeness rate was 79.7% for those eligible and asked to complete overnight pulse oximetry. Referrals to a sleep clinic for either sleep apnea or incidental findings (such as abnormal pulse rise index) were indicated for 57% (21/37) of participants. In total, 4 (11%) participants declined referral due to not wanting a formal diagnosis, not wanting to be put on sleep apnea treatment, and the inconvenience of traveling to the clinic. In total, 17 (46%) participants agreed to a referral.

Digital Sleep Diaries

Although few participants (12/40, 30%) completed all 56 sleep diaries, overall adherence was high. Participants completed an average of 51.7 (SD 8.6) sleep diaries, and only 2 (17%) participants completed fewer than 75% of their sleep diaries. The data completeness rate was 92.3%.

Only 1 (3%) participant completed sleep diaries on paper while her partner, who facilitated entries into MyDignio, was away. In total, 3 (8%) participants had technical issues with data entry into the MyDignio app lasting several days due to a software update and provided some of their sleep diaries via email which were then entered by the study team.

At the time of study setup, Dignio did not offer data format validation, and free-text response boxes were used for several questions. Participants often did not input data in the format requested, and inconsistency in reporting prohibited reliable automated recoding; however, most were manually interpretable by the research team. Where a range of values were provided, a mean was calculated and the value was rounded to the nearest whole minute (eg, 5-10 min was recoded to 8 min). One diary entry was manually corrected by the research team to align with other diary entries and the actigraphy file. It was not possible to recode some responses due to ambiguity (eg, responses of "not long," "several minutes," or "unsure"), leaving 43 completed sleep diaries incomplete on at least one sleep variable. Questions most likely to have a missing value were questions on sleep onset latency and length of nocturnal awakenings.

Video-Based Verbal Memory Tasks

In total, 92% (37/40) of participants completed at least 1 verbal memory task with a researcher. Data were missing for 1 (3%) participant as the task was considered inappropriate due to their specific language difficulties, 1 (3%) participant due to technical issues with video calling, and 1 (3%) participant due to distress during the first learning trial. Most participants (35/40, 88%) completed all 4 verbal memory tasks, with 2 (5%) participants completing only 2 of the tasks due to work or childcare commitments. Overall, the data completeness rate was 90%. In total, 3 (8%) participants reported finding the task difficult, 2 (5%) reported feeling distracted during the encoding tasks, 2 (5%) reported finding the encoding task distracting rather than helpful, and 2 (5%) reported finding that usual memory techniques such as the story technique or rehearsing words in an auditory loop were difficult to do in this task.

Web-Based Cognitive Tests

Few participants completed all 21 cognitive tasks: 6 (15%) out of 40 participants completed all 3 cognitive tasks on all 21 occasions. In total, 7 (18%) participants provided complete data for choice reaction time tasks, 8 (20%) for the self-ordered search, and 9 (23%) for the digit span task. However, on average data completeness was good, with 79.8% of allocated web-based cognitive tasks completed. Only 1 (3%) participant with PD attempted the tasks but discontinued due to frustration at not being able to do the tasks, as they required speed and accuracy. Several participants anecdotally reported misunderstanding the choice reaction time task and clicking outside of the response window but these instances were not formally recorded.

Saliva Samples

Overview

The outcomes for saliva and blood samples are summarized in Table 3.

Table 3. The outcomes relating to data quality and adherence for biomarker analysis: blood biomarkers, salivary dim-light melatonin, and salivary cortisol awakening response.

Study task (sample type) and description; adherence or data quality metric	AD[a] (n=10)	LBD[b] (n=10)	Controls (n=20)	Total (n=40)
Neurodegenerative and AD biomarker samples (blood): participants were asked to have blood drawn for biomarker testing				
Participants who provided blood for biomarker testing, n (%)	9 (90)	10 (100)	18 (90)	37 (92)
Samples analyzed for all biomarkers, n (%)	8 (80)	8 (80)	14 (70)	30 (75)
Samples analyzed for ≥1 biomarker, n (%)	9 (90)	10 (100)	18 (90)	37 (92)
Melatonin samples (passive drool): participants were asked to complete 7 hourly samples across 1 evening, starting from 5 h before bed, and record the sample time				
Analyzable samples provided per participant, mean (SD)	6.3 (2.2)	6.9 (0.3)	7.0 (0)	6.8 (1.1)
Participants who completed all 7 samples, n (%)	9 (90)	9 (90)	20 (100)	38 (95)
Average discrepancy between scheduled time and reported time of completion (min)[c], mean (SD)	5.6 (53.4)	−13.9 (32.6)	−9.2 (37.1)	−7.0 (41)
Cortisol samples (oral swab): participants were asked to complete 3 samples across 1 morning: upon waking up, after 30 min, and after 60 min, and record the sample time				
Analyzable samples provided per participant, mean (SD)	2.7 (0.9)	3.0 (0)	3.0 (0)	2.9 (0.5)
Participants who completed all 3 samples, n (%)	9 (90)	10 (100)	20 (100)	39(98)
Average discrepancy between scheduled time and time completed (min)[c], mean (SD)	22.5 (27.8)	24.3 (17)	24.6 (23.8)	24.0 (23.2)

[a]AD: Alzheimer disease.

[b]LBD: Lewy body dementia.

[c]Positive numbers here refer to a sample being taken later than scheduled, and negative numbers refer to a sample being taken earlier than scheduled.

Dim-Light Melatonin Assay: Passive Drool Samples

Most saliva samples (272/280, 97.1%) were collected as requested. Of 40 participants, 1 (3%) participant provided no saliva samples, and 1 (3%) participant provided 9 out of 10 samples. Data completeness rate for analyzable samples was 92.5% (259/280) across the cohort. Participant-reported sample times were available for 86.7% (236/272) of the total sample. In total, 50.8% (120/236) of the total sample were reported to have been completed within 15 minutes of the scheduled time, as calculated by average bedtimes reported in the sleep diary. On average, participants completed their samples around 7 minutes early (Table 3). Previous studies have identified highly variable salivary melatonin secretion, with peaks from 2 pg/mL to 84 pg/mL [57]. Across the cohort, values ranged from beneath detectable levels (<1.37 pg/mL) to 92.4 pg/mL.

Cortisol Awakening Response: Oral Saliva Swabs

Participants were instructed to provide saliva samples upon waking up, after 30 minutes, and after 60 minutes on one morning during the intensive week. Data completeness was 97.5%, with missing data from only 1 participant who did not provide any saliva samples. Data completeness rate for analyzable samples was 91.7% across the cohort. We compared reported saliva sample timings to their scheduled timings, based on final awakening time estimated by EEG. Participant-reported sample times and EEG awakening time were available for 72.6% (85/117) of cortisol samples. From the 85 samples with timings available, suggested wake times were later than the first sample recording time for 6 samples (7%) and were removed from analysis due to suspected error in recorded saliva timing or date. Participants recorded their first cortisol saliva swab an average of 23 minutes after awakening and overall cortisol samples were generally 24 minutes later than scheduled across the 3 time points (Table 3). Previous studies have identified variable salivary cortisol awakening values from 3 to 19 µg/L in healthy adults [58]. Across the cohort, values ranged from 0.9 to 13.4 µg/L.

Associations Between Participant Characteristics and Adherence

There was some evidence of a weak correlation between MoCA score at baseline and EEG record quality, where those with greater cognitive impairment had lower average EEG record quality (r=0.31; *P*=.05). Spearman rank correlations revealed no evidence of correlations between EEG record quality and age (r=−0.10; *P*=.54); apathy (r=0.16; *P*=.31); or PSQI score (r=0.19; *P*=.24). There was also no evidence of correlation between the number of sleep diaries completed and age (r=−0.15; *P*=.35); MoCA score (r=0.11; *P*=.48); apathy (r=0.07; *P*=.69); or PSQI score (r=0.12; *P*=.47).

Resource Use

Support From Partners and Relatives

In total, 36% (4/11) of individuals with AD, 85% (11/13) of individuals with PD or LBD, and 10% (2/20) of controls attended their consent visit with a partner or relative. In total, 80% (32/40) of participants reported that there would be someone external to the research team (eg, partner or relative) who could support them with study tasks if needed at baseline. However, only 30% (12/40) of participants reported receiving support with completing study tasks (n=3, 30% AD; n=8, 80% LBD; and n=1, 5% control). Support from outside of the study

team was predominantly from partners and included reminders to complete tasks, setting up devices, and troubleshooting technical problems. Of 40 participants, 3 (8%) participants who required technical support from a partner or relative, or used their devices to complete study tasks, reported missing study tasks due to their partner or relative being unavailable during the study period. The participant who withdrew following baseline reported having someone who could support them at home.

Support and Contact With the Research Team

Participants received in person and remote training and support from a researcher to complete study tasks at baseline (including downloading and setting up apps and turning on recording devices) and were offered a refresher training session before the intensive week. Participants were also provided with a written instruction manual, scheduled in-app and email reminders, and ad hoc support as requested by participants or where the team noticed ≥3 consecutive days of missing sleep diary data. All participants had at least 1 in-person visit from a researcher (eg, to download midpoint actigraphy data or retrieve study equipment) during the study period. Participants were advised to contact the research team if they had questions during the study by their preferred method (email, phone, video call, or instant messaging on the MyDignio app). Support from the research team during the study was most often provided by email and involved responding to participant queries on initial setup (eg, downloading the MyDignio app); reminders (eg, tasks to complete or passwords); and technical issues (eg, links not arriving for Cognitron). Some participants also requested telephone-based, video-based, or home-based support (eg, to refresh training on the intensive week study tasks). Most participants did not receive regular reminders from the study team to complete tasks.

Device Use

One participant was provided with a study tablet upon request, as they wanted to keep study activities and apps separate to their personal devices. All other participants used their own smart devices for study activities (ie, smartphones, tablets, and personal computers). Most participants used >1 device to complete web-based study tasks due to personal preference or convenience. No devices provided by the study team were lost or damaged during the study, although some participants cut the actigraphy watch strap for comfort.

Discussion

Principal Findings

In this study, we show that it is feasible to remotely measure sleep and cognition longitudinally in community-dwelling older adults with MCI and dementia due to AD and LBD and healthy older adults. Eligible participants were interested in, enrolled in, and remained in the study, despite being asked to complete a high volume of remote and novel study tasks across an 8-week period while continuing their usual routines. Only 1 participant withdrew from the study, and this was before remote data collection started. Most participants were receptive to multimodal home-based research using technology and alternatives to in-laboratory sleep assessment. Across the cohort, data completeness rate was high and ranged from 79.8% to 97.1%. Our findings support the use of remote, technology-supported research methods to study natural sleep in future trials and indicate some areas where further improvements and refinements would be helpful. With just under two-thirds of our sample (25/40, 63%) having sleep apnea, and only 3 (8%) being aware of this before joining the study, our results also highlight the importance of sleep apnea screening in older adults, as a risk factor and potentially reversible contributor to cognitive impairment and poor sleep quality [59].

Many older adults with MCI and dementia routinely leverage technology for cognitive stimulation, performing activities of daily living (such as shopping and banking), entertainment, and socializing, and use assistive-technology solutions, such as reminders and navigation to support independence [60]. However, cognitive impairment might impact ability to understand or remember to complete remote or technology-based study tasks, resulting in missing data, and may trigger anxiety if patients feel unable to perform tasks correctly [61]. Although a few previous studies had examined the use of sleep wearables in adults with AD, this was typically done over a brief period, examined feasibility of using only 1 digital health technology, or required input from a carer or study partner [31-34,62]. Our study demonstrated that older adults with MCI and dementia can successfully complete novel multimodal sleep and cognitive assessments, including longitudinal concurrent use of wrist actigraphy, web-based cognitive tests, digital sleep diaries, and wireless EEG headbands. However, more effort will be required to recruit samples which are representative of the older adult population and those with MCI or dementia, as our study predominantly recruited White male individuals who were familiar with smart technology, albeit not the devices used in RESTED.

Data completeness rates, reflecting both the ability to complete study tasks and produce data of analyzable quality, were high across all study tasks and participants. Remote data collection comes with a risk of missing data or nonadherence; however, we were able to mitigate this risk by using devices which upload data to servers at regular intervals (eg, Dreem and Dignio) and, less conveniently, by downloading data manually from devices to check compliance and data quality and offer support where needed (eg, actigraphy). Passive monitoring devices and devices that upload to servers automatically can simultaneously reduce the burden on participants and researchers while minimizing data loss by allowing researchers to monitor and respond quickly to any user or technical issues.

Reasons for missing data were usually known and typically related to infrequent but intentional decisions to remove a device (eg, due to a social event or illness) or, in most cases, technical issues with devices or software beyond the participants' control, which would not introduce bias. We observed a weak correlation between EEG record quality and baseline cognitive impairment, which could be explained by cognitive impairment impacting ability to correctly wear the EEG headband for maximal impedance or reflect that patients were moving more during the night. Even subtle movements can shift the headband and reduce

signal quality and getting optimal signal quality across entire or several recordings is a recognized challenge for dry EEG [52]. More comprehensive cognitive assessment than the MoCA, particularly a deeper assessment of executive dysfunction and long-term memory, might reveal a stronger relationship between cognitive impairment and adherence. However, recent studies using remote monitoring technologies found that, although patients with more advanced neurodegenerative disease or cognitive impairment reported more problems and were less compliant, the study remained feasible [63,64]. Larger studies may also want to consider regression analyses to identify key predictors of adherence to identify where support might be most indicated by the research team or caregiver support. However, importantly, overall record quality remained high across the cohort. Having MCI or mild dementia did not preclude study participation, adherence to remote supervised and unsupervised study tasks, or obtaining good-quality data.

Use of remote sleep and cognitive monitoring can help to partly or fully decentralize research, as participants can use their own devices or be provided with technology via post where needed [65], which is more scalable for clinical trials [66]. Frequent or lengthy clinic visits, particularly those that require overnight stays for sleep analysis, can be burdensome for participants, and may reduce inclusivity by requiring participants to live near a study site or travel long distances. More frequent but briefer remote assessments may also help to mitigate against the risk of large amounts of missing data resulting from a missed clinic appointment, can act as “digital biomarkers” that may detect changes more sensitively than an annual follow-up [67], and are more convenient for participants [68]. Although not the focus of our work, research could also explore the use of digital tools to assess fluctuations in cognition over the day in LBD (where fluctuation in cognition is a key diagnostic criteria) and AD (where a sundowning effect of heightened distress is often observed during the evening hours), both of which are difficult to assess in clinical settings [69,70].

While high adherence has been previously demonstrated in feasibility studies of remote monitoring technologies in participants with cognitive impairment or neurodegenerative conditions, most studies have required intensive study partner support throughout the study period as an eligibility criterion [63,71]. It has been argued that study partners are essential for participant safety and well-being in dementia research, even at the preclinical stage where cognitively normal individuals are enrolled [72]. For some participants, partners or relatives provided essential support for study participation. However, many participants provided good-quality data with minimal to no input from others. Crucially, several participants would not have been able to participate if there had been a study partner requirement. Strict eligibility criteria for trials are a recognized barrier to research participation [73]. Requiring a study partner for all studies may unnecessarily increase the burden for relatives already providing care or support, reducing the participant pool, and may disproportionately affect different groups in society who are underserved by research [74,75]. Our findings encourage researchers to consider inclusive and flexible research designs, including options to formally recruit and collect data from study partners without excluding participants who do not have someone available to support them in research studies.

There are an increasing number of options when considering how to measure sleep and cognition from home, including both research-grade and consumer sleep trackers [76,77]. We opted to use existing technologies that were noninvasive, affordable, required minimal training or supervision, were commercially available research-grade or consumer-grade devices that met necessary data privacy regulations, and provided data in a format that could be analyzed using open-source software. Existing technologies can be implemented immediately, reducing time and cost to setup research studies, have a more mature user interface, and are less error-prone than a newly developed solution, and crucially, may be easier to compare among studies for meta-analysis. Several study tasks required ongoing technical support or services from the manufacturers or developers. As a customer rather than a collaborator, we could not always identify or respond to technical problems, and with some providers, we were not informed in advance of several significant changes, which impacted the study or its participants resulting in data loss. Collaborating with industry, ideally at an early stage of the research process, might ensure longevity and continued support throughout the life course of the study and increased flexibility to adapt technology to better fit research (eg, data validation for digital patient-reported outcomes).

Limitations

Women, adults aged >80 years, and minoritized ethnic groups were underrepresented in our study, which is often observed in dementia research [78]. Although some barriers (eg, mistrust and accessibility of research) and motivators (eg, altruism) have been identified, further work is needed to identify how to improve research access, inclusion, and participation in dementia research [79]. There may also have been a self-selection bias, whereby individuals who were likely to be more competent and enthusiastic about using technology volunteered to participate in the study. Most of our participants were regular smartphone users, and several prospective participants declined to participate due to concerns regarding their confidence or interest in using the technologies. Although the proportion of older adults in the United Kingdom using the internet is increasing, a significant proportion of older adults do not regularly use the internet or lack fundamental skills such as being able to turn on a device and enter login details [28]. Older adults with MCI and dementia who regularly use devices report that smartphones and tablets can be useful to support activities of daily living, as well as for communication, entertainment, and recreation, but also list concerns, including cybersecurity and vulnerability to fraud [80]. Education around sleep and brain health, and basic digital skills training on how devices can support individuals living with cognitive impairment, may improve perceptions of capability and motivation to participate in similar studies [56,80]. Exploring the feasibility of more passive monitoring technologies, such as mattress sensors or smartphone-based passive sensing, may help to increase participation and confidence from those with less experience or interest in technology. Although these techniques may invite additional concerns around data privacy, passive monitoring technologies are already being used to support older adults aging in place

[81,82]. Increasing the pool of prospective participants through recruiting via multiple sites and meaningful engagement with community groups, and considering digital inclusivity is likely to enhance recruitment in future studies. Finally, we did not set a priori feasibility cutoffs for study tasks. Despite these limitations, the high completion and retention rate from the RESTED study suggests that remote sleep and cognitive monitoring could offer detailed sleep profiling suitable for tracking change in sleep over disease progression or for monitoring change in sleep clinical trials in older adults with or at risk of dementia.

Conclusions

Practical, detailed, and scalable assessment of sleep is essential for understanding how sleep disturbances affect neurodegeneration over time and for developing and evaluating effective interventions. Our results suggest that older adults with MCI and dementia, as well as healthy older adults, can and do engage in multimodal remote sleep and cognitive research, including using wireless EEG, actigraphy, and mobile apps or web applications. Remote monitoring technologies and research designs offer the opportunity to study natural sleep and its relationship with cognition and dementia over extended periods, are scalable, and should be considered when designing future clinical trials in sleep and dementia in these populations.

Acknowledgments

The authors sincerely thank the Remote Evaluation of Sleep to Enhance Understanding of Early Dementia (RESTED) study participants and their relatives and partners who supported them to take part. They would also like to thank the ReMemBr group lived experience experts for their contributions to improving the study design and supporting them to make the study as accessible as possible. They would also like to thank the North Bristol NHS Trust Respiratory Physiology department and the Bristol Bioresource Laboratories, Anglia Ruskin University Biomarker Lab, and UK DRI Fluid Biomarker Laboratory for providing their services and support for our saliva and blood biomarker analyses.

Finally, the authors would like to thank the teams at Dreem Research, Cognitron, Join Dementia Research, and Ewa G Truchanowicz and Phil Reay, and their teams at Dignio, United Kingdom.

The RESTED study was funded by charitable organizations (BRACE, Alzheimer's Research UK, the Bristol and Weston Hospitals Charity [previously Above and Beyond], and the David Telling Charitable Trust), the NIHR Bristol Biomedical Research Centre, and philanthropic donations from S Scobie and A Graham. JB also received funding from Alzheimer's Research United Kingdom (ARUK) supported by the Margaret Jost Fellowship and the Don Thoburn Memorial Scholarship. The funders had no role in the trial design, patient recruitment, data collection, analysis, interpretation, writing of the manuscript, or the decision to submit it for publication.
