Results: The following themes emerged from focus groups to inform prototype development: (1) designing flexibly to allow users to tailor the intervention experience to their own environmental context and circumstance, (2) designing with the dyad's clinical and relational needs in mind, and (3) accounting for illness and aging-related challenges in design. The following themes emerged from workshops to inform prototype refinements: (1) increasing user support through more feedback and (2) increasing variety of visual and auditory feedback.

Conclusions: Using user feedback throughout the development process, we developed a prototype of an IVET intervention, Toolkit for Experiential Well-Being in Dementia (the Isle of TEND), tailored to the needs of persons living with dementia and their caregivers. Our prototype uses specific design features to promote safety, usability, and engagement in the context of dementia. Future feasibility testing of the intervention is warranted.

Introduction

Background

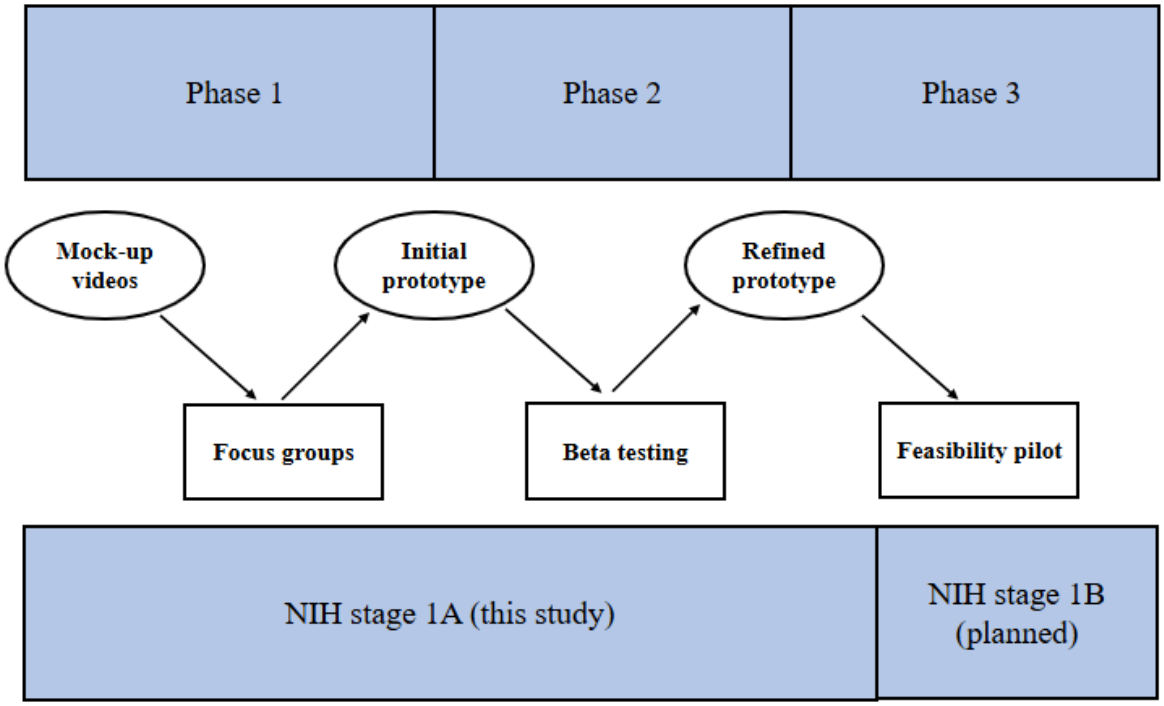
Throughout the course of dementia, emotional health challenges (eg, depression, negative affect, and worry) are common among both persons living with a dementia diagnosis and their informal caregivers (eg, family members and friends) [1,2]. Persons living with dementia and their caregivers present with different emotional needs throughout the course of dementia [3,4]; however, maintaining relationship quality within the context of changing interpersonal dynamics remains an important component of emotional health for both members of the person living with dementia–caregiver dyad [5].

Dyadic research is gaining popularity within the fields of emotional health and dementia care [6,7]. Dyadic research highlights the impact of interpersonal relationships and the transmission of emotional states between members of the person living with dementia–caregiver dyad, which influence the emotional health of each member [8]. For example, perceived relationship strain by the persons living with dementia is associated with increased emotional distress in their caregivers and vice versa [9,10]. Alternatively, positive affective states can be shared among dyad members (eg, laughter), increasing emotional health for both dyad members [11]. Indeed, relationships and the emotional health needs of persons living with dementia and caregivers often change throughout the course of dementia, especially in advanced stages, as cognitive and communication limitations are more common [4,12]. However, despite changes, the need for positive experiences shared between persons living with dementia and caregivers remains common and relates to fewer behavioral and psychiatric symptoms among persons living with dementia and less stress among caregivers [13]. Thus, shared pleasant activities are an important component of emotional health among person living with dementia–caregiver dyads that can be targeted at any stage of illness.

As dementia advances and cognitive impairments become more pronounced, identifying shared activities that can promote emotional health for both persons living with dementia and caregivers may become more challenging [14-16]. Indeed, many dyadic interventions in the context of dementia are concerned with systematic approaches to identifying and engaging in shared activities [17]. For example, the tailored activity program intervention helps dyads identify and engage in personalized shared activities to reduce agitation among persons living with dementia and improve well-being among caregivers [18,19]. However, many of these shared activity interventions rely heavily on caregivers to plan and initiate activities, which may reduce shared positive affective states due to the caregiver-care recipient role, rather than equitable activity engagement [11]. For example, caregivers may find themselves in the role of an “instructor” or “supervisor,” rather than fully engaging in and receiving the emotional benefits of an activity. Therefore, designing interventions that allow both persons living with dementia and caregivers to fully engage in shared activities may create a positive emotional experience for each dyad member, contributing to their emotional health. Technology may aid this endeavor by creating interactive experiences that minimize the need for caregiver initiation (ie, using a technology platform that engages and guides both members of the dyad through an activity, rather than relying on the caregiver to lead the activity). Immersive virtual environment technology (IVET) is one such option for engaging person living with dementia–caregiver dyads in an intervention together.

IVET exists under the umbrella of virtual and augmented reality [20] and is defined as an artificial sensory experience that users actively engage with as if it were a real experience [21]. IVET promotes active engagement between users and computer-simulated environments through multisensory user-driven experiences [13,21,22]. These methods align well with existing approaches to promoting positive affect among persons living with dementia (ie, multisensory stimulation and personalized activities) [23]. IVETs often follow the 3 I’s design framework [24], which suggests that user engagement is achieved through (1) immersion (ie, creating a feeling of presence within the virtual environment), (2) interaction (ie, creating a sense of agency and control over the virtual environment), and (3) imagination (ie, the potential to create new experiences within the virtual environment). In nondementia populations, IVET interventions have demonstrated positive effects on emotional health outcomes, such as positive affect and emotional health (eg, depression and stress) [25]. Importantly, IVET interventions vary in terms of the level of immersion, categorized as low (ie, screen-based intervention), medium (ie, cave automatic virtual environments and surrounding projection screens), or high (ie, head-mounted displays for isolation from physical reality) [25]. In nondementia populations, medium immersion produces the greatest results on emotional health, with little difference observed between low and high immersion [25]. However, given the potential safety risks, such as cybersickness, falls, and agitation associated with higher levels of immersion in the context of dementia [21,26], IVET with low immersion may be suitable for this population. Indeed, most IVET interventions tested within the context of dementia use lower levels of immersion [27].

IVET interventions allow for multiple users to engage jointly (eg, persons living with dementia and their caregivers participate in shared activities) [21]. However, existing interventions have been tested primarily among persons living with dementia and caregivers individually [27-30]. For persons living with dementia, IVET interventions have demonstrated feasibility and usability, primarily targeting cognitive rehabilitation, exercise, or spatial navigation training [27]. For caregivers, IVET interventions have demonstrated feasibility and usability, often focused on caregiver education and skills [31,32]. Fewer IVET interventions have been developed for person living with



XSL•FO
RenderX

dementia–caregiver dyads to participate in jointly (ie, dyadically), with a focus on shared positive experiences for emotional health. SENSE-GARDEN is an example of a dyadic IVET intervention, which creates an immersive environment based on preferred autobiographical experiences, such as music, images, videos, and personal media (eg, family photos), for persons living with dementia who have moderate to severe cognitive limitations, allowing them to navigate along with their caregivers. The intervention is designed to support reminiscence between the persons living with dementia and caregivers in the present moment. Notably, caregivers have an active role in personalizing the information in SENSE-GARDEN but receive a lower "active dose" of the intervention (ie, fewer caregiver-focused experiences). Rather, caregiver benefit is conceptualized as arising from positive interactions with persons living with dementia. A clinical trial is currently underway for this intervention [33].

A major challenge to designing dyadic IVET interventions in the context of dementia is addressing cognitively mismatched dyads, which is more common as dementia advances. Promoting shared engagement among person living with dementia–caregiver dyads across the illness spectrum must embrace the 3 I's of design (ie, immersion, interaction, and imagination) for dyads with potentially different cognitive ability levels. While challenging from a design perspective, if achieved, this type of intervention would be an invaluable opportunity for dyad members to truly engage in shared activities together (ie, not initiated by the caregiver), helping them to briefly abandon the caregiver-care recipient dynamic and, in doing so, derive relational and emotional benefits. These types of more equitable interactions may promote positive affect and interpersonal connection among both persons living with dementia and caregivers, dignity for the persons living with dementia, and positive aspects of caregiving for the caregivers [34]. However, currently, guidelines for designing dyadic IVET interventions to promote shared engagement among person living with dementia–caregiver dyads are lacking, especially for dyads with mismatched cognitive abilities [6,35].

Additional work is needed to guide the development of dyadic IVET interventions throughout the course of dementia, especially in more advanced stages. For this endeavor, user-centered design approaches may be particularly important to ensure that interventions have the potential to be acceptable and feasible for both dyad members at various stages of illness. User-centered design is an iterative approach that centers the user experience early and often throughout the intervention development process [36]. The aim of user-centered design is to maximize the feasibility and acceptability of an intervention [37]. This study followed a multiphasic conceptual model of user-centered design rooted in human factors research, as outlined by Witteman et al [38]; refer to Figure 1. In phase 1, design teams engaged users and other knowledge holders with the goal of understanding user needs, goals, and strengths. In phase 2, design teams iteratively developed and refined an initial intervention prototype with user feedback. In phase 3, design teams observed users' naturalistic interactions with the initial prototype to inform additional refinements [38]. On the basis of user-centered design principles in the context of dementia [39], we prioritized the following factors across each design phase: understandability (ie, the user understands the intervention functions), learnability (ie, the user is able to easily learn the intervention), usability (ie, the user is able to participate in a task with minimal assistance), and safety (ie, tasks do not inadvertently lead to negative affect or other adverse outcomes).

RenderX

Purpose

This study aimed to develop a dyadic IVET intervention to support the emotional health of person living with dementia–caregiver dyads. Our design team represents an academic-industry partnership. In this study, we highlight our multiphasic user-centered design process [38], focused on the early stages of intervention development of a dyadic IVET intervention (phases 1 and 2 of user-centered design). First, we present data from focus groups with clinicians, caregivers, and person living with dementia–caregiver dyads to understand user needs, goals, strengths, and usability and safety concerns (phase 1). Then, we discuss the process of iteratively developing and refining an initial intervention prototype based on user feedback from multiple user workshops with person living with dementia–caregiver dyads (phase 2). The resulting dyadic IVET intervention prototype will be ready for pilot testing in a pilot feasibility trial (phase 3). In this study, by describing phases 1 and 2 of user-centered design, we highlight early design considerations for future teams focused on developing IVET or other novel technologies with person living with dementia–caregiver dyads across stages of dementia.

Methods

Study Design

This study followed a multiphasic user-centered design framework for the early stages of intervention development, as outlined by Witteman et al [38] and with the following dementia-specific considerations incorporated [39]: (1) understanding user needs, goals, strengths, limitations, and safety concerns; (2) iteratively developing and refining an initial prototype with user feedback; and (3) observing users' naturalistic interactions with the initial prototype. In phase 1, we conducted 5 focus groups with clinicians, caregivers, and person living with dementia–caregiver dyads to identify preferred activity features as well as design considerations for usability (ie, preferred intervention activities and accommodations) and safety in the context of dementia. The study team determined readiness to move to phase 2 after we believed that we understood major safety risks and could generate enough content for mock-ups of an intervention prototype. In phase 2, we conducted 8 beta testing workshops with person living with dementia–caregiver dyads to inform the development and refinement of an initial prototype. We determined readiness to move to phase 3 when usability concerns were sufficiently addressed, as evidenced by minimal usability issues reported by workshop participants. At the conclusion of phase 2, we had a finalized intervention prototype ready for feasibility testing in phase 3, which is not reported in this study. Phases 1 and 2 map onto stage 1A of the National Institutes of Health (NIH) Stage Model of Behavioral Intervention Development (ie, intervention generation, refinement, modification, and adaptation), and phase 3 maps onto stage 1B (ie, pilot testing) [40,41].

Phases 1 and 2 of intervention development were informed by our intervention conceptual model, as suggested by Rochon et al [42]. Specifically, we aimed to develop an IVET intervention that could promote sustained attention, positive emotions, and active engagement (ie, mechanistic targets) among both persons living with dementia and caregivers, leading to increased relationship satisfaction, decreased distress, and reduced agitation among persons living with dementia, as well as decreased burden among caregivers (ie, outcomes).

Ethical Considerations

Procedures were approved by the Massachusetts General Hospital Institutional Review Board (2022P001401). The information reported in this manuscript follows the Guidance for the Reporting of Intervention Development standards [43]. Potential clinician participants provided verbal consent before participating in focus group interviews. Caregivers provided verbal consent or e-consent during screening phone calls. A research assistant administered the University of California, San Diego Brief Assessment of Capacity to Consent Questionnaire (UBACC [44]) to persons living with dementia to determine their ability to provide consent. For those unable to provide consent, the persons living with dementia provided assent, and their caregivers provided surrogate consent to participate. All data were deidentified to protect anonymity. In phase 1, clinicians were compensated US $30, and persons living with dementia and caregivers were compensated US $50 each. In phase 2, persons living with dementia and caregivers were compensated US $50 each for their time.

Participant Recruitment

During phases 1 and 2, this study enrolled three categories of participants: (1) clinicians involved in dementia care, (2) caregivers of persons living with dementia, and (3) person living with dementia–caregiver dyads.

Clinicians were recruited via emails to dementia care clinics within the affiliated health care system. Clinicians were eligible if they (1) self-identified as dementia care providers and (2) were able to participate via Zoom (Zoom Communications). Of the 11 clinicians screened for focus groups, 1 (9%) did not participate due to a scheduling conflict.

Caregivers and dyads were both recruited via research registries (eg, study fliers). Recruitment materials were designed to target caregivers. Interested caregivers responded to the research team to obtain additional information about the study and review eligibility. Caregivers were eligible if they (1) aged >18 years, (2) self-identified as informal caregivers for a person living with dementia (eg, a family member or friend providing support), (3) could participate in English, and (4) had access to a video-enabled device for Zoom participation. Of the 31 caregivers screened for focus groups, 5 (16%) were ineligible due to not identifying as a caregiver of a person living with dementia, 13 (42%) had scheduling conflicts, and 5 (16%) could not be contacted.

For person living with dementia–caregiver dyads, caregivers were targeted using similar recruitment strategies discussed above. Interested caregivers identified and contacted their care recipient with dementia to participate in the study. Then, caregivers and persons living with dementia participated in a screening call together. Using the same eligibility criteria stated in the Participant Recruitment section, caregivers provided verbal consent or e-consent during screening calls. Eligibility

XSL•FO
RenderX

criteria for persons living with dementia included (1) having an informal caregiver participating in the study, (2) a self- or caregiver-reported dementia diagnosis, and (3) the ability to participate in an interview conducted in English. The UBACC uses 2 open-ended questions to assess the understanding of informed consent information (eg, "Can you briefly tell me what the purpose of the study is based on what I just read?"); scores range from 0 to 2, with scores <2 indicating lack of capacity to provide consent. The UBACC scores show a strong correlation with global cognition [45], suggesting that lower scores (ie, the inability to provide consent) are indicative of more advanced stages of dementia. Across stages, of the 12 persons living with dementia screened for this study, 8 (67%) scored a 0, a total of 2 (17%) scored 1, and 2 (17%) scored 2 (ie, able to consent independently). Of the 26 caregivers screened for workshops, 1 (4%) was ineligible due to not identifying as a caregiver, 4 (15%) had scheduling conflicts, 3 (12%) declined due to the care partner's worsening medical status, and 9 (35%) could not be contacted.

Phase 1: Focus Groups

Participants

There were 21 participants across 5 focus groups. A total of 10 clinicians participated across 2 clinician-only focus groups, representing the following professions: geriatric medicine (n=2, 20%), neurology (n=3, 30%), social work (n=2, 20%), occupational therapy (n=1, 10%), psychology (n=1, 10%), and psychiatry (n=1, 10%). Clinician degrees included Occupational Therapist (1/10, 10%), Licensed Psychologist (1/10, 10%), Master of Social Work (1/10, 10%), Licensed Clinical Social Worker (1/10, 10%), Licensed Independent Clinical Social Worker (1/10, 10%), Doctor of Medicine (6/10, 60%), Doctor of Science (1/10, 10%), and Doctor of Philosophy (PhD; 3/10, 30%). Participants reported an average of 10.95 (SD 10.20; range 2-20) years of experience in dementia care. The majority were women (6/10, 60%) and White (9/10, 90%) individuals.

A total of 4 caregivers participated in a caregiver-only group. Participants were primarily women (4/4, 100%), and half identified as White (2/4, 50%) individuals.

A total of 3 person living with dementia–caregiver dyads (n=6) and 1 solo caregiver (ie, the corresponding person living with dementia was unable to attend) participated across 2 dyad focus groups. Persons living with dementia were primarily men (2/3, 67%) and White (2/3, 67%) individuals. Caregivers were primarily women (4/4, 100%), and half identified as White (2/2, 50%) individuals.

Procedure

The sequence of focus groups was clinicians (n=2), person living with dementia–caregiver dyads (n=2), and caregiver-only (n=1) group. A PhD-level clinical psychologist with experience in dementia care and qualitative research led 4 focus groups with clinicians and person living with dementia–caregiver dyads. During dyadic focus groups, the facilitator made every effort to ensure active participation from persons living with dementia, including seeking collateral information from dyad members (eg, confirming caregiver statements with persons living with dementia), asking binary questions (eg, yes or no), rephrasing questions when needed, and making behavioral observations with verbal confirmations (eg, "I noticed you perked up when I mentioned music, do you enjoy listening to music?"). Two trained bachelor-level research assistants coled the caregiver-only group. None of the interviewers had previous relationships with the participants. Group sessions lasted an average of 54 (range 51–57) minutes. All focus groups were completed virtually over secure Zoom, audio recorded, and transcribed.

During each focus group, participants responded to semistructured interview questions targeting activity preferences, technology preferences, usability considerations, and safety concerns; refer to Multimedia Appendix 1 for example focus group questions. In addition, participants provided feedback on a series of mock-up videos (ie, disjointed visuals designed to elicit conceptual feedback and ideas for intervention modules), including passive nature views (ie, waves crashing and Northern lights), guided relaxation with nature background (ie, night sky with voice-over), and abstract color flow (ie, colorful viscous swirl). Mock-up videos were previously used by the design team to inform the development of other IVET platforms targeting nondementia populations. Videos were chosen to provide insight into design features that aligned with our proposed mechanistic targets of sustained attention, positive emotions, and active engagement [42]. Participant feedback was designed to elicit preferences, usability considerations, and safety concerns (eg, "What problems do you see with this experience?" and "Do you foresee any concerns for safety or otherwise?"). Consistent with an iterative process of design, videos and interview questions were updated between each round of focus groups, such that videos or topics that elicited concerns for usability (eg, querying about the utility of sensory kits of household items, such as spices, to accompany videos, which elicited concern for feasibility) or safety (eg, abstract color flows, which elicited concern about increasing agitation or confusion) were omitted, and others were added (eg, new nature scenes with multiple points of view).

During each focus group, 1 or 2 bachelor-level research assistants observed the interviews and completed live field notes using a standardized rapid data analysis (RDA) template created for use in this study; refer to Multimedia Appendix 1 for the RDA template. At the conclusion of each focus group, all facilitators and observers completed reflective field notes using a standardized form with categories similar to those in the RDA template.

Phase 2: Beta Testing Workshops

Participants

A total of 9 person living with dementia–caregiver dyad (n=18) participants were recruited across 8 beta testing workshops. Dyads were recruited separately for phases 1 and 2; none of the dyads who participated in phase 1 participated in phase 2. However, dyads enrolled in phase 2 were allowed to participate in multiple workshops if desired. Of the 9 dyads, most (6, 67%) participated in 1 workshop and 3 (33%) participated in 2 workshops; however, none participated in >2 workshops. Participants ranged from 1 to 4 dyads per workshop, with the majority consisting of 1 dyad (6/8, 75% workshops).

XSL•FO
RenderX

Across workshops, 100% (18/18) of participants identified as White individuals. Most persons living with dementia (7/9, 78%) identified as male, and most caregivers (7/9, 78%) identified as female. Caregivers provided proxy reports of dementia diagnoses, per their understanding of the medical records of the persons living with dementia, which included Alzheimer disease (2/9, 22%), unspecified dementia (4/9, 44%), Lewy body dementia (1/9, 11%), primary progressive aphasia (1/9, 11%), and frontotemporal dementia (1/9, 11%). Given that this study did not access medical records, caregiver reports were not confirmed, and the stage of illness was not reported. Multiple dyad relationship types were noted, including spousal (4/9, 44%), sibling (1/9, 11%), and adult child (1/9, 11%) caregivers.

Procedure

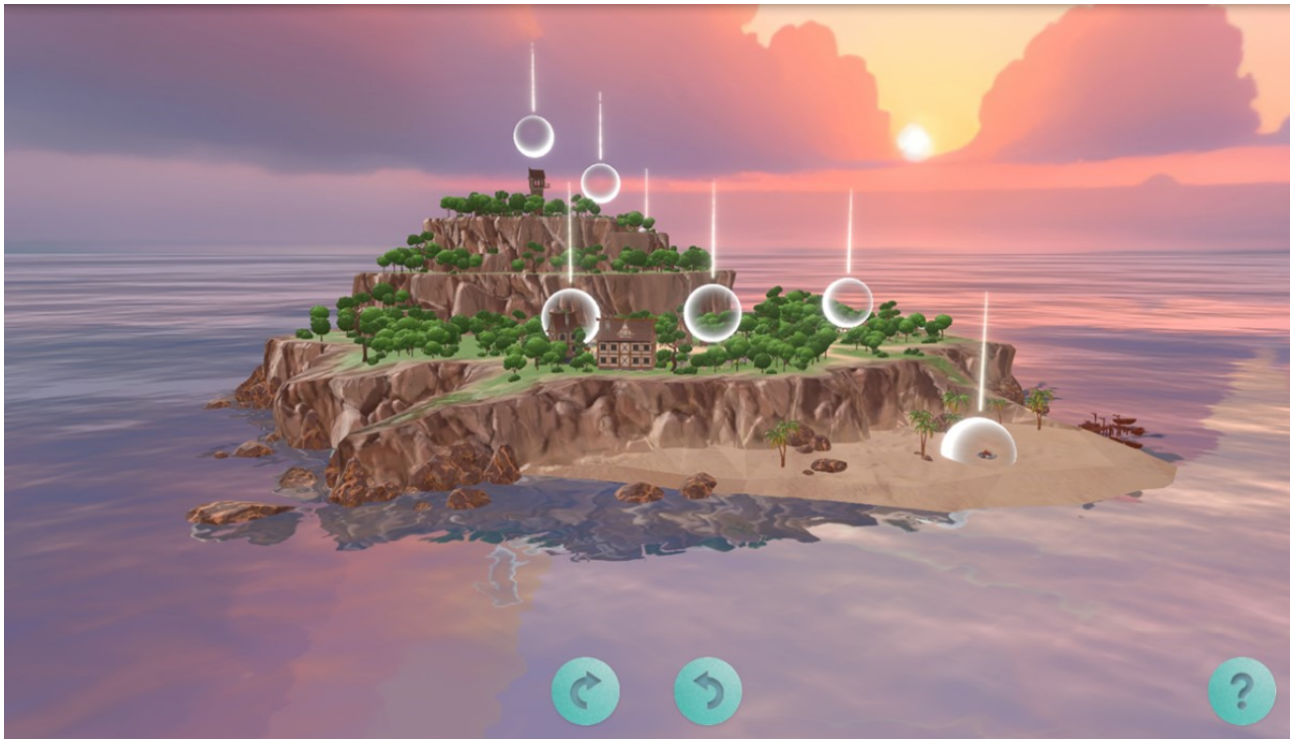
Beta testing workshops were led by members of the industry partner design team, with 1 to 2 trained research assistants in attendance to assist dyads in navigating the platform and to complete live field notes for RDA. All workshops were completed virtually over secure Zoom and recorded for the research team to review after session completion (eg, detailed feedback and behavioral observations). If multiple dyads engaged in 1 session, breakout rooms were used to enable private viewing experiences. Beta testing workshops lasted an average of 63 (range 34-103) minutes.

Workshops were completed via Zoom. At the start of each workshop, the design team shared a website link to the initial IVET intervention prototype with participants. Dyad participants were instructed to share their screen after opening the website. A workshop facilitator then prompted dyads to navigate the intervention both freely (eg, “As you explore the area, please share your thoughts out loud”) and with specific instructions (eg, “Can you figure out how to navigate back to the home screen?”). Participants started by freely navigating the prototype, providing live feedback on usability and acceptability (eg, confusing instructions and enjoyable features). Then, participants were presented with 1 to 3 modules to navigate, guided by facilitator prompts that primarily focused on usability and acceptability (eg, “Are there specific features on the island that drew your interest?” “What are your initial thoughts on the visuals of the activity?” and “Was navigating around the island intuitive or challenging?”). Dyads could choose the module they were most interested in navigating. In some situations, the second or third module was chosen for the dyad to ensure that feedback was gathered for each module. At the conclusion of each workshop, caregivers and persons living with dementia independently responded to quantitative measures assessing the perceived feasibility and usability of the platform. As workshops progressed, feedback became more targeted (eg, preference for specific images) than in earlier workshops (eg, preferred level of feedback from the platform), moving toward an initial prototype.

During workshops, research assistants completed observational field notes using a standardized template created for use in this study; refer to Multimedia Appendix 1 for the template. Field notes were used as part of RDA to inform intervention refinements between each workshop.

Measures

Usability was assessed using the System Usability Scale (SUS) [46]. The SUS consists of 10 items evaluating the perceived usability of technological platforms, including websites. The SUS is the most widely used scale to assess usability for technology-based interventions in the context of dementia, but self-report challenges may exist with more advanced cognitive limitations [47]. However, the SUS is primarily applied to persons living with dementia with mild cognitive impairments and lacks psychometric data across the full spectrum of dementia (ie, limited data available in advanced stages of dementia) [47]. Furthermore, the SUS uses 5-point Likert scale for response options [48,49]. Therefore, following best practices to reduce cognitive load and ensure that persons living with dementia could meaningfully participate, we adapted this scale to reflect yes or no response categories [47,50]. This decision increased the likelihood that persons living with dementia in this study could provide feedback independently.



A total of 3 additional study-specific feasibility questions targeted entertainment, safety, and control. These items were adapted from previous technology-based intervention studies with participants with mild cognitive impairment and their caregivers [48] and provided feedback salient to our conceptual model (eg, engagement and positive affect) and design aims (eg, safety). These items were also asked in a yes or no format to increase inclusivity for persons living with dementia.

Intervention Prototype

Activities outlined in Phase 1: Focus Groups and Phase 2: Beta Testing Workshops sections culminated in the development of an initial prototype of a web-based dyadic IVET intervention, referred to as the Toolkit for Experiential Well-Being in Dementia (Isle of TEND). The Isle of TEND website contained a home page (Figure 2) with the ability to navigate to 8 modules, which contained different shared activities; refer to Multimedia Appendix 2 for an overview of modules. Consistent with our conceptual model [42], each module in the Isle of TEND featured a shared activity intended to promote sustained attention, positive emotions, and active engagement with the intervention. The intervention was designed to be used by both persons living with dementia and caregivers together in the home.

XSL•FO
RenderX

Figure 2. The Toolkit for Experiential Well-Being in Dementia (Isle of TEND) home screen.

Data Analysis

This study used RDA as an analytic framework to identify themes from focus groups and workshops. RDA is used to quickly identify themes in qualitative data [51]. Rather than written transcriptions, this technique relies on live coding directly from interviews, such as taking observational notes during interviews or while listening to an audio recording [52-54]. For this study, RDA was chosen to identify specific feedback from participants related to preferences, usability, and safety that could guide prototype development and refinement. By quickly capturing this information, our research team was able to communicate findings back to our design team to iteratively respond to feedback and update the intervention prototype to gather more feedback from users.

Consistent with previous studies using RDA [55], we compiled RDA template notes from 2 to 3 team members (ie, 1 PhD-level clinical psychologist and 2 bachelor-level research assistants) into a single matrix for each focus group. Data from this matrix were used to guide discussions with the design team and informed design decisions toward initial prototype development.

At the conclusion of the study, matrices were combined and used to facilitate thematic analysis of focus groups and workshops separately. Focus group data were analyzed as a single dataset (ie, clinician, caregiver, and dyad focus groups analyzed together), such that we identified themes that emerged across groups. We did not compare themes across populations, as this was not consistent with the aims of this study. Two research assistants (ER and AT) trained in qualitative RDA methods independently reviewed matrices to identify codes. Coders met on multiple occasions during the coding process to resolve discrepancies. Codes were grouped by content to form themes. The thematic structure was iteratively developed and confirmed with a meeting between coders and a clinical psychologist on the study team with experience in dementia care (EP). After a thematic structure was agreed upon, the research assistants (ER and AT) reviewed transcripts to identify salient quotes for each thematic category. Both focus groups and workshops followed the same analytic steps. However, transcripts were only reviewed for focus groups because the data collected during workshops produced fewer exemplar quotes (eg, workshops contained more “thinking aloud” methods or behavioral observation, making data less relevant for exemplar quotations).

Results

Phase 1: Focus Groups

Three themes emerged from focus groups with clinicians, caregivers, and dyads: (1) designing flexibly to allow users to tailor the intervention experience to their own environmental context and circumstance, (2) designing with the dyad’s clinical and relational needs in mind, and (3) accounting for illness and aging-related challenges in the design.

Theme 1: Designing Flexibly to Allow Users to Tailor the Intervention Experience to Their Own Environmental Context and Circumstance

The ability for users to individualize their experience emerged as an important design feature to increase acceptability and usability as well as to empower choices among users. Participants noted that the option to individualize or tailor intervention content could help accommodate a larger range of users based on their access to and comfort navigating technology. In addition, participants recommended that the IVET intervention be accessible via various platforms. For example, a clinician noted the following:

XSL•FO
RenderX

> *[Consider] an app that is free, that can download the materials into [users] cell phone or their device so it doesn't depend on the Internet connection...and maybe having the option of audio only or audio plus visual.*

Participants also noted the importance of developing stimuli that were familiar to and pleasant for participants of various backgrounds, cohorts, and identities to promote individualization. Furthermore, participants noted that familiar stimuli may especially increase comfort, enjoyment, engagement, and safety for persons living with dementia. A caregiver highlighted the potential benefits of familiar stimuli:

> *Having an inspirational waterfall isn't necessarily going to put me at ease, but maybe hearing my family's familiar voice, or the clattering of my own kitchen, or having something that individualizes this to me would.*

Similarly, a clinician highlighted the need for inclusivity as follows:

> *I just wonder if the salience of some of the images might be different depending on the cultural groups. The aurora borealis is beautiful, but for maybe people who [are] not familiar with that part of the of the world...what are the scenes, the sounds that are most salient and comforting to that individual.*

Of note, related to the environmental context of an at-home IVET intervention, caregivers discouraged the use of a proposed sensory kit of household materials, citing feasibility issues with the ability for a range of users to locate these materials in their home (eg, spices).

Theme 2: Designing With the Dyad's Clinical and Relational Needs in Mind

Participants noted that designing an intervention with a specific purpose and orienting users to a rationale for using the intervention may increase usability. Specifically, participants suggested recommendations for appropriate times and intended outcomes of use (eg, using when calm and avoiding when agitated). For example, a clinician noted the potential clinical utility of an IVET intervention:

> *I think that [the calming sounds are] good, and it appeals to an inherent positive emotional experience which could also aid caregivers when they're trying to prep for redirection or transition. Basically, if we're trying to get somebody to do something that they may not necessarily want to do we're far more likely to be able to if a person is in a positive emotional state versus a negative one and so these types of things could aid in that process of prepping a patient for a transition.*

Caregivers believed that they would likely need to be present to initiate the intervention as well as to guide the persons living with dementia through some of the modules. For example, a caregiver noted the following:

> *[Caregivers] would have to be there to sort of guide [Person living with dementia] or kinda help them figure out what [the intervention] is.*

Participants were skeptical that an IVET intervention could be engaging for both dyad members, noting challenges of achieving sustained attention and immersion for both persons living with dementia and caregivers. This is highlighted by a caregiver who stated the following:

> *[Person living with dementia] loses interest pretty quick, and I think sometimes he has trouble following the storyline. So, it would be hard to find something that would be suitable for both of us, cause we're kind of in very different places now. And that's one of the things that's difficult is we don't have as many shared experiences as we used to.*

Participants recommended structured stimuli to quickly capture and sustain the attention of users, which they noted could be challenging in the context of dementia. For example, a caregiver stated the following:

> *Without having a clear beginning or end, [the person living with dementia] might get bored or discouraged, it needs to have more structure.*

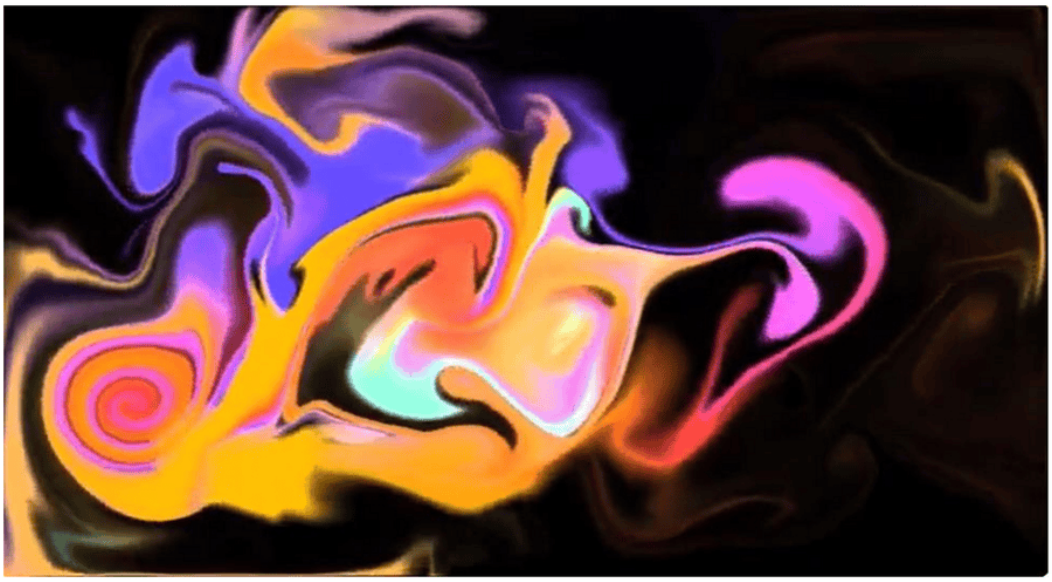
Furthermore, participants emphasized that the IVET intervention would need to be designed to sustain attention and immersion without overstimulating or confusing users with cognitive challenges.

Theme 3: Accounting for Illness and Aging-Related Challenges in the Design

Participants noted the importance of ensuring the reduction, rather than an unintentional exacerbation, of behavioral and psychiatric symptoms of dementia, particularly agitation and hallucinations. This concern is highlighted by a clinician, who stated the following:

> *Dementias with any psychiatric component or psychotic features, paranoia, delusional thinking...you always want to be careful about providing stimulation when we don't know where that may lead the patient's train of thought.*

There were specific stimuli that participants recommended avoiding, such as 1 video with a moving (ie, swirling) bright color scheme against a black background (Figure 3), which participants suggested could potentially exacerbate psychiatric symptoms. For example, a clinician stated the following:



> *I think patients would not like [the swirling color video], they have a lot of visual spatial misperceptions.*

Furthermore, participants cautioned against dark backgrounds, which might increase psychiatric symptoms and confusion or disorientation. For example, a caregiver noted the following:

> *My husband is really paranoid, he thinks people are out to get him. I was thinking of the lighting, if there is darkness that might increase his paranoia.*

XSL•FO
RenderX

Figure 3. Swirling color scheme video.

Another caregiver noted the following:

> *The edges of my video were very dark. So, it gives you almost like that movie theater feel to it, which I worry, if you're immersed in something too much, do you have less grasp on here and now where you are.*

In addition, as noted across multiple themes, participants relayed that certain cognitive symptoms, especially attentional deficits and apathy, could pose a challenge to engagement and usability. One clinician stated the following:

> *I wonder if in some instances this [mock-up videos] may be a little too unstimulating to capture the patient's attention, unless they are really already very calm and wanting to be calm.*

Another clinician stated the following:

> *for images...it might be really, really simple ones, the less complicated you make it, the better received because [person living with dementia] cognitive abilities and processual abilities are impaired.*

Participants also noted that visual clarity was an important design feature and recommended that the IVET intervention accommodate for age-related changes and pathologies more common with older age. For example, 1 caregiver stated the following:

> *There's something about lighting that I would pay attention to for elders...I have another elder in my life who has glaucoma and she can't see things in depth of perception and other things.*

Phase 2: Beta Testing Workshops

Qualitative Results

Two main themes emerged from beta testing workshops with dyads that informed intervention refinement: (1) more feedback to guide using the intervention and (2) more variety of visual and auditory experiences.

Theme 1: Increasing User Support Through More Feedback

Participants noted that more purposeful or goal-directed actions within intervention modules could reduce confusion during use. When engaging with the intervention, caregivers and persons living with dementia frequently inquired about the end goal of modules, especially when feeling "lost" or "stuck." Relatedly, participants recommended more instructions, which, per observation, appeared to be related to participant concerns about making an error or doing the experience "wrong." Together, an open-ended module without clear directions, which was initially developed to increase exploration and reduce the need for caregiver instructions, actually increased confusion and perceived misuse of the intervention by users.

Furthermore, participants voiced the need for continuous instructions throughout use to understand next steps, which was particularly relevant in modules that included multistep tasks. For example, a module that developed a poem based on typed responses to multiple prompts caused some confusion among users because dyads were unsure of the task they were being prompted to complete (eg, not knowing that prompts would generate a poem) or the end goal of the multistep process (eg, the need to press next and respond to another prompt to develop the full poem). In addition to more prompts, participants suggested having multiple methods of engagement, such as a speech-to-text function, to promote accessibility and usability.

Theme 2: Increasing the Variety of Visual and Auditory Feedback

Participants recommended increasing the presence and variability of responsive sounds, background music, and interactive visuals. Caregivers and persons living with dementia both noted that alternating music or background colors might reduce redundancy after multiple uses and make the intervention more engaging. In addition to increasing engagement, dyads noted that sound effects, especially calming nature sounds, improved their experience by creating a sense of calm while using the intervention.

XSL•FO
RenderX

Quantitative Analysis

In general, users rated the intervention positively (Table 1). On the study-specific feasibility scale, 100% (11/11) of caregivers and 67% (6/9) of persons living with dementia (n=2, 22% were unsure or did not respond) felt that the program was safe to use, 82% (9/11) of caregivers and 100% (9/9) of persons living with dementia felt that the program was entertaining, and 82% (9/11) of caregivers and 89% (8/9) of persons living with dementia felt that the program helped them "feel in charge of their own experience." On the SUS, 82% (9/11) of caregivers and 89% (8/9) of persons living with dementia thought that the program was "easy to use," and 73% (8/11) of caregivers and 78% (7/9) of persons living with dementia "felt very confident using the program" (n=1, 11% were unsure or did not respond).

Table 1. Feasibility and usability results of beta testing workshops.

	Caregivers, (n=11), n (%)			Persons living with dementia (n=9), n (%)		
	Yes	No	Unsure or unable to answer	Yes	No	Unsure or unable to answer
"I think that I would like to use this program."	7 (64)	2 (18)	2 (18)	6 (67)	2 (22)	1 (11)
"I found the program unnecessarily complex."	1 (9)	10 (91)	0 (0)	1 (11)	8 (89)	0 (0)
"I thought the program was easy to use."	9 (82)	2 (18)	0 (0)	8 (89)	1 (11)	0 (0)
"I think that I would need the support of a technical person to be able to use this program."	4 (36)	7 (64)	0 (0)	3 (33)	4 (44)	2 (22)
"I found the various functions in this program were well integrated."	9 (82)	2 (18)	0 (0)	6 (67)	3 (33)	0 (0)
"I thought there was too much inconsistency in this program."	2 (18)	9 (82)	0 (0)	2 (22)	5 (56)	2 (22)
"I would imagine that most people would learn to use this program very quickly."	7 (64)	3 (27)	1 (9)	4 (44)	0 (0)	5 (56)
"I found the program very cumbersome to use."	0 (0)	11 (100)	0 (0)	1 (11)	5 (56)	3 (33)
"I felt very confident using the program."	8 (73)	2 (18)	1 (9)	7 (78)	1 (11)	1 (11)

"Did you feel that the program was safe to use for your relative and you?"	11 (100)	0 (0)	0 (0)	6 (67)	1 (11)	2 (22)
"The program helped my relative feel in charge of their own experience."	9 (82)	2 (18)	0 (0)	8 (89)	1 (11)	0 (0)

Feedback-Design Integration

Throughout intervention development, our academic-industry team met weekly to discuss results from focus groups and workshops and translate findings into pragmatic design elements. Often, the research team helped provide the context of findings within the illness context of dementia, as well as guide a systematic approach to intervention design that would prepare the team for a future, scientifically rigorous clinical trial. The industry design team often discussed the possibilities and limitations of an IVET intervention delivered with minimal equipment (ie, via a computer or tablet). These perspectives led to productive discussions about incorporating user feedback into intervention design. Together, this iterative process led to the end product of an IVET intervention ready for initial feasibility testing (NIH stage 1B) that was deemed safe and usable by end users (ie, person living with dementia–caregiver dyads). Feedback and design decisions are provided in Table 2.

XSL•FO
RenderX

Table 2. User feedback and design team responses.

User feedback	Design feature
Focus groups: initial prototyping	
Implement choice-based activities when possible.	The team decided on a web-based IVET[a] format so that users could guide themselves through the platform. The intervention was user driven, and users chose from various modules in the intervention, deciding the type and length of activity within each module.
Establish the ability to adjust audio or visuals depending on preferences.	Developers enabled access to the intervention on the user's own tablet or computer so that users could adjust the volume and brightness to their preference.
Include visuals or audio that are appealing and familiar to diverse populations.	The design team developed 8 different modules, including modules set in a forest, an ocean, a beach, and a lighthouse.
Integrate instructions for the intervention.	The design team included text instructions on the home screen to orient users when they logged into the intervention. The instructions reviewed how to navigate through the home screen and the modules.
Intervention can be used among people with and without cognitive impairment.	Modules were "error-free" so that users were unable to "fail" or choose the "wrong" option, halting the experience; regardless of user choice, the experience continued.
Include stimuli that are reactive to touch or hand or arm movement.	Developers created two activities, which accessed the device's camera to track and react to hand movement: (1) Sound Garden, which used hand movement to control the music pitch and volume in a garden scene, and (2) Art Studio, which used hand movement to create brush strokes on the screen to reveal an art piece.
Design modules that are grounded in reality (familiar structure and clear beginning and ending).	The team set the intervention in recognizable locations, such as a waterfall, a lighthouse, and a beach. The game had a clear beginning with text instructions when users logged on.
Avoid abstract images and darkness in visuals.	The team removed abstract "swirling colors" stimuli. The team discarded a video set in a dark forest environment and brightened the colors in the remaining modules.
Beta testing workshop: prototype refinements	
Clarify the end goal or purpose of the intervention. Include more goal-directed aspects to the intervention.	The design team added an introduction slide clarifying that the intervention was designed to create "shared adventures" between the dyad and "engage the senses and spark imagination." The team included a "help" button across all modules to guide users.
Implement different methods of engagement, such as a speech-to-text option instead of typing.	Developers included a speech-to-text function in modules that required users to type. These activities accessed the device microphone to capture spoken responses from the dyad and convert them into text. To increase engagement, developers created custom soundscapes for scenes and changed them based on the visual stimuli presented.
Add more instructions and audio-to-text instructions.	Developers added a module description when users hovered their mouse over each module location. The team added step-by-step tutorials, which isolated different interactive aspects of the experience when users clicked on each module. In addition, the team added voice-over to text as an accessibility option to all introductions and guides.
Increase the visual stimuli throughout use to reduce redundancy.	The team increased the visual options in modules throughout the experience by creating more artwork and audio clips. For example, in the Storytelling module Campfire Cove, the team increased the number of available pictures to choose from and created an accompanying story.
Include visual and audio stimuli, such as animation or music, in modules that lacked sounds or featured static images. Add calming music or nature audio when possible.	The design team added nature-based animation and sound on the home screen, including auditory and visual waves, so that when logging on, users were greeted with these stimuli. In addition, the design team added nature-based sounds to the background of module instructions, such as birds chirping and "calming" music.

Discussion

Principal Findings

Following a multiphasic user-centered design framework with dementia-specific considerations [38], this study used focus groups and user workshops to develop and refine the initial prototype of a dyadic IVET intervention to support the emotional health of person living with dementia–caregiver dyads (ie, the Isle of TEND). The intervention was rooted in our conceptual model of shared activities that can promote sustained attention, positive emotions, and active engagement among both dyad members simultaneously [42]. The Isle of TEND is now ready for feasibility testing, consistent with NIH stage 1B.

Design Considerations

Overview

Across focus groups and workshops, we identified several key considerations for designing an IVET intervention for person living with dementia–caregiver dyads. Importantly, we did not constrict our intervention to a specific stage of illness. Rather, we engaged users, including those with cognitive limitations as evidenced by UBACC scores, and other knowledge holders who could provide feedback relevant to users with varying degrees of cognitive ability. This approach allowed us to capture multiple voices and perspectives to ensure that we are designing for all persons living with dementia, including those often not considered during the design stage due to significant cognitive impairment.

Personalization and Variety of Experiences

Consistent with previous research on technology-based interventions with persons living with dementia [56,57] and activity engagement in them [58], personalization and variety of experiences emerged as key design features for our intervention. This feedback is not surprising, given the heterogeneity of identities, preferences, and lived experiences of dyads managing dementia. Increasing the number of novel or rotating visuals and sounds in each module allowed for personalization and helped to reduce boredom with repeated use. Our design team was cautious to only make slight variations in activities (eg, sounds or storytelling prompts) to reduce boredom without increasing confusion. Consistently, participants noted that nature-based sounds and animation, such as waves or chirping birds, evoked positive emotions. Therefore, our design team focused on nature scenes for many of our modules. Previous research with persons living with dementia supports that nature sounds introduced through technology, referred to as a soundscape, are perceived positively with minimal safety concerns [59,60].

Optimizing Autonomy and Choice While Sustaining Ease of Use

Feedback related to personalization highlighted an important component of designing in dementia: optimizing autonomy and choice while sustaining ease of use. In addition to increasing acceptability, the ability to tailor interventions to personal preferences may create an opportunity for persons living with dementia to have more control over their user experience. This was important for both members of the dyad to promote a sense of accomplishment, autonomy, and confidence and, ideally, allow the dyad to break the care recipient-caregiver script, enabling both members to feel as though they have ownership of their own experiences with the intervention. Previous technology-based interventions developed for persons living with dementia with mild cognitive impairments also note the importance of prioritizing user control [48]. Furthermore, in the context of dyads, increasing autonomy and choice for persons living with dementia means reducing the need for the caregiver to "deliver" the intervention. While refinements to our prototype are still needed to fully achieve this outcome, it is an important endeavor for dyadic interventionists in the context of dementia, as allowing for a break in the care recipient-caregiver script may produce positive emotional benefits for both dyad members across all stages of illness.

Users consistently provided feedback that some user-driven choices in our platform were too open ended (eg, coming up with a poem without prompts), which could lead to confusion and produce the opposite emotional experience for dyad members than intended (ie, frustration with being "wrong" and the perceived need for caregiver-directed behaviors). To address this balance, our design team attempted to provide ample instructions and feedback for use while not imposing "rules" (ie, "error-free" design) and promoting exploration. For example, several of our modules initially present users with directions for navigating the activity and then provide participants with open-ended (ie, pictures of different scenes) and forced-choice (ie, multiple choices for storytelling) decisions to guide their experience based on their needs and preferences. In addition to providing directions throughout the module, as recommended by users, we developed responsive features to reduce cognitive load and avoid frustration. For example, following effective communication strategies in the context of dementia [61], if a dyad did not respond to a multiple-choice prompt within a period of time, a forced-choice option appeared (ie, this or that). Most users with dementia rated that they felt in control of their own experience and confident in using the Isle of TEND, which may be a product of these design features.

Maintaining Engagement Among Cognitively Mismatched Users

We set out to design an IVET intervention that can maintain sustained attention and engagement among cognitively mismatched dyad users while at the same time not overwhelming the persons living with dementia or underwhelming the caregivers. Participants recommended that to achieve this goal, we needed to have a clear structure, continuous feedback, and novel stimuli, which are consistent with theory (eg, flow) [62]. In response to these recommendations, our design team developed a home screen with an introduction to the IVET intervention, tutorials and instructions for each module, and a navigation guide that appears constantly. Furthermore, our design team developed several modules that are reactive to touch or movement. For example, 1 module, the Art Garden, accesses the device camera and uses hand movement as "brushstrokes" to paint a picture. Despite these features designed to promote sustained attention and engagement, user feedback in the workshops was still mixed regarding the ability to capture and

XSL•FO
RenderX

sustain engagement across cognitively mismatched dyads and reduce caregiver-directed behaviors (eg, caregiver reiterating directions). However, it is important to note that 82% (9/11) of caregivers and 100% (9/9) of persons living with dementia still found the intervention to be entertaining. The field still needs to address the important topic of designing for mismatched cognitive abilities, as there are potential clinical benefits associated with shared engagement for person living with dementia–caregiver dyads managing dementia throughout the course of illness (eg, emotional closeness and relaxation). It is possible that design teams need to attend to more nuanced interactions between users and platforms to evaluate common elements of sustained attention and engagement across users with varying cognitive abilities (eg, movement).

Not Exacerbating Behavioral and Psychiatric Symptoms of Dementia

Regarding safety concerns, participants flagged specific stimuli that could potentially lead to distress or exacerbate behavioral or psychiatric symptoms that accompany certain types of dementia. In particular, participants recommended avoiding abstract stimuli, bright colors, or moving objects against a dark background, as these could potentially increase adverse events (eg, agitation) in more advanced stages of dementia. These images may relate to overstimulation or confusion, which increases behavioral and psychiatric disturbances in the context of advanced dementia when persons living with dementia have increased vulnerability to environmental stressors [63]. Users suggested that, in general, simpler and easily recognizable images may be better received by both persons living with dementia and caregivers. Participants also identified dark or shaded visuals as potentially problematic (eg, blurriness and glare) for users with age-related or other visual impairments. In response to the feedback, the design team removed visuals and modules that relied on limited lighting and highly abstract images. Of note, there were no observed exacerbations of dementia-related behavioral or psychiatric symptoms during workshops.

Limitations

This initial intervention development study has several limitations to consider. First, our convenience sample of caregivers, dyads, and clinicians consisted of a majority of White participants. In future pilot testing, we will ensure that participants are more representative of the US population. Second, we did not administer cognitive assessments to describe the level of cognitive impairment of our sample. Therefore, we cannot empirically comment on the cognitive profile of participants with objective measurement, including the severity of cognitive impairment. This study used self-reports from persons living with dementia and caregivers to capture the presence of dementia, and the UBACC provides additional insight into the presence of cognitive limitations inhibiting the ability to provide autonomous consent. Indeed, dementia research must balance participant burden, the reality of difficulties obtaining a dementia diagnosis, and study goals. In line with our broader goal of offering TEND as a free intervention for individuals in community settings, we included participants with varying levels of cognitive ability, as reflected by the fact that only 17% (2/12) of our sample was able to provide independent consent. To circumvent challenges with reporting on quantitative surveys for those with more advanced dementia, our team took multiple steps to support persons living with dementia in reporting their own outcomes, including using binary scales and reading questions aloud. However, these methods may have reduced the validity of our measures, and we still cannot be sure that all items were fully comprehended. Finally, we chose RDA over other forms of qualitative analysis. For this study, prioritizing a quick summary of information and relaying this to our design team consistent with RDA was necessary, but this analytic approach may also be more susceptible to researcher bias.

Conclusions

The result of this multiphasic user-centered design study with an academic-industry design team was the development of an initial dyadic IVET intervention for persons living with dementia and their caregivers to use together at home. On the basis of our conceptual model, we aimed to promote sustained attention, positive emotions, and active engagement in both dyad members to increase relationship satisfaction and reduce psychosocial distress. In this study, we highlight early intervention development with a focus on designing for usability and safety. While some of our design considerations may be helpful for future investigators and design teams focusing on dyads managing dementia, we also recognize that there are gaps that still need to be filled, such as promoting mutual engagement among cognitively mismatched dyads.

Abstract

Background: The rising prevalence of dementia is a major concern, with approximately 45% of cases linked to 14 modifiable risk factors. The European project LETHE aims to develop a personalized digital intervention model to delay or prevent cognitive decline through risk factor management.

Objective: The objective of our study was to design a clinical trial platform for older individuals at risk of cognitive decline, including a mobile app for study participants and a clinical trial management system (CTMS) for health professionals.

Methods: Using a user-centered design approach, workshops and feedback rounds involved potential participants representing the target group and professionals. The LETHE app's usability was assessed among 156 older adults enrolled in a 2-year

XSL•FO
RenderX

multinational randomized controlled trial evaluating the feasibility of a digitally supported lifestyle program for dementia risk reduction. The randomized controlled trial is currently ongoing; the System Usability Scale (SUS) was administered 1 month after baseline to map first user experiences. Feedback on the LETHE CTMS was collected from 21 users.

Results: Of the 78 participants in the trial intervention group, 66 (85%) provided responses for the mobile app, with a median SUS score of 70 (IQR 55-82). Within the control group, 73% (57/78) of responses were received, with a median SUS score of 73 (IQR 63-90). For the CTMS, we received 71% (15/21) of responses, and the feedback was mostly positive. A ranking of the features that could be considered beyond state of the art showed that the integration of personalized activities (mean 2.23, SD 1.17) and real-time appointments (mean 2.46, SD 1.51) were considered the most novel ones.

Conclusions: The LETHE app and CTMS were developed to support a personalized digital intervention method within a study involving 156 participants. Limitations include participants having digital literacy and internet access, potentially impacting the generalizability of the findings. Despite these limitations, positive feedback and high usability scores suggest promising potential for the LETHE app and CTMS in supporting personalized interventions to prevent cognitive decline in older adults.

Introduction

Background

Overview

The rising prevalence of dementia, driven by sociodemographic changes, constitutes a significant global health challenge. Projections indicate a notable rise from 57 million affected individuals in 2019 to an anticipated 153 million by 2050 [1]. Notably, the Lancet Commission's report underscores that approximately 45% of all cases of dementia are associated with 14 potentially modifiable risk factors at different phases of the life span [2], and diet has also been suggested as an additional factor [3]. Previous multidomain intervention studies have demonstrated their positive impact on cognitive performance while simultaneously targeting various lifestyle domains, including diet, physical activity, cognitive training, management of cardiovascular risk factors, or social interaction [4-6].

Information and communications technology (ICT) solutions such as apps running on phones and tablets, as well as wearable devices that collect user-generated health data (digital biomarkers) in an automated way, could potentially help provide digitally supported interventions for a broader audience and groups at risk of cognitive decline. At the same time, these technologies can collect data to monitor progress and adherence to lifestyle interventions. Other research projects have shown that digital interventions can be effective and feasible for older adults, but this depends on several factors such as digital literacy, usability of the technology, and the design of the study with regard to human support (hybrid intervention) [7-9].

The Horizon 2020 LETHE project [10] has been initiated to provide such a personalized digital intervention model and components for reducing risk of developing cognitive decline by evolving the successful Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability (FINGER) multidomain intervention model [5]. Leveraging ICT-based methods and guided in-person as well as remote sessions, LETHE aims to prevent cognitive decline in at-risk older individuals by providing personalized feedback and intervention methods.

The LETHE project focuses on the aforementioned modifiable risk factors grouped into the following lifestyle domains: "Physical Activity," "Nutrition," "Cognitive Training," "Management of vascular/metabolic risk factors," "Sleep/Relaxation," and "Social Activity."

The LETHE study encompasses a currently ongoing 2-year randomized controlled multicenter, parallel-group feasibility trial (ClinicalTrials.gov; NCT05565170) involving 156 participants at risk of cognitive decline distributed across clinical centers in Austria (Medical University of Vienna), Finland (Finnish Institute for Health and Welfare), Sweden (Karolinska Institute), and Italy (University of Perugia). Participants were equally randomized to one of the study groups (intervention and control), both supported by digital tools (mobile app and smartwatch). At baseline, participants had a mean age of 68.8 (SD 4.5) years, with an average of 14.9 (SD 3.1) years of education. A total of 64.7% of the participants were women. Notably, most participants (84%) used their smartphones at least 6 times per day. Two-thirds of the participants had previous experience using their smartphones for health tracking, and approximately 48% had used lifestyle-related apps. In addition, 63% of the participants reported using the internet for eHealth-related tasks such as booking physician appointments or checking test results [11].

To provide intervention components and continuously collect data from the trial participants, a LETHE smartphone app was designed and implemented. Clinical data, including blood test results, are entered into the LETHE clinical trial management system (CTMS), which was also developed during the course of the project, by health professionals at each visit. The CTMS was developed to ensure seamless integration with the app, allowing all participant-entered data to be displayed for health professionals to review and respond accordingly. Furthermore, data and services from third parties have been integrated, including cognitive training data and data from Fitbit devices, which track steps, sleep, and physical activity. The feasibility

XSL•FO
RenderX

of other novel technologies (audio glasses and a robot that reflect the content of the smartphone app) is being investigated in a substudy.

This study aimed to describe the design and implementation of the LETHE technical components, which were carefully developed through a joint process involving potential users, clinical experts, and designers and technicians.

Hybrid Intervention Approach

LETHE adopts a hybrid intervention (blended therapies) approach, seamlessly integrating digital intervention sessions with in-person and group sessions led by a trained coach (eg, physiotherapist or nutritionist). This comprehensive strategy, meticulously managed by health professionals, is in harmony with the study's mobile app and CTMS concept.

The literature on hybrid interventions for older adults at risk of cognitive decline, incorporating technology with coaching and peer sessions in comparison to stand-alone technology interventions, is still developing and has so far mainly focused on already symptomatic individuals. Nevertheless, emerging studies indicate that fostering social connection and interaction can be pivotal for success in dementia interventions [12]. Digital health platforms, easily accessible via mobile technology, can be efficient and cost-effective tools for dementia prevention. They not only offer individualized cognitive training but can also provide an engaging user experience [13,14]. The currently ongoing prevention of dementia using mobile phone applications (PRODEMOS) study creates an evidence-based dementia prevention strategy using mobile health (mHealth) accessible to at-risk individuals [15]. In contrast, Maintain Your Brain was a completely online lifestyle intervention targeting modifiable risk factors for dementia that was delivered to the participants via a web interface [16]. Wesselman et al [17] conducted a comprehensive overview of web-based multidomain lifestyle programs, combining it with a meta-analysis to evaluate their effectiveness. Through a systematic literature research, they collected a wide range of web-based programs.

Other studies have provided app-supported self-regulation for older adults based on self-determination theory, with a tablet facilitating tailored exercise programs and playing a key role in action planning and execution of behaviors [18]. The involvement of a personal coach was pivotal, adapting exercises to individual preferences and providing motivating remote monitoring to empower older adults to enhance physical activity levels at home. The experience conveyed in the study by Mehra et al [18] emphasizes the value of the personal coach, particularly during the initial phases of goal setting, behavior execution, and evaluation in self-regulation to achieve specific goals by guiding one's own behavior. Their findings indicate that the availability of a personal coach remains crucial even when technology supports the intervention. Nevertheless, concerns about adherence and safety arose in the absence of instructor guidance [18].

The success of this hybrid intervention approach could be further supported by the seamless interaction of a mobile app and a web-based CTMS for professionals. This integrated system allows professionals to interact with and monitor patients' development, enabling timely interventions when needed.

Digital Intervention Applications

mHealth apps are increasingly used by individuals to engage in health behaviors, aid in the self-management of chronic conditions, or enact preventive measures [19]. These apps hold promise in personalizing and tailoring behavior change interventions based on real-time data, thereby enhancing health outcomes [20]. Another crucial consideration is the necessity for co-designing apps in collaboration with the end users and health professionals from the relevant sector [21]. This is particularly vital for older adults as their participation in the technological design process is pivotal for their acceptance and adoption of the technology [22].

Digital interventions, whether delivered through mHealth apps or computers, are subject to evaluation in randomized controlled trials (RCTs) targeting various conditions such as psychotic disorders [23,24], mental health [25-28], eating disorders [29], diabetes [30], chronic pain [31], insomnia [32], or speech disorders [33]. These interventions often incorporate features such as audio or video content for physical activity or relaxation [23,24,26,32]; mood tracking [23,25,26]; personal tasks [23,25,31]; questionnaires [25,27,29,31]; educational materials [23-26,32]; self-tracking of, for example, vital signs in the form of a diary [24,32]; and habit libraries for behavior changes [34].

An umbrella review comprising 48 systematic reviews concentrating on mHealth apps in RCTs across various health conditions such as diabetes or hypertension indicates the potential effectiveness of app-based health interventions [35]. This further strengthens the approach of delivering a mobile-based app for study participants.

CTMSs for Intervention Projects

Equally important when intervention apps are used in clinical trials or research settings is central monitoring and management by the study coordinator or a corresponding physician. Using a CTMS and the integration of electronic data capture has become commonplace to serve this purpose [36]. Such a platform should facilitate and effectively support the multidimensional data management process in clinical trials [37] throughout their phases, from participant onboarding to completion [38].

Electronic systems allow for streamlined data transfer from clinics to the CTMS, remote enrollment capabilities, greater transparency of trial conduct, timeline monitoring such as specific tasks, tracking of participant visits, enhanced research documentation, and robust reporting [36,38,39]. A CTMS presents a variety of advantages; for example, it enables research teams to access up-to-date study information and simplifies collaboration as all project members can work efficiently together on the same task [38]. Moving beyond traditional methods of data collection in clinical trials, which may involve manual completion of paper case report forms (CRFs), leads to increased accuracy in findings, enhanced productivity as all necessary elements for managing the trial are consolidated in a single location, and higher data quality and compliance while reducing the risk of bias in clinical outcomes [36]. Important

XSL•FO
RenderX

considerations when selecting a CTMS include the feature set, usability, customization, and cost [38].

A systematic review of 19 research papers examining the technical features of clinical data management systems revealed that most of these systems were developed on a web-based platform to meet the individual needs of specific clinical trials within a short time frame [40]. Reportedly, such systems used in research centers showed limitations and inability to fully support the automation of all dimensions of the clinical data and workflow management process. In addition, the review found that most of the systems lacked flexibility and extensibility for further system development.

Health professionals such as study nurses, who are key members of the clinical research team and one of the targeted user groups for CTMSs, play a critical role in achieving accurate outcomes for clinical research studies. Furthermore, the effective implementation of a CTMS in RCT studies can have multiple benefits, including improved completion rates and increased fidelity while ensuring the safety of individual research participants [36].

The studies mentioned in this section collectively underscore the value of CTMSs in enhancing the efficiency and effectiveness of complex multisite intervention projects.

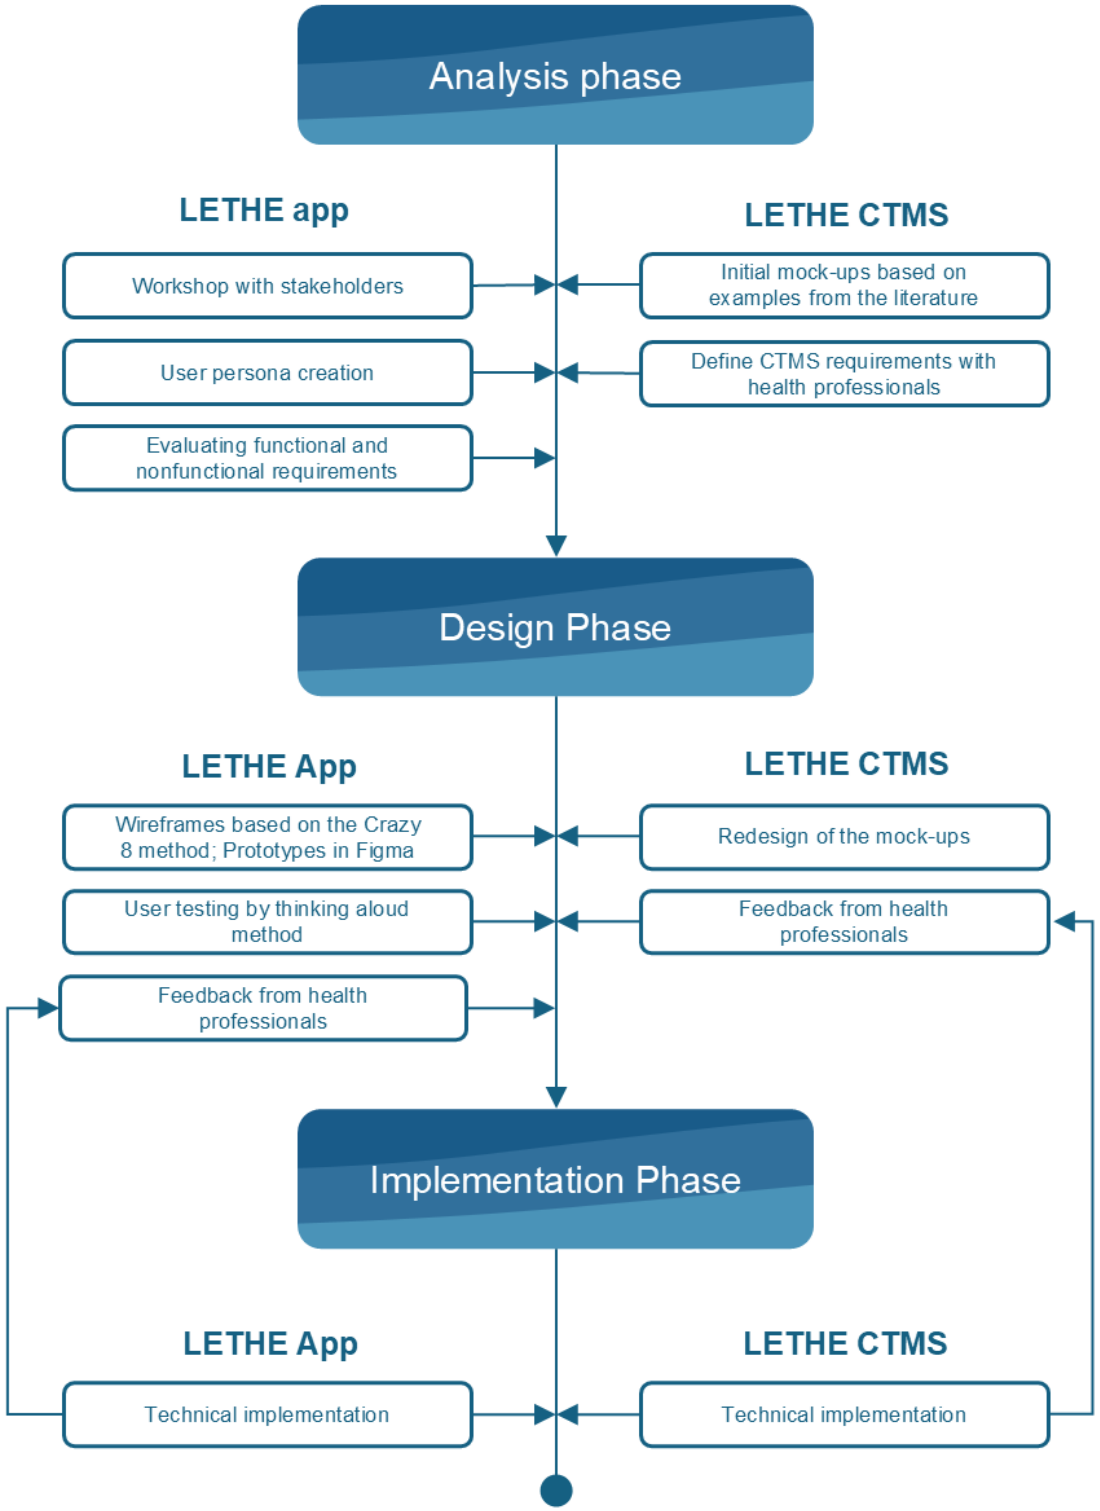
Objectives

This paper describes the iterative design process and reports on the technical implementation of the LETHE app and the LETHE CTMS within the context of a multifaceted and hybrid intervention to prevent cognitive decline in older adults. By sharing the results, we aim to contribute valuable insights to the field of dementia prevention and risk factor management through personalized ICT-supported hybrid intervention methods. We collaborated intensively with end users and health professionals to design the clinical trial platform. In addition, in this study, we evaluated how the trial participants and clinicians accepted the developed applications by using subjective usability assessments. This helped us to understand whether such digital tools keep the participants more engaged and identify directions for further improvement.

Methods

Design of a Mobile App and Clinical Trial Platform

Overview



To ensure high usability, the user-centered design (UCD) approach was chosen for the LETHE app as well as for the CTMS design process. The UCD process involves the participation of end users (in our case, older individuals at risk of cognitive decline and health professionals supporting them during a preventive lifestyle intervention using the CTMS) to define key user requirements. The design approach consists of 3 main phases: analysis, design, and implementation [41].

The UCD approach encompasses 5 key principles: defining user requirements, gathering and considering feedback from users to specify requirements, involving users from the outset to evaluate design iterations, consistently adhering to UCD, and using an iterative design process [42].

Figure 1 illustrates the different design phases of the LETHE app and the LETHE CTMS.

XSL•FO
RenderX

Figure 1. Different phases for the design and development of the LETHE app and LETHE clinical trial management system (CTMS).

Requirement Analysis and Design of the LETHE App

First, a requirement workshop, which was held online, was carried out with the goal of listing requirements for the entire LETHE ecosystem and especially for the LETHE app. A total of 21 individuals from the LETHE project, including clinicians, behavioral experts, and representatives of public involvement in dementia, were invited to the workshop.

During the workshop, 3 user personas [43] were created, which represented typical end users of the LETHE app. General requirements were evaluated via open-ended questions from a clinical view. Specific requirements such as the design or the scientific use were ranked according to importance. The functional requirements of the LETHE app included, on the one hand, the content features according to the FINGER lifestyle domains; on the other hand, general digital requirements were collected from professionals during the workshop. The design

XSL•FO
RenderX

of the digital intervention was based on established behavior change theories to ensure that the app's features were effective. We focused on understanding relevant psychological factors that influence behaviors related to dementia risk [44,45] by relying on multiple behavior change theories to achieve a comprehensive understanding [46]. We used intervention mapping elements [47] and relied on a behavior change taxonomy [48] to select strategies that would best target relevant psychological factors to promote behavior change. Methods such as self-monitoring, setting clear goals, and planning for challenges were built into the app's features. Throughout the design process, a collaboration with health professionals and an advisory board of older adults at risk of or living with dementia was established. The results of this workshop were collected via online collaborating tools such as Mentimeter [49] and Padlet [50].

Afterward, wireframes based on the requirements and identified personas were created. During the user experience design, the method "The crazy 8" for wireframing was used to create as many screens as possible [51]. This method is a fast-sketching method to engage designers in sketching 8 distinct ideas in 8 minutes. In the next step, the wireframes were built using Figma (Figma, Inc) [52] as clickable prototypes to obtain continuous feedback from the involved health professionals.

In addition, a first user test with 4 German-speaking citizens aged between 65 and 85 years was carried out at the Department of Neurology at the Medical University of Vienna, and results were integrated during the implementation phase. One participant had a diagnosis of dementia, whereas the other 3 had no diagnosis. The user tests were conducted using the wireframes as clickable prototypes. First, participants explored the prototype using the thinking-aloud method [53]. Afterward, they were asked to perform 2 specific tasks (ie, choosing among a prepopulated list of pieces of advice for lifestyle improvement and setting them as goals for personal change and entering self-measured blood pressure values). Finally, participants provided verbal feedback and shared ideas and recommendations to further improve the prototypes.

When an implementation-ready design was obtained after the workshop and the user test, the implementation phase (including translation tasks) involved continuous feedback from professionals. Textbox 1 summarizes the phases for creating the design of the LETHE app.

Textbox 1. Phases for creating the design of the LETHE app, with steps 4 and 5 being recurring.

- Workshop for creation of user personas and functional and nonfunctional requirements (step 1)
- Creation of wireframes and clickable prototypes based on the workshop (step 2)
- User testing with potential end users (step 3)
- Adaption of wireframes and implementation phase (step 4)
- Continuous improvement, modification, and development after feedback from professionals and suggestions by study participants and advisory board members (step 5)

Requirement Analysis and Design of the LETHE CTMS

In the initial phase of our UCD methodology, an interactive workshop dedicated to the analysis of user requirements for the LETHE CTMS was conducted. The workshop was held online via Microsoft Teams (Microsoft Corp) with 13 health professionals as participants from different study centers located in Finland, Italy, Sweden, and Austria, as well as technical partners involved in the LETHE project. The professionals of the study centers included neurologists, gerontologists, public health experts, and professionals in the field of quality of life and dementia who represented the end users of the CTMS. The aim was to collaboratively identify the essential features and functionalities required for the LETHE CTMS. The workshop used the Mural tool [54], facilitating the creation of digital whiteboards using sticky notes for brainstorming in smaller breakout rooms consisting of 3 to 4 persons. In those breakout rooms, initial design considerations were discussed. Those considerations included general thoughts on a CTMS, an overview of the participants, data entering, and an artificial intelligence (AI) risk simulation. The process behind the design of the CTMS is described in Textbox 2 [55-57].

The results of the workshop influenced the subsequent design phase, during which multiple design proposals were iteratively developed incorporating feedback from clinical professionals. Once the design phase concluded, we transitioned into the implementation phase.

Textbox 2. Process to design the LETHE clinical trial management system, with steps 3 and 4 being recurring steps.

- Creation of initial mock-ups based on examples from the literature [55-57] and the study protocol of the LETHE trial for workshops together with clinical and technical partners (step 1)
- Conduction of the workshops to gather feedback and potentially missing features (step 2)
- Redesign of the mock-ups and technical implementation (step 3)
- Feedback on the redesign (step 4)

XSL•FO
RenderX

Evaluation of the Mobile App and Clinical Trial Platform

Overview

This section provides a detailed overview of the methodology used to analyze user perspectives within the currently ongoing 2-year clinical feasibility trial, focusing on both the LETHE app and the LETHE CTMS (or LETHE dashboard). The aim was to gather insights on basic usability assessments, encompassing considerations such as satisfaction with the applications.

The analysis was conducted using R (version 4.3.2; R Foundation for Statistical Computing) [58]. The normality test for the data was carried out using the Shapiro-Wilk test (α=.05). To assess the difference in the System Usability Scale (SUS) scores [59] between the study groups, the Mann-Whitney *U* test was used. For pairwise comparisons of the various countries, the Kruskal-Wallis test followed by the Dunn post hoc test with Bonferroni correction was used.

Evaluation of the LETHE App

Older adults who participated in the LETHE RCT provided feedback within the LETHE app through a structured questionnaire, "Experiences with LETHE app," consisting of 10 closed-ended questions based on an adapted version of the SUS, which was simplified for older adults and adults with cognitive impairment [60]. Using a Likert Scale [61] with 5 points ranging from "Strongly Disagree" to "Strongly Agree," participants expressed subjective feelings about the frequency of LETHE app use, perceptions of app complexity, and their need for assistance or confidence in navigating the mobile app. The questionnaire can be found in Multimedia Appendix 1.

This survey will be administered at 3 distinct time points throughout the study: 1 month, 6 months, and 24 months after randomization. Participants have 4 weeks to complete the survey at each time point. This timeline allows for the observation of participant sentiments over an extended duration, offering insights into the subjective aspects of use patterns and the perceived complexity of a mobile app specifically designed for older individuals. As the trial is still ongoing, this study focused on data from the first time point. As a result, we share participants' initial user experiences at this stage.

The LETHE app exists in 2 versions: one for the intervention group and one for the control group. Due to the limited functionality of the version for the control group, which lacks more sophisticated features such as personalized or intervention activities, the analysis was conducted separately for the intervention and control groups.

Within the LETHE trial, 156 study participants were invited to complete the questionnaire, with 78 (50%) in the intervention group and 78 (50%) in the control group. The calculated SUS was assigned a grade [62] as shown in Table 1, with "C" as the average grade and 68 as the center of the range.

Table 1. Interpretation of the System Usability Scale (SUS) score based on a grading scale by Sauro and Lewis [62].

SUS range	Grade	Percentile range
84.1-100	A+	96-100
80.8-84	A	90-95
78.9-80.7	A–	85-89
77.2-78.8	B+	80-84
74.1-77.1	B	70-79
72.6-74	B–	65-69
71.1-72.5	C+	60-64
65-71	C	41-59
62.7-64.9	C–	35-40
51.7-62.6	D	15-34

Evaluation of the LETHE CTMS

To obtain a comprehensive understanding of perspectives from relevant health professionals who used the LETHE CTMS, a 41-question online survey was conducted including both open- and closed-ended questions via Microsoft Forms (Microsoft Corp). The survey was distributed 10 months after the start of the study, and users were given 3 weeks to complete it. The primary objective was to gather feedback on the functionalities of the LETHE CTMS and assess user satisfaction with its implementation. The survey aimed to provide insights essential for mitigating common bottlenecks in the future development of similar tools. Notably, the survey was self-administered and structured into different parts, starting with a brief introduction outlining its objective before participants provided information about their role in the project. Subsequently, general inquiries about the CTMS, such as the onboarding process and overall experience, were posed. Participants then provided feedback on each functionality. Finally, recommendations, challenges, and additional comments were solicited.

All users of the LETHE CTMS were invited to participate and were informed about the survey duration.

The mixing of open- and closed-ended questions served a dual purpose. Closed-ended questions, including Likert scaling and ranking formats, enabled the quantification of participant sentiments, whereas parallel open-ended inquiries facilitated the collection of qualitative feedback. Noteworthy is the

XSL•FO
RenderX

inclusion of a single ranking question designed to identify the beyond-state-of-the-art features of the LETHE CTMS.

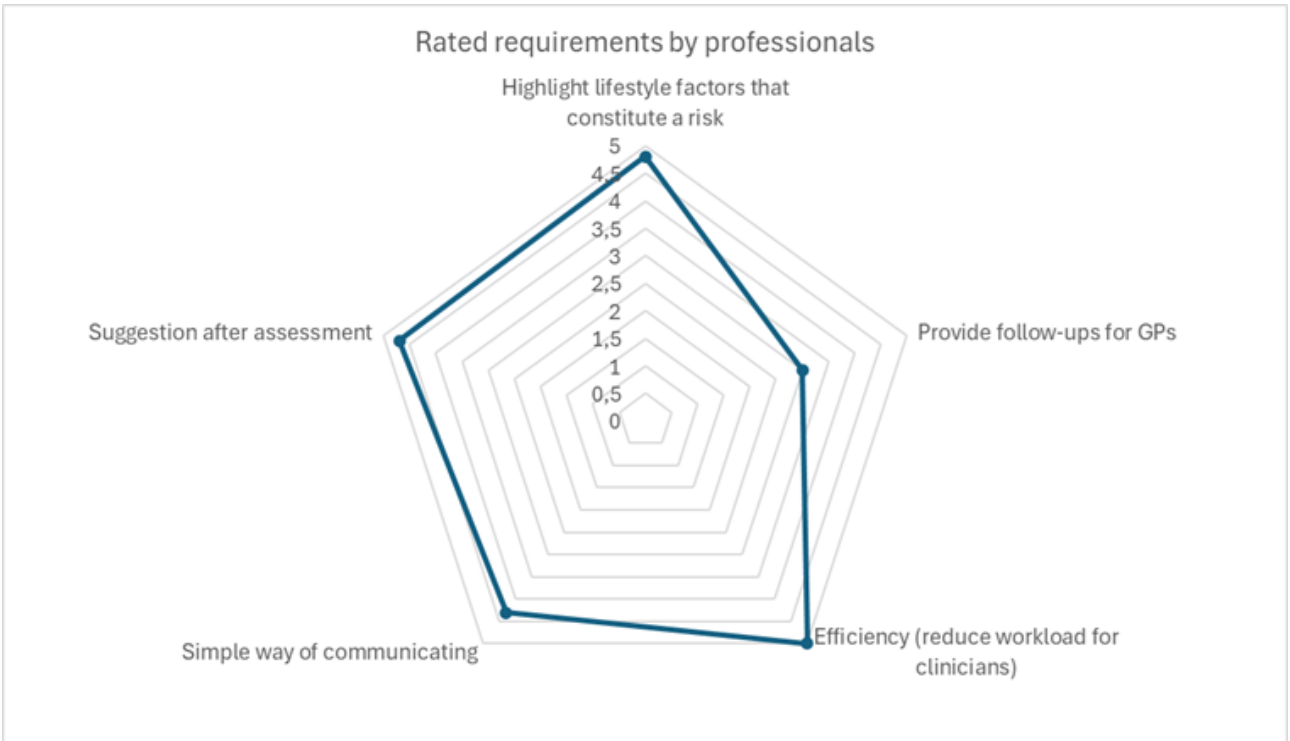
Moreover, a 5-point Likert scale [61] was used for closed-ended questions, encompassing the following response options: “Strongly Agree,” “Agree,” “Neither Agree nor Disagree,” “Disagree,” and “Strongly Disagree.”

The structure of the survey can be found in Multimedia Appendix 2.

Ethical Considerations

The trial has been approved by ethical committees in Austria (Ethics Committee of the Medical University of Vienna; 1392/2022), Finland (Hospital District of Helsinki and Uusimaa Ethical Committee; HUS/13675/2022), Italy (Regional Ethics Committee Umbria; 25723/22/AV), and Sweden (Swedish Ethical Review Authority; 2022-03961-01). All participants provided written informed consent before enrollment. The data used in this study for analysis were anonymized. Study participants received a wearable device, and a phone if they chose to have one. Some of those in the intervention group were additionally provided with a tablet for use during the trial.

Results



Design, Functionalities, and Evaluation of the LETHE App

Results of the Requirement Workshop and End-User Testing

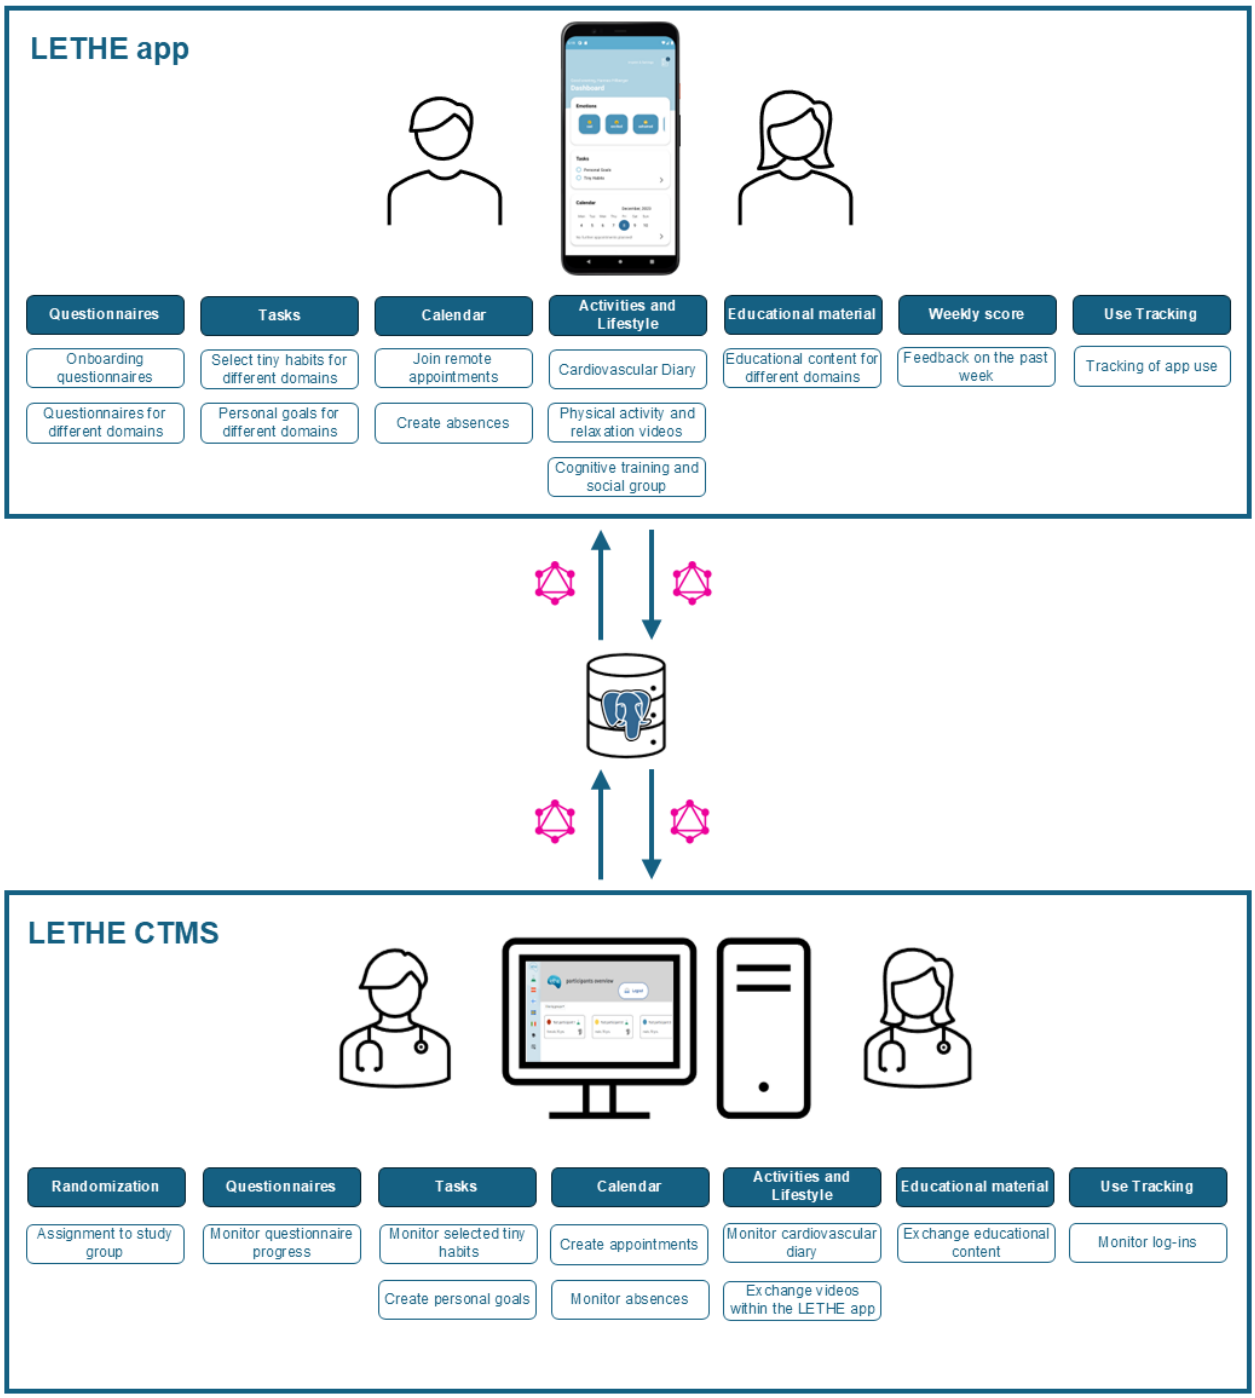
The workshop together with the clinical and technical partners identified several requirements regarding the LETHE app, including the highlighting of lifestyle factors that constitute a risk or where the participant could improve. Additional observations include the LETHE app’s provision of guidelines to identify and flag study participants who are not using it. The communication between the specialists and the study participants should be simple. There was also an emphasis on data transfer and data sharing, highlighting that study participants can independently input data without professional assistance, such as for questionnaires.

The identified requirements were categorized and ranked via a survey. The main outcomes for the LETHE app are summarized in Figure 2. The highest-ranked requirements were to reduce the workload for professionals and highlight the lifestyle factors that constitute a risk. The least important requirement was to provide follow-ups for general practitioners. Those main findings were considered when designing the prototype.

Figure 2. Categorized and ranked requirements for the LETHE app. GP: general practitioner.

While conducting the user evaluation with the 4 participants at the Department of Neurology at the Medical University of Vienna, several key findings were obtained. The size of the user interface elements was criticized as being too small, and the tiles were not understood as large buttons. A section about the summary of the previous week as well as the share function of third-party apps (eg, for cognitive training or videos), which allows users to view content on another device via a QR code or by emailing it to themselves, was not considered intuitive to understand. The given tasks were missing additional information and were not clear without further explanation. Suggestions from the user testing included adding a notification for remembering to eat vegetables and fruits, as well as the marking of special input data values.

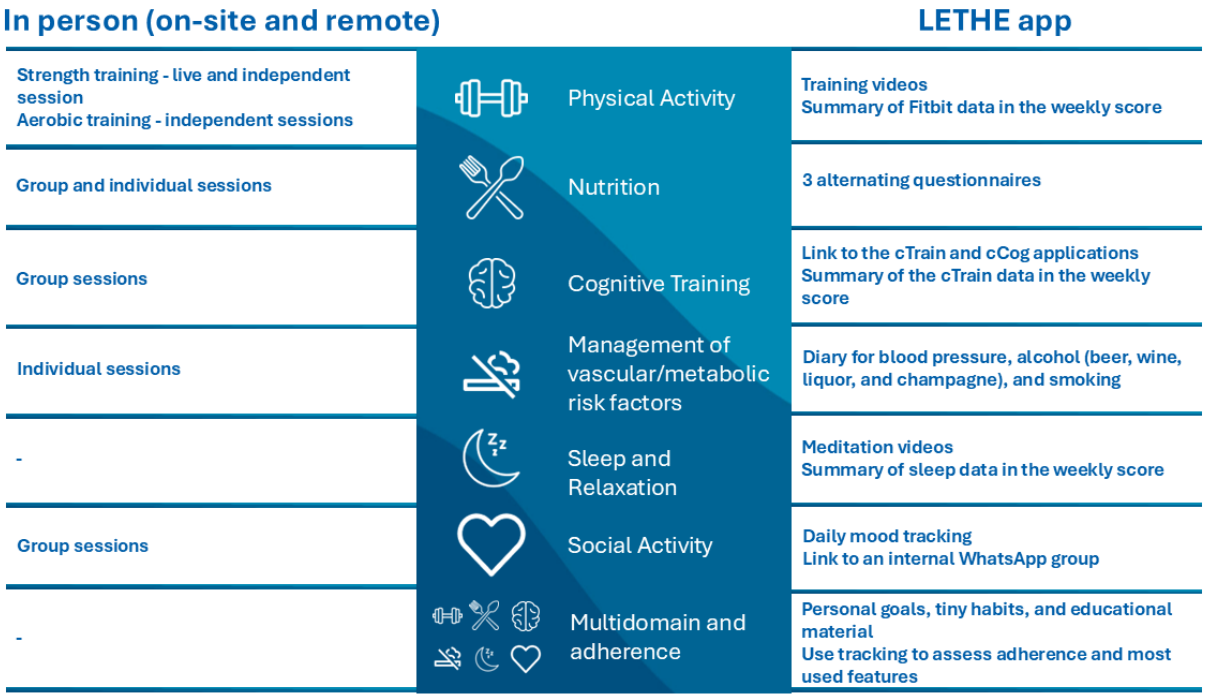
XSL•FO
RenderX



Functionalities of the LETHE App

Overview

The trial incorporates the LETHE app, an Android-native app using Java, to facilitate digital aspects and streamline data collection from study participants. The LETHE app has been released through the Google Play Store and is publicly available for download. However, access to the app's content is restricted to authorized study participants. Data storage and retrieval are managed through a .NET 7 (Core; .NET Foundation) application programming interface, which exposes data via GraphQL (Meta Platforms) protocols for external interaction with a PostgreSQL database (PostgreSQL Global Development Group). Figure 3 illustrates the modules of the LETHE app and the interaction with the LETHE CTMS.



The LETHE app correspondingly aligned the lifestyle domains with a specific digital feature based on the FINGER study [5] and included the additional domains of *sleep/relaxation* and *social activity*. Figure 4 illustrates a comparison between the in-person and digital components of the lifestyle intervention trial.

Figure 3. Overview of the modules, functionalities, and interactions between the LETHE app and the LETHE clinical trial management system (CTMS).

XSL•FO
RenderX

Figure 4. Comparison between in-person and digital components for each lifestyle domain.

After completing the baseline study visit and initial questionnaires through the LETHE app, participants are randomly assigned to either the intervention or control group through the LETHE CTMS. Subsequently, the LETHE app dynamically adjusts the content based on group assignment. Both groups have access to the calendar, settings, questionnaires, mood tracking, and educational content. However, the intervention group has additional functionalities, such as personalized activities and the LETHE lifestyle program.

The LETHE app supports 5 languages (English, Finnish, Italian, Swedish, and German), with translations provided by the study centers. To enhance flexibility for features such as tiny habits and questionnaires, most of the translated content is dynamically retrieved, facilitating faster translation adjustments and content extensions. The translation process involved preparing an initial draft in English, which was then translated by native speakers at the clinical centers. The translations were reviewed to ensure accuracy for each region.

Designed with an older population in mind, the LETHE app uses a tile-based approach with large tiles as entry points for each functionality. This design allows individual elements to be hidden, shown, or reused, creating a modular structure. Following this approach, each component could be packaged independently, facilitating potential reuse in other research projects with similar requirements. Screenshots of each functionality of the LETHE app can be found in Multimedia Appendix 3.

Questionnaires

The questionnaires may be completed at single or multiple time points, with variations based on study group or participant gender. Each questionnaire consists of a title, due date, progress bar, and background color divided into green, yellow, and red, indicating the time remaining to complete the questionnaire. Participants can answer questions across multiple sessions, with answers cached on the device and sent only upon completion. The technical structure adheres to the Fast Healthcare Interoperability Resources (FHIR) standard [63], ensuring interoperability with other systems and enabling the questionnaire module's reuse by incorporating different FHIR questionnaires while maintaining the same structure.

LETHE App Dashboard

Once assigned to either the intervention or control group, participants unlock access to the LETHE app dashboard, which consists of different tiles to access various functionalities. Participants can choose here how they feel daily. Each possible mood item is accompanied by a short description and an emoticon for visualization. The list of the available mood items is dynamically adaptable and could expand in future development based on participant feedback.

Tasks

The *Tasks* section encompasses the personalized intervention module, comprising 2 distinct areas: personal goals and tiny habits. Personal goals are collaboratively established with clinical professionals during visits, targeting specific lifestyle domains for personalized interventions. Personal goals follow the specific, measurable, achievable, realistic, and time-bound principle [64]. Unlike tiny habits, personal goals are not predefined, but they can be packaged as a future library of personalized objectives. These goals can be set daily, weekly, or monthly, offering frequency flexibility, including options such as bidaily or biweekly. Study participants can mark goals as completed or incomplete. Each personal goal is bound to a lifestyle domain, providing participants with an indication of their personal domains for lifestyle improvement.

Tiny habits provide practical everyday tips and behavioral suggestions to help individuals implement manageable healthy

XSL•FO
RenderX

habits [65,66] and is adapted from the StopDia library [34], which is available in Finnish under a CC BY 4.0 license [67]. Tiny habits can be individually set by participants and are available for all lifestyle domains. Each tiny habit includes a description of the activity, a health fact about its benefits, and a place where it should be performed. There are >500 tiny habits in total to choose from, and they are assigned to a lifestyle domain. Given the subjective nature of tiny habit completion, participants are asked weekly about their success based on perceived completion in a questionnaire.

Calendar

The calendar displays all study-related appointments, both remote and in person, with a monthly and daily view. Remote visits can be joined directly from the daily view, which features larger tiles for individual appointments tailored to the target group. Participants can add vacation or unavailability periods, marking them as absences in the calendar. The absence menu is distinct in contrast to all other functionalities, providing a holiday like feel for participants.

Activity and Lifestyle

This section encapsulates the comprehensive LETHE app lifestyle program, featuring various activities tailored to distinct lifestyle domains. In the "Diary" section, study participants can log different health metrics such as blood pressure, alcohol consumption, and daily cigarette intake, directly contributing to the "Management of vascular/metabolic risk factors" lifestyle domain.

A range of activities aligned with different lifestyle areas unfold in the horizontal list at the top of the screen. It starts with a variety of videos dedicated to the areas of "Physical Activity" and "Relaxation." For the "Cognitive Training" domain, there is a link to an external application called cTrain, a cognitive training game package encompassing games similar to those used in the original FINGER study [5,68].

For the "Social Activity" domain, participants from the intervention group can engage with a country-specific and internal WhatsApp group facilitated by clinical staff, ensuring exclusivity for trial participants. The last tile in the list serves as an educational hub, presenting web resources including web feeds provided by professionals via the LETHE CTMS for each lifestyle domain.

Weekly Scores

The weekly score with motivational feedback messages offers participants feedback on the previous week. The feedback message adjusts if the score increased or decreased. The score displays 3 rings representing "App Data/Lifestyle," "Fitness," and "Brain Training." The "App Data/Lifestyle" category includes how often the LETHE app is used. The "Fitness" section displays Fitbit data, including step count, sleep duration, and individual fitness sessions, whereas "Brain Training" presents an overview of cognitive training data.

Use Tracking

To obtain insight into participants' adherence and identify features of particular interest to older individuals in a lifestyle intervention app, a mechanism for use tracking was developed. Each time a participant opens the LETHE app, a unique ID is assigned for the session. Every screen is assigned to an event, and each event is saved with new time stamps when navigating through screens until the participant closes the app. This monitoring technique aims to understand useful features and incorporate measures for adherence analysis [69].

Evaluation of the LETHE App

Overview

Overall, of the 156 participants, 123 (78.8%) provided responses. The distribution of SUS scores in both the intervention group (P=.03) and the control group (P=.02) deviated significantly from normality. However, there was no significant difference in SUS scores between the groups (P=.18).

Intervention Group

A total of 78 participants from the intervention group were invited for the SUS, and 66 (85%) responses were received. Of these 66 participants, 12 (18%) did not answer all the questions. The analysis revealed that the highest satisfaction levels were associated with learning how to use the app, whereas the lowest satisfaction levels were linked to the integration of various components, as shown in Figure 5 and Multimedia Appendix 4. The integration of the various components also received the most neutral responses among the questions. The question regarding the need for assistance when using the app generated the most disagreement, whereas learning about the app before use had the smallest response rate of 85% (56/66) for all questions.

Multimedia Appendix 4 provides an additional analysis for all 4 countries. Finland achieved the highest response rate (19/20, 95% of participant responses), and Sweden achieved the lowest response rate (12/18, 67%).

As 18% (12/66) of the participants did not provide complete answers, missing values were replaced with the neutral value of 3 following the approach outlined by Lewis [70] to calculate the SUS. Figure 6 highlights the presence of 1 outlier with a total score of 0, which was not excluded.

The median SUS score was 70 (IQR 55-82), which is above the average score and qualifies the app for a grade C, as shown in Table 2.

XSL•FO
RenderX

Figure 5. System Usability Scale (SUS) responses for the LETHE app in the intervention group. Panel (A) shows positively formulated questions, whereas panel (B) highlights negatively formulated questions. Green indicates high user satisfaction, and red indicates low user satisfaction. Q: question.

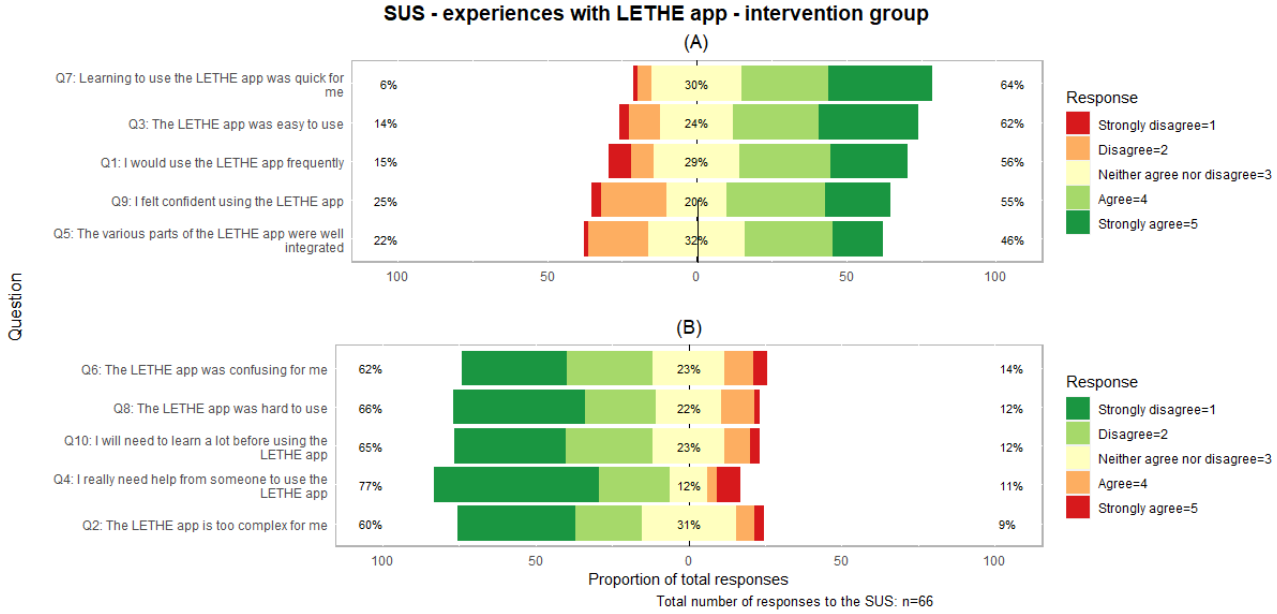


Figure 6. Box plot of the System Usability Scale (SUS) scores for each country in the intervention group.

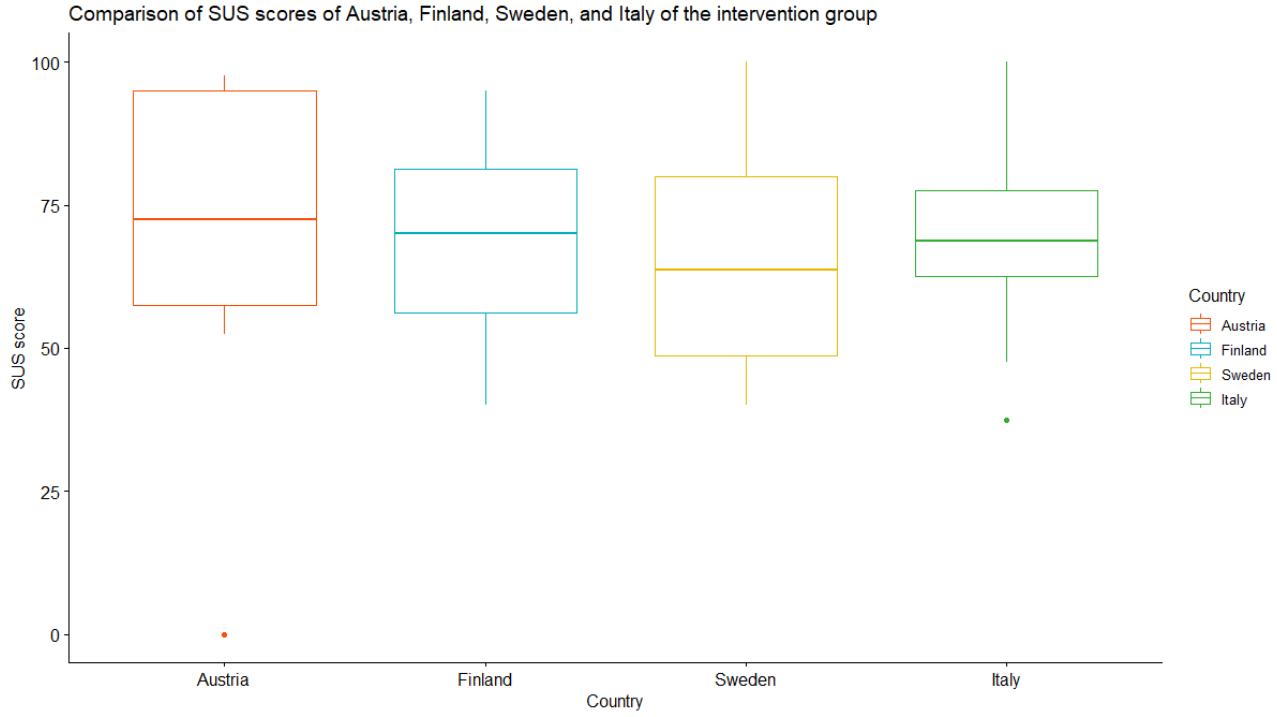

Table 2. Scores on the System Usability Scale (SUS) and its subscales for study participants in the intervention group.

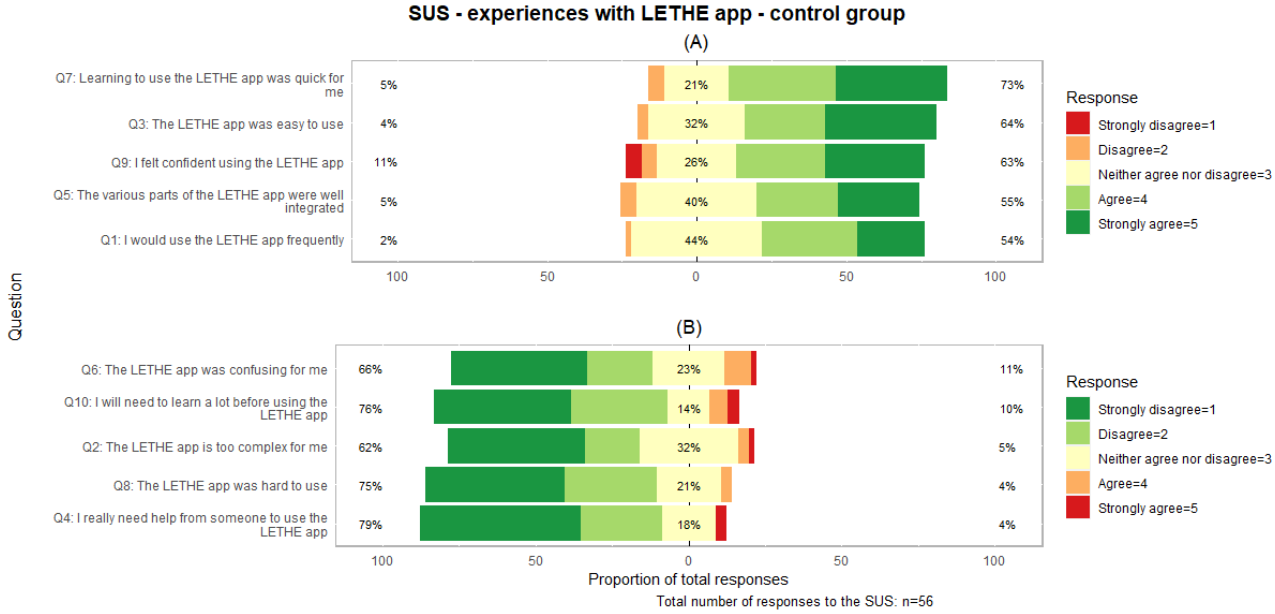
	Measure[a]	Values, median (IQR)	Grade
Total (n=66)	SUS	70 (55-82)	C
Austria (n=17)	SUS	73 (58-95)	C+
Finland (n=19)	SUS	70 (57-82)	C
Sweden (n=12)	SUS	64 (49-80)	C–
Italy (n=18)	SUS	69 (63-78)	C

[a]The SUS ranges from 0 to 100, with 100 as the highest score.

XSL•FO
RenderX



Austria achieved the highest median SUS score at 73 (IQR 58-95), whereas Sweden recorded the lowest median score at 64 (IQR 49-80). Austria was the only country where the app received a C+ score, distinguishing it from the others. Austria had 1 participant who was classified as an outlier with a total score of 0 but was still included in the analysis.

The distribution of SUS scores in Austria departed significantly from normality (P=.01). The distribution of SUS scores in Finland (P=.66), Sweden (P=.19), and Italy (P=.94) did not show evidence of nonnormality. The median SUS score did not differ significantly between the countries in the intervention group (P=.74).

Control Group

For the limited version of the LETHE app, 73% (57/78) of the study control group participants responded. Notably, 18% (10/57) of the respondents did not answer all questions. Figure 7 and Multimedia Appendix 5 indicate that the highest satisfaction was achieved in terms of how quickly participants could learn to use the LETHE app, followed by its ease of use. The only instance of a "Strongly disagree" response was regarding the confidence in using the LETHE app. The question about the LETHE app's frequent use gathered the most neutral responses, possibly due to its limited functionalities compared to the intervention version. A total of 79% (44/56) of the participants disagreed with the idea of needing help from others while using the LETHE app. Similarly to the intervention group, the question about learning about the LETHE app before using it received the smallest response rate of 98% (56/57) of all questions.

Figure 7. System Usability Scale (SUS) responses for the LETHE app in the control group. Panel (A) shows positively formulated questions, whereas panel (B) highlights negatively formulated questions. Green indicates high user satisfaction, and red indicates low user satisfaction. Q: question.

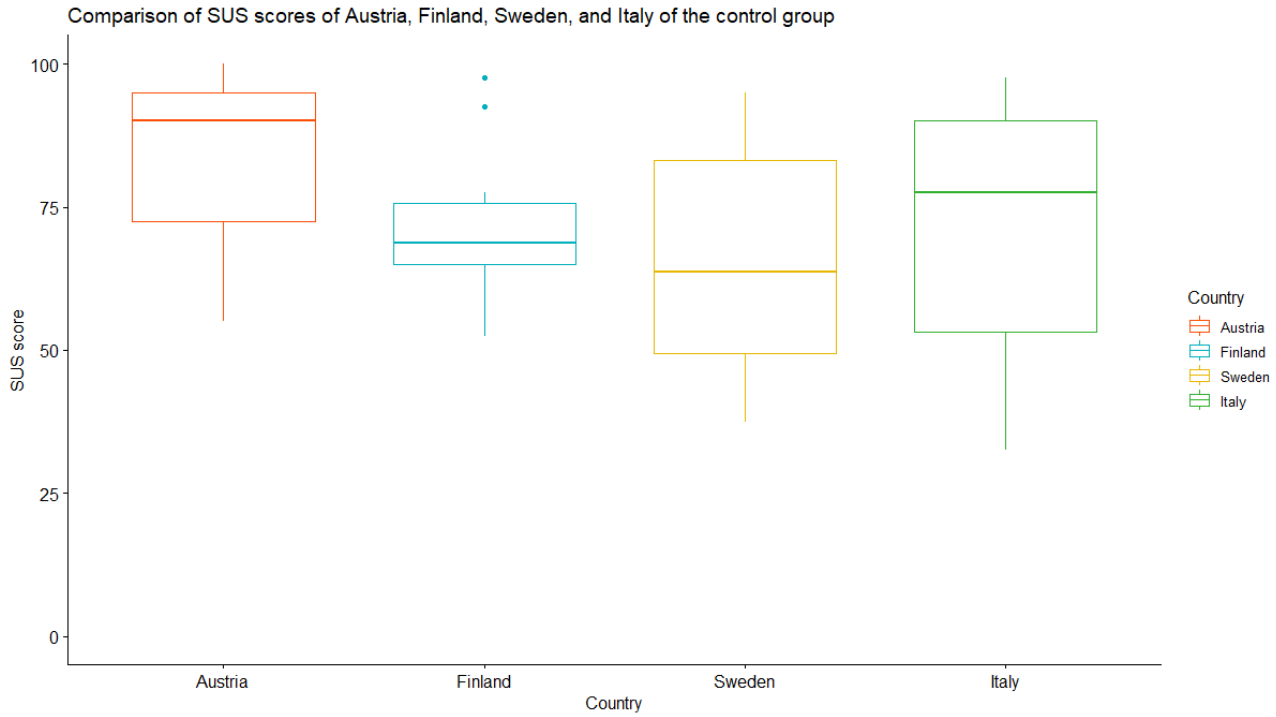
In the control group, Italy exhibited the lowest response rate, with 60% (12/20) of the participants responding, whereas Austria had the highest response rate, with 85% (17/20) of the participants responding. A detailed breakdown of responses per country is available in Multimedia Appendix 5.

To calculate the SUS, all missing values were substituted with the neutral value of 3, mirroring the approach taken with the intervention group. Table 3 illustrates that the median SUS score was 73 (IQR 63-90), corresponding to a B– grade.

Table 3. Scores on the System Usability Scale (SUS) and its subscales for study participants in the control group.

	Measure[a]	Values, median (IQR)	Grade
Total (n=57)	SUS	73 (63-90)	B–
Austria (n=17)	SUS	90 (73-95)	A+
Finland (n=16)	SUS	69 (65-76)	C
Sweden (n=12)	SUS	64 (50-84)	C–
Italy (n=12)	SUS	78 (54-90)	B+

[a]The SUS ranges from 0 to 100, with 100 as the highest score.



Austria had the highest median SUS score at 90 (IQR 73-95), giving the app an A+ grade, whereas Sweden had the lowest median score at 64 (IQR 50-84), giving the app a C– grade. The app obtained a C grade in Finland and a B+ grade in Italy, with median scores of 69 (IQR 65-76) and 78 (IQR 54-90), respectively. Notably, in contrast to the intervention group, the

XSL•FO
RenderX

median SUS score was higher in Austria and Italy and lower in Finland, and it stayed the same in Sweden. Figure 8 visualizes the box plot for each country.

The SUS scores of Austria (P=.03) and Finland (P=.047) departed significantly for normality. The distribution of the SUS scores of Sweden (P=.41) and Italy (P=.11) did not show evidence of nonnormality. The SUS scores did differ between the countries in the control group (P=.03). Pairwise comparisons showed that the median SUS score of Austria was significantly different than the median SUS score of Sweden (P=.02). For the other pairwise comparisons, no significant difference was found. Specifically, the comparisons between Austria and Finland (P=.33), Austria and Italy (P=.36), Finland and Sweden (P=.99), Finland and Italy (P=.99), and Sweden and Italy (P=.99) all yielded P values greater than the threshold for statistical significance.

Figure 8. Box plot of the System Usability Scale (SUS) scores for each country in the control group.

Design, Functionalities, and Evaluation of the LETHE CTMS

Feedback From the Workshop

After an examination of the LETHE study protocol and the examples from the literature [55-57] for a design perspective, initial mock-ups for the LETHE CTMS, a web application, were created. The mock-ups were kept very general and built the foundation for the discussions in the workshop with health professionals. These mock-ups encompassed (1) an overview page featuring details on all study participants, (2) a dedicated view for an individual study participant, (3) the conceptualization of an AI simulation, and (4) a data entry page aligned with the study protocol.

The feedback on the mock-ups included the exclusion of real names given that all study participants would be collectively visible on one page in the mock-up. Emphasis was placed on the immediate visibility of adherence using colors (eg, green, yellow, and red) and dropouts. In addition, diverse roles were implemented to restrict access to sensitive information, such as ensuring that health professionals could only view data related to their own country as well as a blinded role to not see the group of the study participants. Workshop participants also expressed the desire for a descriptive overview of the dataset variables.

Subsequently, the discussion turned to the overview page, where all study participants are listed. Key considerations included the inclusion of adherence information and the need for clear differentiation between participants from the intervention and control groups. Given the sizable participant list of 156 individuals, there was a request for sorting and search functionalities.

During discussions regarding the page presenting information for an individual study participant, workshop participants advocated for distinct perspectives tailored to individuals in the intervention and control groups, emphasizing adherence and dropout summaries. Further dialogues included role-specific views, aiming for the visibility of only relevant data. The workshop participants also expressed a preference for a comprehensive presentation of lifestyle categories, including detailed information and distinct sections for different clinical professionals as well as additional risk factors such as the consumption of alcohol or cigarettes. Requests for additional functionalities included the presentation of the Clinical Dementia Rating [71], allergies, questionnaire responses and scores, notes on participant interactions, details of adverse events such as muscle pain after a prescribed aerobic workout, and automated calculations such as BMI. Another necessity identified was the inclusion of a data export functionality.

XSL•FO
RenderX

When considering the AI dementia risk simulation, there was a discussion about whether it could be used during the study intervention or solely for research purposes. The AI risk simulation is currently available only to researchers due to ethical considerations. As the models used in the simulation have not yet been fully tested or validated, they were not implemented with real participants at this stage. Moreover, the risk information generated by the simulation is not disclosed to participants. Should the disclosure of this risk information be considered in the future, it would require careful evaluation. This process would involve consulting with both the participants and experts in ethics to assess the potential psychological impacts and the broader ethical implications of sharing risk-related information with participants.

The workshop discussed the insertion of all CRF data into the LETHE CTMS, encompassing visit-related data and scores such as the Clinical Dementia Rating and Neuropsychological Test Battery as in the FINGER study. Workshop participants underscored the inclusion of medications, validation checks, and prefillable fields. The study protocol served as a reference for defining the data entry page fields.

Following the conclusion of the workshop, participants were given a clickable prototype. Subsequently, a follow-up workshop was conducted to incorporate adaptations based on the initial workshop insights. The most significant modification was made to the data entry page, necessitating a complete restructuring due to a higher-than-anticipated number of data fields. After several iterations, a design for the beginning of the study was proposed.

Functionalities of the LETHE CTMS

Overview

Following the completion of the LETHE CTMS design, pivotal components were identified to commence the clinical trial. This included an overview of all study participants, a detailed view of a study participant, and the data input portal for clinical professionals. The LETHE CTMS was developed as a web application using React and uses the same backend infrastructure as the LETHE app. The LETHE CTMS is deployed as a Docker container (Docker, Inc). Once a new version is pushed to the main branch of the GitLab repository, a Continuous Integration/Continuous Delivery or Deployment (CI/CD) pipeline is automatically triggered, handling the build, release, and deployment process. After the container is pushed to the GitLab container registry, deployment is carried out using an Ansible playbook (Ansible Inc).

The LETHE CTMS has a consistent design throughout the application, achieved by using a fundamental page structure featuring headers, card-based content representation, a uniform color scheme inspired by the LETHE project colors, and font selection. Ensuring that the data are relevant only to the relevant users was achieved through ongoing communication with end users, and various roles were defined. There are roles that have access to all participants from all study centers; roles that are blinded and, therefore, can only enter visit forms; and roles that are not blinded and can have access to all participant details from their study center.

The LETHE CTMS underwent iterative modifications over time driven by continuous user feedback and evolving requirements. In particular, each section has been given a standardized nomenclature. At the moment, the following sections are included: overview page, detail page, clinician data entry page (containing the electronic CRF [eCRF]), and the configuration pages to adapt the content in the LETHE app. For now, the AI risk simulation is only available for research purposes and not visible to the end users, so a further description is not provided. Screenshots of the different pages can be found in Multimedia Appendix 6.

Overview Page

The overview page serves as a visual representation of all study participants within the selected country. Upon initializing this page, the study participants are loaded based on the study site affiliation of the clinical professional. The header features a legend outlining variables encompassing distinct adherence pathways and the respective participant groups. Color-coded adherence pathways range from “low” (red) to “medium” (yellow) to “high” (green) and include a category of “not calculated.” These pathways are grouped into distinct types, with more details provided on the detail page.

The central section of the page displays all participants from the current site within individual rounded boxes, which encompasses variables such as the participant’s ID, and other essential participant information, including adherence, group affiliation, age, and gender, is also presented.

There is also the possibility to access the configuration pages, allowing for the modification of content related to educational material and videos on the LETHE app.

Detail Page

Upon selecting an individual on the overview page, a more detailed view is presented, encompassing comprehensive data on that particular participant.

The detailed view interface is organized into 3 columns, each with functional components. In the first column, baseline visit data are featured, encompassing demographics, cardiovascular metrics, comorbidities, medications, allergies, and blood values. Users can review completed and pending questionnaires as well as access the responses and corresponding scores. This column concludes with a messaging feature that allows professionals to schedule notifications directly sent to study participants’ smartphones.

The second column commences with notes about adverse events, the entering and tracking of personal goals, and the monitoring of the selected tiny habits and cardiovascular risk factor data entered into the LETHE app. Professionals can also view participant absences to adjust appointment scheduling and reschedule personal goals accordingly.

In the last column, professionals can schedule recurring remote or in-person meetings with study participants together with reminders. Each meeting can be marked as completed to help track the adherence. Participant-professional contacts are recorded, and additional information is displayed, including last

XSL•FO
RenderX

LETHE app log-in, participant consent status, and participation in substudies.

At the bottom of the page, adherence to various categories, such as app use, cognitive activity, diet, and physical activity, is visually displayed, providing an overview of the participant's engagement with key aspects of the study protocol. Table 4 shows the thresholds used to assign each pathway to one of the adherence levels. On the basis of adherence and lifestyle domain, participants receive tailored messages on specific weekdays: physical activity on Mondays, app use on Tuesdays, diet on Wednesdays, cognitive activity on Thursdays, cardiovascular risk factors and social interaction on Fridays, and relaxation and sleep on Saturdays. Participants consistently in the red pathway receive domain-specific or holistic messages. In addition, tiny habit messages are sent on Mondays, Wednesdays, and Thursdays based on reported engagement.

Table 4. Adherence pathways and thresholds for different categories.

	Data type	Instrument used to measure the data and frequency of measurement	Green threshold	Yellow threshold	Red threshold
Physical activity	Activity min and frequency (moderate to vigorous intensity)	Fitbit; weekly (Mondays); passive	Months 1-3: 30-45 min (1 time per wk); months 4-6: 30-45 min (2-3 times per wk); months 7-9: 30-60 min (3-4 times per wk); months 10-24: 45-60 min (3-5 times per wk)	Months 1-3: 15-29 min (1 time per wk); months 4-6: 15-29 min (1 time per wk); months 7-9: 15-29 min (1-2 times per wk); months 10-24: 15-44 min (1-2 times per wk)	1 wk with 0 min or 3 weeks in a row in the yellow path
App use	Changes between the screens within the LETHE app	App; weekly (Tuesdays); passive	≥3 screens (4-7 d)	≥3 screens (0-3 d)	0 screens for 14 d
Diet patterns	Completing food-monitoring item questionnaire within the LETHE app (3 alternating questionnaires)	App; weekly (Wednesdays); active	2/3 or 3/3 blocks completed (in 3 wks)	1/3 blocks completed (in 3 wks)	0% completed (in 3 wks)
Cognitive training	Use of cognitive training program	cTrain; weekly (Thursdays); active	2-3 times per wk	0-1 times per wk	0 times for 3 wk

Data Entry Page

Diverging from the workshop, a series of design iterations led to the decision that the data entry page would act as a repository for information gathered from all study visits, whereas tasks such as contacting study participants and scheduling appointments were moved to the detailed view of an individual participant.

Within the eCRF, each primary section, covering screening, baseline, and subsequent visits, contains subforms that address different documentation areas (eg, forms to report results for blood tests, medication use, and neurological assessments such as the Mini-Mental State Examination [72]).

Each subform within the eCRF incorporates features such as automatic calculations and validation checks, whereby abnormal values trigger a visual highlighted in yellow. This ensures data accuracy and enhances the efficiency of data entry. The eCRF design, embedded with these functionalities, serves as a comprehensive and streamlined platform for recording and managing diverse aspects of study visit documentation.

Evaluation of the LETHE CTMS

Overview

This section analyzes the feedback from the CTMS survey completed by health professionals. First, user-specific details, such as their role in the project and within the application are presented. Second, the quantitative and qualitative feedback for each of the functionalities and the design is analyzed. Finally, a ranking of the state-of-the-art features is presented. The survey refers to the LETHE CTMS as *LETHE dashboard*, but both terms are interchangeable.

Users of the LETHE CTMS

The survey targeted all users of the LETHE CTMS, gathering general information such as their role in the project, their function within the application, and the frequency of their application access. When the survey was conducted, 21 users had access to the LETHE CTMS, and 15 (71%) responded to the survey. The summarized results are presented in Table 5. Most respondents held roles as coordinators or in unblinded positions, with access to almost all features. Of the 15 respondents, 12 (80%) accessed it at least once a week.

XSL•FO
RenderX

Table 5. Role of professionals in the LETHE project and in the LETHE clinical trial management system (CTMS) and frequency of CTMS use (N=15).

Answer option	Professionals, n (%)
"Could you please describe your role in the project?"	
Coordinator	1 (7)
Digital coach	2 (13)
Neuropsychologist	3 (20)
Nutritionist	2 (13)
Physiotherapist	1 (7)
Principal investigator	1 (7)
Study nurse	4 (27)
Study physician	1 (7)
"What dashboard role do you have?"	
Blinded role	1 (7)
Coordinator role	6 (40)
Unblinded role	8 (53)
"How frequently do you access the dashboard?"	
Daily	1 (7)
More than once a week	6 (40)
Once a week	5 (33)
More than once a month	1 (7)
Once a month	2 (13)

Feedback on the Design and Functionalities of the LETHE CTMS

Figure 9 and Table 6 indicate that the highest level of user satisfaction was related to the comprehensive display of relevant participant information in an easily understandable way, with a score of 100% above neutral. A detailed breakdown of all quantitative responses can be found in Multimedia Appendix 7. Overall, feedback was positive, reflecting successful integration of design approaches from workshops and feedback. Users found the LETHE CTMS intuitive, with a visually appealing and clear layout featuring consistent colors, logically divided sections, and pictograms. Pop-ups during item saving aided navigation and provided feedback on actions. Suggested improvements included reducing the steps to move between participants, addressing inconsistencies in single- and double-click requirements, and ensuring visibility of study participant phone information on the participant overview page.

XSL•FO
RenderX

Figure 9. Survey responses for the LETHE clinical trial management system from health professionals. Green indicates high user satisfaction, and red indicates low user satisfaction.

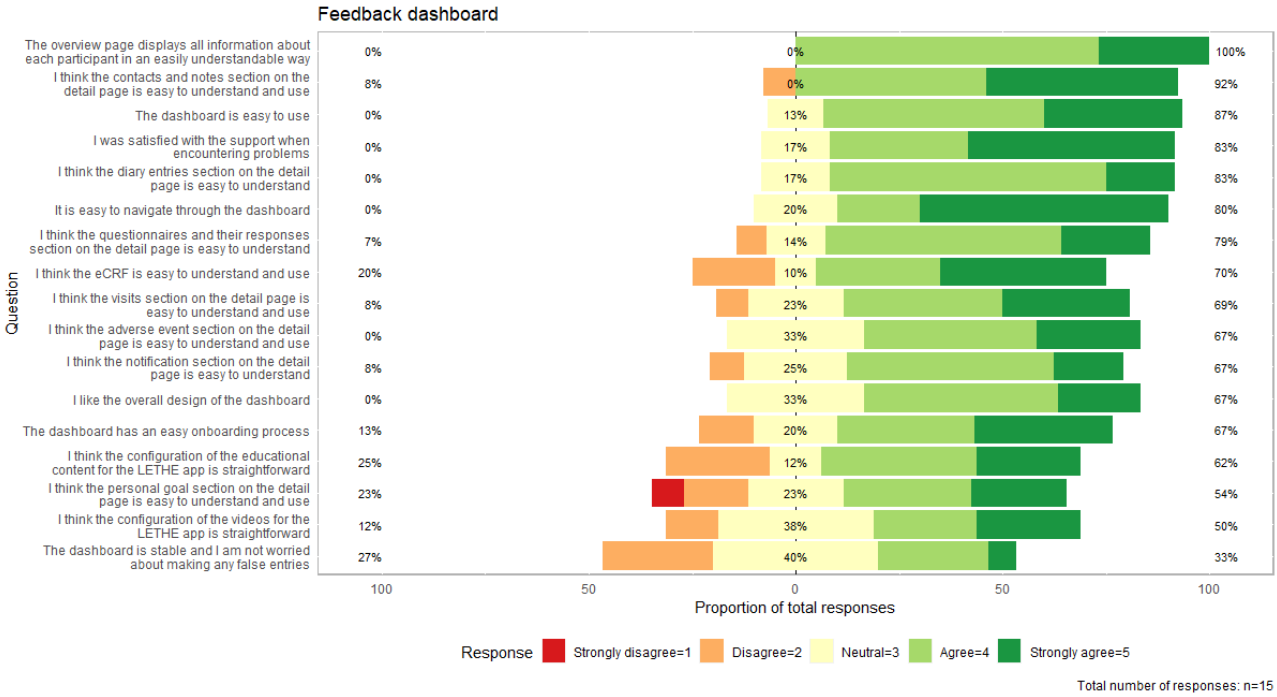


Table 6. Means and SDs of the LETHE clinical trial management system feedback survey targeting the different functionalities.

	Values, mean (SD)[a]
“The overview page displays all relevant information about each participant in an easily understandable way” (n=15)	4.27 (0.46)
“I think the Contacts/Notes Section on the Detail Page is easy to understand use” (n=13)	4.31 (0.85)
“The Dashboard is easy to use” (n=15)	4.20 (0.68)
“I was satisfied with the support when encountering problems” (n=12)	4.33 (0.78)
“I think the Diary Entries Section on the Detail Page is easy to understand” (n=12)	4.00 (0.60)
“It is easy to navigate through the Dashboard” (n=15)	4.40 (0.83)
“I think the Questionnaires and their Responses Section on the Detail Page is easy to understand” (n=14)	3.93 (0.83)
“I think the eCRF is easy to understand and use” (n=10)	3.90 (1.20)
“I think the Visits Section on the Detail Page is easy to understand and use” (n=13)	3.92 (0.95)
“I think the Adverse Event Section on the Detail Page is easy to understand and use” (n=12)	3.92 (0.79)
“The Dashboard has an easy onboarding process” (n=15)	3.87 (1.06)
“I like the overall design of the Dashboard” (n=15)	3.87 (0.74)
“I think the Notification Section on the Detail Page is easy to understand” (n=12)	3.75 (0.87)
“I think the configuration of the Educational Content for the LETHE App is straightforward” (n=8)	3.63 (1.19)
“I think the Personal Goal Section on the Detail Page is easy to understand and use” (n=13)	3.46 (1.27)
“I think the configuration of the Videos for the LETHE App is straightforward” (n=8)	3.63 (1.06)
“The Dashboard is stable and I am not worried about making any false entries” (n=15)	3.13 (0.92)

[a]The scale ranges from 1 (*Strongly disagree*) to 5 (*Strongly agree*). A higher level of agreement indicates greater satisfaction.

Concerning the onboarding process, users expressed that it involved multiple steps and should be streamlined further. However, once granted access, the general opinion was that the process was straightforward. The lowest satisfaction regarding functionalities was observed in the educational content and video configuration, where users missed options for uploading videos and materials instead of web links. The stability and prevention of false entries, particularly in the eCRF, received the lowest satisfaction rating. Users reported issues with scrolling affecting eCRF values and occasional problems with

XSL•FO
RenderX

saving values. Suggestions included implementing a log to track data edits for added transparency, a measure already in place but not visible to users. Another notable disagreement in the *Personal Goals* section was that users found it difficult to set goals at regular intervals, and the lifestyle domain associated with each personal goals was not visible in the detailed view of a study participant.

Feature suggestions included displaying follow-up data, editing values in different sections, providing additional Fitbit data insights, and summarizing clinical test names and scores at the bottom of the eCRF page. Positive aspects highlighted satisfaction with support, emphasizing quick response times, correction of implementations, and clear explanations.

Other feedback suggested the ability to send messages to groups of study participants as well as create group meetings. Overall, those surveyed commented on the effectiveness of the LETHE CTMS for study staff and participants, noting a continuous improvement since its first use.

Ranking the Most Useful and Beyond-State-of-the-Art Features

One of the survey questions asked respondents to rank various features integrated into the LETHE CTMS based on their perceived usefulness and how they surpassed state-of-the-art capabilities. As shown in Table 7, the integration of personalized activities (mean 2.23, SD 1.17) and real-time appointment planning (mean 2.46, SD 1.51) stood out as the most impactful features. An additional comment from a respondent highlighted the novelty of the interplay between the LETHE CTMS and the LETHE app, with a note that further optimization was needed. In addition, the LETHE CTMS holds the potential to serve as both an eCRF and a tool to assist in intervention delivery. This dual functionality was seen as a valuable development for the future to meet the evolving needs of professionals conducting clinical trials.

Table 7. Ranking of different features based on surpassing state-of-the-art capabilities, with R1 being the best-ranked feature and R7 being the worst-ranked feature.

	Choices (n=13), n (%)							Total (n=91), n (%)
	C1[a]	C2[b]	C3[c]	C4[d]	C5[e]	C6[f]	C7[g]	
R1	2 (15)	2 (15)	1 (8)	0 (0)	1 (8)	4 (31)	3 (23)	13 (14)
R2	1 (8)	0 (0)	0 (0)	0 (0)	1 (8)	4 (31)	7 (54)	13 (14)
R3	1 (8)	0 (0)	2 (15)	4 (31)	3 (23)	2 (15)	1 (8)	13 (14)
R4	0 (0)	3 (23)	3 (23)	3 (23)	1 (8)	2 (15)	1 (8)	13 (14)
R5	1 (8)	1 (8)	3 (23)	2 (15)	5 (38)	0 (0)	1 (8)	13 (14)
R6	2 (15)	5 (38)	1 (8)	3 (23)	1 (8)	1 (8)	0 (0)	13 (14)
R7	6 (46)	2 (15)	3 (23)	1 (8)	1 (8)	0 (0)	0 (0)	13 (14)
Total (n=91)	13 (14)	13 (14)	13 (14)	13 (14)	13 (14)	13 (14)	13 (14)	91 (100)

[a]Overview page of different study participants in different countries, including their digital intervention adherence pathways (mean 5.08, SD 2.43).

[b]Direct notifications to study participants via the dashboard (mean 4.84, SD 1.99).

[c]Electronic case report form (mean 4.69, SD 1.80).

[d]Immediate results of onboarding and questionnaires on the dashboard (mean 4.54, SD 1.40).

[e]Configuration of the content of the app via the dashboard (mean 4.15, SD 1.68).

[f]Real-time planning of appointments within the dashboard for the app (mean 2.46, SD 1.51).

[g]Integration of personalized intervention tasks (*Personal Goals*; mean 2.23, SD 1.17).

Discussion

Principal Findings

This paper outlines the design process, functionalities, and evaluation of the digital intervention study components within the LETHE project, focusing on older individuals at risk of cognitive decline and clinical professionals. The design process involved multiple sessions with potential end users and clinical experts. Furthermore, the setup is currently being evaluated in a 2-year intervention study, and the first results have been presented [11,69].

The original FINGER multidomain trial, along with related studies, demonstrated that cognitive benefits can be achieved through a 2-year intervention. As a result, this duration was established as the timeline for the LETHE trial. However, there is only limited information available on longer studies supported by ICT components, such as digital apps requiring daily interactions and wearable devices.

These requirements made it necessary to carefully design the study in terms of human support and create user-friendly ICT components for both participants and clinical professionals. The learnings regarding ICT use in clinical studies, as well as data collected in intervention studies (clinical data and digital biomarkers), are essential and can influence future studies and clinical trial setups using ICT.

XSL•FO
RenderX

To emphasize the importance of user-friendly design, this paper presents the process from requirement gathering to the design of the components. The findings will be evaluated and will inform further improvements to the setup.

Overall, the median SUS score of the intervention group of 70 (IQR 55-82) was comparable to that of the control group of 73 (IQR 63-90). The slightly higher median score of the control group might be attributed to the less complex functionalities compared to those of the intervention group version, specifically the absence of personalized and intervention activities. However, both median scores surpassed 68, indicating above-average user acceptance and satisfaction according to SUS guidelines [62]. Given that the initial user experience for the control group was quite positive even with fewer features, there is hope that they will remain engaged throughout the trial. It is anticipated that these values will improve as participants gain more experience with the LETHE app during the 2-year RCT [73]. Evaluating the other time points will give us more information about the longer-term usability and user engagement.

Noteworthy is the variation in median SUS scores between countries, with Austrian participants providing the highest scores (intervention group: median 73, IQR 58-95; control group: median 90, IQR 73-95) and Sweden providing the lowest scores (intervention group: median 64, IQR 49-80; control group: median 64, IQR 50-84). Performing a pairwise comparison using the Dunn test, a significant difference in median SUS scores between Austria and Sweden was found (P=.02).

While the LETHE lifestyle intervention program is centrally coordinated, and the activities in the 4 countries are harmonized to ensure comparable content, certain local adaptations are allowed to optimize feasibility (eg, in the detailed intervention delivery [balance between in-person and digital sessions] and how the digital components are leveraged). A qualitative study is currently underway to collect additional data on the barriers to and facilitators of the use of digital tools among participants in the LETHE trial.

Overall, users expressed satisfaction with the LETHE CTMS, and workshops on design, usability, and functionality proved beneficial. However, clarity regarding the purpose of an AI risk simulation and addressing user concerns about inaccurate data entry emerged as key challenges during the design process. Further exploration into user satisfaction with the intervention's introduction by clinical professionals across different countries is warranted for future research.

Research should investigate reasons behind decreased personal engagement in long-term ICT-supported studies. The LETHE protocol, with its 2-year ICT-supported design, offers a unique contribution to support cognitive health in older individuals.

In terms of future research, several key directions should be explored. First, a thorough evaluation of the platform's use and usability after the completion of the full 2-year trial would provide valuable insights into its long-term effectiveness. Second, further investigations could focus on the AI-driven risk simulation within the CTMS, with a particular emphasis on its potential role in guiding future interventions. Finally, exploring the adaptability of the LETHE platform among populations with low digital literacy and assessing the feasibility of a hybrid approach would be an important area for future research.

We are confident that LETHE app's diverse features, together with high retention, positive feedback and frequent use [11,69], provide promising directions for future hybrid multimodal interventions.

Strengths and Limitations

This study has several strengths, particularly in how the LETHE app and CTMS incorporate perspectives from both northern and southern Europe. This allows for a broader range of views to be considered. Moreover, this study is regularly improved through feedback from professionals, suggestions from study participants, and input from advisory board members, ensuring ongoing refinement and relevance. One limitation lies in assuming that all participants have sufficient digital skills and internet access, which was an inclusion criterion for the RCT. However, according to a recent study, the gap in digital health trends between younger and older people may vanish in 10 years as today's individuals aged <65 years are highly adapted to digital solutions [74].

Furthermore, all participants were provided with introductory materials and manuals for the LETHE app to facilitate use. Those factors could impact their ratings. Moreover, the subjective nature of the SUS, which relies on participants' self-reported perceptions of usability, might not fully grasp the nuanced usability challenges, especially among older users who may have varying cognitive and physical abilities. Another limitation is that the LETHE app content (eg, educational materials or videos) varies between countries and may influence the ratings.

Another consideration is that the initial user testing involved a small sample size, with only 4 German-speaking participants for the first user testing. However, the evaluation of the LETHE app is part of a study in which health professionals and 156 study participants are included.

The LETHE app was developed exclusively for the Android platform. This decision was based on practical considerations, including resource constraints, time limitations, and the need for a streamlined pilot phase. Focusing on a single operating system allowed for a more efficient development, testing, and release process, ensuring that the feasibility trial could be completed within the available time frame. Android was chosen due to its widespread use and compatibility with various devices, facilitating broader accessibility. To mitigate potential accessibility barriers, participants who did not have an Android device were given the option to receive one for the study. This approach enabled a standardized evaluation of the app's functionality and user experience. Future iterations of the app may consider cross-platform availability, including an iOS or web version.

Regarding the LETHE CTMS, a limitation of the survey is that most users held roles with the highest level of privileges in terms of functionalities, with frequent role changes occurring throughout the project. Improved planning of roles is advisable for future applications to mitigate this issue.

XSL•FO
RenderX

Comparison With Prior Work

Previous studies indicate declining user engagement with mHealth interventions over time due to multiple factors, such as unengaging content, complex protocols, or poor design. For instance, studies such as predictive model-based decision support for diabetes patient empowerment (POWER2DM) [75] have investigated ICT-supported health systems integrating features such as shared decision-making, personal goal setting, mood tracking, and exercise components, which is similar to the interaction between the LETHE app and LETHE CTMS but within the context of diabetes self-management.

Compared to existing digital interventions for dementia prevention, such as PRODEMOS [15] and Maintain Your Brain [16], LETHE introduces several additions and refinements. LETHE builds on standard goal setting but also includes the tiny habits method as an add-on. It also covers additional lifestyle domains, including social engagement and sleep, which are not included in PRODEMOS but are, meanwhile, part of the Lancet Commission's report [2].

In terms of data collection, LETHE uses Fitbit devices to passively monitor physical activity and sleep, whereas PRODEMOS relies on self-reported step counts. Both interventions use a hybrid approach, but LETHE's study duration is extended to 24 months (compared to 18 months in PRODEMOS) and builds on the successful FINGER protocol [5].

LETHE differs from Maintain Your Brain by offering immediate access to all modules rather than introducing them sequentially. Although LETHE does not include a separate mental health module, it collects related information through questionnaires. Maintain Your Brain, compared to LETHE, is entirely internet based and spans 3 years, with only quarterly booster activities after the first year and yearly follow-up assessments for the remaining 2 years.

Finally, unlike both PRODEMOS and Maintain Your Brain, a primary outcome of LETHE is the feasibility of a digitally supported multimodal lifestyle intervention, assessed through participant engagement with the LETHE app and a Fitbit device, attendance to study activities, and implementation of a hybrid approach that combines active and passive data collection across 4 countries.

One significant factor contributing to the unsatisfactory use of ICT components in ICT intervention studies is the usability of the functions provided. This paper provides a comprehensive account of the design process for both the app and the CTMS, aiming to maximize their usability. Subsequent publications will detail the outcomes concerning use and user satisfaction. Identified gaps in involving older adults in the design process of digital health technologies shed light on issues such as the exclusion of individuals with low digital skills during recruitment, emphasizing the importance of using diverse methods such as focus groups, interviews, or workshops [76]. While both the LETHE app and LETHE CTMS design processes incorporated various methods to solicit continuous feedback from diverse user populations, they did not explicitly include persons with low digital skills.

Conclusions

In summary, this paper presented and evaluated the design and functionalities of a comprehensive clinical trial system involving a mobile app tailored for older individuals at risk of cognitive decline. The LETHE app and a web-based monitoring and configuration system for clinical professionals, the LETHE CTMS, were thoroughly evaluated through survey-based assessments. Overall, our approach facilitates real-time interaction, providing 2 distinct applications for professionals and study participants. The results elucidated the design principles, stakeholder involvement, and essential functionalities of such an eHealth system. Subsequent research will delve into the posttrial use of the LETHE app over the 2 years, shedding further light on its effectiveness and user engagement.

Acknowledgments

The LETHE project has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement 101017405 [77] (accessed on January 31, 2024). FM is also supported by an ALF (Region Stockholm) grant. This research is supported by a larger consortium, including FH JOANNEUM GmbH, Medical University of Vienna, University of Perugia, Karolinska Institute, Finnish Institute for Health and Welfare, Alzheimer Europe, Foundation for Research and Technology–Hellas, Maastricht University, Kaasa solution GmbH, Innovation2Grow, the EGI Foundation, Extra Red SRL, Infotrend Innovations Company Limited, Combinostics Oy, and the Lisbon Council for Economic Competitiveness asbl.

Abstract

Background: In the context of an aging population and increasingly medicalized end-of-life practices, it is crucial to promote early discussions to help patients express their view on what is essential in their life as well as articulate their preferences regarding future medical treatments and end-of-life issues. An interprofessional research team at Geneva University and the Geneva University Hospitals has developed Anticip'action, a card game designed to help initiate and conduct advance care planning and end-of-life discussions. It is available for free in paper format in diverse languages and in a digital version in French.

Objective: This study aims to assess the ergonomic quality of the digital version of the game with primary users.

Methods: Overall, 10 users (women: n=5, 50%; men: n=5, 50%; mean age 41, SD 13.4 years; range 25-65 years; education: upper level; comfortable with smartphones) completed an online usability test. The test began with a rapid desirability test to capture initial impressions of the game's main screen without knowing what it is about. This was followed by a think-aloud procedure, including 26 tasks to perform all steps of the game. Posttest questionnaires were administered to collect participants' subjective perceptions of the usability (System Usability Scale), attractiveness (AttrakDiff), and relevance as well as overall endorsement of the game (Mobile Application Rating Scale). Open-ended questions were used to further explore usability issues. Usability problems were categorized and evaluated using standard evaluation grids. Content readability was assessed with Scolarius.

Results: The rapid desirability test revealed an overall good or average impression. In 83.2% (208/250) of the cases, participants successfully completed the think-aloud tasks without assistance. Some of the tasks (4/25, 16%) revealed multiple usability issues requiring assistance. Analysis of the 23 failures and difficulties encountered revealed that 3 (13%) issues were due to suboptimal wording of the task instructions and that there were 9 (39%) major usability problems. All could be addressed through minor modifications. The Scolarius test indicated that the card titles were understandable at an elementary school level, while the explanations on the back of the cards required a high school reading level. Participants rated Anticip'action as good or excellent in usability (79 out of 100 on the System Usability Scale), attractiveness (1.57 on the −3 to +3 AttrakDiff scale), and relevance (4.1 out of 5 on section F of the Mobile Application Rating Scale). Participants provided overall positive qualitative feedback.

Conclusions: The usability testing of the digital French version of Anticip'action produced positive results, with some areas for improvement identified. It can be recommended as a valuable resource for patients, families, and caregivers to prompt reflection, raise awareness, and support advance care planning conversations. Further tests should be conducted on wider population groups, including older patients and individuals less comfortable with digital solutions.

Introduction

Background

In the context of an aging population and increasingly medicalized end-of-life practices, it is crucial to promote early discussions to help patients express their view on what is essential in their life as well as articulate their preferences regarding future medical treatments and end-of-life issues [1,2]. Advance care planning and end-of-life discussions may include clarifying one's own values and priorities in life; preferences regarding situations or medical treatments that are expected or not desired; and other important matters that should be addressed in case of loss of decision-making capacity or death, such as the management of financial matters, funeral planning, organ donation, the designation of a surrogate medical decision maker, and so on. These discussions are mostly relevant for patients facing a life-threatening illness or for older people with increased fragility. They help increase patient empowerment and decrease distress among loved ones and health professionals when important decisions have to be made [3]. However, these anticipatory discussions are often delayed or avoided due to a multitude of barriers such as health care professionals' lack of trust in their communication abilities, time constraints, emotional burden, and fear of generating misunderstandings or conflicts [4-7]. To overcome these obstacles, it is crucial to develop strategies and communication tools that facilitate the initiation and conduction of end-of-life discussions.

Studies indicate that free online digital tools (websites, apps, online games, etc) could enhance interest, communication, and decision-making related to advance care planning [8-12]. These communication tools may serve as icebreakers, provide a supportive structure for conducting a discussion, and save clinicians' time. Indeed, digital tools are easy to share with patients and can provide relevant information and input to conduct part of the reflection in a private and familial context ahead of the medical consultation. However, with some exceptions [13], existing solutions are mostly in English and not necessarily adapted to the European cultural context.

An interprofessional research team at Geneva University and the Geneva University Hospitals (HUG), composed of ethicists, physicians, nurses, trained patients as partners, and IT professionals, has developed information and communication tools to support the culture of advance care planning. In particular, the digital tool Accordons-nous ("Let's agree") is available for free as a module integrated into the larger Concerto application available on the HUG website [14]. The Concerto app can also be downloaded from the Google Play Store and Apple App Store. Accordons-nous [15] is currently only available in French. It includes information on advance care planning, discussion prompts, an advance care directive form, and a digital version of the card game Anticip'action.

Anticip'action, the Card Game

Anticip'action is a card game designed to help users clarify their values and priorities in life, discuss them with their loved ones and health care professionals, and plan concrete actions regarding care and end-of-life decisions. It is inspired by the game Go Wish [16] but contains its own set of cards adapted to the Swiss cultural context and additional rules and content. It can be used with caregivers during structured advance care planning discussions, or it can be proposed as an icebreaker to be played independently at home with loved ones. A printable version of Anticip'action is available in different languages (English, French, German, and Italian) for people who are not at ease with digital tools. The digital version is currently only available in French in Accordons-nous (Textbox 1; Figures 1-6). In this paper, we present the results of the usability test of the digital version of the game.

Textbox 1. Short description of the game rules of Anticip'action.

The game is divided into three phases

1. "Prioritize"—in this phase, the task is to sort 32 cards into 4 categories ("Very important," "Important," "Not important," and "Unsure"). Examples of card statements are "Looking after my appearance" and "Expressing what I couldn't stand." Each card includes explanatory text on the back.
2. "Specify"—in this phase, the task is to add personal details to the cards that have been marked as "Very important" and decide whether the topic has already been addressed or still requires action.
3. "Act"—in this phase, the task is to write down actions that could be taken to address the important issues highlighted in the previous phase. To assist in this task, each card suggests possible actions (eg, scheduling an appointment with a health care provider or arranging a meeting with a loved one). The output of the game is a PDF summary of cards ranking, specifications provided during the game, and to-do-list of actions to be done.

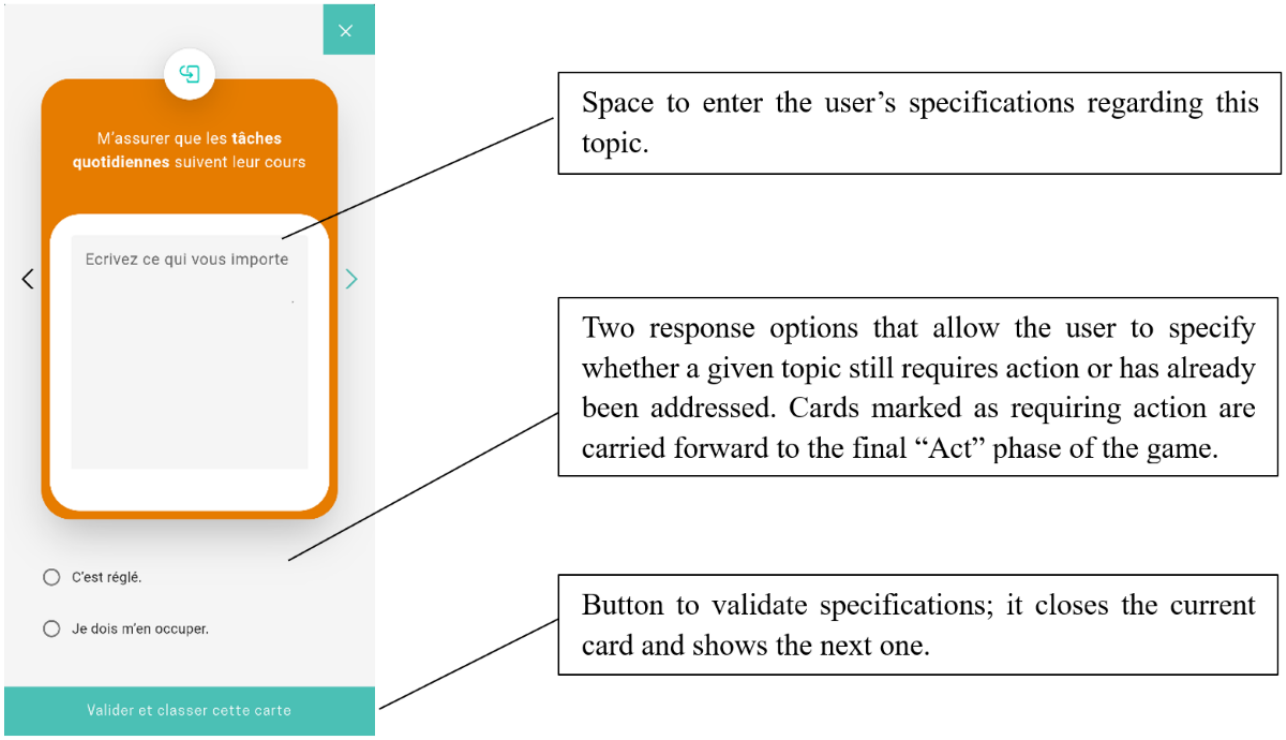

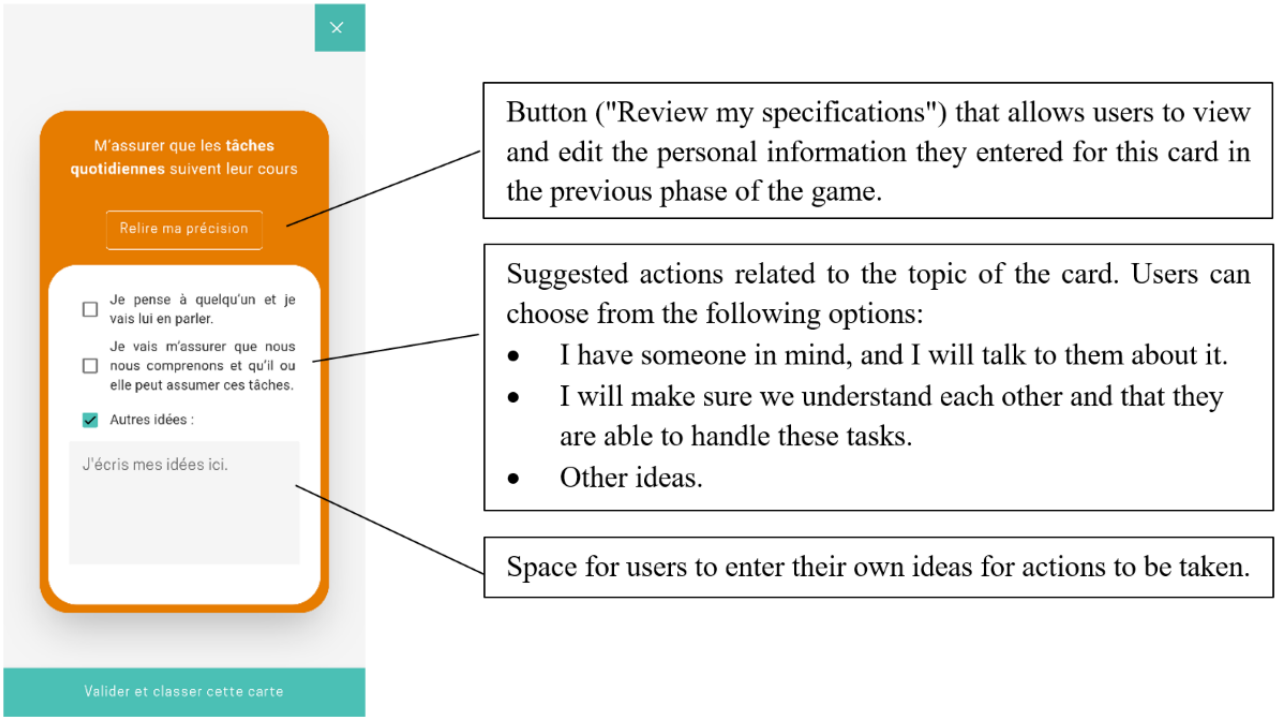

Figure 6. Game phase 3: “Act”—screen that allows users to choose actions to complete in relation to the topic of the card.

Methods

Recruitment

The aim was to collect data from 10 participants, as Nielsen and Landauer [17] have demonstrated that a usability test conducted with 10 users can identify >98% of usability issues. The inclusion criteria were as follows: being an adult, having oral and written proficiency in French, and feeling comfortable using a smartphone. A single exclusion criterion was applied: participants should not be familiar with or have previously navigated the Accordons-nous module in the Concerto app. The exclusion criterion was enforced to prevent testers from being biased by prior knowledge that could facilitate ease of use. Overall, the aim was to ensure diversity in gender and age and to include individuals with at least minimal comfort using digital tools. Participants were recruited through the patients-as-partners platform at the HUG as well as via snowball sampling and networking. Participation was voluntary, and participants

XSL•FO
RenderX

received an information sheet and consent form in advance. The study was preregistered on the OSF platform [18].

Ethical Considerations

The research protocol was submitted to the Geneva Commission Cantonale d'Ethique de la Recherche (Req-ID 2024-00994), which determined that the project did not fall within the scope of the Human Research Ordinance and therefore waived the requirement for ethics approval (decision date: September 17, 2024). This study was conducted in accordance with the Declaration of Helsinki. Willing participants were informed of the study aims and procedures and signed an informed consent form. During the data collection and analysis phase, only 3 authors (DC, FE, and CC) had access to the recorded interviews. The recordings were destroyed after analysis. No identifying information was retained in the remaining study files.

Study Intervention

The entire evaluation was conducted online (via email and videoconference using Zoom [Zoom Video Communications, Inc]). Participants received in advance via email the information sheet and consent form along with instructions on how to join the videoconference with the experimenter and how to install the Concerto app. They were asked not to use the Concerto app before the test and were not informed about the name of the game or where to find it in the app. On the day of the test, the experimenter answered any questions, made sure that informed consent had been signed and returned, and assisted participants in connecting their smartphone to the Zoom videoconference to observe and record their navigation behavior.

The test began with a few demographic and technical questions (age, gender, level of education, type of smartphone used, and smartphone use habits), after which participants were shown a screenshot of the game to gather their first impressions. They then completed a series of think-aloud tasks [19] during which they used the main functions of the game. The 26 tasks were designed to evaluate the usability of the game and to ensure that an average user could navigate effectively through it. Participants were asked to imaging being an individual aged 50 years concerned about illness and advance care directives, who had been advised to use the game Anticip'action. The experimenter then presented the scripted task instructions one by one (Table 1). While completing the tasks, participants were encouraged to verbalize their thoughts, actions, and decisions.

XSL•FO
RenderX

Table 1. List and description of the tasks completed during the think-aloud procedure.

Tasks	Expected achievement	Exact wording of the instruction	When the task was considered complete
1. Find and open the game.	Find the game nested in the Accordons-nous module in the Concerto app.	Your friend told you about the game. He told you that the game is in Concerto. You are now in Concerto. More precisely, the game is in the Accordons-nous module. Your first task is to find the game and open it. Let's go!	The participant opens the Concerto app, scrolls to and clicks on the Accordons-nous module, clicks on the "Talk about it" menu at the bottom of the screen to access the game entry point, and then clicks on the "Play" button.
2. Read rules and start.	Understand the logic of the welcome page, which includes 2 buttons: one for accessing the rules of the game and one for starting a new game (Figure 1).	First, read the rules, and start the game.	The participant clicks on the "Game rules" button, reads the rules, closes the rules page by clicking on the X icon, clicks on the "New game" button, reads the pop-up instructions when they appear, and then closes the pop-up.
3. Select "Feelings and relationships."	Understand that there are 4 thematic card piles that can be opened (Figure 2).	Select the "Feelings and relationships" pile, and open it.	The participant clicks on the third (pink) icon at the bottom of the screen, which represents the "Feelings and relationships" pile.
4. Flip the first card.	Understand that the card can be flipped to obtain more information on the topic (Figure 3).	Flip the first card.	The participant clicks on the "flip card" button at the top of the screen.
5. Scroll through cards.	Understand that the content of the opened pile can be explored by scrolling (Figure 3).	Scroll once to the left and once to the right to see the other cards in this pile.	The participant uses the navigation arrows to scroll through the cards in the pile.
6. Classify as "Unsure."	Understand the classification system, including the "Unsure" category (Figure 3).	Classify the first card as "Unsure."	The participant clicks on the rectangular "Unsure" button.
7. Classify as "Very important."	Understand that the first filled heart icon represents the "Very important" category (Figure 3).	Classify the next 3 cards as "Very important."	The participant clicks on the filled heart icon.
8. Exit the pile.	Understand how to return to the main screen of the game when a pile is opened (Figure 3).	Exit this pile.	The participant clicks on the X icon on the top right of the screen.
9. Open the "Practical questions" pile.	Identify and open another thematic card pile (Figure 2).	Open the "Practical questions" pile.	The participant clicks on the second (orange) icon at the bottom of the screen.
10. Classify 9 cards as "Very important."	Learn the rule limiting the number of cards classified as "Very important" to a maximum of 10 (Figure 3)	Classify the first 9 cards as "Very important."	The participant clicks on the filled heart icon until a pop-up message appears.
11. Read and close pop-up.	Understand the content of an instruction pop-up and close it.	[Pop-up appears] Read this message, and close it.	The participant reads the pop-up message and clicks on either the X icon or the "Understood" button.
12. Find and scroll through surplus cards.	Discover where to find already classified cards (Figures 2 and 4).	Find the surplus cards, and scroll through them.	The participant clicks on the X icon on the top right of the screen to exit the pile, clicks on the "Prioritized cards" button icon on the main screen (top left) to view and update already classified cards, clicks on "Very important," and scrolls through the cards.
13. Classify surplus cards as "Important."	Understand how to reclassify cards in another category (Figure 4).	Classify the surplus cards as "Important" and then confirm.	The participant clicks on a card classified as "Very important" and clicks on the half-filled heart icon, repeating the process until task completion.
14. Classify all cards.	Understand that all cards must be classified in the first "Prioritize" phase of the game (Figure 2).	Classify the following cards as "Not important."	The participant clicks on card piles and clicks on the empty heart icon below each card, repeating the process until no more cards are available.

XSL•FO
RenderX

Tasks	Expected achievement	Exact wording of the instruction	When the task was considered complete
15. Check card count in each category.	Understand the logic of the 4 classification categories and their associated numbers (located on the main screen; Figure 2).	Do you know how many cards are present in each classification category ("Very important," "Important," "Not important," "Unsure")?	The participant reads and interprets the classification numbers located under the category's icons.
16. Go to next phase of the game.	Understand how to go to the second phase of the game.	You can proceed to the next step.	The participant clicks on the "Next step" button (it appears at the bottom of the main screen when all cards have been classified).
17. Read instructions and continue.	Discover the game rules for the next phase ("Specify") of the game.	[Pop-up appears] Read the instructions, and continue the game.	The participant reads the instructions and closes the pop-up by clicking on either the X icon or the "Understood" button.
18. Add text to a card.	Understand how to add text to a card (Figure 5).	Write comments on the first card by adding text in the designated space (eg, a letter).	The participant clicks on the card pile (which opens the first "Very important" card) and enters text in the designated space on the card.
19. Validate and define whether to act.	Understand that the specifications provided on a card can only be validated after it is additionally specified whether the topic still requires action or has already been addressed (Figure 5).	Validate the card to move on to the next one, knowing that action is still required.	The participant clicks on the second radio button ("I have to take care of this") and then clicks on the "Validate and classify this card" button.
20. Locate the rules.	Identify how to access the game rules at any time during the game (Figure 2).	Imagine that you suddenly have doubts about some game rules and would like to consult them. Where do you find the rules of the game?	The participant clicks on the X icon to exit the pile and, on the main screen, clicks on the "?" icon (top left); alternatively, the participant quits the game by clicking on the X icon on the main screen and then clicking on the "Game rules" button on the welcome page.
21. Validate as "Resolved."	Understand that for all cards in the "Specify" phase, a decision has to be made about whether or not it calls for an action (Figure 5).	Validate the following cards (without writing text on them) as "Resolved" and continue the game.	The participant clicks on the pile of cards not yet specified (located at the bottom of the main screen); for each card, the participant clicks on the first radio button ("This has been taken care of") and then clicks on the button "Validate and classify this card."
22. Review and check all actions.	Understand how to handle the cards remaining in the final phase ("Act") of the game: open each card, review the specifications, and choose related actions (Figure 6).	Review your specifications, and check all the actions.	The participant clicks on the pile of cards requiring action (located at the bottom of the main screen), clicks on the "Review my specifications" button, clicks on the "flip card" button again, and clicks on all actions.
23. Add more text to a card.	Understand how to enter one's own ideas about actions to be taken (Figure 6).	Add text in the designated space (eg, a letter).	The participant clicks in the "Other ideas" textbox and enters text.
24. Validate the card.	Understand how to validate action choices related to a card (Figure 6).	Validate the card.	The participant clicks on the "Validate and classify this card" button.
25. Export results and return to the game.	Understand how to export a summary of the game.	Export your results, and return to the game.	The participant clicks on the "Export game summary" button (it appears when all actions have been defined), reads the data confidentiality pop-up, and clicks on the "Understood" button.
26. Erase data and exit the game.	Understand that a decision can be made to erase or retain the data when exiting the game.	Exit the game, and delete the data.	The participant clicks on the "Quit" button and, when the pop-up appears, clicks on the "Quit and delete my data" gray band.

Finally, posttest questionnaires were administered to gather participants' subjective evaluation of the usability, attractiveness, and relevance of the game as well as their overall endorsement. The questionnaires included open-ended questions to further explore usability issues (Multimedia Appendix 1). While usability was the primary focus of the study, these additional measures helped provide a broader understanding of users' perceptions and expectations.

XSL•FO
RenderX

Measures Used and Data Analysis

First Impressions

The 5-second test [20] was used to gather participants' spontaneous first impressions of the game. In this test, the main screen of the game (Figure 2) was shown for exactly 5 seconds before being replaced by a black screen. Participants were then asked four questions: (1) "What do you remember about the visual elements of the interface?" (2) "What do you think are the objectives of the game?" (3) "What is your overall impression of the game (on a 5-point scale ranging from *very bad* to *very good*)?" (4) "How do you evaluate the aesthetics of the game (on a 5-point scale ranging from *very unsightly* to *very attractive*)?" The 2 open-ended questions were presented first because this has been shown to better support memory recall [21].

Think-Aloud Procedure

Task Success

Performance was assessed based on whether participants succeeded or failed in completing each task, with or without assistance from the experimenter. The following scoring system was applied: 0=the participant failed, and the experimenter ultimately provided the answer; 1=the participant succeeded but only with the experimenter's help; 2= the participant succeeded after the experimenter repeated the task instructions (in cases where the participant had forgotten the task; this was not considered assistance); 3=the participant succeeded independently but explored the interface before arriving at the correct result (correct result and path but after some exploration); 4=the participant succeeded without help but did not use the shortest path (correct result via an alternative route); and 5=the participant succeeded without assistance and easily found the shortest path.

Clicks to Complete Tasks

The number of clicks required to complete each task was recorded. As shown in Table 1, some tasks required more clicks than others, whereas for certain tasks, multiple response paths were possible.

Time Spent on Tasks

The time (in seconds) that participants took to complete each task was recorded. Timing began when the experimenter finished giving the task instruction for the first time and ended when the participant successfully completed the task. Any time spent digressing during the task (eg, making critical comments about the game's design or sharing a personal memory) was recorded as "digression time" and subtracted from the total time.

Analysis of Errors and Problems Encountered

The errors and problems encountered by participants while completing the 26 tasks were recorded and analyzed. Each issue was documented in a Microsoft Excel file; categorized according to the heuristics (such as information density, consistency, and code meaning) of Bastien and Scapin [22]; and assigned a severity score using a 0 to 4 scale based on the recommendations of Nielsen and Landauer [17]: 0=disagreement on whether it constitutes a usability problem; 1=cosmetic issue—need not be fixed unless extra time is available; 2=minor usability issue—fixing this should be given low priority; 3=major usability issue—important to fix and should be given high priority; and 4=usability catastrophe—imperative to fix this before the product can be launched.

Data Analysis

To ensure reliability, all authors independently coded 2 recordings. The results were then compared and discussed to resolve discrepancies or doubts about specific interpretations. The first author coded the remaining data independently.

Questionnaires

Perceived Usability

The French version of the standard System Usability Scale (SUS) was used to evaluate participants' perceptions of the game's usability [23]. The SUS provides an indication of the effectiveness, efficiency, and overall ease of use of a digital product. It consists of 10 items rated on a 0 to 4 Likert scale, yielding a score ranging from 0 to 100 (each item contributing up to 10 points). A score of approximately 85 is considered excellent, approximately 72 good, approximately 53 average, and approximately 38 poor.

As discussing end-of-life and advance care planning issues is not an everyday activity, Anticip'action is not expected to be played repetitively. Consequently, the first item of the SUS—"I think I would like to use this system frequently"—is only partially applicable to evaluating the game. To address this, a slightly modified version was added to the original 10 items: "I think that if I need to consider what is important to me at the end of life, I would give priority to this game." This adjustment allowed for the calculation of 2 SUS scores: the standard version and an adapted version that included the modified item.

Perceived Attractiveness

The French version of the standard 28-item AttrakDiff questionnaire [24] was used to evaluate participants' experience across four dimensions of user experience, each comprising 7 items: (1) pragmatic quality, which measures the product's usability and the perceived ease with which users can achieve their goals; (2) hedonic quality–stimulation, which assesses the extent to which the product satisfies the need for stimulation by offering new, interesting, and engaging content, features, and interaction styles; (3) hedonic quality–identity, which examines how well the product supports a social function and communicates a sense of user identity; and (4) overall attractiveness, which represents the perceived value of the product based on its pragmatic and hedonic qualities. This questionnaire includes pairs of contrasting adjectives rated on a 7-point scale ranging from −3 to +3. Scores close to the mean (between 0 and 1) indicate that the product has achieved its objectives without any significant negative impact, although improvements could be made to create a more positive user experience or to enhance attractiveness. Scores outside the neutral zone should be interpreted as either positive (from 1 to 3) or negative (from −1 to −3).

XSL•FO
RenderX

Perceived Relevance and Endorsement

To assess participants' perceptions of the app's impact on user awareness, knowledge, attitudes, intention to change, and likelihood of actual change in advance care planning behavior, the 6 "perceived impact" items (section F) of the validated Mobile Application Rating Scale (MARS) were used [25]. These items yield an overall mean score on a 5-point Likert scale, interpreted as follows: 1=inadequate, 2=poor, 3=acceptable, 4=good, and 5=excellent. To evaluate endorsement, the first 5-point Likert item of the "subjective quality" section (section E) of the MARS was used. This item asks participants whether they would recommend the digital game to others who could benefit from it. This questionnaire was translated into French in accordance with the best practices described by Wild et al [26].

Participants' Qualitative Feedback

At the end of the study, participants were asked 5 open-ended questions to gather their final feedback on the game. These questions aimed to assess (1) what participants appreciated about the game, (2) what aspects they disliked, (3) which tasks they found particularly challenging, (4) what they felt was missing in the game, and (5) whether they had any additional comments to share. To analyze the responses, the guidelines set by Paillé and Mucchielli [27] for qualitative data analysis were followed. Specifically, Excel was used for organizing and working with the material, with integrated in-text notes that were differentiated by color to facilitate categorization. A continuous thematic analysis approach was applied to systematically identify emerging themes and patterns throughout the feedback.

Content Readability

To assess the readability of the game's textual content, all text was compiled into a Microsoft Word document and evaluated using the Scolarius test [28], which was developed by Influence Communication, a Canadian media analysis organization. The readability score is calculated similarly to the Flesch Reading Ease score (commonly used for English-language materials). The test measures word and paragraph length to provide a score ranging from 50 to 250, interpreted as follows: a score between 50 and 89 corresponds to an elementary school reading level, 90 to 119 indicates a high school reading level, 120 to 149 reflects a college reading level, and 150 to >189 represents a university reading level.

Results

Recruitment

The procedure was pilot-tested with 2 participants to master the technical aspects of conducting the test online with multiple devices and to refine the multiple task instructions. These data are not included in the results. During September and October 2024, we recruited 12 participants for the online usability test. However, data from 2 participants could not be analyzed due to major technical issues: a failure of the screen-sharing functionality on Zoom in 1 case and bad quality recording in the other. The final dataset includes complete responses from 10 participants.

The mean age of the participants included in the final dataset was 41 (range 25-65) years, and the sample was diverse in terms of gender (men: 5/10, 50%; women: 5/10, 50%) and type of smartphone (operating system) used (Table 2). All participants reported using their smartphones daily, demonstrating familiarity with digital interfaces and technological tools, and they had a rather high level of education. Overall, the sample was skewed toward younger adults, with only 1 (10%) of the 10 participants being aged >60 years. All participants reported at least moderate digital literacy.

Table 2. Participants' characteristics.

Participant	Gender	Age (y)	Education	Smartphone operating system
P1	Woman	54	Professional higher education	iOS
P2	Woman	25	University	iOS
P3	Woman	35	Professional higher education	iOS
P4	Man	53	High school	iOS
P5[a]	Woman	36	High school	iOS
P6	Man	34	High school	Android
P7[a]	Man	59	University	iOS
P8	Man	35	University	Android
P9	Woman	32	University	iOS
P10	Man	27	University	iOS
P11	Man	65	University	iOS
P12	Woman	49	University	iOS

[a]Data from these participants could not be used because of technical issues.

XSL•FO
RenderX

First Impressions

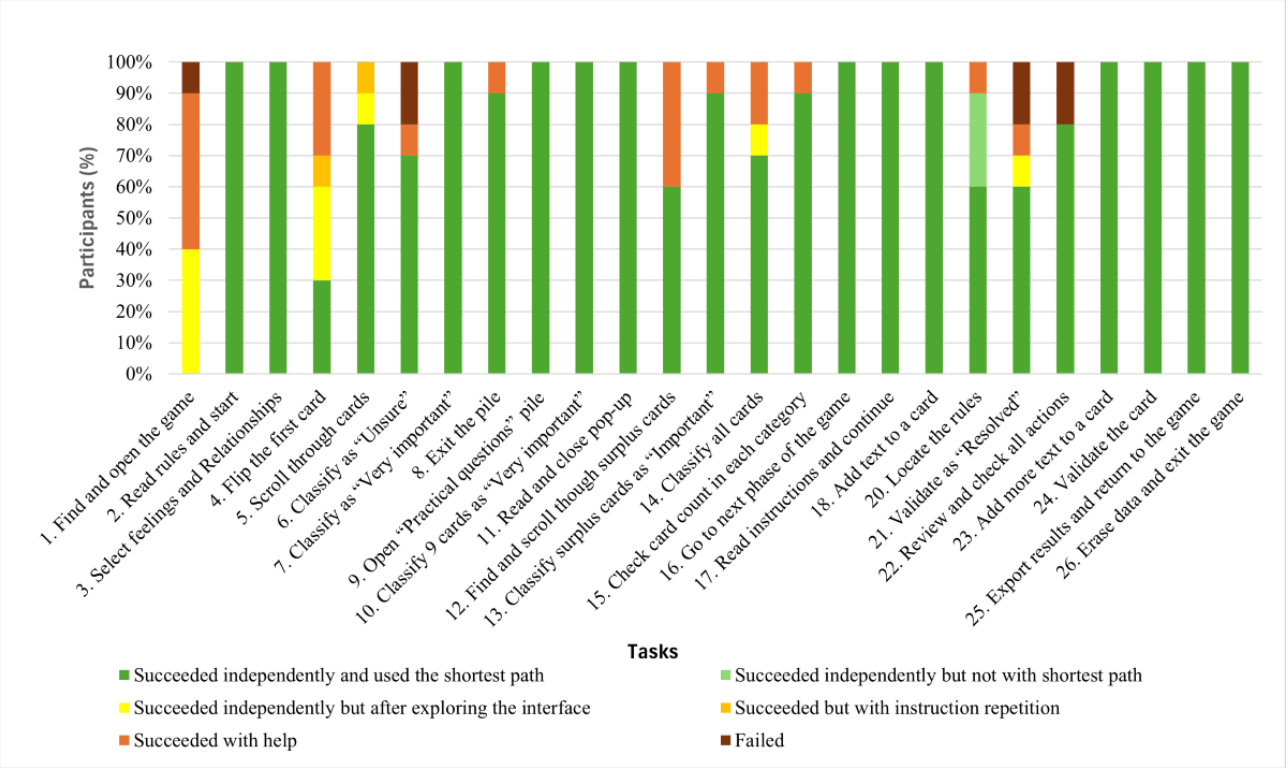
In the visual recall task, 80% (8/10) of the participants noticed the presence of colored cards. Of these 8 participants, 3 (38%) observed that the cards had titles, and 2 (25%) noted the numbers displayed in the center of each card. The second most frequently recalled element (5/10, 50%) was the instruction bubble positioned in the center of the screen. Finally, the 3 circular button icons representing the game's 3 phases were remembered by 5 (50%) of the 10 participants; within this group, 3 (60%) also noticed the grayed-out card images, and another 3 (60%) noticed the text beneath the icons. Some elements remained unnoticed, including the gray background of the game; the title of the game phase at the top of the screen; the 2 square buttons on the top left (question mark icon) and top right (X icon) to access the rules or exit the game, respectively; the classification symbols (heart icons and question mark); and the numbers below these symbols. Some participants had false memories. Of the 10 participants, 1 (10%) remembered the presence of a question, possibly confusing it with the instruction bubble in the center of the screen; 1 (10%) reported 4 button icons at the top of the screen (instead of 3); and 1 (10%) mentioned "choices with several options," possibly referring to the instructions and heart icons. In addition, there was evidence of imprecise recall and potential misinterpretation of certain elements; for example, of the 10 participants, 1 (10%) described a white background for the game, 1 (10%) reported that the colored cards were placed in the center of the screen (instead of at the bottom), and 1 (10%) misremembered the position of the text as being below the cards rather than above them.

Regarding participants' understanding of the game's objectives, half (5/10, 50%) were unable to provide an answer, while the other half (5/10, 50%) identified it as a card game. Of those who recognized it as a card game, 60% (3/5) suggested that the objective might involve making choices. Each of these 5 participants provided at least 1 interpretation of the game: asking questions about various hospital-related topics, completing a multiple-choice quiz, associating each card pile with a specific value, obtaining information with the option to change one's mind, sorting cards by theme, and clicking on heart icons to indicate preferences (this participant seemed to recall the presence of the heart icons although this was not explicitly expressed during the visual recall task).

Participants' general impression of the game was mixed: of the 10 participants, 4 (40%) rated it as good, 3 (30%) as average, 2 (20%) as bad, and 1 (10%) as very bad.

Their evaluation of the game's aesthetics was also mixed: of the 10 participants, 1 (10%) found it very attractive, 2 (20%) rated it as attractive, 5 (50%) as neither attractive nor unsightly, 1 (10%) as unsightly, and 1 (10%) as very unsightly.

Think-Aloud Procedure



Task Success

At the analysis stage, task 19 (which overlapped partially with task 21) was excluded from the results because it seemed that most participants failed to understand the instruction due to suboptimal wording. The instruction began with "Validate the card" before unclearly alluding to the constraint that a card can only be validated once a decision has been made about whether one should do something about the card topic. Consequently, participants attempted to validate the card prematurely, before ticking the appropriate box. Unfortunately, this methodological flaw was not identified during the pilot testing phase.

As illustrated in Figure 7 and Table S1 in Multimedia Appendix 1, most of the tasks (21/25, 84%) were completed successfully by all participants, while some (4/25, 16%) required assistance. In 83.2% (208/250) of the cases, participants successfully completed tasks without assistance and found the shortest path. In 1.2% (3/250) of the cases, participants succeeded independently but did not follow the most direct route. In 4% (10/250) of the cases, participants explored the interface before finding the correct solution. Meanwhile, 8.8% (22/250) of the cases required intervention from the experimenter. Finally, 2.8% (7/250) of the cases resulted in failure, as participants were unable to complete the tasks even with assistance.

XSL•FO
RenderX

Figure 7. Proportion of participants who succeeded or failed in completing study tasks during the think-aloud procedure, with or without input from the experimenter, the type of input received, and whether the shortest path was used.

Some tasks required only minimal assistance (eg, tasks 4 and 14), while other tasks presented notable usability issues (Table 3). In particular, for completing task 1—finding the game in the Concerto app—6 (60%) of the 10 participants required assistance, such as instruction repetition, hints, additional information, or the correct answer. For task 4, which involved flipping a card, 6 (60%) of the 10 participants experienced difficulties locating the dedicated button (Figure 3). For task 6—classifying a card in the "Unsure" category—3 (30%) of the 10 participants needed substantial intervention (such as additional information, guiding questions, or answers to questions) to understand that the square "Unsure" button was clickable (the other clickable categories were represented by round buttons; Figure 3). For task 12, which involved finding the surplus cards classified as "Very important," 6 (60%) of the 10 participants faced difficulties, necessitating multiple forms of assistance, such as instruction repetition, additional information, hints, answers to questions, or guiding questions. The nature of these difficulties indicates that the wording of the task instruction was not optimal: specifically, the phrase "cartes en surplus" ("surplus cards") used in the instruction could be misleadingly interpreted as the existence of some "extra cards" in the game, although the aim was to convey the information that too many cards had been allocated to the "Very important" category, and some would need to be removed from the category before moving on to the next phase of the game. Task 21 was challenging for 3 (30%) of the 10 participants. It required understanding that in the "Specify" phase of the game, each card needed to be evaluated to determine whether it required further action before it could be marked as "resolved," after which the participant could proceed to the "Act" phase of the game (Figure 5). However, the task instruction was short and allusive, which could explain the participants' need for more guidance. In task 22, of the 10 participants, 1 (10%) failed to understand that the pile in the center needed to be "resolved," and 1 (10%) failed to click on the "Review my specifications" button to check the specifications related to the card (Figure 6). In both cases, the experimenter provided the answer.

XSL•FO
RenderX

Table 3. Description of the problems encountered by participants (n=10) during the think-aloud tasks.

Tasks and problems encountered by participants	Frequency, n (%)	Category (according to the heuristics of Bastien and Scapin [22])	Severity (0 to 4 scale based on the recommendations of Nielsen and Landauer [17])
1. Find and open the game.			
1.1. Could not find the game and clicked on the wrong tab	3 (30)	Guidance: grouping and distinction	4
1.2. Could not find the game: did not see the menu at the bottom	2 (20)	Guidance: grouping and distinction; consistency	4
1.3. Thought they were already in the game when they were on the wrong page in Accordons-nous	2 (20)	Guidance: prompting; workload: information density	3
1.4. Complained about too much text	1 (10)	Workload: information density	1
1.5. Did not see the “play” button, which allows entry into the game	1 (10)	Guidance: legibility	3
1.6. Misunderstood the “Anticip’action” tab as a way to enter the game, although it is actually a tab to navigate within sections in the Accordons-nous module	2 (20)	Guidance: grouping and distinction	3
2. Read rules and start.			
2.1. Felt overwhelmed by the text	2 (20)	Workload: information density	1
4. Flip the first card.			
4.1. Did not see the button to flip the card	4 (40)	Guidance: grouping and distinction; compatibility	3
4.2. Interpreted the return icon as a door to return to the menu	1 (10)	Consistency	1
4.3. Interpreted the card title as a clickable button	1 (10)	Consistency	0
6. Classify as “Unsure.”			
6.1. Used drag and drop to classify a card (which is not a function in the game)	2 (20)	Consistency and compatibility	1
6.2. Clicked on the wrong button	2 (20)	Consistency and significance of codes	2
8. Exit the pile.			
8.1. Did not see the X icon (located on the top right of the screen) to exit the pile	1 (10)	Guidance: prompting	0
12. Find and scroll through surplus cards.			
12.1. Tried to find the extra cards by clicking on the heart icons on the main page (which is not a function in the game)	3 (30)	Guidance: prompting and grouping and distinction; significance of codes	3
12.2. Could not find the extra cards after exploring the screen	6 (60)	Guidance: grouping and distinction; consistency	3
13. Classify surplus cards as “Important.”			
13.1. Did not see the confirmation button after completing the task	1 (10)	Workload: minimal actions; adaptability: flexibility	2
18. Add text to a card.			
18.1. Did not understand that to validate the written text, one needs to click on the X icon	1 (10)	Guidance: prompting; compatibility	2
18.2. Clicked in the text area when only the written area was active	1 (10)	Compatibility	1
20. Locate the rules.			

XSL•FO
RenderX

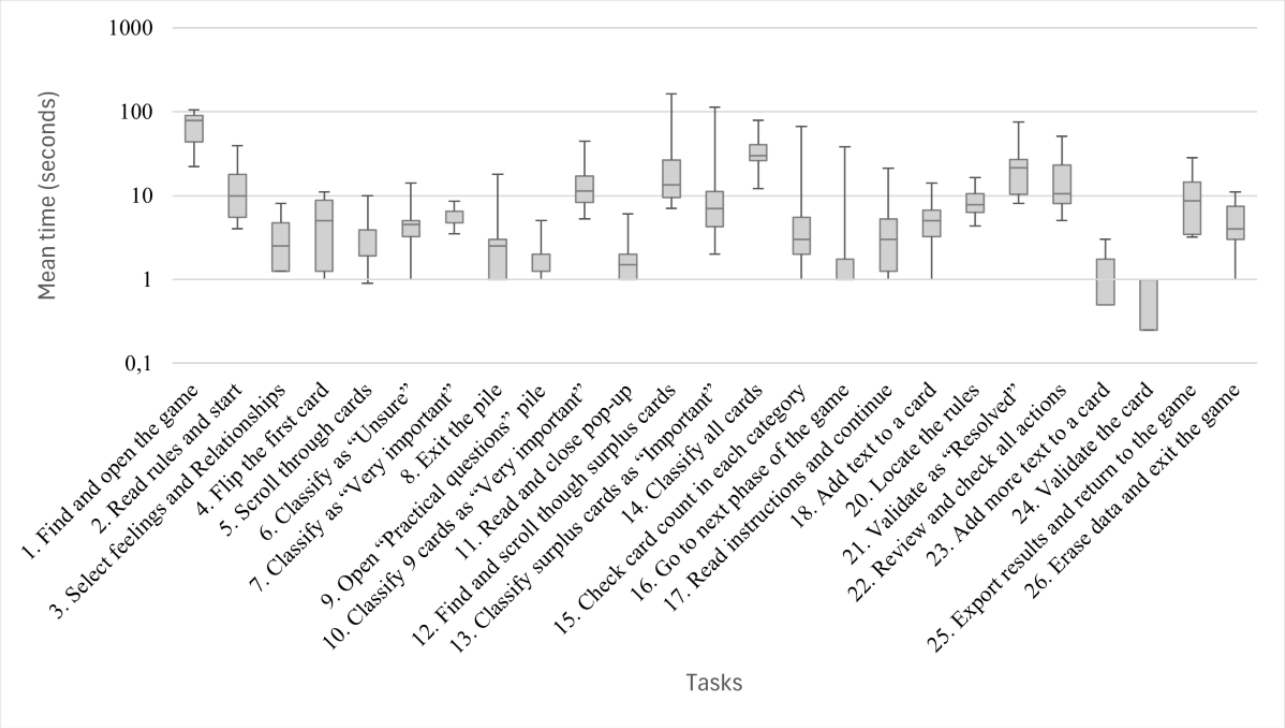
Tasks and problems encountered by participants	Frequency, n (%)	Category (according to the heuristics of Bastien and Scapin [22])	Severity (0 to 4 scale based on the recommendations of Nielsen and Landauer [17])
20.1. Did not see the button to find the rules	3 (30)	Guidance: legibility	1
20.2. Did not want to exit the game for fear of losing data	1 (10)	Error management: error protection; workload: information density	2
21. Validate as "Resolved."			
21.1. Did not click on the card pile in phase 2 to continue the game	1 (10)	Guidance: grouping and distinction; workload: information density	0
22. Review and check all actions.			
22.1. Clicked on the specified cards button instead of the blue pile at the bottom	1 (10)	Guidance: prompting; significance of codes	1
22.2. Did not see the button to review the details	2 (20)	Guidance: immediate feedback and legibility; significance of codes	3

Clicks to Complete Tasks

As shown in Table 4, a comparison between participants' actual number of clicks and the expected optimal number reveals varying levels of efficiency across tasks. For most of the tasks, participants generally stayed close to the expected optimal number of clicks, indicating a solid understanding of the interface and task requirements. However, several tasks stand out with higher click counts, suggesting areas where participants may have encountered challenges or required additional exploration before completing the task. In particular, task 1, which involved finding the game in the Concerto app, was completed with a mean of 10.30 (SD 4.47) clicks compared to the expected 3.

XSL•FO
RenderX

Table 4. Participants' overall click performance per task: mean number of clicks used, expected optimal number of clicks, and deviation from the optimal number.



Tasks	Number of clicks, mean (SD)	Optimal number of clicks, n	Difference
1. Find and open the game.	10.30 (4.47)	3.00	7.30
2. Read rules and start.	4.00 (0.00)	4.00	0.00
3. Select "Feelings and relationships."	1.00 (0.00)	1.00	0.00
4. Flip the first card.	2.50 (1.43)	1.00	1.50
5. Scroll through cards.	3.00 (1.70)	2.00	1.00
6. Classify as "Unsure."	2.40 (2.84)	1.00	1.40
7. Classify as "Very important."	3.20 (0.42)	3.00	0.20
8. Exit the pile.	1.20 (0.63)	1.00	0.20
9. Open "Practical questions" pile.	1.00 (0.00)	1.00	0.00
10. Classify 9 cards as "Very important."	8.10 (0.32)	8.00	0.10
11. Read and close pop-up.	1.00 (0.00)	1.00	0.00
12. Find and scroll through surplus cards.	5.20 (2.30)	4.00	1.20
13. Classify surplus cards as "Important."	3.40 (0.97)	3.00	0.40
14. Classify all cards.	25.40 (0.97)	25.00	0.40
15. Check card count in each category.	0.00 (0.00)	0.00	0.00
16. Go to next phase of the game.	1.00 (0.00)	1.00	0.00
17. Read instructions and continue.	1.00 (0.00)	1.00	0.00
18. Add text to a card.	2.70 (0.95)	2.00	0.70
20. Locate the rules.	2.40 (0.52)	2.00	0.40
21. Validate as "Resolved."	20.30 (2.26)	19.00	1.30
22. Review and check all actions.	6.30 (3.13)	5.00	1.30
23. Add more text to a card.	2.40 (0.70)	2.00	0.40
24. Validate the card.	1.00 (0.00)	1.00	0.00
25. Export results and return to the game.	3.00 (0.00)	3.00	0.00
26. Erase data and exit the game.	2.00 (0.00)	2.00	0.00

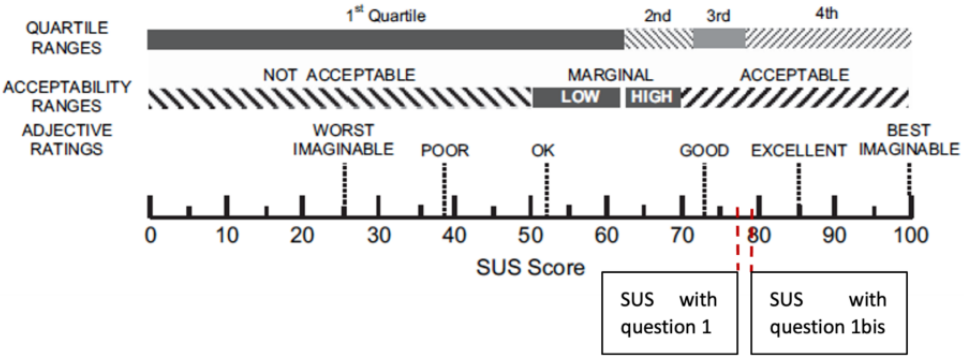
Time Spent on Tasks

As illustrated in Figure 8, the analysis of time allocation per task reveals substantial variability among participants. Nevertheless, some patterns and deviations from precalculated optimal times provide insight into specific usability challenges. Notably, task 1 ("Find and open the game") required considerably more time than anticipated, indicating that participants faced initial difficulties with the game's discoverability. Participants 6 and 8 displayed markedly extended times for task 1, suggesting that the entry point for locating the game lacked intuitive visibility or clarity. Divergence from the optimal could also be observed in tasks 10, 14, and 21, which required participants to categorize or "resolve" numerous cards. By design, these tasks were lengthy rather than difficult to navigate: while some participants elected to read each card before sorting it, others proceeded with the task more quickly without detailed review, leading to substantial individual variations in completion time. A similar pattern could be observed with task 2, which asked participants to read the rules of the game and start: some participants took much more time to read the rules than others. The time taken to complete tasks 12 and 21 (discussed previously) also diverged notably from optimal times, partly due to issues stemming from unclear instructions and partly due to suboptimal guidance in the game.

XSL•FO
RenderX

Figure 8. Mean time (in seconds) spent by participants to complete each of the 25 tasks during the think-aloud procedure, displayed on a logarithmic scale.

Analysis of Errors and Problems Encountered



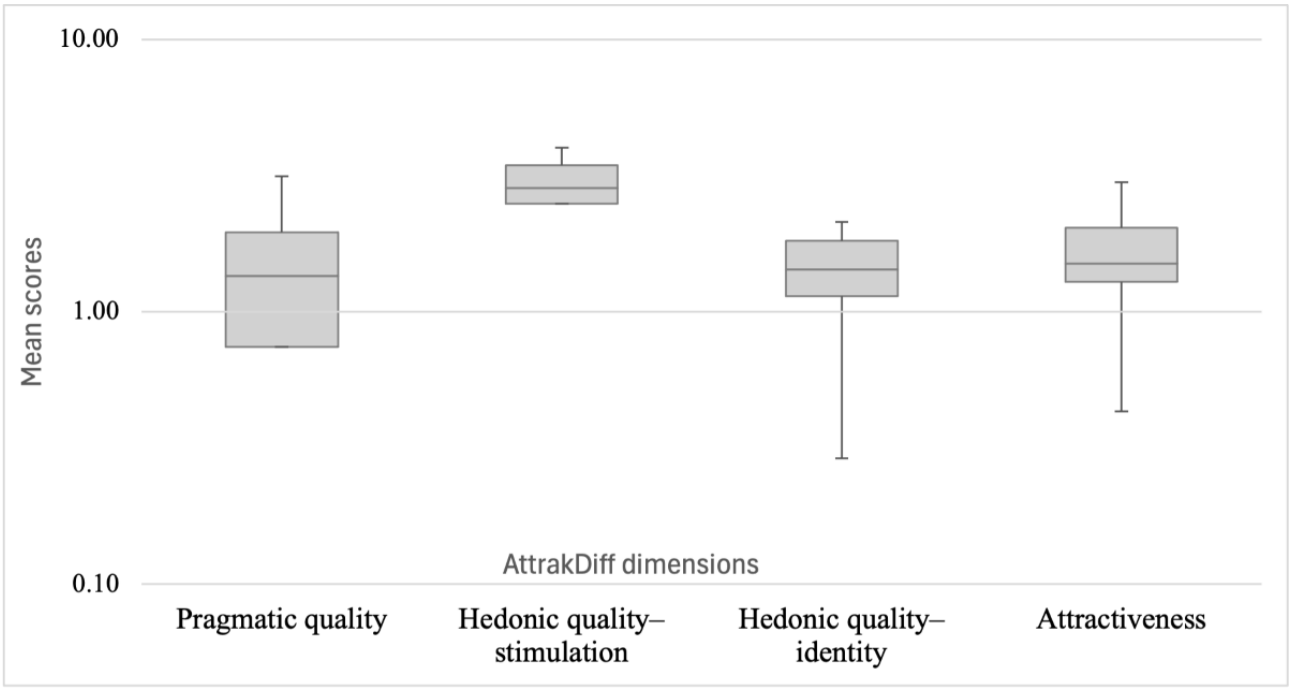
Following the criteria formulated by Bastien and Scapin [22], we recorded 23 problems encountered by the participants while completing the 26 tasks (Table 3). Of these 23 problems, 2 (9%) were classified as usability catastrophes, 7 (30%) as major usability problems, 5 (22%) as minor usability problems, 6 (26%) as cosmetic issues, and 3 (13%) as not constituting a usability problem. A majority of the problems (14/23, 61%) were related to guidance difficulties, such as the visibility of visual items or the way they were displayed in relation to one another.

Questionnaires

Perceived Usability

As illustrated in Figure 9, the mean score on the standard SUS was 77.75 (SD 5.1) out of 100. The adapted version of the SUS, which included a more fitting variant of the first question, yielded a slightly higher mean score of 79.25 (SD 5.6) out of 100. These results indicate that participants rated the game's usability between good and excellent.

Figure 9. Scores of Anticip'action on the standard and adapted versions of the System Usability Scale (SUS).



Perceived Attractiveness

The game obtained an overall attractiveness score of 1.57, indicating a positive assessment. As illustrated in Figure 10, positive results were obtained on all 4 dimensions of the test, with scores ranging from 1.16 to 1.57.

XSL•FO
RenderX

Figure 10. Mean scores of Anticip'action on the 4 dimensions of the AttrakDiff questionnaire, displayed on a logarithmic scale.

Perceived Relevance and Endorsement

The mean score on the MARS questionnaire was 4.1 (SD 2.1), indicating that participants evaluated the relevance of the game as good. As illustrated in Table 5, participants were mostly convinced that the game can increase awareness, knowledge, and intention to change regarding the topic of anticipating difficult situations that may arise in the future.

The game also ranked positively on the "I would recommend" question, with a mean score of 3.3 (SD 1.1). Of the 10 participants, 2 (20%) indicated that they would highly recommend the game to everyone who could benefit from it, 1 (10%) would recommend it to many people, 5 (50%) to several people, and 2 (20%) to very few people. No participant stated that they would not recommend the game.

Table 5. Average responses of the 10 participants to the Mobile Application Rating Scale (MARS) questionnaire, section F. All questions ended with "[...] the anticipation of difficult situations that may arise in the future."

	Scores, mean (SD)
Awareness: this game is likely to increase awareness of the importance of...	4.5 (2.4)
Knowledge: this game is likely to increase understanding of...	4.2 (1.9)
Attitude: this game is likely to change attitudes toward improving...	3.8 (1.9)
Intention to change: this game is likely to increase motivation to address...	4.1 (1.4)
Help seeking: use of this game is likely to encourage further help seeking...	4.0 (2.6)
Behavior change: use of this game is likely to increase...	4.0 (2.7)

Participants' Qualitative Feedback

Participants generally provided positive feedback about the game. Most found it user-friendly, with clear visuals and easy navigation. Of the 10 participants, 7 (70%) highlighted that the game addressed the sensitive topic of advanced care directives and end-of-life care in an approachable and meaningful way, while 6 (60%) stated that the game encouraged reflection on complex health-related issues and promoted awareness of often-overlooked topics.

Areas for improvement were also suggested. Several participants reported feeling overwhelmed by the amount of information and recommended adjustments to reduce cognitive load. They suggested adding an onboarding tutorial to help users understand the game's mechanics. Some participants proposed that offering personalized content options (eg, an option to filter cards based on user profile) may help to better tailor the game to individual users' needs. Navigation issues were also mentioned: participants indicated that the "Unsure" and the "flip card" buttons were not visually intuitive as clickable elements, and navigation could be improved through clearer visual cues such as more prominent buttons. Moreover, some participants recommended incorporating dynamic features such as animations, which could increase accessibility and maintain user engagement. Finally, several participants noted that the term "jeu" ("game") does not fit with the seriousness of the content and suggested some rephrasing or providing a content advisory to prepare users for the sensitive nature of the topics discussed.

XSL•FO
RenderX

Content Readability

The readability analysis of the game cards, assessed using the Scolarius program, yielded distinct scores for the rectos (card titles) and versos (explanatory text). The rectos had an average score of 50.5, indicating content accessible to individuals with an elementary school education. By contrast, the versos scored 119.8, which corresponds to a high school reading level. Specifically, in terms of readability, 61% (20/33) of the verso cards were at the elementary school level, 18% (6/33) at the high school level, and 21% (7/33) at the university level.

Modifications to Be Made Based on the Results

Analysis of the 23 usability issues and the proposed solutions (Table 6) showed that most problems were related to users' difficulty in identifying which visual elements were actionable. Some buttons were not consistently interpreted as clickable, while certain titles were occasionally mistaken for buttons. No substantial structural modifications seem to be required to address these usability issues, with the exception of the location of the game: it is currently nested within a section of a module (Accordons-nous) inside an app (Concerto), making it difficult for users to access Anticip'action.

Table 6. Changes to be made to the game in response to the identified usability issues.

Items	Problems encountered by participants	Changes to be made
1.1, 1.2, and 1.3	Could not find the game nested in the Accordons-nous module	Create a video explaining where the game is located
1.4	Complained about too much text	No changes to be made
1.5 and 1.6	Did not see the "play" button, which allows entry into the game	Highlight the button by bolding the text
2.1	Felt overwhelmed by the text	No changes to be made
4.1	Did not see the button to flip the card	Move the button to the corner or bottom of the card
4.2	Interpreted the return icon as a door to return to the menu	No changes to be made
4.3	Interpreted the card title as a clickable button	Redesign the title by, for example, removing the border
6.1	Used drag and drop to classify a card (which is not a function in the game)	No changes to be made
6.2	Clicked on the wrong button	Align the 4 buttons on the same level, enlarge the question mark, ensure that it uses the same visual weight and style as the heart buttons (eg, same height, rounded shape, and icon structure). Alternatively, add a heart icon with a question mark in the center and place the phrase "I am unsure" below it.
8.1	Did not see the X icon (located on the top right of the screen) to exit the pile	No changes to be made
12.1 and 12.2	Could not find the extra cards	Gray out the hearts or make them clickable to access the menu
13.1	Did not see the confirmation button after completing the task	Change the button design, round the edges, and ensure consistency
18.1	Did not understand that to validate the written text, one needs to click on the X icon	Add a button to validate the text
18.2	Clicked in the text area when only the written area was active	No changes to be made
20.1	Did not see the button to find the rules	No changes to be made
20.2	Did not want to exit the game for fear of losing data	Specify more clearly that exiting the game will not result in data loss
21.1	Did not click on the card pile in phase 2 to continue the game	No changes to be made
22.1	Clicked on the specified cards button instead of the blue pile at the bottom	No changes to be made
22.2	Did not see the button to review the details	Redesign the button, which resembles the card titles too closely, to make it more visible

XSL•FO
RenderX

Discussion

Principal Findings

This study evaluated the usability, readability, and user experience of the digital version of the game Anticip'action, designed to facilitate end-of-life discussions and advance care planning decisions. The findings indicate overall satisfactory results.

After 5 seconds of visual exposure to the main screen of the game, participants were able to recall key visual elements, such as the colored cards and accompanying text. However, they struggled to notice other important interface components, including classification symbols and navigation buttons. Some misinterpretations of visual elements were observed, which was confirmed by participants' fragmented and diverse understanding of the game's objectives. Moreover, the aesthetics of the game left participants mostly indifferent. These results indicate that there is room for improvement in the visual appearance of the game to better engage users. However, these findings should be interpreted in light of the fact that in a real-world scenario, before reaching the main game screen used for the 5-second test, users would always receive preliminary information about the game's content, purpose, and rules. Specifically, the welcome page included a pictogram with cards and introductory text explaining the game's purpose (Figure 1). Moreover, a pop-up explained the card sorting task and classification symbols at the start of a new game.

The think-aloud procedure yielded a high overall success rate. In 83.2% (208/250) of the cases, participants completed the tasks without assistance. Participants' performance also closely matched the expected number of clicks, indicating that the game offered clear navigation paths. However, for some tasks (4/25, 16%), participants required assistance, revealing serious usability problems. Analysis of the 23 failures and difficulties encountered revealed that 3 (13%) issues were partly due to a suboptimal wording of task instructions (tasks 12 and 21), that 14 (61%) problems were related to guidance, and that there were 9 (39%) major usability issues that needed to be addressed (Table 3). Specifically, the following tasks highlighted important difficulties related to navigation and discoverability: task 1, which involved finding the game within the Concerto app; and task 12, which involved finding and reclassifying the surplus cards classified in the "Very important" category. About half of the participants needed guidance and took longer than the expected optimal time to complete these tasks (Figure 7; Table 7). These issues need to be addressed with clearer instructions and improved visual guidance. Moreover, the test revealed occasional design inconsistencies (eg, some buttons were not visible enough in tasks 1, 4, and 13), excessive cognitive load (eg, some pages had numerous elements and text), and inadequate error prevention (eg, once players opened a pile of cards, they expected to navigate by scrolling, whereas "resolving" cards required clicking on a button; task 21). All identified usability issues could be addressed through minor modifications, as highlighted in Table 6.

Table 7. Summary of relevant usability problems encountered during the think-aloud test.

Tasks	Difference between the average time spent by participants per task and the expected optimal time (seconds)	Problems (n=23), n (%)	Participants affected (n=10), n (%)
1. Find and open the game.	29	6 (26)	7 (70)
2. Read rules and start.	7	1 (4)	2 (20)
4. Flip the first card.	2	3 (13)	5 (50)
6. Classify as "Unsure."	2	2 (7)	3 (30)
8. Exit the pile.	3	1 (4)	1 (10)
12. Find and scroll through surplus cards.	16	2 (7)	5 (50)
13. Classify surplus cards as "Important."	16	1 (4)	1 (10)
18. Add text to a card.	4	2 (7)	2 (20)
20. Locate the rules.	4	2 (7)	4 (40)
21. Validate as "Resolved."	8	1 (4)	1 (10)
22. Review and check all actions.	5	2 (7)	3 (30)

At the end of the test, Anticip'action was rated between good and excellent on the SUS. It obtained a mean score of 77.75 out of 100 on the standard SUS and a mean score of 79.25 out of 100 on the adapted version. The increase in score resulting from the adaptation of the first question highlights the importance of context-specific adjustments to usability assessment tools.

The game also received an overall positive assessment of its attractiveness, although there remains room for improvement. The global score of 1.57 on the AttrakDiff questionnaire reflects a generally positive perception. Scores on the pragmatic and hedonic scales ranged from 1.16 to 1.57, all above zero, indicating a baseline level of user satisfaction. Hedonic quality received the lowest score, suggesting that improvements are needed to better engage users and sustain their interest. Enhancements to the design and animated and visually attractive content, such as the inclusion of more visually dynamic elements in the game, could increase its attractiveness while addressing some navigation or cognitive load issues. Reducing the number

XSL•FO
RenderX

of actions required in certain steps, notably for re-sorting the cards or "resolving" them in the "Specify" phase of the game, could help maintain user engagement. At a minimum, greater clarity and streamlining of these task processes would improve user experience.

Although this test included a small number of participants and no quantitative conclusions should be drawn, we noticed that older participants and those recruited via the patients-as-partners program at the hospital rated the game more positively. This may be due to a higher baseline receptivity to the topic of advance care planning discussions.

Anticip'action was also evaluated as relevant, with an overall score of 4.1 out of 5 on the MARS. Specifically, the game was judged as particularly impactful in raising awareness, improving knowledge, and motivating behavior change regarding advance care planning. Participants also endorsed the game with a mean score of 3.3 out of 5 on the "I would recommend" question. Given the specificity and sensitivity of the topic, this result is promising.

The readability analysis showed that the card titles are understandable for individuals with an elementary school education, which is an excellent result. However, the longer explanations on the versos of the cards require a high school reading level, indicating room for improvement. Part of the difficulty may be due to the use of gender-neutral language (which has the effect of increasing the lengths of sentences in French) as well as to the use of unavoidable technical terms such as *surrogate decision maker*, *digital legacy*, or *lasting power of attorney*. Efforts are underway to streamline and simplify the card content while preserving its informational value.

Participants provided overall positive qualitative feedback while pointing out aspects that could be improved. Most described the game as user-friendly, with clear visuals and easy navigation. They highlighted its relevance in fostering engagement and encouraging reflection on complex topics such as advance care directives.

However, some participants identified areas that needed improvement. Their concerns included the cognitive overload and some unclarity in the navigation process related to specific tasks. Regarding cognitive overload, some parts of the game contained dense textual information. Although the game achieved good usability scores overall, this suggests that some refinement may be necessary to improve accessibility, for instance, through progressive disclosure, pictorial supports, or guided onboarding elements. Some participants emphasized the need for an onboarding tutorial to improve accessibility as well as more animations, intuitive interactive elements, clearer buttons, and personalized content pathways to improve visual clarity and user engagement. Some participants also disagreed with the label "game" for such a conversation tool and expressed the need for providing a content advisory to prepare users for the sensitive nature of the topics discussed. This highlights a semantic tension between the playful connotation of the term "game" and the seriousness of the topic, which may require careful framing to ensure user acceptance.

To address the identified issues while taking participants' recommendations into account, several improvements are envisaged. Easily implementable solutions are detailed in Table 6. Furthermore, modifications may include the introduction of an onboarding tutorial to enhance initial navigation and reduce cognitive load. Options to personalize some features of the game (eg, relaxing the 10-card limit) or to filter subgroups of cards may also help further align the game with diverse user needs and preferences. In addition, enhancing the game's visual appeal by incorporating more dynamic features (eg, animated movement of cards between piles) could increase engagement and satisfaction, especially among younger users.

Limitations

Although this study reports positive usability results, it does not demonstrate that Anticip'action is an effective tool to promote end-of-life discussions. Moreover, the quantitative results from the SUS, AttrakDiff, and MARS questionnaires should be interpreted with caution, given the limited number of participants (n=10). Complementary studies with appropriate designs and more diverse populations are necessary to confirm the game's perceived value and effectiveness.

One important limitation of this study is the demographic profile of the participants. The sample included 10 individuals of different ages (ranging from 25 to 65 y), of whom 6 (60%) were in the younger-to–middle adult range (25-45 y). Prior research has shown that age can influence usability metrics, including task performance and perceived ease of use [29]. The limited sample size in this study does not allow for an evaluation of this effect. Moreover, the sample included a participant aged >60 years and none with low digital literacy or lower levels of education. As such, the findings may not be generalizable to these groups. Usability outcomes may differ significantly among older adults or individuals with low digital literacy, who may face greater barriers in navigating the tool. This possibility should be considered when interpreting our findings. Future work should explicitly include a more diverse participant pool, encompassing a wider range of health statuses and cultural backgrounds, to evaluate the accessibility and acceptability of the tool in broader populations.

Participants were asked to imagine being an individual aged 50 years reflecting on end-of-life preferences. This scenario was used to standardize the testing context, but it does not replace real-life engagement with the topic. Future studies should include participants who are directly involved in advance care planning processes.

The test was conducted online with the game displayed on participants' devices. Therefore, their facial expressions could not be observed and used as nonverbal cues to assess the gravity of usability issues.

Part of the participants' failure to complete some tasks (in particular, task 19, which was removed from the analysis, as well as tasks 12 and 21) may be due to suboptimal wording of the instructions.

Some participants took more time than others to read the text on the cards before completing the tasks. This difference in participants' behavioral style could have influenced the time

XSL•FO
RenderX

spent on tasks, although it is not an indication of failure to complete them. This was particularly obvious on task 14 ("Classify all cards") and may have also affected tasks 10 and 21. Therefore, time-based measures are difficult to interpret as usability factors in this study.

Conclusions

Anticip'action is a conversation tool aimed at initiating end-of-life and advance care planning discussions and increasing patients' empowerment during these discussions. It offers accessible content, simple navigation, and thoughtful discussion prompts to support individuals, families, and health care professionals in exploring these important and often challenging topics. It is also designed to motivate related action planning, such as writing advance directives.

This study evaluated the usability, readability, and user experience of the digital version of the game with participants of different ages (ranging from 25 to 65 y) who were already familiar with digital interfaces and technological tools. The results demonstrated that participants found the game generally user-friendly, with clear visuals and intuitive navigation. Qualitative feedback highlighted its relevance. Specific challenges were identified, including cognitive overload and some unclear navigation elements. Addressing these issues through improved design, clearer instructions, and better user guidance would further enhance user experience and engagement.

Overall, the usability findings validated Anticip'action as an accessible conversation game for patients who are minimally at ease with digital tools and the French language. While additional testing with health care professionals and broader user groups (including older patients and individuals less comfortable with digital solutions) would strengthen its evidence base, our findings indicate that Anticip'action could be a valuable resource for some patients, families, and caregivers navigating end-of-life decisions and advance care planning. It would be interesting to translate it into other languages, as is the case for the printed version of Anticip'action.

Acknowledgments

The authors would like to thank everyone who contributed to the development of the game, notably Catherine Bollondi, Marta Fadda, Samia Hurst, Pascale Lefuel, Sophie Pautex, Arnaud Ricci, Marianne Rubio, Céline Schöpfer, Inès Serre, Pierre Sutter, and Aida Yamani. The authors also wish to thank the 2 anonymous reviewers who helped improve the draft during the review process. The project received financial support from the Geneva University Hospital and the Fondation Privée des Hôpitaux Universitaires de Genève, a nonprofit organization that had no involvement in any stage of the study.

Data Availability

The datasets generated and analyzed during this study are available in the Open Science Foundation (OSF) repository [30].

Authors' Contributions

CC, DC, and FE conceptualized the study. AB and FE were responsible for software. All authors contributed to data curation. CC and FE were responsible for resources, supervision, validation, and project administration. DC conducted the formal analysis and was responsible for investigation. CC was responsible for acquiring funding. AB and DC were responsible for visualization. CC, DC, and FE were responsible for methodology. CC and DC wrote the original draft. All authors reviewed and edited the manuscript.

Conflicts of Interest

None declared.

Multimedia Appendix 1
Table showing task completion success rates and related details, along with the questionnaires and the discussion grid used for the final qualitative feedback, provided in both the original French and English translation.

Abstract

Background: Approximately 20% of the global population is affected by mild cognitive impairment (MCI), with around 15% progressing to dementia within 2 years. Touch-based multimedia applications can support cognitive, social, and physical functioning, potentially enhancing daily life and strengthening caregiver-patient relationships through shared engagement. Although interest in dyadic, technology-assisted interventions is increasing, empirical evidence on their feasibility and acceptability in home-based settings remains scarce. In particular, little is known about their impact on caregiver–care recipient dynamics and the factors that facilitate or hinder their use.

Objective: We aimed to evaluate the feasibility of a dyadic, tablet-based multimedia intervention for individuals with MCI and their caregivers in a home setting, focusing on user experiences, use barriers and facilitators, and the intervention's impact on the caregiver-patient relationship.

Methods: We applied qualitative triangulation, combining naturalistic observations and semistructured interviews. Data were analyzed using qualitative content analysis. The intervention was codeveloped by a multidisciplinary team and implemented as a user-centered, tablet-based modular platform with customizable cognitive, physical, and interactive exercises.

Results: We recruited a total of 40 participants, comprising 20 (50%) individuals with MCI and their 20 (50%) caregivers. Our study confirmed the feasibility of a touch-based multimedia intervention for both groups. Despite initial challenges with navigation and touch interfaces, most participants demonstrated increased confidence and competence, particularly with tailored caregiver support. Instances of enhanced communication and emotional connection were described by care partners and then became visible during their interaction with the intervention. Shared moments of laughter, mutual encouragement, and coordinated task execution indicated that the intervention could create opportunities for relational closeness. Biography-related tasks proved particularly effective, stimulating meaningful conversation and storytelling that facilitated the sharing of personal memories and experiences. While some dyads experienced occasional tensions due to impatience, differing expectations, or dominant behavior by one partner, the overall atmosphere was one of cooperation, support, and adaptability. The intervention demonstrated how technology can serve as a tool to facilitate shared experiences, promote cognitive engagement, and enrich interpersonal relationships in everyday caregiving contexts.

Conclusions: Our findings show that the home-based implementation of a dyadic, touch-based multimedia intervention can be feasible for individuals with MCI and their caregivers. A key finding is that biographically oriented content fosters caregiver-patient

XSL•FO
RenderX

relationships by acting as a catalyst for personal dialogues and collective reminiscence. These interactions enhance emotional intimacy and mutual understanding, highlighting the potential of technology-driven interventions in dementia care. The intervention incorporated multiple domains, including cognitive stimulation, physical activation, and communicative-social interaction, all of which proved highly promising. In addition, the regular implementation of the intervention in home settings appears to be a realistic and achievable approach.

Introduction

Epidemiology of Dementia and Mild Cognitive Impairment

Approximately 50 million people are living with dementia, and the prevalence of dementia is projected to increase to 152 million by 2050 [1]. Mild cognitive impairment (MCI) is characterized by a decline in cognitive function that is more pronounced than normal aging but not as severe as dementia, often manifesting as memory impairment [2]. Approximately 15% of individuals with MCI progress to dementia within 2 years [3]. While MCI does not typically lead to significant impairments in activities of daily living [2], individuals with dementia often experience substantial limitations in performing everyday tasks [4].

Tablet-Based Interventions and Dyadic Interaction

Given the potential progression to dementia and the increasing prevalence of MCI with advancing age, early interventions, such as cognitive training applications, are particularly important in an aging society [3]. Maintaining cognitive, social, and physical functioning is essential for preserving quality of life. Assistive technologies, including touch-based multimedia applications, have been shown to support daily activities, enhance quality of life, and reduce the financial burden of inpatient care [4]. Cognitive stimulation, such as through touch-based multimedia applications, may contribute to the management of MCI and mitigate the cognitive decline of affected individuals [5].

While tablet-based interventions for individuals with MCI may offer cognitive and physical benefits, research suggests that these interventions, particularly those incorporating reminiscence activities and fostering dyadic interactions between caregivers and individuals with MCI in both inpatient and home settings, can also enhance communication and social engagement [6]. Moreover, tablet-based interventions provide an engaging and enjoyable means of interaction for individuals with MCI, potentially strengthening social relationships [7].

Some interventions incorporate activity content such as photos, audio elements, and videos, which have been shown to facilitate memory activation and increase social engagement. However, research on the effects of technology-based interventions on caregiver-patient relationships and social interaction in individuals with cognitive impairments remains limited [6]. Nevertheless, existing evidence indicates a reciprocal relationship between the perceived burden of caregiving and the caregiver-patient relationship. While the ongoing cognitive decline of care recipients can heighten role strain for caregivers, dyadic relational resources, such as mutuality, have been shown to alleviate this burden [8].

To strengthen the dyadic relationship, it is essential to continuously adapt to changes in cognitive health and relational dynamics as the condition progresses [9]. This also applies to changes in communication and social interaction, which can be impaired in individuals with MCI and may affect their ability to participate socially and maintain relationships [10]. Given that cognitive decline in individuals with MCI can negatively impact their relationships with caregivers and potentially lead to interpersonal tensions [11], further research is needed to explore the positive effects of dyadic tablet-based interventions on individuals with MCI and their caregivers. In addition, involving both patients and caregivers in the design of digital applications is crucial for the early identification of design and usability challenges in technology intended for individuals with cognitive impairments [12].

Study Objectives and Research Questions

We designed this study based on the findings from an earlier investigation by Klein et al [13], in which a prototype of the intervention for cognitive and motor activation, as well as stimulation of social interaction, was tested with individuals with MCI. Insights from Klein et al [13] informed the further development of the touch-based multimedia tablet intervention, incorporating user feedback and refinements to enhance its usability and effectiveness.

Building on previous research, we introduced a dyadic approach involving individuals with MCI and their caregivers to examine how shared tablet-based interventions affect their interaction. By integrating elements of physical, social, and cognitive activation within the touch-based demonstrator, we sought to explore the feasibility of the intervention and the effects experienced by individuals with MCI and their caregivers with regard to their interaction and relationship.

In this study, we addressed the following research questions:

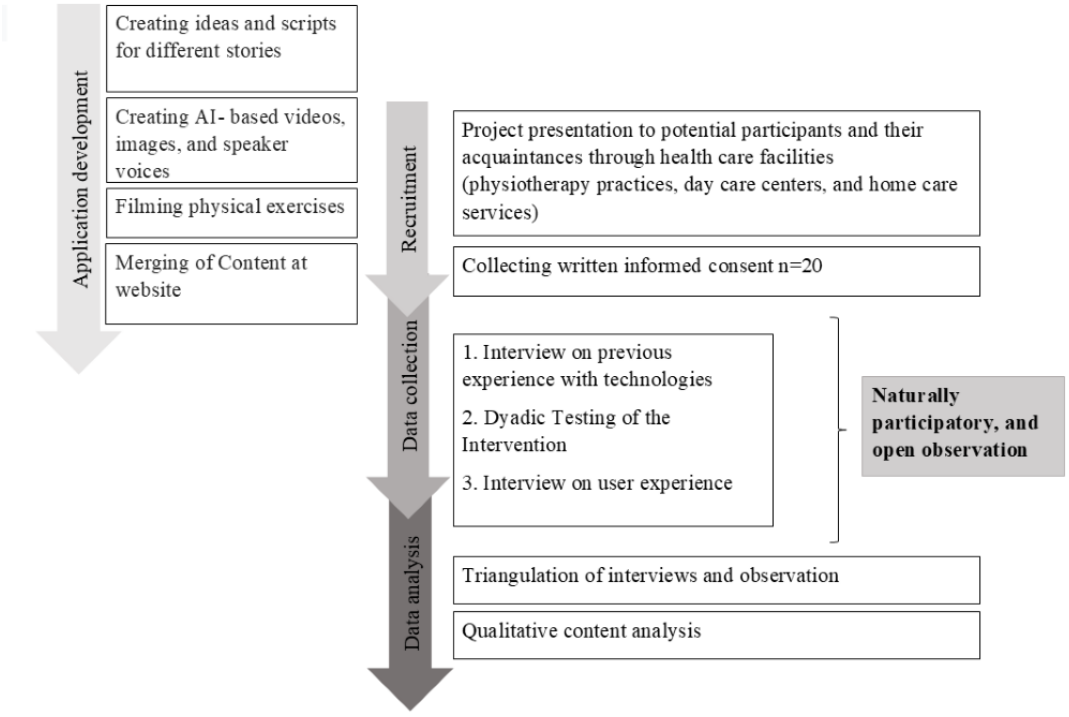
1. Caregiver-patient relationship—How does the use of the intervention influence the relationship between individuals with MCI and their caregivers from their perspectives? What relational dynamics become visible during its use, and how can the intervention be leveraged to foster positive interactions and strengthen the caregiver-patient bond?

XSL•FO
RenderX

2. Feasibility—To what extent is the implementation of a touch-based multimedia tablet intervention in a home environment practicable for individuals with MCI and their caregivers? What challenges and facilitators do they experience during its use?

Methods

Ethical Considerations



Following a thorough review process, this study received approval from the Ethics Committee of the University of Furtwangen (application number 24-052). It complies with the tenets of the Declaration of Helsinki. In accordance with institutional guidelines and ethical standards, all participants were assessed for their capacity to provide informed consent before enrollment. A letter containing pertinent information in an easily understandable form and a consent form were distributed to the participants in advance. Only individuals with MCI were included in the study; those with moderate or advanced dementia were excluded to ensure the ability of participants to provide informed and voluntary participation. The informed consent process was conducted with both the person with MCI and their caregiver present. This arrangement allowed for clarification of the study aims and procedures, and provided an additional opportunity to confirm the participant's comprehension and willingness to participate. Throughout the testing sessions, both members of the dyad were present, ensuring that the person with MCI was always accompanied by a familiar individual to promote comfort and emotional support during the intervention.

All participants were anonymized. No financial compensation was given to the participants.

Overview of This Study's Design

We used a qualitative triangulation approach, combining 20 naturalistic observations of participants and 20 interviews, with data from each method systematically aligned. The research was conducted in Germany and the reporting adheres to the Standards for Reporting Qualitative Research [14]. A summary of the application development and the study procedure is provided in Figure 1.

Figure 1. Application development and study procedure. AI: artificial intelligence.

Intervention Development Process

We drew upon the TiDIER (Template for Intervention Description and Replication) [15] checklist as a guiding framework to structure the description of the intervention (Table 1). This checklist provides a structured approach to outlining how interventions are designed, delivered, and evaluated, supporting transparency, reproducibility, and adaptability. Using these guidelines as a reference, we aimed to enhance the clarity and rigor of the intervention's description while allowing for flexibility in its adaptation to the specific research context. The intervention was collaboratively designed and developed by a multidisciplinary research team with expertise in health, computer science, and professional health care (including occupational therapists and physical therapists). This approach ensured that both technical and therapeutic aspects were thoroughly considered, resulting in a user-centered, holistic solution.

XSL•FO
RenderX

Table 1. Template for Intervention Description and Replication (TiDIER)–based description of the intervention.

Item	Description of item
Why (rationale)	• The intervention aimed to improve cognitive, physical, and social functioning in older adults with MCI[a] and their caregivers. This may include family members, friends, or professional care staff with whom these people with MCI interact on a regular basis.

What (materials and procedures)	• A tablet-based digital intervention was developed using a modular design for ease of use. The overarching design principle of simplicity in implementation was adopted to ensure accessibility and ease of use. To this end, a dedicated web platform was developed to support the design and delivery of the tablet intervention. This platform functioned as a modular toolkit, empowering researchers to assemble the stories by combining various media elements, including self-created recordings (images, sounds, and videos); royalty-free images; and sound files. In addition, AI[b]-generated avatars were facilitated through HeyGen and AI-generated speech through ElevenLabs. The interventions were administered through the website as well. The intervention involved the use of a tablet computer (Galaxy Tab A9+), which was provided by the study team. The tablet contained the demonstration tool. An introductory module was included to explain the website's operation and the nature of the tasks (cognitive, physical, and interactive), ensuring caregivers could effectively facilitate intervention. Participants then selected 1 of 4 stories to engage with. These stories included a city trip to Berlin, a visit to a farm, a trip to Spain, and a day in the forest. The explicit design of these stories aimed to address three core task areas:
	  • cognitive exercises with a focus on ADLs[c]—these exercises are designed to stimulate memory, attention, and problem-solving skills while maintaining a practical focus on ADL [5]. Examples include planning a travel day, shopping for groceries, and managing the process of paying (examples of the task types can be found in Multimedia Appendix 1).
	  • physical exercises related to ADL [6]—these exercises are carefully designed to promote movement and enhance functional independence. Examples include activities such as simulated stair climbing, exercises involving hand movement exercises, and relaxation exercises. These exercises are adapted to the participant's fitness level and performed either while seated or while standing.
	  • interaction exercises [7]—the objective of these exercises is to promote social engagement and the exchange of personal experiences, thereby fostering the relationship between people with MCI and their caregivers. These interactions are structured to incorporate biographical references, enabling participants to share meaningful memories and build connections during the intervention.
	• The selection of exercises and task areas was based on expert consensus [16] and interdisciplinary team input. The chosen story was played through once. Following the story, feedback questions with predefined answer options appeared on the screen, which the participants responded to.

Who provided (intervention delivery)	• The intervention was designed to be facilitated jointly by a person with MCI and their caregiver at home. The digital application guided them through the story-based sessions and interactive elements. Before implementation, participants received a structured introduction and training session to familiarize them with the application and its components, ensuring that they felt confident in using the intervention autonomously at home.
How (mode of delivery)	• The intervention was delivered through a tablet-based application, designed for independent, dyadic use at home. The tasks and stories were experienced via touchscreen interaction and audiovisual playback.
Where, when, and how much (setting and dose)	• The intervention was designed to be used in a home environment or any familiar setting of the participant's choice. Each session involved playing one story and engaging in associated tasks, with a total intervention duration of approximately 15 to 20 minutes. The intervention was applied in a single session, as this was a demonstration version. For future implementation, regular joint use on a weekly basis is recommended to support continuity, strengthen dyadic interaction, and enhance potential therapeutic effects over time.
Tailoring (customization)	• . Participants could choose between 4 stories and 2 levels of difficulty. Within each story, chapters could be skipped or selected freely to adjust the experience to individual preferences and needs. In addition, each story included movement exercises that could be performed at different levels of difficulty, either in a seated or standing position, to accommodate individual physical abilities and safety considerations.
Modifications	• No modifications were made during the delivery of the intervention.

[a]MCI: mild cognitive impairment.

[b]AI: artificial intelligence.

[c]ADL: activities of daily living.

Participant Selection and Recruitment Process

We conducted the intervention in German to ensure linguistic and cultural relevance, as the study took place in rural areas of southern Germany. Recruitment was conducted using a multipronged, community-based approach designed to ensure low-threshold access and preserve voluntariness throughout the process. We initially contacted local institutions (eg, day care

XSL•FO
RenderX

centers and physiotherapy practices) via email to introduce the study. After establishing contact, we visited selected facilities in person to present the project to staff and—in the case of day care programs—directly to older adults and their caregivers during regular group sessions. Recruitment in these settings always included an open invitation format, allowing participants to approach us voluntarily after the presentations for further questions or to express interest.

In addition, we actively recruited in dementia cafés and volunteer services. In the cafés, short presentations with a few Microsoft PowerPoint slides were integrated as program points into the regular schedule, usually in informal settings, such as coffee and cake gatherings. These events often attracted individuals with MCI and their family members together, creating a familiar and trusting atmosphere. We demonstrated small elements of the intervention to make it more tangible and understandable, encouraging attendees to decide freely whether they would like to participate. Flyers were distributed to supplement the verbal information.

Interested individuals could then approach us directly and schedule an individual appointment for testing the intervention. The timing and location of these sessions were arranged entirely based on the preferences and availability of both the person with MCI and the caregiver. This flexible and person-centered approach helped build trust and facilitated participation.

The study included participants aged 65 to 95 years with MCI, along with their caregivers. The term “caregiver” was defined as an individual who maintains a close and ongoing relationship with the person with MCI and provides assistance in daily activities, independent of their participation in the study. This could include spouses, family members, caregivers from day care facilities, friends, volunteers, or other relevant individuals who are regularly involved in the care and support of the person with MCI.

Individuals were excluded from participation if they (1) had severe cognitive impairment and were unable to provide informed consent; (2) were diagnosed with delirium, schizophrenia, or depression; (3) had a high risk of falling or significant mobility limitations; and (4) were living in residential care facilities.

Participants were recruited via local health care providers, home care services, and day care centers to ensure sample diversity. Dyadic appointments were arranged by personally contacting potential participants.

Data Collection

The data collection process was executed during the period spanning from September 2024 to November 2024. A total of 20 dyads participated in testing the tablet-based demonstrator and providing semistructured dyadic interviews [17].

The interviews were conducted either at participants’ homes or during their time in day care and in accordance with a pre-established, semistructured interview guideline (Multimedia Appendix 2), which provided a framework of deductive categories. The guideline was developed by the interdisciplinary research team and was informed by the overarching research questions, previous research on dyadic technology use in dementia care, and the team’s experience with related qualitative studies. It aimed to explore participants’ previous digital experiences; their handling of the intervention; perceived usability and usefulness of the different task types (cognitive, physical, and interactive); and any observed or experienced relational effects. This structure allowed for open-ended responses and follow-up questions based on participant input.

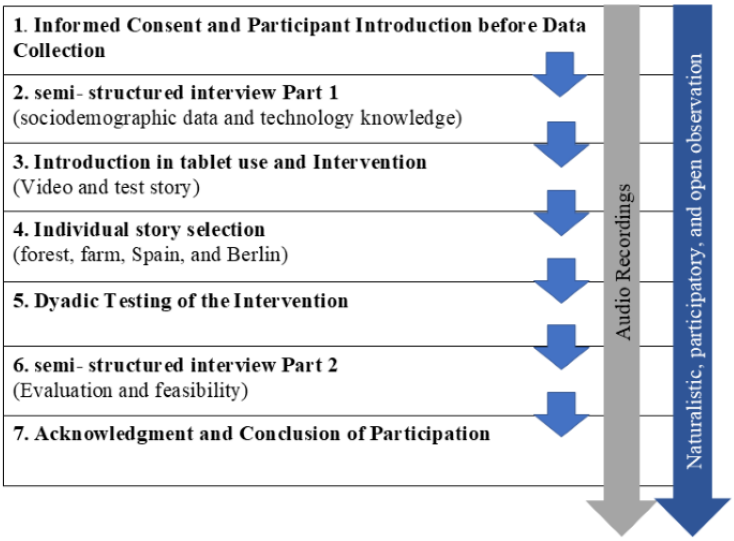
The first part of the interview focused on collecting demographic and personal data, including gender; age; ownership; use; and knowledge of devices such as tablets, PCs, and smartphones. After a brief introduction to the intervention, the caregiver and the respondent tested the tablet-based intervention together. As the last step, a second short interview took place to evaluate and discuss the feasibility of the tablet-based intervention. In addition, participants were asked about their perceptions of one another during the use of the intervention. The interviews were conducted in accordance with a pre-established interview guideline (Multimedia Appendix 2), which provided a structured framework of deductive categories. This process was recorded by audio recordings and naturalistic, participatory, and open observations, and took from 30 to 60 minutes for each dyad. Relevant interview topics were as follows: previous experience with digital technology, user skills, and personal characteristics of dyads; evaluation of tablet use; overall evaluation of the content; evaluation of different task types (physical, cognitive, and social); and shared use and influence on the relationship.

Furthermore, a naturalistic, participatory, and open observation was accomplished by 2 researchers, following an observation protocol that was created based on the deductive categories [18]. During the intervention sessions, one researcher assumed a dual role: one researcher facilitated the session by providing support to the dyads as needed (eg, with technical questions regarding the tablet application) and simultaneously took part in observing the interactions. The second researcher adopted a nonparticipant observer role, sitting slightly apart from the dyad and focusing exclusively on the documentation of field notes using a structured observation protocol.

The observation protocol was developed by the interdisciplinary study team based on previous experience in qualitative feasibility studies and informed by the relevant literature on dyadic interaction and intervention research in dementia and MCI contexts. The guiding questions served to focus the observations on key domains of interest, such as task feasibility, motivation, and dyadic communication, without applying standardized rating scales.

In the observation protocol, the place, time, and sequence of the observed processes were recorded. Also, it was distinguished between observations, contextual information, methodological and role reflections, and theoretical reflections. This distinction ensures that the observations could later be interpreted as such without being prematurely shaped by hasty theorizing [18]. The protocol supported a systematic but open-ended documentation of relevant behaviors, reactions, and interaction patterns, which were later analyzed qualitatively. Specifically, it consisted of 3 parts (Multimedia Appendix 3). One part of the observation protocol was dedicated to the observation of the care dyad. A

XSL•FO
RenderX



second part focused on the observation of the caregiver, while the third part entailed the observation of the communication dynamics within the dyad. For better comparability and assignability, guiding questions for each observation category were created. Parts 1 and 2 contained identical topics and guiding questions, whereas part 3 contained other topics that aimed to provide a comprehensive description of the communication dynamics within the dyad. The relevant topics and observation criteria are listed in Textbox 1.

The data collection process is summarized in Figure 2.

Textbox 1. Relevant categories and guiding questions of the observation protocol.

1. Person with MCI (overall feasibility, cognitive tasks, physical tasks, and interaction tasks). For example, how was the motivation during the exercise?
2. Caregiver (overall feasibility, cognitive tasks, physical tasks, and interaction tasks). For example, how was the reaction to the exercise? (positive or negative)
3. Care dyad: communication dynamics and relationship within the dyad (communication, mood, and change in mood; support; attitude of caregivers toward tablet computer; shared use; stimulus for conversation; and overall impression). For example, did the mood undergo any changes? To what extent did the caregiver's support meet the needs of the patient, and how well was it accepted?

Figure 2. Intervention and data collection process.

Data Analysis

The methodological approach followed a systematic and rigorous process to ensure the reliability and validity of the qualitative analysis. The first step involved the creation of a deductive category system based on the overarching themes of the research questions, which provided a structured framework for the analysis, along with a detailed coding guide to ensure consistency during the coding process. Audio recordings of interviews and observations were transcribed. The structured field notes during the observation underwent a double-validation process, whereby 2 researchers independently reviewed the observation data from each other and resolved any discrepancies through discussion. Following this, triangulation of the transcribed interview data and the validated observation protocols was carried out to align insights from multiple sources and enhance the depth of the analysis. The combination of methods allowed us to create results from different perspectives, particularly regarding relationship dynamics. The observations made it possible to include nonverbal communication patterns, power symmetries or asymmetries, and subtle interactions into the analysis.

The qualitative content analysis was conducted based on the methodological approach described by Kuckartz [19] and followed a structured, multistep process. After transcription, both coders independently conducted the initial coding of the interview and observation data using the MAXQDA software (Verbi GmbH), using a combination of deductive categories based on the research questions and inductively emerging subcategories from the material. Theme development was conducted collaboratively. The 2 coders jointly identified and refined preliminary themes through iterative discussions, comparing and synthesizing their interpretations. To ensure analytical rigor and increase trustworthiness, these themes were subsequently reviewed and discussed with additional members of the research team. Discrepancies were resolved through consensus, and categories were adjusted where necessary to better reflect the data. This reflexive and team-based approach aimed to ensure consistency and credibility throughout the analysis process.

Anchor quotations representative of key themes and findings were also identified to illustrate the findings.

XSL•FO
RenderX

Researcher Characteristics and Reflexivity

In line with the COREQ (Consolidated Criteria for Reporting Qualitative Research) criteria [20], the research team's backgrounds and positions in the field were considered throughout the research process to enhance transparency and reflexivity. The interdisciplinary study team consisted of health and social scientists with academic training and professional experience in gerontology, rehabilitation sciences, nursing, and qualitative research methods. All researchers had previous experience conducting studies with older adults, including individuals with cognitive impairments and their caregivers. They were trained in qualitative interviewing and observational techniques and were familiar with the ethical and communicative considerations required when working with cognitively vulnerable populations. To ensure reflexivity and reduce potential bias, the research team engaged in regular debriefing sessions in which preliminary impressions and interpretations were discussed throughout the data collection and analysis process. Throughout all interactions, researchers maintained a respectful, nondirective stance to minimize influence on participants' behavior and responses.

Results

Overview

Overall, we recruited 40 individuals, including persons with MCI (n=20, 50%) and their caregivers (n=20, 50%), to participate in our study. The level of experience in using technical devices was grouped into 4 categories: minimal experience, basic experience, moderate experience, and advanced experience. The description of the variables is provided in Table 2.

Table 2. Description of the participants' characteristics.

Variables	People with MCI[a] (n=20)	Caregiver (n=20)
Age (y), mean (SD)	80.95 (8.27)	60.63 (18.1)
Sex (female), n (%)	15 (75)	16 (80)
Previous technical experience, n (%)		
Minimal experience[b]	7 (35)	2 (10)
Basic experience[c]	7 (35)	2 (10)
Moderate experience[d]	2 (10)	1 (5)
Advanced experience[e]	4 (20)	15 (75)
Relationship, n (%)		
Spouse	—[f]	5 (25)
Child	—	4 (20)
Caregiver of a person attending a day care center	—	4 (20)
Friend	—	3 (15)
Volunteer	—	3 (15)
Other	—	1 (5)

[a]MCI: mild cognitive impairment.

[b]Minimal experience: use of simple, traditional technologies (eg, radio, television, and telephone) and have little or no experience with modern technology (eg, tablets and smartphones).

[c]Basic experience: limited access to or occasional use of modern technology; may own devices (eg, cell phone and tablet) but rarely use them or have had difficulty using them.

[d]Moderate experience: regular use of modern devices, but mainly for basic applications or with support from others.

[e]Advanced experience: in-depth experience and independent, either through intensive previous use or current skills; varied use of modern technology.

[f]Not applicable.

The results were organized along the 2 overarching research questions. On the basis of the qualitative data analysis, 5 main categories were developed deductively and supplemented by inductively derived subcategories. To enhance clarity and traceability, these categories were assigned to the respective research questions according to their thematic relevance:

1. Caregiver-patient relationship—relational dynamics and the influence of the intervention

1.1 Dyadic interaction and support

1.2 Impact of the intervention on communication and engagement

2. Feasibility—practicability, challenges, and conditions for successful implementation

2.1 Personal characteristics and experiences with digital technology

2.2 Feasibility, media, and task engagement

2.3 Future use and recommendations for the intervention

XSL•FO
RenderX

A visualization of this structure is provided in Table 3 to support the reader in contextualizing the categories within the scope of the research questions.

Table 3. Deductively developed main categories in relation to superordinate research questions.

Categories	Research question 1: caregiver-patient relationship	Research question 2: feasibility
1.1 Dyadic interaction and support	✓	—[a]
1.2. Impact of the intervention on communication and engagement,	✓	—
2.1 Personal characteristics and experiences with digital technology	Indirectly relevant	✓
2.2 Feasibility, media, and task engagement	—	✓
2.3 Future use and recommendations for the intervention	Implicit, relationship perspective	✓

[a]Not applicable.

Research Question 1: Caregiver-Patient Relationship—Relational Dynamics and the Influence of the Intervention

Dyadic Interaction and Support

The dynamics within dyads were characterized by mutual trust, encouragement, and humor, fostering a positive and engaged atmosphere. Praise and nonverbal reassurance, such as eye contact, helped maintain concentration:

> *Very good! Where did you learn that? So on with the story.* [Caregiver 4]

While most dyads communicated harmoniously, differences in communication styles emerged, particularly among married couples, where disagreements over pacing were observed. Some dyads adapted over time, shifting from skepticism to more relaxed interactions. Decision-making varied, with some caregivers assuming control (eg, “don’t keep pressing, I have to read first” [person with MCI 4]), while others facilitated joint decision-making, promoting autonomy. A key aspect was “getting to know each other better” through biographical storytelling (eg, “talking about Berlin or the farm—I think it’s great that you can talk about things you’ve experienced yourself” [caregiver 13]), shared memories, and collaborative tasks. Many dyads perceived the joint implementation as enriching (eg, “yes, that’s good. Two is always better than one [...] and one person can help the other a bit” [caregiver 4]). The medium itself was secondary to the interaction it facilitated, whether through a tablet or other activities. However, challenges such as impatience, paternalism, physical differences, or differing expectations could lead to tension.

Caregivers played a crucial role in technical and content-related support, adapting their assistance based on the person with MCI’s abilities. Some caregivers encouraged independence:

> *Or do you want to press? With your finger on it.* [Caregiver 14]

Other caregivers guided tablet use through instruction:

> *Exactly. Most of the time you have to use the fingertip.* [Caregiver 1]

As familiarity increased, caregiver intervention decreased, allowing for greater autonomy. However, excessive assistance risked creating dependency, limiting engagement:

Caregiver 5: “If you could choose now, where would you rather go?”

Person with MCI 5: “Spain.”

Caregiver 5: “Yeah. If you want, you can get up. But I don’t care. It’s up to you.”

Content-related support varied from cooperative problem-solving to task takeover. Some caregivers dominated tasks, limiting opportunities for independent learning (eg, “that brings us to 42” [caregiver 13]), while others facilitated responses through guidance and rephrasing. When caregivers provided encouragement and structured support, participation and self-confidence improved. Joint problem-solving fostered a sense of security and trust, allowing individuals with MCI to engage more actively:

> *You see, it’s very important that you’re there.* [Person with MCI 2]

Impact of the Intervention on Communication and Engagement

The intervention stimulated conversation, particularly through biographical topics and open-ended questions. References to personal experiences (eg, travel, markets, and gardens) encouraged storytelling, deep discussions, and caregiver engagement:

> *She [Avatar] asked what your best trip was? Do you want to tell?* [Caregiver 13]

Collaborative exercises enriched interactions, alternating between independent efforts and joint decision-making. Participants valued this approach, stating the following:

> *Oh yes, but rather together than alone.* [Caregiver 12]

> *It gives more motivation, and when you do it as a pair, where both can give answers, that’s nice.* [Person with MCI 10]

Laughter and shared experiences enhanced motivation, yet caregiver dominance sometimes led to answer anticipation,

XSL•FO
RenderX

impacting engagement. Differences of opinion occasionally arose but were mitigated by the structured research setting. While knowledge-based questions occasionally led to uncertainty and insecurity, the intervention proved effective in fostering dynamic exchanges, particularly when topics were personally relevant. In addition to self-reported experiences, observations during the joint use of the intervention revealed moments of closeness and shared engagement. These appeared socially meaningful, particularly when task complexity, autonomy, and role distribution were attuned to the dyad's needs.

Research Question 2: Feasibility—Practicability, Challenges, and Conditions for Successful Implementation

Personal Characteristics and Experiences With Digital Technology

Overview

Interview and observation analyses revealed that the personal backgrounds of individuals with MCI—shaped by their life experiences, social environments, and daily routines—strongly influenced their perspectives and engagement. Key themes emerged, including regional origins, cultural influences, former professions, and family roles. For example, one participant described how her career as a seamstress and raising her children structured her daily life. Health limitations, such as visual or hearing impairments, as well as technological barriers, also impacted their independence and activities.

Family support played a crucial role in overcoming daily technological challenges. One participant shared how her daughter introduced her to mobile phones:

> *Yes, and when my daughter got a new cell phone, she always gave me her old one and always said, do it, and I've been doing it for a few years. My grandson always helped me at the beginning when he was there, yes, then we write emails to each other and try to do something like that.* [Person with MCI 17]

Participants' experiences with technology varied widely, from complete unfamiliarity to routine use. Personal attitudes and biographical contexts influenced these differences. Some participants expressed skepticism, rejecting digital devices as unnecessary:

> *Well, I'm definitely not a computer freak.* [Person with MCI 8]

> *I have my TV, that's enough.* [Person with MCI 11]

However, others had extensive experience and integrated technology into their daily lives:

> *I did all my written work online. And then I have six grandchildren of all ages. And they keep me fit.* [Person with MCI 9]

Professional and family contexts played a crucial role in the development of technical skills.

Acceptance and Rejection of the Technology

Survey responses showed a complex picture of both acceptance and skepticism regarding the intervention. Some participants were enthusiastic, viewing the technology as stimulating and beneficial (eg, one participant stated that they "absolutely wanted to take part in the study" [person with MCI 17]). Key factors for acceptance included feelings of success, motivation, and interactive elements. Two participants were motivated by the desire to promote their own health through the movement exercises (eg, "it's healthy" [person with MCI 5] and "movement promotes blood circulation, and blood circulation in turn promotes the ability to think" [person with MCI 20]). Participants also highlighted the value of memory activation and cognitive stimulation:

> *It was fun to name the things that you know. Yes, then you're happy that you already know something and that you're somehow making progress.* [Person with MCI 17]

> *I'm interested in something like that, so that it sticks in my memory. I have a problem with my memory because the doctor said it wasn't very good.* [Person with MCI 18]

The social aspect contributed positively to acceptance, with some participants emphasizing that technology facilitated shared experiences:

> *It was nice to do it together.* [Caregiver 6]

However, technical challenges and design limitations posed barriers to acceptance. Some participants were skeptical about the relevance of the technology in their daily lives:

> *Do you really need it?* [Caregiver 1]

The success of the intervention depended on intuitive usability, cognitive stimulation, and interactive design, while obstacles included technical difficulties, content adaptation, and perceived relevance. In summary, acceptance was driven by positive user experiences, while rejection stemmed from usability concerns and doubts about the technology's practical value.

Content Aspects and Choice of Stories

Participants' topic preferences were strongly influenced by personal interests and past experiences. The "forest story" was the most frequently chosen, as the forest is a familiar and meaningful place for many. Familiarity with a topic often led participants to engage more, as they associated it with positive past experiences, such as family vacations. Conversely, a lack of personal connection acted as a barrier, leading some to reject certain topics:

> *Spain, that's not for us, we've never been there.* [Person with MCI 3]

However, for others, unfamiliar topics sparked curiosity and provided an opportunity to learn something new. The forest theme received broad acceptance and positive responses due to personal connections with nature:

> *We lived in the Black Forest for many years and spent a lot of time in the forest, and we still talk about those beautiful walks today.* [Person with MCI 3]

XSL•FO
RenderX

> *I am a nature lover through and through.* [Person with MCI 17]

Many recalled special memories, such as hiking, animal-watching, or past experiences in the military, particularly from a time when they were not yet physically restricted. The farm story also resonated well with participants, as it was both biographically relevant and generally familiar. Many had childhood memories or past visits to farms, while others found the rural lifestyle intriguing:

> *We have four sons, and when they were relatively young, we always spent our vacations on a farm.* [Caregiver 9]

The Spain story provided various points of reference, particularly for those with travel experiences or a general interest in the region:

> *I have already driven through Spain. As I said, above Coimbra, to Portugal, to Fatima, and then back via Madrid and back to Germany.* [Person with MCI 20]

The Spain story was often described as informative and entertaining, although some found it more challenging than other stories. The Berlin story triggered reflections on the city's history, especially regarding the Berlin Wall and the divided past of the city:

> *Berlin is beautiful, big, loud, all sorts of things, but um, the wall, it makes you thoughtful.* [Person with MCI 13]

Participants' interaction with the buttons varied widely. While some tapped independently, others were hesitant, required assistance, or sought clarification. The floating "Next" button caused occasional confusion, as its function was not immediately clear. Similarly, uncertainty arose with selection buttons under images, as some participants attempted to tap the images directly, leading to frustration when no response occurred. In addition, prolonged pauses between slides without interactive elements resulted in uncertainty about the next steps, with one participant explicitly asking for guidance:

> *So where do I press? It's a bit of uncharted territory, isn't it? You have to think about it.* [Person with MCI 3]

At the beginning of cognitive questions, answer options were initially hidden, leading to confusion that diminished once they became visible.

Initial difficulties in using the tablet were common, often due to unfamiliarity with the technology. Typing proved challenging for some, especially those with long fingernails or those who exerted excessive pressure on the touchscreen. While some participants remained hesitant at first, many gained confidence over time and eventually typed independently. Notably, participants with no previous tablet experience were initially skeptical but adapted quickly. One participant described typing as "new territory" but ultimately found it enjoyable. Despite early uncertainties, many reported increasing speed and confidence with continued use.

Feasibility, Media, and Task Engagement

The use of rewards, such as animal pictures after task completion, proved to be an effective emotional motivator, fostering joy and enthusiasm in both individuals with MCI and caregivers. Statements such as "once a lamb and once the dog. That builds you up" (person with MCI 2) illustrate how such elements encouraged engagement. The reward system not only increased motivation and attention but also enhanced social interaction within dyads:

Tom (avatar): "Well done. That was correct."

Caregiver 2: "The contestant has 100 points" (laughs).

Person with MCI 2: "Yes, yes. Now he's continuing. Look there the donkey said 'Bravo' That's funny."

Visual media, particularly nature-related images (eg, forest paths, flower meadows, streams, and animals), were consistently well received and described as visually appealing and emotionally uplifting:

> *They were beautiful, especially the forest and everything.* [Person with MCI 1]

Videos featuring landscapes and moving animals provided an immersive experience:

> *Seeing the landscape again, from a different perspective from above.* [Caregiver 1]

Narrator: "Ella watches as an orange butterfly lands on a blade of grass. To remember the moment, Ella takes another."

Person with MCI 1: "Oh, that's a beautiful fellow. I think I've barely seen any this year. Oh wait, a yellow one did fly by the other day."

Artificial intelligence (AI)–generated content (eg, images, speaker voices, and avatars) was widely accepted, seamlessly integrating into participants' experiences without compromising authenticity:

Interviewer: "Tom—this person—we created him using artificial intelligence. So it's not a real person, but someone we generated with a computer."

Caregiver 15: "Oh, but at the time, it wasn't really noticeable that it wasn't a real person."

Computer-generated voices and sound effects were generally perceived as clear and natural, although minor issues such as choppy audio or low volume were noted, but did not significantly affect comprehension. Background sounds, such as birdsong and flowing water, were praised for enhancing the atmosphere. A well-balanced combination of voices and ambient sounds was found to improve the overall user experience. Text-based and interactive elements received mixed feedback. While most found the font legible, some suggested increasing the font size, stating, "slightly larger" (dyad 17). Button placement and touch recognition issues were noted, with recommendations to space buttons further apart for better usability.

XSL•FO
RenderX

The range of tasks was generally well received, particularly movement-based activities, which were seen as beneficial for both physical health and cognitive activation:

> *Movement promotes blood circulation, which supports thinking.* [Person with MCI 20]

Personal anecdotes often accompanied exercises, for example, "feeding chickens" (farm story) or "running up the cathedral tower" (Spain story), enhancing engagement. Dyadic interaction influenced task acceptance, while relaxation and breathing exercises elicited mixed reactions—some found them calming, others reacted humorously. Interaction exercises encouraged quick responses and biographical storytelling (eg, farm visits, nature, and markets), effectively activating memories and fostering dialogue. Cognitive tasks were generally perceived as appropriate, although some participants, particularly those with relevant backgrounds, desired greater challenges. Many participants enjoyed problem-solving tasks, expressing enthusiasm through clapping, smiling, or laughing. Open-ended knowledge questions encouraged discussions and thought sharing, making them especially popular. The variety of question types was widely appreciated.

Future Use and Recommendations for the Intervention

The tablet-based intervention received positive feedback. One participant noted the following:

> *Time passed quickly, and it was a nice change.* [Caregiver 16]

Many participants were open to future use, even those with limited previous tablet experience:

> *Very good, it was very good. I'm surprised. She [Person with MCI] read and listened to everything, responded, and with such great interest. Better than usual.* [Caregiver 18]

One participant with MCI 3 expressed confidence:

> *I think I can do it now...What do you call it? Tablet? That's easy.*

In response, caregiver 5 added, "You can still learn to use a tablet at 92, right?" However, some saw limited personal use, mainly as an activity to share with grandchildren:

> *If my grandson suggested it, I'd join in.* [Caregiver 8]

Others viewed it as a one-time experience:

> *That was nice, but just once.* [Person with MCI 15]

Some rejected it outright:

> *I don't feel like it. Why should I learn this?* [Caregiver 5]
>
> *I have my TV, that's enough for me.* [Person with MCI 1]

Overall, willingness to use the intervention was mostly positive, but some participants preferred alternative health-promoting activities over learning new technology. Participants suggested adding more animals and matching sounds to the forest story, making background noise quieter to improve focus, and using more relevant feedback images. They recommended a larger touchscreen with bigger, clearly highlighted buttons and a more intuitive introduction with arrows pointing to where to press. Zooming options for images would help people with vision impairments. Shorter pauses between slides and longer stories (eg, the Berlin story was "too short") were also preferred. Participants favored focusing on one type of exercise (cognition, interaction, or movement) and wanted more feedback on quiz answers, as well as opportunities for independent writing tasks. A sing-along song for more interactivity was suggested. In terms of content, participants expressed interest in travel stories set in places such as Spain, the Netherlands, or local cities with landmarks, castles, and regional foods. They also wanted stories about trips to the sea, the mountains, the Camino de Santiago, or farm visits. Other ideas included traditional crafts, iconic routes such as Route 66, boat tours, market visits, and exploring local heritage and cuisine.

Discussion

Principal Findings

This study explored the feasibility of a dyadic, touch-based multimedia intervention for individuals with MCI and their caregivers in a home setting, focusing on its impact on caregiver-patient relationships and dyadic communication. The intervention, incorporating physical, cognitive, and interactive exercises, aimed to address cognitive and relational challenges through shared activities.

A key finding was the positive influence on caregiver-patient relationships. Shared activities facilitated connection, mutual support, and emotional intimacy, particularly through biographical elements, which sparked meaningful dialogue and strengthened bonds. Humor, encouragement, and collaborative problem-solving enhanced communication. Caregivers played an essential role, with varying levels of involvement. Some encouraged autonomy, while others were more controlling, occasionally limiting independence. Striking a balance in caregiver support is key to maintaining a collaborative dynamic.

The intervention was feasible for home use, with participants adapting well despite initial unfamiliarity. The integration of AI-driven visual and auditory elements was particularly promising, as most participants did not perceive these features as unnatural. However, challenges such as confusion with interactive buttons, slide transition delays, and difficulties for those with limited previous experience pointed to areas for improvement, such as an intuitive interface, larger buttons, and faster system responsiveness. Mixed reactions on future use highlighted a preference for customization. While many participants were enthusiastic about continuing, others preferred traditional activities, emphasizing the need for relevant and varied content. Feedback mechanisms, adaptive difficulty, and offline accessibility could enhance its appeal.

Comparison With Previous Work

According to our study, a dyadic, touch-based multimedia intervention for individuals with MCI and their caregivers in a home setting is feasible. Participants' difficulties mainly depended on their previous technical experience, with those having moderate or advanced experience finding the tablet easier

XSL•FO
RenderX

to use. Despite initial uncertainties, most individuals with MCI gained confidence over time. An introductory video facilitated familiarization with the tablet, supporting findings by Quintana et al [21]. However, unfamiliarity with touch surfaces and interactive fields created challenges, such as pressing too hard or not knowing where to press. These issues were exacerbated by inconsistent button positioning, suggesting the need for uniformity in future designs. The dyadic concept proved helpful, as caregivers provided support, enhancing interaction and helping overcome difficulties, as noted by Klein et al [13].

User acceptance was high, with participants describing the intervention as both enjoyable and cognitively engaging. Two levels of difficulty were implemented to accommodate varying conditions and daily performance, which the participants appreciated. Our findings support the importance of adapting multimedia applications to users' needs [16]. However, technical barriers, such as limited Wi-Fi access, posed challenges, leading to disruptions such as audio interruptions. These issues could be mitigated with an offline version, now available, which should be considered for future interventions. The perceived relevance of the technology played a crucial role in acceptance, as users who found the tablet relevant demonstrated higher levels of engagement. This point has been emphasized by Chen et al [7] and Thordardottir et al [22]. These findings can be better understood through the lens of the technology acceptance model [23], which posits that 2 key factors—perceived usefulness and perceived ease of use—determine users' acceptance of a technology. In our study, both aspects emerged as highly relevant: while many participants appreciated the intervention's cognitive and relational value (usefulness), others were discouraged by technical hurdles or limited familiarity with touch-based interfaces (ease of use). This aligns with previous findings [24,25] that emphasize the importance of intuitive design and contextual relevance in enhancing user engagement. Integrating the technology acceptance model in future evaluations may provide a more structured framework for understanding acceptance dynamics and guide further refinement of the intervention.

Content relevance also played a role, with participants preferring stories connected to their own experiences, such as those involving forests and farms. City stories were less engaging, which aligns with the findings of Klein et al [13] that content relevance impacts user acceptance. A participatory approach in design could further ensure that the content meets users' needs, as suggested by Holthe et al [26]. Our results indicate that targeted adaptations, involving both people with MCI and caregivers in the design process, are key for long-term acceptance and success.

The study highlights both positive impacts and challenges for the relationship between individuals with MCI and their caregivers. A key finding is that biographically oriented content can strengthen the caregiver-patient relationship by facilitating personal dialogues and shared reminiscence, which enhances emotional intimacy and mutual understanding. This finding aligns with that of Ryan et al [27], who showed that biographical content strengthens emotional bonds in tablet-based interventions. Similarly, Hoel et al [6] highlighted how technology can enhance social interaction and alleviate communication pressures. Klein et al [13] also noted that caregiver support is crucial for the success of tablet-based interventions.

Caregivers played a central role in guiding and encouraging active participation of individuals with MCI, reinforcing the importance of adaptive support as seen in the study by Ingebrand et al [28]. However, challenges arose when caregivers became overly controlling, limiting the autonomy of individuals with MCI. This finding aligns with that of Ingebrand et al [28], who emphasized the need for a balanced approach to caregiver involvement. Gilson et al [29] similarly pointed out that while technology-based interventions can strengthen emotional bonds, they also risk inducing frustration if caregivers overstep their supportive roles or if the technology is perceived as too complex.

Moreover, our study suggests that the home environment positively influenced the intervention's success, supporting the findings of Gilson et al [29], who showed that home-based interventions can yield favorable outcomes for individuals with dementia. Future research should focus on investigating long-term relational dynamics, optimizing caregiver involvement, and assessing the scalability of such interventions. Tailoring content to cultural and biographical contexts will be crucial for maintaining relevance and increasing acceptance. Future studies should focus on optimizing caregiver involvement, tailoring content to cultural and biographical contexts, and assessing scalability.

Strengths and Limitations

We used a qualitative research approach, which is particularly well suited for exploring lived experiences and subjective meanings in complex social contexts [30]. By implementing methodological triangulation, we combined different data sources and perspectives, increasing the robustness and validity of our findings. In addition, the study explicitly addressed the dyad as a unit, acknowledging the dynamic interaction and relational dynamics between individuals with MCI and their caregivers. This holistic approach reflected the real-life caregiving context, ensuring that both social and cognitive aspects were considered in evaluating the intervention's impact. The study also benefited from a diverse recruitment strategy, including participants from various caregiving settings, such as home care, daycare facilities, and physiotherapy practices, which enhanced the practical relevance of the findings. Furthermore, the integration of observational data alongside interviews provided deeper insights into participants' actual behavior, reducing the risk of self-report bias.

Despite these strengths, several limitations must be acknowledged. One limitation was the lack of internet access among a substantial portion of the target population, posing challenges as the intervention was exclusively online. However, the dependence on technology may have posed a barrier for individuals less familiar with digital tools. Another potential limitation was social desirability bias, as participants may have provided overly positive feedback during interviews. This risk was mitigated by observations and researcher cross-validation. Furthermore, the study provides a short-term perspective on the intervention, meaning that insights into long-term engagement

XSL•FO
RenderX

and effects remain limited. Future research should explore how sustained use influences outcomes over time.

Overall, this study offers valuable insights into dyadic interactions in a digital intervention while highlighting both opportunities and challenges in its implementation. While this feasibility study was not designed to evaluate relational outcomes, the data suggest that shared use of the intervention may open opportunities for meaningful dyadic interaction. Future research should further explore the potential relational impact in a targeted design.

Conclusions

This study evaluated the feasibility of a dyadic, tablet-based multimedia intervention for individuals with MCI and their caregivers in a home setting, with a focus on its impact on caregiver-patient relationships. The findings indicate that the intervention was feasible, with initial uncertainties mitigated by thematic introductions and caregiver support, even for participants with limited technical experience.

A key factor in user acceptance and feasibility was the relevance of the intervention to participants' daily lives. One of the study's strengths was the implementation of 2 difficulty levels, allowing for adaptability to the fluctuating cognitive performance of individuals with MCI. Participants generally provided positive feedback, partly attributing benefits to cognitive and physical engagement. Our findings also underscore both the potential and challenges of using technology to support caregiver-patient relationships. Biographically oriented content appeared to facilitate social interaction and strengthen bonds. Furthermore, the integration of AI-generated visual and auditory elements was well received, as most participants did not perceive them as unnatural. This suggests that AI-based storytelling can enhance engagement and provide more personalized content. In future interventions, AI could be used to generate individualized, person-centered narratives that spark meaningful conversations within the dyad, further strengthening relationships and improving communication.

However, as this was a cross-sectional study, no conclusions about long-term effects can be drawn. Future research should prioritize longitudinal studies to assess sustained relational impacts and explore strategies to optimize caregiver involvement.

Acknowledgments

This study was funded by the German Federal Ministry of Education and Research (BMBF) as part of the KoMoS (Kognitiv-motorisches Spiel [cognitive-movement game]) project (reference 16SV9255) within the startInteraktiv (START-interaktiv [START-interactive]) research program.

Abstract

Background: Social isolation and weakened intergenerational ties pose significant threats to the emotional well-being and social support networks of older adults. Although structured intergenerational programs can reduce age-related stereotypes and promote connectedness, their accessibility is often hindered by physical and logistical constraints. The increasing digital literacy among older populations presents new opportunities for technology-based interventions to support meaningful cross-generational engagement.

Objective: This study aimed to design and evaluate a mobile app that fosters intergenerational communication and enhances perceived social support in older adults using a user-centered design framework grounded in the double diamond model.

Methods: The development process followed the 4 phases of the double diamond model. In the discover phase, surveys with older and younger adults identified distinct usability preferences. The define phase synthesized these insights into key design principles. In the develop phase, a prototype was created and iteratively refined through usability testing. Finally, in the deliver phase, a 2-week experimental study involving 39 participants (20 older adults aged 68-82 years and 19 younger adults aged 22-39 years) assessed changes in intergenerational interaction, perceived social support, and user satisfaction.

Results: The app appeared to enhance intergenerational communication and perceived social support, particularly among older participants. Users reported increased comfort and emotional connection in cross-generational conversations. Accessibility features and engaging content were noted as contributing to positive user experiences across age groups.

Conclusions: This study suggests the potential of user-centered digital platforms to promote social well-being among older adults. By addressing the unique needs of multiple generations, such interventions may help foster inclusive digital environments and contribute to age-friendly, connected societies. Despite limitations related to sample size, duration, and cultural context, the study provides preliminary evidence for the potential of co-designed digital tools in supporting intergenerational communication and aging-in-place.

Introduction

Intergenerational conflict has emerged as a critical social issue, undermining societal cohesion beyond mere differences in opinions between older and younger generations. Such conflicts manifest as misunderstandings, stereotypes, discriminatory attitudes, and competition for resources, resulting in tensions that hinder effective intergenerational collaboration and societal harmony [1,2]. This phenomenon is prevalent across various cultural contexts and is often exacerbated by the increasing generational divide, which limits opportunities for mutual understanding and interaction [2,3]. According to social identity theory [4], individuals tend to categorize themselves into in-groups and out-groups, fostering biases and discriminatory attitudes toward those outside their group. The generational divide intensifies such perceptions, leading to heightened tensions and societal fragmentation.

In preindustrial societies, intergenerational communication was inherently facilitated by extended family structures and community-based living arrangements, where multiple generations coexisted and engaged in shared responsibilities. However, the shift toward nuclear family living arrangements and the advent of digital media have significantly reduced these opportunities, reinforcing psychological and physical distances between age groups. This decline in direct contact between age groups has contributed to social alienation and hindered the formation of intergenerational trust. According to the contact hypothesis [5], sustained intergroup contact reduces prejudice and promotes positive relationships. This has been empirically demonstrated in structured intergenerational programs, which consistently reduce stereotypes and foster mutual respect [6,7].

To address the widening generational divide, intergenerational programs have been widely implemented to facilitate direct engagement between older and younger generations. Such programs yield mutual benefits; older adults experience enhanced emotional well-being, cognitive stimulation, and increased social participation, while younger participants benefit from identity formation and skill acquisition [8]. Despite their well-documented advantages [9], face-to-face engagement remains constrained by physical distance, mobility limitations, and logistical barriers [10,11].

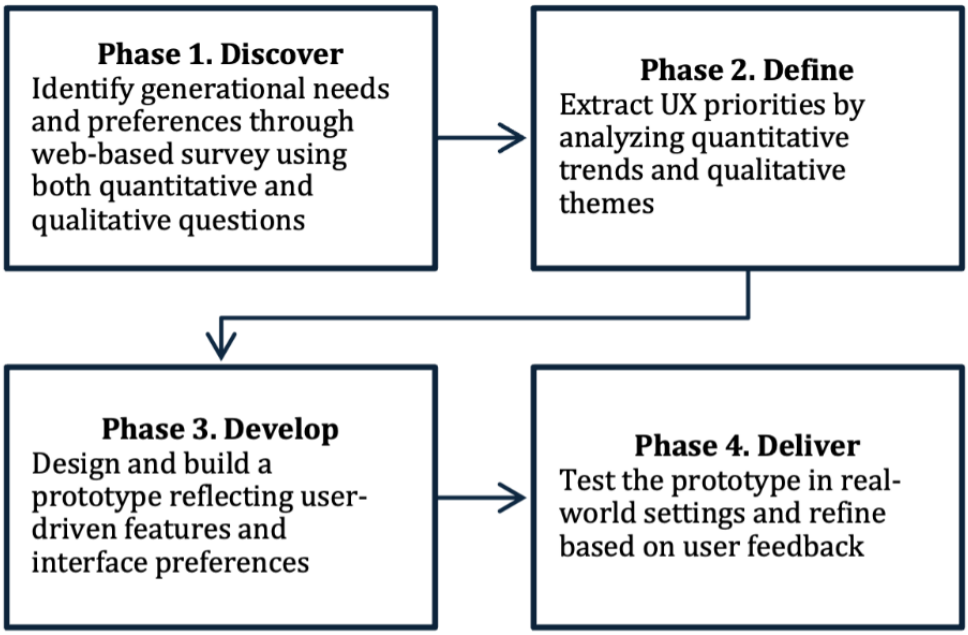
Digital communication tools offer a scalable and accessible alternative, particularly for populations with restricted opportunities for in-person interaction. The COVID-19 pandemic further accelerated digital adoption among older adults; in Germany, for instance, internet use among older individuals increased from 58% to 81% during the pandemic [12]. Moreover, empirical evidence suggests that even indirect or extended intergenerational contact can reduce age-based prejudice among younger people [7], underscoring the potential of digital platforms to foster intergenerational understanding. These findings highlight the value of digital environments as a means of promoting meaningful engagement across generations, extending the reach and impact of conventional face-to-face programs.

In line with this shift, various digital interventions have emerged globally to enhance intergenerational engagement. For example, Müller et al [13] developed a web-based platform to improve communication between older adults and their families through shared modules and collaborative learning. Similarly, Phang et al [14] identified diverse programs using accessible technologies—such as smartphones, video calls, and messaging apps—to strengthen emotional connection and intergenerational bonding. However, most existing platforms lack mechanisms for sustained, bidirectional interaction. Although older adults' digital literacy has increased [14], many platforms still fall short of addressing the nuanced needs and co-design preferences of both age groups. This gap underscores the need for inclusive, user-centered digital solutions that enable emotionally reciprocal and goal-oriented communication across generations.

In response to these limitations, this study introduces CoGen (Ewha Institute for Age Integration Research), a mobile app designed to promote intergenerational communication. Unlike prior platforms that rely on structured prompts or 1-way content delivery, CoGen supports user-generated, bidirectional interaction designed to accommodate the nuanced needs and co-design preferences of both younger and older users. To achieve this, CoGen's development is anchored in user-centered design (UCD) principles [15,16] and operationalized through the double diamond model [17], a 4-phase process (discover, define, develop, and deliver) that facilitates a structured, iterative approach for identifying user needs and refining design solutions in response to ongoing feedback. Implicit in this design philosophy is the contact hypothesis [5], which posits that sustained interaction under conditions, such as equal status, common goals, intergroup cooperation, and institutional support, can reduce prejudice. While this study does not directly test the hypothesis, its framework serves as a useful theoretical lens for understanding how intergenerational communication—especially in structured digital settings—might contribute to prejudice reduction.

Rather than simply developing a communication tool, this study aims to create CoGen as a user-centered, age-inclusive digital environment that enables users to exchange experiences, share cultural knowledge, and engage in collaborative activities. By fostering sustained and meaningful digital interaction, the project seeks to bridge the intergenerational divide, enhance older adults' social connectedness, and support global efforts toward digitally inclusive aging. In doing so, the development and evaluation of CoGen align with international movements advocating for scalable, human-centered technologies that empower older populations and promote equitable participation.

Methods



Double Diamond Model and Research Process

To guide the design and evaluation of the proposed mobile app, this study adopts the double diamond model [17], a 4-phase framework comprising discover, define, develop, and deliver. Alternating between divergent and convergent thinking, this model enabled a user-centered, iterative approach to address challenges in intergenerational digital communication. Each phase incorporated continuous input from both younger and older users to ensure that the final design was both accessible and responsive to real-world needs. Figure 1 presents a visual

XSL•FO
RenderX

summary of the study design, showing the sequential flow of the 4 phases along with key methods and objectives associated with each phase.

Figure 1. User-centered app development for intergenerational communication using the double diamond model. UX: user experience.

Phase 1: Discover: User Research

Research Focus

In the discover phase, the technology acceptance model [18] guided the identification of key factors influencing user attitudes and adoption intentions across age groups. A cohort-specific survey approach was used to capture generational differences in communication needs, motivations, and feature preferences. By incorporating both usability concerns of older adults [19] and engagement drivers for younger users [20], this phase laid the groundwork for a user-centered app design.

Participants and Research Procedure

Recognizing the distinct usability barriers faced by older adults and the engagement drivers influencing younger adults, this study recruited 2 age groups: younger adults (20-39 years) and older adults (60-79 years). A nationwide web-based survey was conducted in South Korea, using proportional stratified random sampling from an existing panel database managed by a professional research firm. Stratification criteria included age, gender, and prior digital communication experience to ensure demographic diversity within each group. Email invitations outlining the study's purpose were sent, and a total of 413 participants—202 younger adults and 211 older adults—voluntarily completed the survey.

Measures and Data Collection

Measurement Approach

To assess participants' attitudes, expectations, and key adoption factors for an intergenerational communication app, we used a mixed methods approach with quantitative survey items and qualitative open-ended responses. Our measurement strategy primarily used single-item indicators, carefully adapted from established multi-item scales for their high face validity and relevance [21-27]. This approach prioritized feature-level granularity over composite scoring, aligning with our exploratory UCD goals. Furthermore, we followed prior methodological support for single-item measures when constructs are narrow, concrete, and easily understood [28-30]. As these items were not intended to form reflective scales, internal consistency metrics like Cronbach α were not computed.

Attitudes Toward Intergenerational Communication

Participants' overall attitudes toward intergenerational communication were assessed using an adapted version of the scale by Lee and Lee [21]. Two conceptually distinct items measured interest and perceived importance (eg, "How interested are you in communicating with other generations?" and "How important do you think it is to have communication between generations?"), rated on a 5-point Likert scale (1=not at all and 5=very much).

Perceived Necessity and Willingness to Use an Intergenerational Communication App

To assess both the perceived necessity of an intergenerational communication app and participants' willingness to use it, two key items were included: (1) "How necessary do you think an app for intergenerational communication is?" (1=not necessary at all and 5=very necessary). (2) "If an app for intergenerational communication were developed, how often do you think you would use it?" (1=not at all and 5=very often). These items aimed to evaluate both the demand for such an app and participants' likelihood of adoption.

Motivational Factors for App Use

This section examined the anticipated use cases of the app, including social communication (eg, maintaining relationships across generations), entertainment (eg, engaging in shared recreational activities), information exchange (eg, learning about generational perspectives), and emotional support (eg,

XSL•FO
RenderX

alleviating social isolation). Participants rated 8 motivational factors on a 5-point Likert scale (1=not relevant at all and 5=very relevant) to assess their perceived significance. These factors included social communication, passing time (relieving boredom), entertainment and enjoyment, exchanging necessary information or opinions, reducing loneliness, health management, discussing concerns not easily shared with same-generation peers, and cultural exchange. The items were adapted from Lee and Na [22] and Jun et al [23] to align with prior research on intergenerational communication and digital engagement.

Preferred App Features

Guided by Davis's [18] technology acceptance model, participants evaluated both content and design attributes likely to influence perceived ease of use and perceived usefulness of the app. For perceived ease of use, 7 items were assessed (eg, ease of access to content, clarity and accuracy of information, and simplicity of design). For perceived usefulness, 9 items were included (eg, convenience, sense of belonging, emotional satisfaction, and health relevance). These items were adapted from prior studies on digital content evaluation and intergenerational engagement [24,25].

Aesthetic and Gamification Components

Six aesthetic and gamification components were assessed to evaluate their perceived importance in enhancing user engagement. These included rewards (eg, points, badges, and levels), customization options (eg, avatars and profiles), friend integration (eg, KakaoTalk and Facebook), immersive meeting spaces (eg, augmented reality or virtual reality), visual appeal (eg, icons and backgrounds), and auditory appeal (eg, sounds and music). All items were rated on a 5-point importance scale (1=not important at all and 5=very important). The items were adapted from Choi et al [26] and Kim and Kim [27] to ensure consistency with prior research on digital engagement and user experience (UX) design.

Qualitative Responses on Cross-Generational Information and Conversation Topics

In addition to structured survey items, participants provided open-ended responses about specific topics and types of information they believed would best facilitate meaningful intergenerational interactions. These qualitative insights supplemented the quantitative findings, ensuring that the app's design aligns with real-world conversational preferences.

Statistical and Thematic Analysis

Quantitative data were analyzed using descriptive statistics and independent-samples 2-tailed *t* tests to examine generational differences across key variables, including perceived necessity, willingness to use the app, motivational factors, and preferences for content and design features. Mean comparisons allowed for the identification of statistically significant age-related patterns in user needs and expectations.

In parallel, qualitative data from open-ended survey responses were analyzed using inductive thematic analysis. One researcher (JJ) conducted an initial review of all responses to identify semantically similar ideas and organized them into preliminary categories. These were grouped into broader conceptual themes through a data-driven approach—for example, responses referencing real estate, stock investments, and financial planning were grouped under "finance," while those related to exercise, dieting, and eating habits were categorized under "health." To enhance the credibility of the analysis, a second researcher (HL) independently reviewed the categorized data and cross-checked the thematic structure. Discrepancies in categorization were discussed and resolved collaboratively.

Phase 2: Define: UX Design Extraction Through Data Analytics

In the define phase, findings from the quantitative and qualitative analyses conducted in the discover phase were synthesized to establish key UX objectives and design requirements. This phase focused on translating user insights into actionable design principles, aligning core functionalities and content strategies with generational communication patterns and technological expectations. No new analyses were conducted; instead, this phase served as a bridge between empirical findings and UCD decisions.

Phase 3: Develop: Prototype Development and UX Optimization

Design Objectives

This phase focused on translating key insights from the define phase into a functional prototype that supports intergenerational communication through an intuitive, engaging, and accessible design. The primary goal was to develop an interface that balances structured discussions with active engagement while ensuring seamless navigation for both younger and older users. The prototype underwent preliminary usability testing to validate design decisions and inform further refinement.

User Interface or UX Design and Wireframing Strategy

In the develop phase, findings from the define stage were translated into concrete interface components through low- and high-fidelity prototyping. Design decisions were guided by age-specific user preferences identified in previous phases. For older adults, design emphasis was placed on simplicity, clarity, and visual accessibility, including large font sizes and high-contrast modes. For younger adults, vibrant color palettes and dynamic layouts were incorporated to enhance visual engagement and usability.

Wireframing began with a streamlined home screen comprising 5 core functions to reduce cognitive load while maintaining structural clarity. To support long-term engagement, visual elements such as level indicators and progress bars were introduced, emphasizing intuitive feedback mechanisms.

Prototype Feature Integration Plan

Based on the motivational and usability patterns revealed in the discover and define phases, a set of core features was developed. These included theme-based discussion boards, digital conversation prompts, proprietary 1:1 friend matching, and progression-based gamification. Design mapping was used to align each feature with specific user needs—for example, older adults' emphasis on meaningful social bonding informed the

XSL•FO
RenderX

inclusion of noncompetitive reward systems, while younger adults' preference for entertainment-driven experiences led to the development of dynamic prompts and visual engagement indicators.

Preliminary Usability Testing Procedure

Before broader evaluation, a pilot usability test was conducted to evaluate the prototype's interface, features, and overall usability. In total, 8 participants—5 younger adults (aged 20-39 years) and 3 older adults (aged 60-79 years)—were recruited to test core functions including onboarding, feature navigation, and emotional appeal. Feedback was collected through structured observation and posttask interviews. Key points of friction and areas of positive engagement were identified to guide iterative improvements before moving into the final testing phase.

Phase 4: Deliver: Usability Testing and User-Centered Refinement of CoGen

Phase Overview

The deliver phase aimed to evaluate the CoGen prototype's effectiveness in fostering intergenerational engagement in real-world settings. A 2-week experimental study using a mixed methods approach was conducted to assess UX, communication outcomes, and app usability.

Study Design and Procedures

A total of 39 participants (17 men and 22 women) aged 20 to 82 (mean 48.57, SD 24.56) years took part in a 2-week experimental study conducted from October 28 to November 12, 2024. The sample included 20 older adults (aged 68-82 years) recruited from 2 senior welfare centers in Seoul and 19 younger adults (aged 22-39 years) recruited via web-based advertisements. To minimize usability barriers, only older adults who owned and regularly used smartphones were eligible to participate.

Prior to the intervention, all participants attended an orientation session held at a welfare center in Seoul, with simultaneous Zoom (Zoom Video Communications) access for those unable to attend in person. The orientation lasted approximately 1 hour and included an explanation of the study purpose and procedures, followed by the administration of the preintervention survey. Over the subsequent 2 weeks, participants were instructed to log in daily to the CoGen app, post or respond to discussion prompts, and engage with others through comments and reactions.

Following the 2-week use period, participants completed a postintervention survey. Subsequently, focus group interviews (FGIs) were conducted to gather qualitative feedback on UX, perceived value, and emotional engagement. All 39 participants were divided into 7 small groups (fewer than 6 participants per group), and each group participated in a single FGI session, resulting in 7 sessions in total. Interviews took place in November 2024, either in person at senior welfare centers or on the web via Zoom, depending on participant accessibility. All younger adults participated through web-based sessions, whereas older adults primarily attended in person unless remote participation was required. Each session lasted approximately 1 hour and was moderated by a lead researcher (HL), with a second researcher (JJ) observing and taking notes. Participants provided both verbal and written consent for audio recording and transcription. A structured open-ended question guide was used to explore experiences of intergenerational communication, app usability, emotional responses, and perceived facilitators and barriers.

Measures

Postuse App Evaluation and Behavioral Intentions

Participants' postuse evaluation of the app and their behavioral intentions were assessed using a multidimensional measurement strategy comprising both multi-item and single-item indicators, all rated on 5-point Likert scales. Items were adapted from instruments used in the discover phase and modified to capture users' emotional, cognitive, and behavioral responses after 2 weeks of app use. Single-item measures were selected for their clarity and conceptual precision, consistent with prior methodological recommendations [28-30].

Affective and Overall Evaluation

To evaluate affective aspects of intergenerational communication facilitated through the CoGen app, participants were asked to rate their comfort during cross-generational conversations ("How comfortable did you feel while having conversations with individuals from other generations using the CoGen app?") and their satisfaction with those conversations ("How satisfied were you with the intergenerational conversations through the app?"). These items captured users' emotional responses and overall impressions of the app-mediated interaction.

Emotional Engagement

Emotional engagement was measured through 4 items: "enjoyment," "happiness," "interest," and "a sense of similarity or affinity with others." These were presented under the prompt, "To what extent did you experience the emotions or values you had expected from using the intergenerational communication app?" and were designed to evaluate participants' subjective emotional experiences during app use.

Functional Usability

Functional usability was measured using 2 items: "It was easy to find the information I needed in the CoGen app" and "The information and content provided in the app were easy to understand." These were also rated on a 5-point Likert scale (1=strongly disagree and 5=strongly agree). All items were analyzed individually, and descriptive statistics were used to examine users' perceptions of the app's usability, clarity, and interface design.

Perceived Necessity, Use Intentions, and Recommendation Willingness

Participants' attitudes toward the CoGen app were assessed using 3 single-item measures, each rated on a 5-point Likert scale. Two items (eg, "Do you think the CoGen app is necessary?" and "Do you intend to continue using the CoGen app in the future?") were administered both before and after the intervention to assess perceived necessity and continued use intention, respectively. An additional item (eg, "Would you

XSL•FO
RenderX

recommend the CoGen app to others?") was included in the postintervention survey to assess participants' willingness to recommend the app to others.

Intergenerational Communication

Changes in intergenerational communication were measured using 6 items administered before and after the 2-week intervention, rated on a 5-point Likert scale (1=strongly disagree and 5=strongly agree). Items were adapted from the European Values Study and the revised Solidarity Scale [31,32], modified for app-based cross-generational contexts. Intergenerational interaction was assessed with 2 items (pre: α=.76; post: α=.79), such as "I now talk with members of other generations more frequently than before." Intergenerational understanding was measured with 4 items (pre: α=.87; post: α=.91), including "I have come to respect the culture of other generations" and "I have come to understand the realities faced by other generations."

Psychosocial Outcomes

Perceived social support was assessed using 8 items from the Medical Outcomes Study Social Support Survey [33], rated on a 5-point Likert scale (1=strongly disagree and 5=strongly agree) before and after the intervention (pre: α=.91; post: α=.93). Example items include "There is someone who makes me feel cared for" and "I have someone to talk to about work or household problems."

Depressive symptoms were measured using the 10-item short form of the Center for Epidemiologic Studies Depression Scale, validated in Korean [34], with responses rated on a 5-point scale (1=not at all and 5=almost always; pre: α=.83; post: α=.85). Sample items include "I felt depressed" and "I had trouble concentrating on what I was doing."

Data Analysis

A mixed methods approach was used to analyze both quantitative and qualitative data. For the quantitative component, paired-sample 2-tailed *t* tests were conducted to compare participants' pre- and postintervention responses on key outcome variables, including intergenerational interaction, perceived understanding, social support, and depressive symptoms. Descriptive statistics were also used to summarize postuse evaluations, usability perceptions, and emotional engagement indicators.

For the qualitative component, transcripts were analyzed using thematic analysis [35]. Three members of the research team—including 2 senior researchers with expertise in aging and 1 qualitative methods specialist—independently reviewed transcripts and field notes. An inductive coding process was used to identify recurring patterns and refine overarching themes such as perceived benefits, design-related frustrations, and recommendations for improvement. Triangulation and consensus meetings were used to enhance the trustworthiness and analytical rigor of the findings.

Ethical Considerations

This study received institutional review board approval from Ewha Womans University (IRB ewha-202203-0022-01). All participants provided written informed consent prior to participation, and data were anonymized to ensure confidentiality. Identifiable information was removed during transcription and analysis to protect participant privacy. As compensation, each participant received a gift voucher worth approximately US $15.

Results

Phase 1: Discover; Key Findings From User Research

Attitudes Toward Intergenerational Communication

Older adults exhibited significantly higher interest in intergenerational communication (mean 3.87, SD 0.63) compared to younger adults (mean 3.61, SD 0.81; t_{411}=–3.63; *P*<.001; *d*=0.36). They also placed greater importance on exchanging necessary information (mean 4.05, SD 0.66) than younger adults (mean 3.86, SD 0.82; t_{411}=–2.59; *P*=.01; *d*=0.26).

Perceived Necessity and Willingness to Use an Intergenerational Communication App

Older adults rated the perceived necessity of an intergenerational communication app significantly higher (mean 3.82, SD 0.73) than younger adults (mean 3.47, SD 0.83; t_{411}=–4.54; *P*<.001; *d*=0.45). They also demonstrated a greater willingness to use the app (mean 3.81, SD 0.71) compared to younger adults (mean 3.17, SD 0.87; t_{411}=–8.17; *P*<.001; *d*=0.81).

Motivational Factors for App Use

Distinct differences emerged in how and why users expected to use the app. Older adults were more likely to use the app for social communication (mean 3.87, SD 0.63) than younger adults (mean 3.61, SD 0.81; t_{411}=–3.63; *P*<.001; *d*=0.36), indicating a stronger interest in maintaining intergenerational relationships. They also placed greater importance on passing time (mean 2.97, SD 0.86) than younger adults (mean 3.19, SD 1.01; t_{411}=2.38; *P*=.018; *d*=–0.23), although the difference favored younger adults. In addition, older adults expressed significantly greater interest in entertainment and enjoyment (mean 3.50, SD 0.73) than younger adults (mean 3.19, SD 1.03; t_{411}=–3.52; *P*<.001; *d*=0.35).

Regarding exchanging necessary information or opinions, older adults again rated this higher (mean 4.05, SD 0.66) than younger adults (mean 3.86, SD 0.82; t_{411}=–2.59; *P*=.01; *d*=0.26). They also viewed the app as more useful for reducing loneliness (mean 3.10, SD 0.89) than younger adults (mean 2.89, SD 1.12; t_{411}=–2.10; *P*=.04; *d*=0.21) and placed greater emphasis on health management (mean 3.77, SD 0.88) compared to younger adults (mean 3.31, SD 1.02; t_{411}=–4.90; *P*<.001; *d*=0.47).

Younger adults, on the other hand, reported significantly greater interest in discussing concerns not easily shared with same-generation peers (mean 3.59, SD 0.94) than older adults (mean 3.06, SD 0.94; t_{411}=5.73; *P*<.001; *d*=–0.56). Finally, older adults rated cultural exchange significantly higher (mean 3.72, SD 0.72) than younger adults (mean 3.44, SD 0.94; t_{411}=–3.39; *P*=.001; *d*=0.33), suggesting a stronger openness to learning about different generational perspectives.

RenderX

Preferred App Features

Perceived Ease of Use

Both younger and older adults highly prioritized the reliability of provided information (younger adults: mean 4.26, SD 0.86 and older adults: mean 4.41, SD 0.66), with older adults showing a marginally higher preference (t_{411}=–1.98; *P*=.048; *d*=0.20). Similarly, clarity and accuracy of information received high, comparable ratings from both groups (younger adults: mean 4.16, SD 0.83 and older adults: mean 4.26, SD 0.68; t_{411}=–1.34; *P*=.18; *d*=0.13).

A significant difference emerged in the ease of access to information, where older adults placed notably higher importance (mean 4.14, SD 0.60) than younger adults (mean 4.00, SD 0.73; t_{411}=–2.12; *P*=.03; *d*=0.21), underscoring the need for an intuitive and navigable interface for this demographic. While simplicity and readability of content were also more valued by older adults, this difference was not statistically significant.

Both groups rated the relevance, appropriateness, and immediate accessibility of content similarly, with no significant differences. Interestingly, younger adults placed slightly more emphasis on engagement and entertainment value, though this difference was not significant.

Perceived Usefulness

Older adults consistently reported significantly higher expectations across several usefulness-related values. They notably emphasized health as a critical factor (older adults: mean 4.02, SD 0.79 vs younger adults: mean 3.60, SD 1.03; t_{411}=–4.64; *P*<.001; *d*=0.46), highlighting their preference for health-related features. Additionally, novelty was rated significantly higher by older adults (mean 3.97, SD 0.74) than by younger adults (mean 3.45, SD 0.89; t_{411}=–6.44; *P*<.001; *d*=0.62), suggesting an attraction to fresh and innovative experiences.

In terms of emotional and social benefits, older adults consistently placed greater importance on convenience (mean 3.91, SD 0.62), fun (mean 3.85, SD 0.70), and friendship (mean 3.37, SD 0.72) compared to younger adults (convenience: mean 3.59, SD 0.95; fun: mean 3.46, SD 0.96; and friendship: mean 3.03, SD 0.97). They also rated confidence (mean 3.66, SD 0.81) and a sense of belonging (mean 3.54, SD 0.79) significantly higher than younger adults (confidence: mean 3.21, SD 0.91 and belonging: mean 3.25, SD 1.01). While not statistically significant, both age groups similarly recognized the emotional benefits related to memories, though these were less differentiated between them.

Aesthetic and Gamification Components

In evaluating aesthetic and gamification components, older adults generally expressed a greater interest in several features compared to younger adults. Specifically, older adults showed a significantly stronger interest in customization options like avatars and personalized profiles (older adults: mean 3.28, SD 0.89 vs younger adults: mean 2.92, SD 1.08; t_{411}=–3.69; *P*<.001; *d*=0.36), suggesting a desire for more personalized UXs.

A notable difference also emerged in friend integration, with older adults showing a much higher preference for linking the app with external platforms like KakaoTalk or Facebook (mean 3.64, SD 0.88 vs mean 3.04, SD 1.17; t_{411}=–5.87; *P*<.001; *d*=0.57). This highlights the importance of seamless social connectivity for older users. Furthermore, older adults reported greater interest in immersive meeting spaces (eg, augmented reality or virtual reality features) compared to younger adults (mean 3.12, SD 0.87 vs mean 2.91, SD 1.12; t_{411}=–2.12; *P*=.03; *d*=0.20), suggesting that immersive environments may enhance their digital engagement.

While older adults appreciated rewards like points and badges more than younger adults (mean 3.49, SD 0.84 vs mean 3.32, SD 1.12), this difference was not statistically significant (t_{411}=–1.74; *P*=.08; *d*=0.17). Finally, visual appeal (eg, icons and backgrounds) was rated similarly across both age groups (older adults: mean 3.50, SD 0.81 and younger adults: mean 3.46, SD 0.93; t_{411}=–0.47; *P*=.64; *d*=0.04), indicating a shared preference for aesthetically pleasing user interface (UI).

Table 1 summarizes generational differences in attitudes toward intergenerational communication, perceptions of app necessity and willingness to use, motivational factors, and preferred app features.

XSL•FO
RenderX

Table 1. Comparison of younger and older adults' attitudes, perceptions, motivations, and preferred features for an intergenerational communication app (N=413).

	Younger (n=202), mean (SD)	Older (n=211), mean (SD)	*t* test (*df*=411)	*P* value
Attitudes toward intergenerational communication				
Interest in cross-generational communication	3.61 (0.81)	*3.87 (0.63)* [a]	*–3.63*	*<.001*

Qualitative Responses on Intergenerational Information and Conversation Topics

Participants expressed strong interest in sharing hobbies, health tips, financial advice, travel experiences, and pet care—topics that may serve as effective entry points for intergenerational dialogue. These findings support the use of thematically structured discussion boards to guide user-generated content, providing a flexible yet focused environment for sustained and reciprocal interaction based on shared interests.

Phase 2: Define; UX Priorities and Design Implications

This phase translated the findings from phase 1 into concrete design priorities for the CoGen prototype. Quantitative and qualitative analyses revealed distinct generational differences in usability preferences, interaction styles, and motivational drivers.

Generational Differences in UX Preferences

Older adults emphasized clarity, structure, and accessibility. For instance, 73.4% (n=155) of older users selected "easy navigation" as a top priority compared to 52.6% (n=106) of younger users. They also rated the need for structured information layouts as significantly higher (mean 4.26, SD 0.62) than younger adults (mean 3.68, SD 0.81; t_{411}=–4.57; $P<.001$).

In contrast, younger adults favored engaging and dynamic elements. A total of 68.3% (n=138) of younger users prioritized "fun and dynamic design" compared to 41.2% (n=87) of older adults. They also showed greater interest in gamified features such as conversation streaks and badges (mean 3.92, SD 0.77) than older users (mean 3.41, SD 0.84; t_{411}=–3.21; P=.002).

Both groups expressed strong interest in structured discussion themes, though topic preferences varied. Older adults preferred themes such as health, pets, and daily life tips, while younger users leaned toward travel, hobbies, and financial advice. Open-ended responses supported these findings, with one older adult stating, "If I could talk about gardening or health tips, I would join more often," and a younger participant noting, "It's fun when it feels like social media, not a lecture."

Design Implications for the CoGen App

These generational patterns directly informed the prototype development of CoGen. The interface was designed to balance simplicity with visual appeal, offering a minimalist layout suited to older users while providing customizable elements to satisfy younger users' preferences. Accessibility features such as optional auditory cues (eg, notification sounds and voice-based guidance) were included to accommodate diverse needs without overwhelming the user. Thematic discussion boards organized around popular topics such as health, hobbies, and finance were implemented to support guided yet flexible interactions. Additionally, participatory components like conversation streaks, shared milestones, and feedback prompts were incorporated to foster social engagement and maintain user interest over time, especially among younger participants.

Phase 3: Develop; Finalized Features and User-Driven Adjustments

This phase focused on translating insights from earlier phases into a functional CoGen prototype through iterative development. Drawing on findings from phases 1 and 2, the design process integrated key generational preferences into the app's structure and functionality, followed by small-scale usability testing and refinement.

UI or UX Design and Wireframing Outcomes

Based on generational needs identified in earlier phases, the CoGen prototype was wireframed with a focus on accessibility for older adults and visual engagement for younger users. Older participants responded positively to features such as enlarged font sizes and high-contrast modes, frequently describing them as "easier to read" and "less tiring on the eyes." In contrast, younger users favored vibrant color schemes and modern layouts, stating that the design "felt more like a social space." The home screen—structured around 5 core functions—was perceived as intuitive and manageable across age groups. Additionally, the inclusion of a numeric level indicator with a horizontal progress bar was initially well received as a simple motivator, though later feedback suggested a need for more emotionally resonant visualizations.

Prototype Development and Feature Integration Outcomes

Prototype Features and User Feedback

The functional prototype incorporated features designed to foster sustained intergenerational engagement, informed by user needs identified in earlier phases. Feedback from older and younger participants highlighted differing priorities—older adults emphasized meaningful conversation and ease of use, while younger users favored interactivity and entertainment-driven engagement. Four key features were evaluated and refined based on user reactions.

Discussion Boards

Theme-based forums were designed around topics such as hobbies, travel, and health. This structure aimed to support older users' desire for organized, topic-specific discussions while offering younger users spaces for more casual and spontaneous interaction.

XSL•FO
RenderX

Conversation Triggers

Participatory elements, including prompts and quizzes, were introduced to ease the initiation of conversations. These features were intended to reduce entry barriers and encourage mutual storytelling, particularly among younger users who prefer playful engagement.

1:1 Friend Matching

A proprietary friend-matching feature was included to support more personalized interactions, especially for older adults who seek deeper, one-on-one conversations. This function was designed as an in-app alternative to social media integration, minimizing complexity and maintaining user privacy.

Generational Identity Icons

To promote age-aware interaction, generation-specific icons (eg, youth and older adult symbols) were added next to each user ID. This visual cue enabled users to identify the generational background of their conversation partners, fostering mutual understanding and respectful communication across age groups (Figure 2).

Figure 2. Generational identity icons: youth (left) and older adult (right).

Progression-Based Gamification

To encourage consistent app engagement, a light-touch gamification system was implemented. Users could earn points through participation (eg, posting or commenting), which contributed to levels and badges. The system was intentionally noncompetitive, reflecting older users' preference for collaborative over competitive dynamics.

Preliminary Usability Testing and Prototype Refinement

Preliminary Testing Outcomes

Initial usability testing with 8 participants (5 younger adults and 3 older adults) revealed critical insights that informed refinements to the CoGen prototype. Participants evaluated the app's overall appeal, navigability, and clarity of features. Several features were refined based on this feedback.

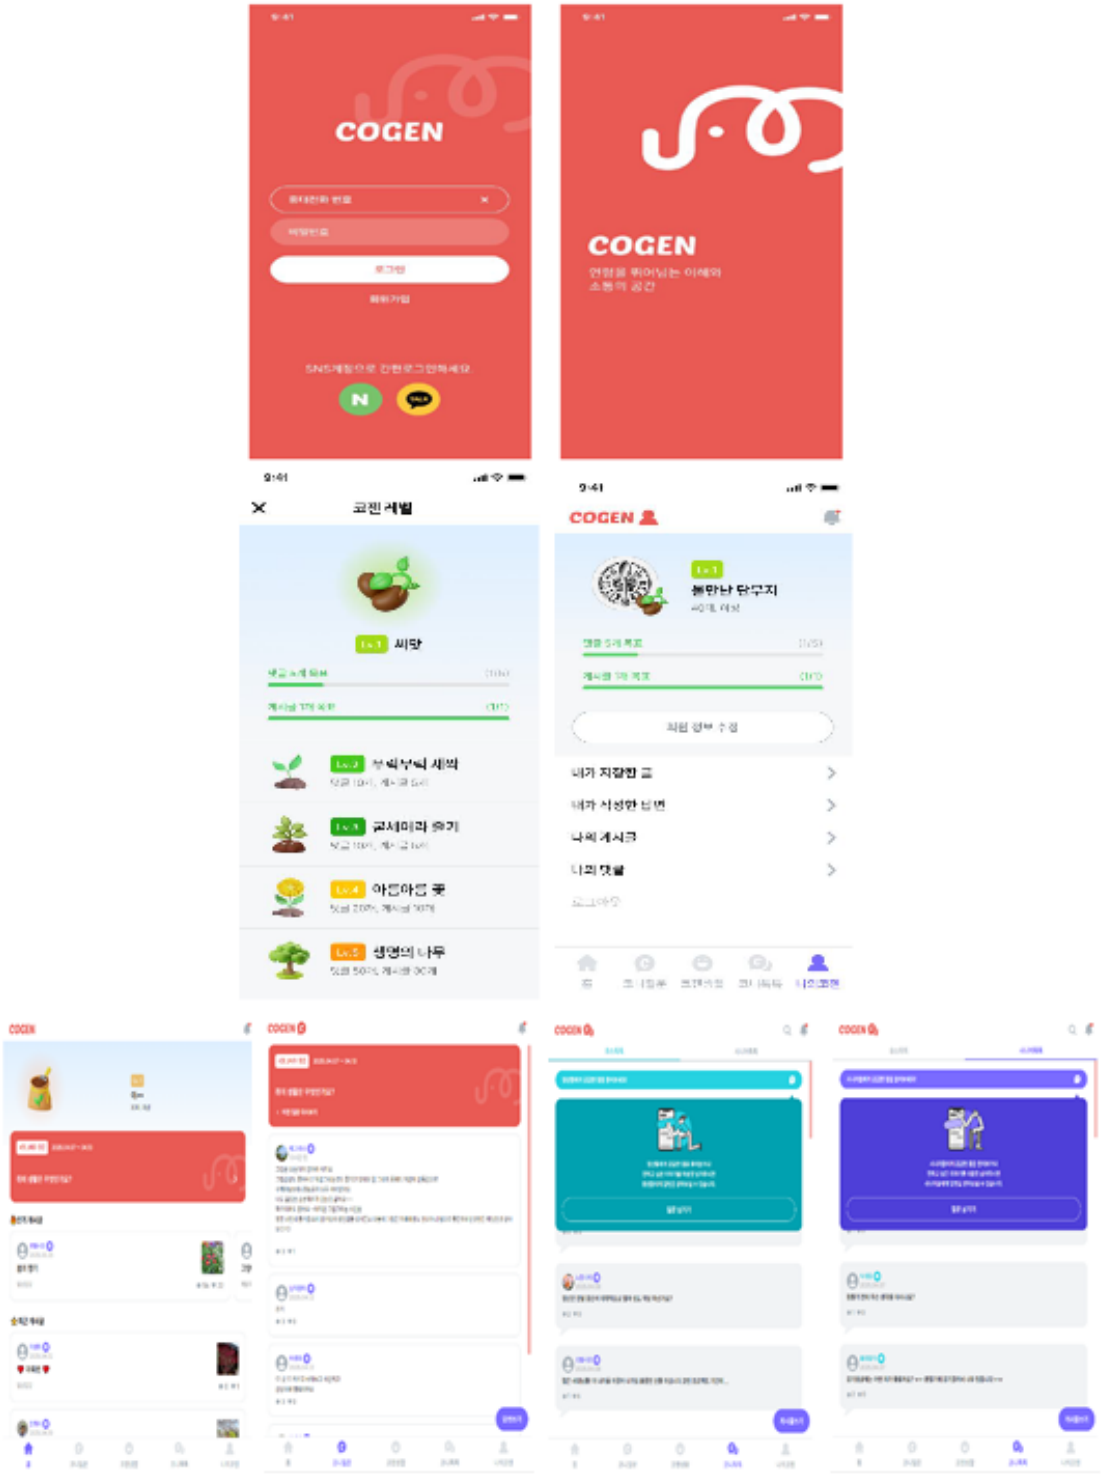
Branding and Identity

The app was named "CoGen" to reflect its focus on cogenerational engagement. The elephant logo—symbolizing wisdom, memory, and social bonds—resonated with participants' desire for meaningful and emotionally grounded experiences.

Weekly Question Feature

Participants favored prompts that evoked shared memories and generational perspectives. Based on this input, the "Weekly Question" was redesigned to include open-ended questions that invite storytelling and nostalgic reflection.

Engagement Indicator



The original numeric level and progress bar were perceived as impersonal. In response, the engagement indicator was redesigned into a metaphorical growth journey—a seed blossoming into a flower—offering a more intuitive and emotionally resonant representation of user progress, especially appreciated by older participants.

Tone of Feature Labels

Younger participants emphasized the importance of a conversational tone. In response, feature names were modified to be more inviting and playful. For example, the discussion board was renamed "CoGen Life," and the weekly prompt became "Coni's Question." These refinements finalized the CoGen prototype by incorporating user-driven feedback into its core features and design, setting the stage for real-world testing in the deliver phase (Figure 3).

XSL•FO
RenderX

Figure 3. Final version of the CoGen app interface, displaying (from top to bottom): the login screen, level indicator, home screen with "Coni's Question," and "Cogen TalkTalk" features.

Phase 4: Deliver; Real-World Testing Outcomes and Final Revisions

User Engagement Patterns Based on Activity Log Data

To assess the feasibility and user engagement of the CoGen platform during the 2-week intervention, activity log data were analyzed. Participants logged into the app an average of 31.43 (SD 10.56) times, with a total of 2975 posts and comments generated—equivalent to an average of 76.28 (SD 20.13) entries per user. This indicates both frequent access and active participation in intergenerational discussions.

Engagement with in-app features—such as quizzes and feedback prompts—was also high, with 80.3% (n=31) of users completing them at least once. The dropout rate remained low at 5.3% (n=2), and activity levels were stable throughout the period, suggesting sustained engagement.

XSL•FO
RenderX

UX: Functional Satisfaction

Participants reported moderate to high levels of comfort in cross-generational conversations (mean 3.62, SD 0.81) and relatively high overall satisfaction (mean 3.82, SD 0.76) with intergenerational conversations via the app.

Regarding emotional engagement, users reported high levels of enjoyment (mean 3.74, SD 0.85) and happiness (mean 3.79, SD 0.77), with perceived interest being the highest measured variable (mean 4.05, SD 0.79). While the perceived sense of similarity or affinity was moderate (mean 3.46, SD 0.94), it still indicated a positive trend in user closeness.

Conversely, ease of access received a comparatively lower rating (mean 2.59, SD 0.88), indicating potential navigation difficulties. Similarly, perceived understanding of content was moderate (mean 3.23, SD 0.71), suggesting opportunities for optimizing content presentation and guidance.

Impact on Perceived Necessity, Use Intentions, and Recommendation Willingness

No statistically significant changes were observed in participants' perceived necessity (t_{37}=1.58; *P*=.13; *d*=0.45) or intention to continue using the app (t_{37}=0.81; *P*=.43; *d*=0.25; Table 2). However, perceived necessity was already high before the intervention (mean 3.70, SD 0.73; mean 4.05, SD 0.83), suggesting a potential ceiling effect. Intention to use remained moderate but stable (mean 3.30, SD 0.86; mean 3.50, SD 0.69). Participants also showed a moderate willingness to recommend the app (mean 3.55, SD 1.01), reflecting its perceived value in fostering cross-generational communication.

Table 2. Changes in key variables before and after the intervention (n=39).

Variable	Pre, mean (SD)	Post, mean (SD)	*t* test (*df*=37)	*P* value
Intergenerational interaction	2.85 (1.04)	3.85 (0.75)	–3.82	.001
Intergenerational understanding	1.42 (0.40)	3.02 (0.72)	–10.26	<.001
Perceived social support	3.03 (0.53)	3.85 (0.78)	–5.53	<.001
Depressive symptoms	1.85 (0.36)	1.82 (0.37)	0.4	.69
Perceived necessity of the app	3.70 (0.73)	4.05 (0.83)	1.58	.13
Intention to continue using the app	3.30 (0.86)	3.50 (0.69)	0.81	.43
Willingness to recommend the app (post)	—[a]	3.55 (1.01)	—	—

[a]Not available.

Changes in Intergenerational Communication: Interaction and Understanding

Paired-sample 2-tailed *t* tests revealed statistically significant improvements in both intergenerational interaction and understanding after the 2-week intervention (Table 2). Intergenerational interaction increased significantly (t_{37}=–3.82; *P*=.001; *d*=0.52), signifying more frequent and natural conversations. Intergenerational understanding also showed a substantial and statistically significant improvement (t_{37}=–10.26; *P*<.001; *d*=1.16), indicating that the app effectively enhanced empathy toward different generational perspectives.

Impact on Psychosocial Outcomes: Social Support and Depressive Symptoms

Perceived social support significantly increased following 2 weeks of CoGen app use (t_{37}=–5.53; *P*<.001; *d*=0.66), suggesting that the app strengthened emotional bonds (Table 2). In contrast, depressive symptoms showed no statistically significant change (t_{37}=0.40; *P*=.69; *d*=–0.06), implying that while social connectedness improved, immediate effects on emotional well-being were not observed within the short time frame.

Qualitative Insights From the FGI

To supplement the survey findings, an FGI was conducted, revealing that participants from both age groups found the app emotionally enriching and socially meaningful. They especially appreciated the structured yet open environment that supported respectful and thoughtful dialogue.

Mutual Adaptation and Respectful Communication

Participants reported that their attitudes toward intergenerational communication shifted positively during the 2-week period. Younger adults initially expressed concern about potential generational conflict but noted that the platform encouraged the use of respectful and considerate language. In turn, older adults also exercised caution to avoid appearing condescending or outdated, demonstrating a shared effort to communicate with mutual respect. This digital form of etiquette was recognized by both groups as an important cultural adjustment, especially when engaging with unfamiliar age cohorts.

Psychosocial Gains and Shifting Perceptions

The app served as a space where younger users could seek emotional support, practical advice, and broader perspectives from older participants. Many reported gaining comfort, validation, and a renewed appreciation for the insights of older generations. Meanwhile, older adults described feeling revitalized by the interactions, often expressing surprise at the empathy and openness of younger users. They also viewed the app as a rare opportunity to reflect on their own life stories while learning about new cultural trends and digital practices.

Common Recognition of Generational Diversity

Participants across age groups highlighted how the experience disrupted stereotypical perceptions. Younger users came to recognize the diversity among older adults, moving beyond

XSL•FO
RenderX

generalized assumptions. Conversely, older participants reported gaining a more nuanced understanding of younger people's struggles and viewpoints, fostering empathy and solidarity.

Conditions for Sustained Use

Despite the positive feedback, participants noted several functional improvements necessary for long-term engagement. Many called for real-time chat features, simplified login processes, and improved content navigation to support more spontaneous and efficient communication. Additionally, participants expressed that future iterations of the app should focus on enabling users to "gain something meaningful" through dialogue—such as wisdom, emotional encouragement, or practical advice. Both groups emphasized the need for structured prompts and shared interests (eg, health and hobbies) to sustain motivation.

Design Suggestions

Users also offered specific UI or UX recommendations, including expressive elements like emojis or stickers, and personalized notification systems. These enhancements were seen as important for maintaining emotional resonance and playful interaction across generations, supporting more engaging and expressive communication for all users.

Discussion

Principal Findings

This study provides preliminary evidence that the CoGen app may contribute to improvements in interaction, perceived social support, and comfort in cross-generational conversations. These results align with previous findings, indicating that intentional and structured opportunities for age-diverse contact can reduce prejudice and strengthen social bonds [5,7]. Specifically, the observed improvements in dialogue across generational lines are consistent with the principles of the contact hypothesis, suggesting that digital platforms hold potential spaces for meaningful engagement when designed to facilitate regular and constructive exchanges among different age groups.

Improvements in perceived social support align with previous research, indicating that older adults benefit from increased digital communication by maintaining social ties and mitigating feelings of isolation [36,37]. Younger adults also reported gaining fresh perspectives and insights from older generations, suggesting that positive, bidirectional exchanges can foster empathy and reduce generational stereotyping. This finding is aligned with prior studies, highlighting the significance of qualitatively rich interactions over mere contact frequency in achieving prejudice reduction and mutual understanding [8].

Furthermore, the study's results suggest that participants experienced an increased sense of comfort and satisfaction in conversations with individuals from different generations. These findings tentatively support the view that intergenerational communication can be nurtured beyond physical copresence, especially as digital literacy expands among older adults. Although ease of access scored relatively lower, it underlines the importance of continued efforts to design age-friendly digital interfaces that reduce navigation barriers and enhance older adults' confidence in adopting new technologies [38]. Participants specifically emphasized the need for auto-login features, clearer content categorization, and easier navigation to locate new or popular posts. Older adults in particular faced challenges in understanding the interface layout and expressed a desire for simplified, intuitive pathways to access discussions. To enhance emotional engagement, suggestions included incorporating expressive elements such as emojis and stickers.

A key emergent finding from the FGIs was the positive reception of the generational badge feature, which visually distinguished older and younger users. Despite initial concerns about reinforcing age-based divisions, many participants noted that it surprisingly encouraged respectful and age-sensitive communication, even in anonymous interactions. Younger users, in particular, reported feeling a greater sense of obligation to maintain courtesy, while older users appreciated being addressed with politeness. These findings suggest that CoGen's features organically aligned with Korean cultural norms rooted in Confucian values, such as intergenerational respect and age-based etiquette. Rather than merely enabling conversations, the app fostered a communicative atmosphere marked by mutual consideration—an emergent property shaped by both interface design and cultural expectations.

Moreover, younger participants shared in the FGIs that the app served as a psychologically safe space to seek advice or express concerns they might hesitate to bring up in face-to-face settings (eg, with parents). In contrast to offline environments where social expectations and *noonchi*—the culturally embedded sensitivity to others' feelings—can act as barriers, and the app allowed for open and honest exchanges without fear of breaching generational decorum. This illustrates how CoGen's design facilitated not just communication, but culturally meaningful connection, by providing users with both symbolic cues for respectful interaction and a space that eased the emotional burden of navigating age hierarchies.

In contrast to many existing digital interventions that often emphasize structured prompts or 1-way content delivery, CoGen was specifically designed to support user-generated content and dynamic, reciprocal communication between generations. Most prior platforms still lack robust mechanisms for sustained, bidirectional interaction, and despite increasing digital literacy among older adults [13,14], many fall short in addressing the nuanced interaction needs and co-design preferences of both younger and older users. Addressing this critical gap, CoGen positions itself as a hybrid model bridging formal programs and informal social interaction—an area still underdeveloped in the digital aging landscape. The app integrates both synchronous and asynchronous communication, encourages user-generated content, and offers structured prompts to support long-term engagement. This approach is strongly reinforced by CoGen's adherence to principles of inclusive co-design and iterative user-centered development [15]. As literature increasingly highlights the digital literacy of older adults [39] and the importance of inclusive co-design [40], CoGen specifically reflects these principles through its iterative development and participatory UX testing. These practices not only improve usability but also enhance users' sense of ownership and

XSL•FO
RenderX

emotional attachment to the platform, further supporting long-term adoption.

Despite its promising outcomes, the relatively lower usability scores underscore the need for improved accessibility. Participants emphasized visual clarity, reduced click-depth, and features like auto-login and richer emotional expression tools. These findings reinforce the importance of UCD and inclusive codevelopment, ensuring that intergenerational digital tools remain not only functional but also emotionally engaging and culturally responsive. CoGen's iterative design process and hybrid communication structure offer a promising model—particularly in societies like Korea, where age-based etiquette shapes interaction norms—by fostering respectful and psychologically safe exchanges across generations.

Theoretical and Practical Implications

The structured features of CoGen—such as discussion boards, quizzes, and shared achievements—appeared to reduce social distance and foster mutual understanding across generations. These affordances reflect core principles of empathy-building and cooperative engagement found in offline intergenerational programs [7,41], while offering scalable digital alternatives. Although the contact hypothesis was not directly tested, several of its key conditions—such as equal status, shared goals, and structured interaction—were naturally embedded in the design of CoGen. These elements may have contributed to the observed improvements in mutual understanding and reduction of age-based bias. This highlights the value of grounding digital intervention development not only in UCD principles but also in theoretically informed frameworks, which together can enhance both usability and psychosocial outcomes.

As digital connectivity expands globally, platforms like CoGen hold promise for supporting intergenerational relationships, despite physical separation. This function aligns with models of digital age-friendly communities [38] and aging-in-place strategies [42], both of which emphasize the role of sustained social engagement in promoting healthy aging. By enabling remote yet meaningful interactions, CoGen represents a digital extension of the World Health Organization's vision of inclusive, communicative, and socially connected environments for older adults [43].

The observed improvement in perceived social support reinforces previous findings that emotionally resonant communication enhances older adults' well-being and cognitive engagement [44,45]. CoGen's focus on sustained dialogue may thus contribute to improved life satisfaction and emotional resilience. In line with World Health Organization guidelines [42], promoting regular digital interactions through accessible platforms can also support independent living and active aging.

In the Korean context, where Confucian values such as filial piety and age-based respect remain culturally salient, CoGen's emphasis on structured, respectful dialogue aligns well with traditional norms of intergenerational harmony. Participant feedback indicated that the platform created a safe space for expressing concerns—especially for younger users—while maintaining cultural expectations around age hierarchy. This suggests the culturally adaptive potential of digital tools to bridge generational gaps by balancing modern communication and traditional values.

Finally, design feedback points to future opportunities for enhancing cross-generational engagement. Participants emphasized the value of algorithm-based matching systems to facilitate interest-based dialogue, as well as the need for simplified UI or UX for older adults. Incorporating expressive features such as emojis and stickers may further support engagement among younger users. These insights highlight the importance of participatory, multigenerational design frameworks in creating emotionally inclusive and functionally accessible digital environments.

Limitations and Future Research

Despite its promising findings, this study has several limitations that offer clear directions for future research. First, the sample size was relatively small, and the 2-week intervention period was short. These factors may limit the generalizability of our findings and the understanding of long-term engagement. Future research should involve large-scale, longitudinal studies to track sustained engagement and relational outcomes over an extended period. Such studies would allow us to verify if the observed benefits persist and evolve across more diverse cultural and demographic contexts.

Second, our design could be enhanced by incorporating real-time interaction and deeper personalization. While the app effectively supported asynchronous communication, participants expressed a strong desire for synchronous features like direct messaging. Moreover, to move beyond basic usability and better capture the emotionally sensitive nature of intergenerational dialogue, future design cycles will integrate formal tools from design thinking. Specifically, we plan to use empathy maps and user journey visualizations to inform the development of more sophisticated features, such as adaptive dialogue prompts and sentiment-aware interaction flows, thereby creating a more responsive and emotionally resonant UX.

Third, our reliance on self-reported measures could be complemented by objective data. While valuable, self-reports on comfort or connection may not capture the full picture of user behavior. Future studies could create a more holistic understanding by integrating use analytics—such as the frequency, duration, and content analysis of interactions—with self-report data to triangulate findings on how digital communication truly evolves.

Finally, several key constructs were measured using single-item indicators. This was a deliberate methodological choice grounded in both practical and theoretical considerations. Rather than combining conceptually distinct items into composite scores, we retained item-level granularity to capture feature-specific responses that could directly inform app development. This approach aligns with prior research indicating that single-item measures can be valid and useful, especially when constructs are concrete, unidimensional, and behaviorally specific [28]. Although the items were carefully adapted from previously validated multi-item instruments, we acknowledge that multi-item scales generally offer higher reliability. Future studies should incorporate established multi-item measures to

XSL•FO
RenderX

validate the findings and enable more robust analyses, such as latent variable modeling, to advance theoretical understanding. By addressing these limitations, future research can build upon our work to design inclusive digital interventions that foster meaningful connections and contribute to the broader goals of healthy aging and creating age-friendly societies.

Abstract

Background: In Latin American countries, the prevalence of noncommunicable diseases has increased rapidly in recent decades. Mobile health (mHealth) apps are now widely available at low cost and are easy to implement, offering an opportunity to encourage healthy lifestyles in older adults. However, at present, there are no mHealth apps that integrate multidomain healthy lifestyle interventions specifically adapted for older adults in Chile.

Objective: This study aims to describe the development and validation of NeoMayor, an mHealth app designed to promote healthy lifestyles as well as cardiovascular and brain health in older adults in Chile.

Methods: NeoMayor was developed iteratively with feedback from users and input from a multidisciplinary team of clinicians, researchers, and software developers. Using lean user experience methodology, we ensured user involvement throughout the design and validation process. The research was conducted in 2 phases. In the design and development phase, we created and adapted evidence-based recommendations. In the validation phase, we conducted a pilot study to assess usability, adherence, and cardiovascular health (CVH). A total of 60 functionally independent and cognitively healthy participants used the NeoMayor app

XSL•FO
RenderX

for 2 months. Clinical and cognitive assessments were conducted before and after app use. We held 26 cocreation sessions with users, consulted experts, performed a literature review, and collaborated with a team of app developers to create a functional prototype.

Results: The mean age of the participants was 71 (SD 15) years, and 85% (51/60) were female. Participants had an average of 9.8 (SD 3.6) years of education. At the end of the 2-month intervention, usability testing indicated high engagement and adherence, with participants using the app for an average of 6.6 (SD 11.85) minutes per day twice a week. Improvements were observed in global CVH, with the mean Life's Essential 8 CVH index score increasing from 64 (SD 10) to 68 (SD 11; $P<.001$). Reductions were noted in systolic blood pressure (10 mm Hg) and waist circumference (7 cm), along with increased high-density lipoprotein cholesterol levels. Participants also showed improvements in self-reported physical activity and diet, higher scores on the Short Physical Performance Battery, and faster performance times on the sit-to-stand and gait speed tests. The app was optimized for broad compatibility with Android devices, safe data collection and storage, and compliance with data privacy regulations following good clinical practices. The final product is ready for testing in a randomized controlled trial.

Conclusions: This study represents the first initiative in Chile to develop and validate an mHealth app to promote healthy lifestyles as well as cardiovascular and brain health in older adults, offering an effective, accessible, and affordable solution for promoting healthy aging in Latin American countries.

mobile health; mHealth; healthy aging; noncommunicable diseases; brain health; dementia prevention

Introduction

Background

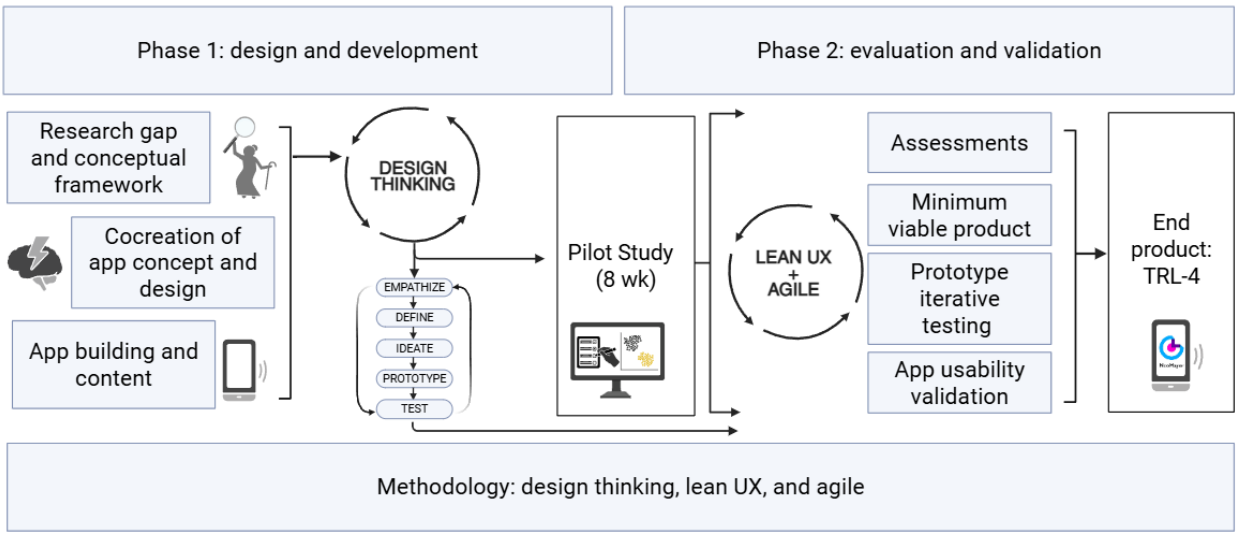
Accelerated population aging in recent decades, particularly in low- and middle-income countries, has led to an increase in the prevalence of noncommunicable diseases (NCDs) in adults [1,2]. Among people aged ≥70 years, cardiovascular diseases and dementia are now the leading causes of disability [3,4]. In Latin America and the Caribbean, dementia prevalence is projected to rise by 200% to 300% over the next 30 years [5]. Globally, an estimated 80% of cardiovascular disease risk factors are potentially modifiable [5,6]; in Latin America and the Caribbean, approximately 54% of dementia risk factors are also potentially modifiable [7]. This highlights the urgent need for preventive initiatives aimed at reducing the burden of cardiovascular diseases and dementia [8].

Increasing evidence supports the effectiveness of multidomain healthy lifestyle interventions—including physical activity, healthy diet, cognitive stimulation, social engagement, and health control—for treating and preventing NCDs, reducing stroke risk, and enhancing cognitive reserve [9-11]. In Chile, despite the existence of public primary prevention programs for NCDs, there has been a significant increase in the prevalence of diabetes and obesity in the past decade [12,13]. These unfavorable outcomes of Chilean prevention campaigns could be attributed to their limited outreach; low population adherence; and multiple implementation challenges [14], including health care inequities [15].

To address this implementation gap in health promotion, mobile health (mHealth) platforms have emerged as promising tools. mHealth encompasses medical practices supported by mobile devices such as smartphones, tablets, and wearable sensors. These technologies are easily accessible, widely available, have affordable costs, and are easily implementable [16-18]. Recent evidence supports the effectiveness of web-based and smartphone interventions in promoting cardiovascular health (CVH) in adults [16,19], providing insights for the design of user-friendly and accessible health technologies for older adults [20,21]. In high-income countries, numerous initiatives have been developed to promote healthy lifestyles through the use of mHealth [22]. Although many of these mHealth solutions can be easily adopted by young adults, older adults face several barriers to using mHealth, reducing its effectiveness in this demographic group [21,23]. These barriers include lower digital literacy and technological skills [24], physical and cognitive limitations [21,25], lack of trust and privacy concerns [26], and cost and technology access [23]. Regarding technology access, in Chile in 2022, 65% of older adults owned a smartphone (rising to 82% among people aged 60-69 y), and 60% had home internet access (rising to 90% among those living with younger people) [27-30]. Educational level is the most important factor related to technology use in Chile's older adults, possibly associated with technology use skills and technology access [29]. Therefore, the design of mHealth tools targeting older adults should incorporate a user-centered approach that accounts for their physical and cognitive capacities as well as their technological skills [31]. Prior research recommends solutions that are intuitive, easy to navigate, supported by health care professionals, and accessible, for example, apps with large interfaces and simplified interactions [32,33]. However, in Chile, despite relatively good smartphone access, there are currently no mHealth solutions for promoting healthy lifestyles that are adapted to older adults. Our main hypothesis was that health care content delivered through a mobile app—cocreated using participatory design methodologies and based on a multidomain intervention approach—would be easy to use and would improve CVH in older adults.

Objectives

We aim to describe the development and validation of NeoMayor, a mobile app cocreated with older adults to promote healthy lifestyle habits, support NCD management, and enhance cardiovascular and brain health in this population.



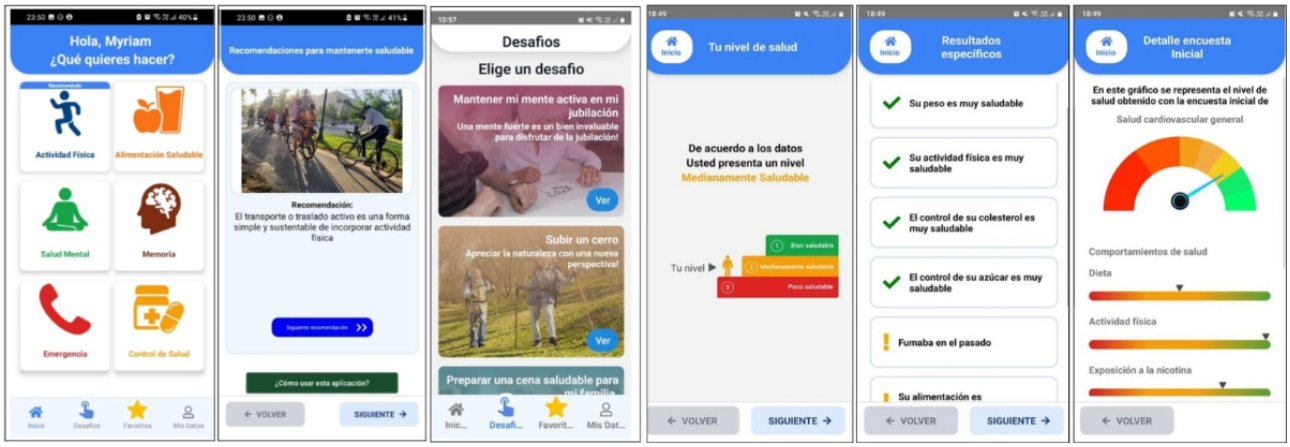
XSL•FO
RenderX

Methods

Study Design

The development and validation of NeoMayor were planned using a user-centered design approach [31]. The study was conducted in 2 phases: phase 1 (design and development with older adults, guided by lean user experience [UX] methodology) and phase 2 (prototype validation through a 2-mo pilot study in which participants used NeoMayor on their smartphones). The entire process lasted 26 months, from February 2022 to April 2024 (Figure 1 [34]).

Figure 1. The 2 phases of the NeoMayor app study. RCT: randomized controlled trial; TRL: technology readiness level; UX: user experience. Created with BioRender [34].



Phase 1: Design and Development

The NeoMayor app was developed to promote healthy lifestyles as well as cardiovascular and brain health in older adults in Chile. From the outset, the app was designed to provide personalized lifestyle recommendations based on each user's baseline health status. Its architecture includes a secure electronic database compliant with clinical data privacy standards [35].

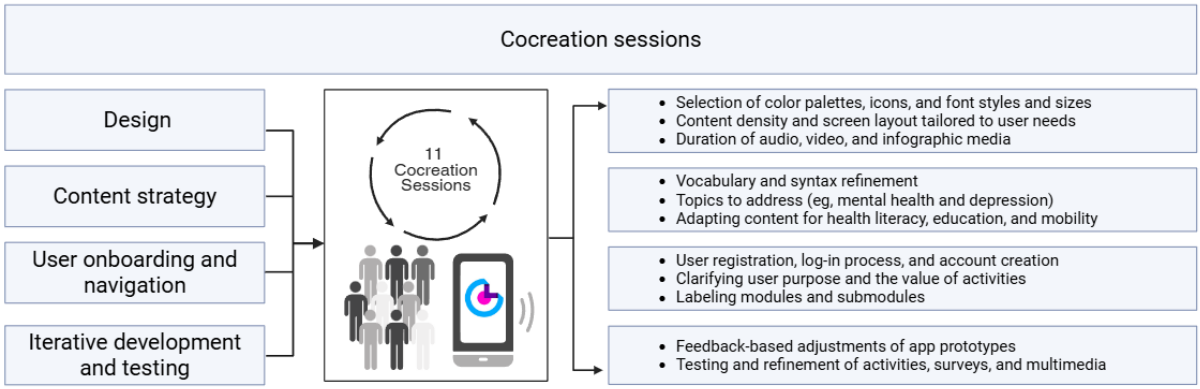
The clinical multidisciplinary team, which included experts in neurology, geriatrics, physical therapy, nutrition, psychology, and biomedical sciences, led the creation of the NeoMayor app and collaborated closely with software developers to design and program the software. Using a design thinking process, we first identified user needs (empathy approach) and analyzed existing health technologies (definition approach). After gathering theoretical information, hypotheses were formulated, and proposed content from the clinical teams was validated by expert peers. Content creation was based on multiple guidelines, such as the World Health Organization (WHO) Integrated Care for Older People (ICOPE) handbook [36], the WHO guidelines for risk reduction of cognitive decline and dementia [36,37], the Chilean Cardiovascular Health Program [38], and the American Heart Association's Life's Essential 8 [39]. Life's Essential 8 provides self-care recommendations to manage 8 modifiable risk factors for cardiovascular disease by adopting healthy lifestyle behaviors: eat better, be more active, quit tobacco, get healthy sleep, manage weight, control cholesterol, manage blood glucose, and manage blood pressure. Each risk factor can be measured on a semiquantitative scale from 0 (poorest) to 100 (healthiest), with the average corresponding to the global CVH index [25]. We selected the CVH index as our primary outcome because it has been validated as a predictor of cardiovascular events [40], brain health, and dementia risk [41]. In addition, because it comprises only modifiable risk factors, the CVH index can change over time, making it suitable for tracking progress in CVH [39]. We adapted the CVH index into a mobile questionnaire that provides feedback on health status and tailors recommendations accordingly. Participants are categorized as optimal (score: 79-100), moderate (score: 50-79), or poor (score: <50), using graphic images (Figure 2A). The app recommends periodic assessments to monitor changes in CVH over time.

XSL•FO
RenderX

Figure 2. Screens of the NeoMayor app. (A) Categorization of cardiovascular health. (B) Initial menu and goal-directed navigation.

The lifestyle content is structured into 6 modules: physical activity, healthy eating, mental health [42,43], memory, health control [6,38,39] (Figure 2B; based on guidelines from the WHO [44,45], the Chilean Ministry of Health [38], and Life's Essential 8 [39]), and "emergency" (incorporated at the request of participants, who wanted quick access to emergency numbers and official resources on legal and health benefits). Content is delivered through video, audio, and educational images. Currently, the app features a repository of 33 videos, each approximately 5 minutes long; 30 audio recordings, each lasting 15 minutes; and 50 educational images. The app includes 2 navigation options: the first is free navigation, in which users can choose from 6 modules on the menu screen; and the second is challenge-based navigation, in which users set a specific goal (eg, "being able to climb a hill"), prompting customized, targeted training suggestions that combine content from multiple modules over a defined period (Figure 2B).

The next step was NeoMayor's iterative refinement and development, guided by a combination of lean UX [46], agile [47], and design thinking methodologies [48]. The selection of lean UX and design thinking was intentional, given their strong alignment with the specific challenges and needs of older adults. These user-centered frameworks facilitate continuous feedback integration, empathy-based exploration of UX, and rapid prototyping, all of which are essential for optimizing usability and ensuring the app's relevance for older adults with medium to high digital literacy [49]. Lean UX enabled rapid iteration to refine accessibility features such as color contrast, touch target size, and interface clarity [50]. In parallel, design thinking fostered cocreation through structured empathy and ideation stages, ensuring that the final product resonated with the lived experiences of older users [51]. Low-fidelity prototypes of the NeoMayor app were iteratively refined to emphasize accessibility, intuitive navigation, and content clarity.



The development team followed agile Scrum practices, with biweekly sprints and sprint retrospectives involving clinicians and software engineers. Tasks were managed using Trello, and code repositories were version-controlled using Git and GitHub. Continuous integration was achieved using GitHub Actions, which facilitated automated testing and deployment to staging environments before release to the Play Store.

As part of this cocreative and coconstructive process [52], we implemented several interface adjustments, including high-contrast colors, large touch targets, simplified gestures, and accommodations for motor and cognitive needs. This combined approach enabled the development of a tool that is not only clinically robust but also practical, intuitive, and acceptable to older adults across a spectrum of technological familiarity. Classification algorithms and user surveys further guided customization of the UX.

We held 26 cocreation sessions with 30 older adults (female: n=21, 70%; male: n=9, 30%; age: range 60-75 y) to validate the language, content, and user interface elements (Figure 3 [53]). These sessions provided critical feedback on layout, navigation, and instructional clarity, which shaped the app's design.

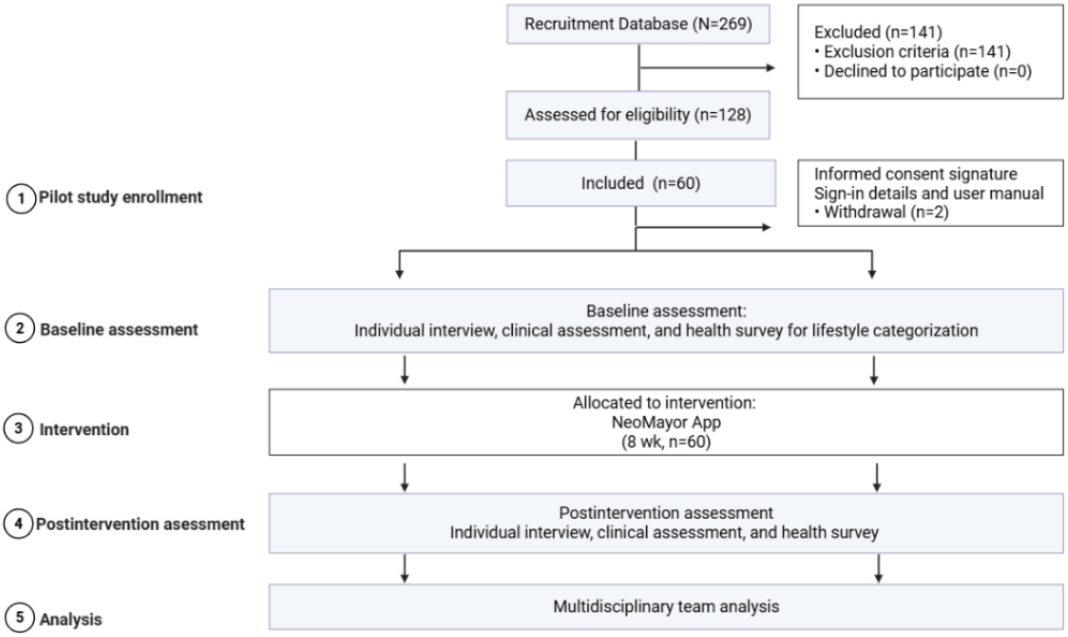
XSL•FO
RenderX

Figure 3. The NeoMayor iterative participative design process. Created with BioRender [53].

After the content was finalized, the software development team generated both front-end and back-end components. The app was built using the open-source React Native framework for cross-platform compatibility on Android devices and a Django backend on servers maintained by the Web Intelligence Center for secure data handling. Once compiled with Gradle, the NeoMayor app was validated through the Google Play Console and released on the Google Play Store as a downloadable app.

The app deployment was managed through the Google Play Console, with version tracking and staged rollouts to monitor performance and crash reports. Updates were issued using semantic versioning (eg, v1.0.0) and were preceded by internal QA cycles. A dedicated beta testing group of older adults provided feedback on each release candidate.

Throughout the iterative design process, the team (users, clinicians, designers, and engineers) validated the app's content, navigation flow, and overall UX. As suggested by pivotal software development literature [54], we conducted micro-usability tests to evaluate ease of navigation, icon comprehension, and text readability. These tests provided insights on interface improvements, leading to high-contrast designs, labeled icons, and enlarged touch targets (Figure 3). Thus, the NeoMayor app was evaluated at the prototype level in terms of usability, functionality, and efficacy, achieving positive results across all evaluated domains. After 12 months, we obtained a minimum viable product: a mobile app that classifies users according to CVH and mobility and offers personalized content organized into 6 modules.



Phase 2: Evaluation and Validation (Pilot Study)

Participants

We recruited functionally independent older adults aged 60 to 77 years living in Santiago, Chile, who were able to read, write, and use technology (digital skills sufficient to independently use a mobile smartphone; Figure 4 [55]). Participants were recruited through voluntary sign-up notices from ambulatory programs at the Hospital Clínico de la Universidad de Chile, civil society representatives of the Servicio Nacional de Personas Mayores, and the advisory committee of the Instituto Nacional de Geriatría. Printed invitation posters were also distributed in various community and public spaces across Santiago. To qualify for inclusion, participants were required to have a moderate to high cardiovascular risk, defined as the presence of at least three of the following cardiovascular risk factors: (1) hypertension (blood pressure >140/90 mm HG or receiving pharmacological treatment), (2) diabetes or fasting glycemia level of >100 mg/dL, (3) obesity (BMI ≥30 kg/m^2), (4) current smoking status, and (5) elevated total cholesterol level (>240 mg/dL). In addition, participants had to be free of dementia, defined as a total score of ≥8 on the memory, fluency, and orientation test, which is a 5-minute screening test for cognitive decline validated for the Chilean population [56]. The exclusion criteria included significant impairments in independent mobility, substantial auditory or visual impairments, neurodegenerative diseases, untreated psychiatric disorders or psychological diagnoses, and the presence of a severe or terminal illness. Participant recruitment began 1 month before the initiation of the pilot study. Different participants were involved in the 2 phases of the NeoMayor design: those engaged in cocreation sessions, design, and development (n=30), described in the previous section; and those who participated in the pilot study (n=60).

XSL•FO
RenderX

Figure 4. The NeoMayor pilot study flowchart. Created with BioRender [55].

Pilot Methodology

A database of 269 individuals who expressed interest in participating in the pilot study was established, and we contacted 128 (47.6%) by telephone to assess their eligibility based on the inclusion and exclusion criteria. Of these 128 individuals, 62 (48.4%) met the inclusion criteria. Subsequently, 2 (3%) of these 62 participants withdrew voluntarily for personal reasons, leaving a final sample of 60 (97%) participants. Participants then underwent face-to-face interviews and received a complete clinical, physical, and cognitive assessment at baseline and after the 2-month NeoMayor app use period. Trained professionals (physicians, physical therapists, and psychologists) performed the assessments. For consistency, the same evaluator performed the pre- and postpilot assessments, blinded to adherence results. The clinical assessment lasted approximately 1 hour and included a structured interview to collect demographic and sociocultural data, current health conditions, and medication use; measurement of biometric data, including anthropometry; assessment of blood pressure; blood tests (glucose and lipid levels); and structured questionnaires to assess lifestyle habits adapted for Latin America [11]: the Pittsburgh Sleep Quality Index [57], the Mediterranean-DASH Diet Intervention for Neurodegenerative Delay Diet Scale [58], and the International Physical Activity Questionnaire [59]. By using these data, we calculated the CVH index, including the total score and 8 subscores [39]. The cognitive evaluation included the administration of the Mini-Mental State Examination [60]; the Geriatric Depression Scale [61]; self-perception of memory scales (MCA) [62]; and the memory, fluency, and orientation test, which is a 5-minute screening test for cognitive impairment [56]. The physical performance assessment included the use of the handgrip test; the 5-repetition chair stand test, as recommended by the WHO ICOPE handbook [36]; the timed up and go test (both simple and dual tasks); and the Short Physical Performance Battery (SPPB) [63].

The NeoMayor app was installed on participants' smartphones, and they received both training in its use and a printed user manual. For those who did not have a smartphone, the project provided one. All participants used the NeoMayor app for 2 months. In case of significant problems with the app or smartphones, assistance was provided. After 3 weeks, we contacted half of the users (30/60, 50%) via telephone to address any problems in using the app. Finally, to evaluate the pilot implementation, we used the RE-AIM (Reach, Effectiveness, Adoption, Implementation, and Maintenance) [64] methodology. At the conclusion of the pilot study, all participants completed surveys to provide qualitative data about usability, user satisfaction, and content preferences. Further assessments will be included in a randomized controlled trial (RCT).

Data Management

The data were collected in a REDCap (Research Electronic Data Capture; Vanderbilt University) database. All data analyses were conducted using R (version 4.0.0, 64-bit; R Foundation for Statistical Computing) and SPSS software (version 27.0; IBM Corp). After checking the distribution of the data, we performed descriptive statistics. Continuous variables were expressed as mean (SD) and 95% CI, and categorical variables were reported as percentages and 95% CIs. The potential effect of NeoMayor app use on participants' CVH was measured using a paired sample *t* test comparing the CVH index before and after app use (within-group analysis) [65]. We calculated the effect size of within-group changes by using Cohen *d*.

Finally, we categorized the participants according to whether they showed improvement. Improvement was defined as significant if the difference between the CVH index before and after app use was >1 SD from the baseline CVH index. We then performed a binary logistic regression to establish which variables were associated with the improvement, using improvement (yes or no) as the dependent variable, with age, educational level, sex, baseline depressive symptoms, and baseline CVH index as independent variables.

Ethical Considerations

The study was approved by the scientific and research ethics committee of the Hospital Clínico de la Universidad de Chile (Acta 36, OAIC 1220/21, FONDEF ID21I10096). All study participants provided signed informed consent.

Results

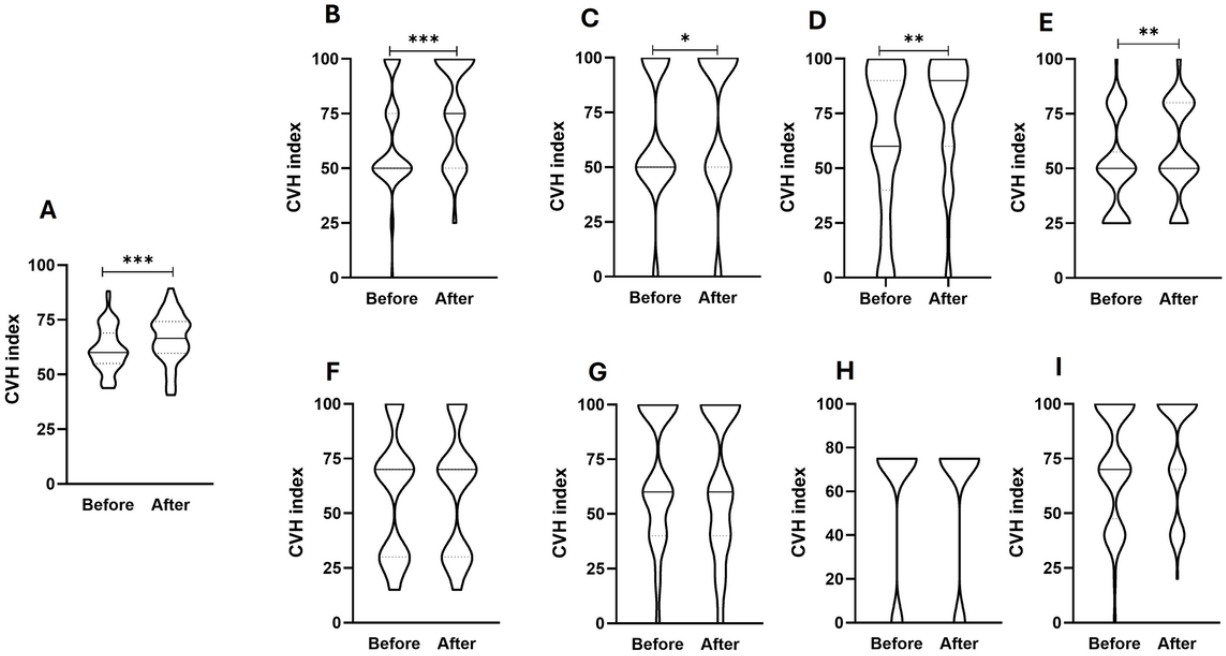
Demographic and Biomedical Data

A total of 60 older adults were included in the pilot study. The participants' mean age was 71 (SD 15) years, and they had an average of 9.8 (SD 3.6) years of education. Of the 60 participants, 51 (85%) were female. Most of the participants used the internet at home (57/60, 95%) and owned an Android smartphone (49/60, 82%). We provided a smartphone to 11 (18%) of the 60 participants (n=7, 64% owned an iPhone; n=4, 36% did not have their own smartphone, or their smartphone was too old). The baseline characteristics of participants are detailed in Table 1.

Table 1. Participants' baseline characteristics (n=60).

Characteristics	Values
Age (y), mean (SD)	71 (15)
Sex, n (%)	
Female	51 (85)
Male	9 (15)
Education: ≥12 y, n (%)	37 (62)
High blood pressure, n (%)	35 (58)
Obesity, n (%)	28 (47)
Dyslipidemia, n (%)	47 (78)
Tobacco use, n (%)	14 (23)
Hypothyroidism, n (%)	14 (23)
Mild vision problems, n (%)	60 (100)
Mild hearing problems, n (%)	1 (2)
Heart failure, n (%)	4 (7)
Chronic respiratory disease, n (%)	12 (20)
Diabetes, n (%)	14 (23)
Lives alone, n (%)	13 (22)
Has internet access at home, n (%)	57 (95)
Knows how to use a smartphone, n (%)	56 (93)
Has Android smartphone, n (%)	49 (82)

Validation of the App's Assessment



To validate the CVH categorization, we compared the NeoMayor app categorization and the face-to-face clinical assessment, which yielded a κ index of 0.51 (P<.001), indicating a moderate level of agreement between the 2 evaluations. In addition, the Pearson correlation between the 2 assessments (r=0.692; P=.001) indicated a good correlation for the total CVH index score. At baseline, our results indicate that 54 (90%) of the 60 participants had intermediate CVH, 4 (7%) had low CVH, and 4 (7%) had optimal CVH.

Potential Effectiveness

The average CVH index score at baseline was 64.3 (SD 10.8), which improved significantly to 69.0 (SD 11.03) after 2 months of NeoMayor app use (P<.001; Figure 5A), resulting in a moderate effect size (Cohen d=−0.548, −2.55 to 1.46). Participants showed significant improvements in 4 of the 8 subscores of the CVH index: blood pressure (Figure 5B), blood glucose level (Figure 5C), physical activity (Figure 5D), and diet (Figure 5E). However, no significant changes were observed in BMI, blood lipids, tobacco use, and sleep (Figures 5F-5I; Table 2). Indeed, the number of participants who smoked remained unchanged. Next, we classified the participants into those who showed improvement and those who did not: 32% (19/60) showed improvement. There were no significant predictors of improvement after testing the effects of age, sex, educational level, baseline depressive symptoms, and baseline CVH index, but there was a tendency for a negative effect of higher baseline depressive symptoms (odds ratio 0.69, 95% CI 0.48–1.00; P=.05) and healthier baseline CVH status (odds ratio 0.94, 95% CI 0.88–1.00; P=.06) on the possibility of improvement.

Figure 5. Changes in the cardiovascular health (CVH) index after NeoMayor use. (A) Total Life's Essential 8. (B) Blood pressure. (C) Blood glucose level. (D) Physical activity. (E) Diet. (F) BMI. (G) Blood lipids. (H) Tobacco use. (I) Sleep. Violin plots compare the global CVH index and its subscores before and after NeoMayor use. The solid lines represent the median, and the dashed lines represent the quartiles. A paired sample t test compared CVH index differences. *P<.05, **P<.005, ***P<.001.

Regarding other results, we observed changes in anthropometric measurements, with an average weight reduction of 1 kg and a decrease in waist circumference of 7 cm, both indicative of improved body fat distribution. Physical performance showed improvement, with faster gait speed (an average reduction of 2 s), enhanced upper limb strength (measured by the handgrip test), increased lower limb strength (measured by the 5-repetition chair stand test), and improved SPPB scores. In addition, a significant reduction of 10 mm Hg in systolic blood pressure was noted. Blood tests revealed a decrease in high-density lipoprotein cholesterol levels, although low-density lipoprotein cholesterol and triglyceride levels showed nonsignificant increases. There were no differences in cognitive assessment or depressive symptoms, but there was an improvement in self-perceived memory after app use (Table 2).

Qualitative Results

Overview

The usability as well as barriers and facilitators to using the NeoMayor app were evaluated through an iterative process involving the clinical team and cocreation session participants. Among the participants, 88% (53/60) stated that their primary motivation for using the app was "to improve overall health," followed by improving physical fitness and enhancing memory. In addition, 79% (47/60) of the participants considered improving their lifestyle especially important, and the same proportion believed that the app would help them achieve this goal. Regarding usability, 85% (51/60) of the participants found the app easy and intuitive to use. For the initial health survey, 90% (54/60) considered the personalized results delivered by the survey useful and easy to understand. In terms of user satisfaction, 66% (39/60) found the app highly engaging, and 64% (38/60) were very satisfied with their UX. Moreover, 63% (38/60) rated the app as highly motivating and found the app intuitive to use.

Adherence

To assess study adherence, we monitored app use during the first month. Participants spent an average of 12,242.6 (SD 2359.0) seconds using the app, equivalent to approximately 204.0 (SD 5.9) minutes. This corresponds to approximately 400 seconds (6.7 min) of app use per day.

Discussion

Principal Findings

In this study, we described the design, development, and validation of NeoMayor, the first mHealth app aimed at promoting healthy lifestyles as well as cardiovascular and brain health in older adults in Chile through multidomain healthy lifestyle interventions. The NeoMayor app categorizes users' CVH profiles based on a survey inspired by Life's Essential 8, which was adapted and validated in this pilot study. The app then delivers personalized recommendations and content covering physical activity, nutrition, mental health, memory, and general health management for healthy brain promotion [66], providing a personalized guide to healthier living. This structured and systematic development process, combined with the validation of the content and design, allows for potential replication in other mHealth apps, particularly for populations with limited digital literacy or access to health technologies [52]. These findings also align with previously described barriers and facilitators to adopting mHealth-mediated strategies [21,26,27].

Although several international initiatives exist to promote health care in older adults, most have been developed in high-income countries and are not designed for populations with lower educational levels, who require special adaptations and cultural validation to meet their needs [67]. In this context, NeoMayor is the first app specifically adapted for Chilean older adults to support integral health care promotion.

Regarding adherence, the average daily use time of the NeoMayor app was notably higher (6.7 min/d) than that reported in other studies of older adults using mobile apps (2 min/d), indicating a high level of engagement [68], which could be associated with the participants' high technological skills and motivation. One important factor to consider in the adoption of mHealth technology is technology-related anxiety [69] in people with limited digital literacy, which may require positive management to encourage app use [17]. Although this study included participants with functional independence, cognitive ability, and basic digital skills, broader implementation for older people with low digital literacy or cognitive issues [70] may require alternative strategies. These could include health care professional– or coach-assisted mHealth interventions to overcome moderate mHealth literacy or social digital barriers to engagement and empower health literacy [71].

The findings of the pilot study suggest that using the NeoMayor app led to improvements in both metabolic health and lifestyle habits, which are key indicators of the app's potential effectiveness [72]. The improvements observed in blood pressure (a reduction of 10 mm Hg in systolic blood pressure), blood glucose levels, physical activity, and diet—key elements in the prevention of cardiovascular disease and other NCDs—represent a relevant finding that should be confirmed in a larger-scale RCT [65]. Although we did not find significant changes in BMI, participants experienced a significant reduction in waist circumference, which is more closely associated with cardiovascular risk than BMI [73]. This is a very important result, considering that 47% (28/60) of the participants were obese.

The significant enhancement in functional physical performance, measured by the SPPB [74], gait speed alone, and the 5-repetition chair stand test alone, is relevant, considering its critical importance in reducing the risk of physical fragility and falls in older adults [75]. Moreover, the 2-second reduction in the 5-repetition chair stand test represents a statistically significant and clinically relevant change among older Chileans, which is associated with higher survival rates [76]. These improvements in physical performance may be attributed to the physical activity module, which includes instructional videos, consistent with findings from previous research on the impact of video-guided physical activity interventions [52,77]. In addition, these improvements contribute to enhanced metabolic health. Furthermore, we found an increase in self-perceived memory, which could be associated with both physical activity and the global cognitive activity promoted by the use of the app. Previous studies report that physical activity combined with cognitive training can improve self-perceived memory in

XSL•FO
RenderX

older adults [78], and exercise is a main component of cognitive health [79].

As an additional strength, usability testing demonstrated easy user navigation, with a main menu that provided intuitive access to the app's modules. Participants reported a preference for challenge-based navigation, which allowed them to set specific health goals and stay motivated. However, minor modifications should be addressed in future iterations of the app, including more engaging navigation elements, considering the importance of structural measures to support lifestyle changes [14,80].

Limitations

This study included only participants without sensory or cognitive impairments and with good technological skills. Future adaptations could expand the intervention's applicability by considering the co-design of an inclusive version of the app tailored to varying levels of digital literacy. In addition, because most of the participants were female—a common proportion in similar studies [81]—the generalizability validity of our findings may be limited. This is a frequent issue in pilot studies, where feasibility is the main objective, and could be overcome in future studies using the NeoMayor app in population-based samples. As a pilot study, the methodology used cannot establish the efficacy of NeoMayor in CVH independent of confounding factors, but it provides a solid foundation for a subsequent RCT with strategies to overcome sample bias. Indeed, with the implementation of the design improvements, the NeoMayor app has reached technology readiness level 4 (Figure 2). The next phase will involve evaluating the effectiveness of NeoMayor on CVH and lifestyle in an RCT, which should include at least 200 participants with different digital literacy and technological skills, based on sample size estimation considering the moderate effect size with regard to CVH observed in this pilot.

Conclusions

This study described the design, development, and validation of a comprehensive mHealth app that aims to promote healthy lifestyles as well as cardiovascular and brain health in older adults in Chile. Using a person-centered, multidisciplinary approach grounded in lean UX and agile methodology for co-design and codevelopment, NeoMayor demonstrated good feasibility and potential effectiveness in improving CVH and physical performance, which will be evaluated soon in a larger RCT. These findings indicate that the NeoMayor app can provide an accessible, affordable, and implementable strategy to support healthy aging.

Acknowledgments

The authors thank the NeoMayor team, the Healthy Brain Unit personnel at Hospital Clínico de la Universidad de Chile in Santiago, the Web Intelligence Centre team at the Universidad de Chile in Santiago, and all participants in the cocreation and testing sessions. This research was funded by a grant from the Chilean Fund for the Promotion of Scientific and Technological Development (ID2110096 [CDD]) and the Chilean National Agency for Research and Development grant for doctoral studies (21221932 [MG]) and Centro Nacional de Inteligencia Artificial CENIA (FB210017, BASAL, ANID [RV]). The article processing charge was funded by Universidad Mayor (MG). Figures 1, 3, and 4 were created using BioRender (BioRender Inc).

Authors' Contributions

CDD conceptualized the study. CDD, J More, and CDS were responsible for methodology. VDC, CA, CV, JV, V Cortes, and PV were responsible for software. CDD, J More, FS, and MIB were responsible for validation. CDD, MG, V Cabello, and CDSM were responsible for formal analysis. MT, CDD, V Cabello, MG, CM, GM, CDSM, CDS, RB, DP, and NR were responsible for investigation. CDD and MIB were responsible for resources. CDD, J Mauro, CDS, and MG were responsible for data curation. MG wrote the original draft. MG, V Cabello, J More, J Mauro, and CDD reviewed and edited the manuscript. CDD supervised the project. CDD and MT were responsible for project administration. CDD, MG, and RV were responsible for funding acquisition. All authors have read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Dementia is a global health priority. Early identification in asymptomatic or mildly symptomatic individuals (ie, dementia risk detection) is proposed as a clinical solution for early intervention and could support researchers to identify novel neuropathological targets and recruit to clinical trials. Digital biomarkers of behavioral or physiological markers, including sleep, are cited as a potential low-cost, noninvasive, and objective method for dementia risk detection. Understanding perspectives on digital biomarkers, particularly acceptability, from potential end users and clinical staff is required when considering implementation within any clinical service. With emerging evidence of sleep as a risk marker for dementia, the efficacy of the Dementia Research Institute Sleep Index (DRI-SI), based on continuous remote monitoring of sleep patterns detected by a digital sleep mat, for dementia risk detection, is currently being explored by the InSleep46 study.

Objective: This qualitative substudy aimed to explore perspectives of potential end users and primary care physicians regarding the use of a digital sleep mat to measure the DRI-SI and its application towards dementia risk detection.

Methods: Thirty-one potential end users (age: 31-82 years, 11 female and 20 male) from Newcastle and London, United Kingdom, with personal or caregiving experience related to dementia, participated in qualitative focus group workshops. They shared opinions on integrating the sleep mat into their homes, the DRI-SI's potential for identifying dementia risk, and the necessary information for engagement with related clinical services. Seven primary care physicians from across England participated in semistructured interviews regarding the potential application of the DRI-SI in dementia risk detection and its integration into current clinical practice. Inductive thematic analysis was conducted to identify key themes.

Results: Four key themes emerged from end user focus groups: (1) practical use, (2) prospective acceptability, (3) clinical management, and (4) data concerns. Three main themes came from the semistructured interviews with physicians: (1) prospective acceptability, (2) health care provision, and (3) practical considerations. Common themes were identified in both groups but held differing perspectives. End users were focused on practical aspects of integrating the digital sleep mat within their daily life, the effect of the DRI-SI on clinical care, and privacy concerns regarding data use. Primary care physicians were concerned more

XSL•FO
RenderX

broadly with how the DRI-SI and dementia risk detection service would integrate into current clinical practice, the impact on clinical resources and patient well-being, and the need for clinical actionability and guidance on discussing results with patients.

Conclusions: End users would find the DRI-SI acceptable as part of their clinical care, but primary care physicians require a more robust evidence base. Future research should explore the integration of the DRI-SI into clinical care/research pathways to enhance clinical acceptability. Five key recommendations have been made for further development of digital biomarkers for dementia risk populations.

(JMIR Aging 2025;8:e74307) doi:10.2196/74307

KEYWORDS

dementia; digital technology; digital health; mass screening; qualitative research; community-based participatory research

Introduction

Dementia is considered a global health priority by the World Health Organization and the leading cause of disability and dependency amongst older adults [1]. Dementia is a syndrome characterized by significant cognitive impairment leading to impairments in functional abilities. Fifty-five million people are currently living with the condition worldwide, with numbers expected to rise to 139million by 2050 [2]. Dementia is not an inevitability; the recent Lancet Commission suggested that ≈45% of all dementia cases are preventable, reporting 14 known modifiable risk factors [3]. Further risk factors, such as sleep, are under investigation [4]. In the absence of a globally accessible cure or treatment, the World Alzheimer's Report 2023 declared dementia risk reduction to be the most proactive and feasible way to combat dementia [2].

Dementia risk detection, which involves screening for dementia-causing diseases in those who are apparently well, has been proposed to enhance identification of high-risk individuals in asymptomatic populations [5-8]. For patients, this would provide access to earlier treatments, such as personalized risk reduction interventions [6], or disease-modifying therapies for Alzheimer disease; shown to be most efficacious when given early in the disease course [9]. From a scientific perspective, dementia risk detection may support identification of neurodegenerative changes in asymptomatic individuals, providing novel disease-modifying targets, and aiding recruitment of high-risk individuals into clinical trials [10]. There is a growing interest in "digital biomarkers," defined as objective, quantifiable physiological and behavioral data measured using digital technologies, to act as low-cost, noninvasive methods to detect dementia risk [5,10]. Digital sleep biomarkers may be one such method [5,11].

Sleep disturbances are a common symptom of dementia, presenting as difficulties falling or remaining asleep, excessive daytime napping, "sundowning" whereby people become confused and agitated during evenings, and rapid eye movement sleep behavior disorder [12-15]. Although the cause-and-effect process is unclear, sleep disturbances may occur prior to cognitive symptom onset as they are associated with an increased risk of developing dementia in both cognitively normal older adults and people with Parkinson disease [16,17]. Early evidence indicates that differences in sleep patterns, quantified by a digital sleep biomarker, known as the Dementia Research Institute Sleep Index (DRI-SI), may be able to distinguish dementia from normal ageing [11]. The DRI-SI can be objectively measured through continuous remote monitoring of sleep patterns using an under-mattress digital sleep mat (Withings Sleep analyzer) and is now being explored in asymptomatic individuals, with the view of assessing its utility to detect dementia risk prior to cognitive symptom onset.

This research is timely, given the rising interest in a "digital first" health care system in England. Most recently, the UK's Digital Health and Social Care Plan set out government-level goals to improve patient access to health care services via digital means and expand remote monitoring to manage long-term conditions [18]. National and international policies, coupled with significant international efforts to technically and clinically validate digital biomarkers and endpoints, indicate that digital dementia risk detection tools may soon be a feasible and useful avenue to support dementia risk reduction by identifying high-risk individuals requiring intervention [4,5,19-24]. However, such tools and resulting digital risk scores must be acceptable to both the potential end users (ie, the general public) and clinicians in order to be commissioned within health care services [8,25], especially primary care, where most screening occurs [26]. Recent surveys of the public, including underserved groups, have indicated that dementia risk detection is generally acceptable to the public [27]. However, there has been limited exploration regarding their perspectives on the use of a continuous remote monitoring digital device, such as a digital sleep mat, for this purpose [27,28]. A recent systematic review has indicated that primary care physicians have mixed views on the implementation of dementia risk screening but are interested in engaging in dementia risk reduction approaches [29]. Negative perspectives on dementia risk screening were largely attributed to limited time, resources, and clinicians' lack of education and knowledge in the area. Conversely, the review highlighted positive perceptions of a dedicated dementia screening service that would provide protected time and resources to conduct screening and communicate results with patients in a nonstigmatizing manner. Regarding digital biomarkers, one study has reported that primary care physicians recognize the potential of wearable technology to detect dementia but hold concerns regarding health inequities caused by direct-to-consumer products [30]. As such, there is currently not enough literature on this topic to infer how potential end users and primary care physicians would perceive a digital sleep mat and the DRI-SI, and their use within a potential dementia screening service. Further research is therefore required to identify prospective barriers to acceptability and to proactively consider solutions prior to resource-intensive development of

XSL•FO
RenderX

the DRI-SI, ensuring that issues around appropriateness and uptake are addressed from the outset. The aim of this study is to understand the perspectives of (1) potential end users and (2) primary care physicians regarding the use of a digital sleep mat for dementia risk detection.

Methods

Overview

This study is part of a larger study (InSleep46: Detecting and monitoring dementia using dynamic digital biomarkers of night-time behavior and sleep) with the overall aim to produce a digital biomarker, the DRI-SI, for use in screening for neurodegenerative pathology and progression towards dementia [11]. The purpose of the qualitative substudy was to consult the public and relevant professionals on the acceptability and practicality of using digital sleep data as part of a hypothetical dementia screening service, whereby a digital sleep mat would be supplied to participants' homes for 3 months, and the DRI-SI would be derived and communicated. An exploratory, health services research approach was adopted, using qualitative methods, to explore the perspectives of potential end users, including those who were worried about their dementia risk, with a family history or caregiver experience of dementia, and physicians regarding the potential implementation of the digital sleep mat for dementia risk detection [31]. This approach studies how health care services are organized, delivered, and experienced by multiple stakeholders, and seeks to understand how these interactions affect access and outcomes of care.

Ethical Considerations

The study was approved by the Imperial College Ethics Committee (reference number: 6554509) on May 15, 2023. Participants were provided with written information about the study, and their written informed consent was obtained prior to participation. Each participant received remuneration in the form of either shopping vouchers or financial payment in line with National Institute for Health Research (NIHR) guidance for their involvement after participation [32]. No identifiable information about participants is provided.

Recruitment

Potential end users were recruited via local research and community networks in the North East of England and London using purposeful sampling, particularly advertising through organizations inclusive to rural and low socioeconomic communities [33]. The inclusion criteria for potential end users were as follows: experience of dementia diagnosis from perspective of a family caregiver, professional role, or recent experience of own diagnosis; or at risk of developing dementia, or aged 65 years, or worried about their own memory or cognitive abilities; able to communicate effectively in English; resident in the United Kingdom; physically able to attend and participate in an in-person workshop or having the digital skills and equipment to join a web-based group meeting (Zoom/Teams Call). Potential participants were excluded from the study if they had moderate/advanced dementia or if they lacked capacity to understand the project and consent to involvement in line with the principles set out in the Mental Capacity Act (2005) Code of Practice [34].

This study was also designed to capture clinical perspectives; during end user interviews (ie, general public), participants highlighted that the most appropriate clinical context for implementation would be primary care. We therefore focused our recruitment on primary care physicians to ensure that the clinical perspectives reflected where the tool might be applied in practice. Primary care physicians were recruited using convenience and snowball sampling from across England [35]. All physicians worked in the National Health Service (NHS) in England as general practitioners, with experience of providing health care to people with suspected cognitive impairment and dementia. Physicians were included if they had experience in dementia diagnosis in a professional role, were residents in the United Kingdom, and could communicate effectively in English.

Data Collection

Data collection was conducted with potential end service users prior to exploring physician views to allow us to structure physician interviews based on the emergent findings from focus groups with end service users.

Four in-person focus groups with potential end users took place between September 2023 and January 2024, two in Newcastle and 2 in London, facilitated by 2 experienced (MP and LR) and 3 novice qualitative researchers (SH, MH, and RMA; 4 female and 1 male).

Before beginning the focus group discussion, the moderators outlined the InSleep46 study to participants, including the associations between sleep and dementia risk, the practical use of the sleep mat, an example of the data received from the sleep mat, and a brief explanation of the DRI-SI. A semistructured topic guide was developed to explore initial perceptions of the sleep mat, probing on practicalities of use and trust in the data; willingness to use the proposed screening service and DRI-SI to identify dementia risk, probing on using the sleep mat for 3 months and receiving feedback following this, and the information provided when receiving the DRI-SI score; and where participants envisioned this service sitting within health care or as the consumer-based landscape (Multimedia Appendix 1). The topic guide evolved iteratively during data gathering through discussions within the research team. All focus groups were audio recorded and transcribed verbatim using a university-approved transcription company, then checked and anonymized by the research team (RMA).

A semistructured interview approach was used with physicians (Multimedia Appendix 2 for interview schedule). Key themes and considerations identified in the end user focus groups were embedded into an interview schedule, which guided questioning, with ad hoc follow-up questions used to explore salient points. A total of 6 of 7 interviews were conducted by one of 2 researchers (MP and RMA) via one-to-one teleconferencing call, while one interview was in person. Informed consent was obtained in writing prior to the interview and verbally recorded at the beginning of the interview. All interviews were audio recorded, transcribed verbatim, checked, and anonymized by the research team (RMA) prior to analysis.

XSL•FO
RenderX

Public Patient Involvement

Two contributors with lived experience of dementia were involved in this substudy. One contributor supported the development of the aims and methodology at the grant proposal stage, before withdrawing due to changes in their condition. The second contributor has been involved in the conduct of the research, including but not limited to reviewing interview schedules, supporting recruitment efforts, attending project meetings, and contributing to the thematic analysis process and interpretation of data, by providing insights from their lived experience.

Data Analysis

All transcripts were analyzed using inductive thematic analysis, aligned with a critical realism epistemology [36]. NVivo (version 14; Lumivero) software was used for the management of transcripts [37]. This systematic, "bottom-up," reflexive approach involved multiple phases, and data collection and analysis ran in parallel. A member of the research team (RMA) familiarized herself with the data through repeated reading of transcripts. She generated initial codes and discussed these with the research team, including all focus group moderators (MP, MH, SH, and LR) and a Public Patient Contributor with lived experience of dementia, using triangulation to ensure a unified interpretation and relevance to study aims. First-order themes were constructed through researchers' interpretation of the coded data; these were reviewed regularly in discussions with the research team and refined further, ensuring credibility and consistency in analysis and minimizing bias in interpretation. First-order themes were clustered into a second-order series of themes based on commonality of meaning and patterns in the data. This was further refined, with second-order themes expanding to encompass others or shrinking for specificity. Themes were reviewed against the coded data and the entire dataset (either end users or primary care physicians, where relevant) to ensure participants' perspectives were accurately captured.

Reflexivity

The research team was multidisciplinary, including expertise in dementia research, qualitative methods, human-centered design, digital health, and primary care practice. While the team collaborated with the wider InSleep46 team, this work package operated independently from the team developing the DRI-SI. The development of the end user topic guide was developed prior to the first author (RMA) joining the team, although she observed all end user focus groups and kept field notes, using these to input into the interview schedule for primary care physicians, which she conducted. She led the analysis on both sets of data. The first author's expertise is in digital health and dementia research, with prior involvement in dementia risk detection research; this may have initially shaped expectations around the perceived acceptability and value of the DRI-SI. Reflexive engagement was maintained throughout analysis through memoing, maintaining, and iteratively refining a codebook, and regular team discussions. The codebook evolved from an initially broad set of descriptive codes to a refined structure that captured the conceptual relationships between themes. Discussions with other team members were used to challenge assumptions, refine theme definitions, and ensure interpretations remained grounded in participants' accounts rather than disciplinary biases.

Results

Participants

Thirty-one potential end user participants (age: 31-82 years; 11 females and 20 males; 25/31, 81% White) from Newcastle and London, United Kingdom, with personal or caring experience related to dementia, took part in focus group workshops. Seven primary care physicians were recruited from across England and had a range of clinical experience and related interests, outlined in Table 1.

XSL•FO
RenderX

Table 1. Demographic information on primary care physicians.

Participant	Sex	Practice area	Common types of patients	Additional expertise
GP1	Male	Two practices: Urban, suburban; Newcastle, North East	• University students • Older patients • Families • Care home residents	Academic researcher in dementia risk
GP2	Female	Two practices: Urban, suburban; Newcastle, North East	• Care home residents • Dementia/memory problems	Technology Lead for Clinical Commissioning Group (CCG) previously
GP3	Female	Two practices: Urban, suburban; Newcastle, North East	• University students • Wide age range • Dementia risk cases	—[a]
GP4	Male	Semirural, Northumberland, North East	• Older patients • Care home residents • Lower risk profile than other areas	Researcher focused on chronic illness in care homes
GP5	Male	Urban, London, South East	• Older patients with cognitive issues/dementia • Frailty management • Nursing home residents	Researcher in technology and dementia
GP6	Male	Semirural, Bristol, South West	• Patients with dementia • Farming communities	Researcher in dementia diagnostic tests
GP7	Female	Urban, Manchester, North West	• Patients with memory concerns and dementia • Health disparities	Researcher on health inequity in dementia and primary care

[a]Not available.

Briefly, four main themes were constructed through research interpretation from the end user focus groups: (1) practical use, (2) prospective acceptability, (3) clinical management, and (4) data concerns. Three main themes were generated from analysis of the semistructured interviews with primary care physicians: (1) prospective acceptability, (2) health care provision, and (3) practical considerations. Although common themes were identified for both groups concerning prospective acceptability, practical considerations, and health care management, the groups approached these from different perspectives. End users were primarily concerned about the practicalities of using the digital sleep mat and had privacy concerns about personal data. Primary care physicians wanted to know how the device and corresponding DRI-SI would fit into broader health care delivery and decision-making processes. Tables 2 and 3 provide definitions of themes and subthemes, with examples of common topics, for each stakeholder group, respectively. Thematic analysis results are presented below for end users, followed by the primary care physicians.

XSL•FO
RenderX

Table 2. Themes and subthemes which were generated from focus groups with potential end users.

Theme and subtheme	Definition	Common topics
Practical use: considers every day, tangible aspects of using the sleep mat		
Considerations for practical use	Refers to the practicalities of using the sleep mat, which an end user may consider an issue or barrier for use.	• Bed features • Design features • Digital connectivity • Out-of-home activities • Reminders/prompts • Safety considerations • Technical support • Time period for device use
Cost implications	Refers to the costs associated with the sleep mat and proposed dementia screening services, whether experienced by end users, clinicians, or the National Health Service.	• End user costs • Cost-benefit analysis • Supplementation of costs
Prospective acceptability: focuses on perceptions and attitudes of end users regarding the sleep mat		
General acceptability of device and digital technology	Perception of acceptable components or uses of the sleep mat and digital technology.	• Positive perceptions • Negative perceptions • Use of technology • Data monitoring • Trust in commercial or third-party organizations • Trust in data access • Trust in technology
Comparison to other digital products	Perceptions of the sleep mat to other digital devices, such as smart watches, or experiences of using similar devices to the sleep mat, that is, devices which assess sleep.	• Competition with existing devices • Information provision
Comparison to other clinical markers	Perceptions of how the sleep mat compares to other clinical markers for dementia or health (eg, blood biomarkers).	• Part of the clinical toolkit • Preferential perception of the sleep mat • Time period
Clinical management: considers the integration of the sleep mat into the end users' health care journey		
Service provision	Considers who the dementia risk detection service should be provided to and at what clinical timepoint and stage.	• Early detection • Memory impairments • Prevention tool • Sleep problems • Population of interest • Concerns with sleep • Safety device • General health and well-being • Monitoring disease progression
Reciprocal communication	Two-way communication of information relating to the sleep mat/service (eg, results) from both the device itself or from clinical services.	• Clinical service • Communication of data to the patient • Communication of results • Patient to clinician communication
Postscreening actions	Actions that would be taken following results from the sleep mat/clinical service.	• Clinical support • Self-management
Data concerns:considers data handling, access, and accuracy		

XSL•FO
RenderX

Theme and subtheme	Definition	Common topics
Data accuracy	Experiences or confounding factors that may impact the accuracy of the sleep data.	• Accessibility • Alcohol • Bed features • Bed partners • Erratic sleep patterns • Medication • Mental Health • Microphone disturbances • Nonsleep bed behaviors • Sleeping outside the bed • Dementia subtype • Cultural differences • Toilet behaviors • Dementia subtype • Sleep apnea • Hawthorne effect
Data management	Management of data from a processing or governance perspective.	• Patient access • Societal benefit • Data sharing across clinical services • Data processing

XSL•FO
RenderX

Table 3. Themes and subthemes generated from the semistructured interviews with primary care physicians.

Theme and subtheme	Definition	Common topics
Prospective acceptability: considers what makes the sleep mat acceptable to clinicians, from functionality to clinical feasibility and consequences		
Feasibility, reliability, and validity	Reflects concerns regarding practical implementation and trustworthiness of using the sleep mat for dementia risk detection.	• Complexity of sleep behavior • External influences affecting data accuracy • Feasibility of use in end users' homes • Behavioral changes due to Hawthorne effect • Patient acceptance of the mat. • Comparison with existing digital products.
Dementia risk detection	Refers to both patient and health care providers' challenges in interpreting, communicating, and understanding dementia risk scores, and concerns regarding the potential outcomes of dementia risk screening.	• Perception of risk • Purpose of the risk score • Communication of risk • Desire for diagnosis • Patient Choice • Actionability • Negative consequences for patients
Health care provision: c onsiders broader infrastructure and logistical elements needed for risk score successful deployment		
Current clinical practice	Refers to the existing landscape of how sleep and related digital data are managed in primary care.	• Sleep concerns • Sleep management • Consideration of consumer digital products in decision-making
Service provision	Refers to logistical aspects of implementation, such as who, where, and when the dementia sleep risk score should be offered.	• Service delivery • Clinical timepoint • Target population
Health care readiness and actionability	Refers to how equipped the current health care system is to act on the dementia sleep risk score.	• Actionability of risk score • Resource readiness • Integration into current pathways
Requirements for implementation	Factors required to be met to ensure successful deployment of the dementia risk score.	• Cost and value • Trust and credibility
Practical considerations: focuses on how results will be presented and understood by both patients and clinicians		
Data visualization	How the report is presented and shared with end users.	• Report preferences • Comparison with other reports for chronic condition screening • Sharing the report with patients
Clinical interpretation and decision-making	Requirements for the clinician to interpret the data and make informed decisions.	• Need for training and guidance • Meaningful metrics • Identification of reasons for poor sleep or anomalies • Standardized decision-making tool

Thematic Analysis: Potential End Users

Theme 1: Practical Use by End Users

Overview

The first theme was practical use of the device and its use in a dementia screening service, which has 2 subthemes: considerations for practical use and cost implications.

Considerations for Practical Use

Participants identified practical considerations for using the sleep mat in an optimal way. Commonly, they considered bed (eg, mattress type, electric blanket usage, and bed size) and design features (eg, size and robustness of the device), safety issues such as fire hazards, and the need for digital connectivity, such as access to Wi-Fi. They highlighted the need for technical support to set up the device, and reminders and prompts to ensure the device was switched on and collecting data during the required period.

> *I was just going to say, when you wrote 'a patient would install it,' in some ways it may be better to explicitly refer to 'or family or friend' because even though they probably can install it, it's a very simple thing, but I know my grandma, with dementia, would have a lot of insecurity. She would think she's done it wrong. She wouldn't know where to put it.* [G3P02, female, London]

XSL•FO
RenderX

Participants felt that a longer time period than the recommended 3 months would be required and suggested multiple follow-up assessments (eg, once a year) to assess progression or identify new risk signs. Additionally, there was some interest in keeping the device as a permanent monitoring feature. These perspectives may reflect a shift towards personal responsibility and autonomy in managing one's own health, alongside growing expectations of continuous, data-driven engagement with health and well-being data in the emerging digital landscape.

Cost Implications

Cost implications of the device were discussed from the perspective of the end user, such as the price of purchasing the device personally and the additional expense of running the device in one's own home. There was some advocacy for receiving the device on prescription and having running costs supplemented by the health care services, which may reflect an expectation that such costs are the responsibility of a publicly funded health care system rather than the individual. Other participants expressed willingness to purchase the device for their own use, reflecting a broader interest in investing in their personal health. Differing views may be shaped by individuals' socioeconomic status, influencing whether participants regarded cost as a barrier to participation.

> *It would be the same as if you had to pay to have a medical test done. In this country, we don't. It may take that bit longer, or whatever, but everyone has the chance to get treatment. Whereas, if you're having to pay for something, people put it off.* [G2P01, male, Newcastle]

There was also some consideration as to whether the benefit of the device and dementia screening service would benefit the health care service by reducing medication and care costs.

> *I suppose as well, if you've got doctors that realize that early intervention is going to be better for them, they're going to save money on their practice and they're going to save on medication in the long term as well. So, if they're sold on the fact that it's going to make a difference, well that would be a big difference for the practice.* [G1P05, female, Newcastle]

Theme 2: Prospective Acceptability by End Users

Overview

The second theme was prospective acceptability of the device and its use in a dementia screening service, with 3 subthemes: general acceptability of the device, comparison to other digital products, and comparison to other clinical markers.

General Acceptability of the Device and Digital Technology

Overall, the device was viewed positively, considered "unobtrusive," "easy," and beneficial to wider society. Possible negative perceptions related mainly to the microphone feature due to perceived intrusion of privacy, and anxiety over the possible results.

> *Knowing the mat is underneath you, recording this data, might cause you anxiety in itself. Thinking, "If I move-"* [G3P06, female, London]

Familiarity with technology was cited as an important factor for the general acceptability of using the device. Participants highlighted willingness to have their sleep data recorded for use in health care services or to support health care research, but expressed distrust in having the data stored, accessed, and used by commercial organizations or third parties. Similarly, some participants cited distrust in technology generally as a barrier to use.

Comparison to Other Digital Products

The sleep mat was compared with other digital products such as smart watches and phone apps, particularly considering the comparative accuracy to determine sleep, the ability to capture napping behaviors outside bed, and the incentive to use the sleep mat rather than an existing product. Data about sleep can be provided from existing devices, and this information was of interest to participants. Participants considered the sleep mat an additional tool to use to observe their sleep behaviors, alongside existing devices, suggesting an inherent trust in familiar technologies already used to monitor health and well-being This trust appeared linked to perceptions of visibility and access to data, with devices providing continuous real-time feedback viewed as more reliable or desirable because one could actively observe and interpret their own data. Contrastingly, the sleep mat's limited scope of only capturing in-bed activity reduced its perceived value, with concerns that it would miss napping behaviors in other locations (eg, an armchair) and not provide an accurate report to clinicians.

> *There are lots of apps that track, for example, when you went to bed, when you woke up, and then they can do your REM cycles. How would you incentivize someone to see the value of putting a device under their bed when they could actually change nothing and still get that data for themselves?* [G3P02, female, London]

Comparison to Other Clinical Markers

Some participants suggested a preference for the sleep mat over other clinical tests they were aware of or had experience of, such as cognitive interviews, stool samples, blood tests, and sleep diaries, as it is less obtrusive and stigmatizing. They felt it could be paired with other tests to support screening efforts, suggesting a desire for a holistic screening service.

> *I can see the benefits of the mat if it's used in conjunction with other tests, rather than being a sole determinant.* [G3P01, male, London]

Theme 3: Clinical Management

Overview

The third theme was clinical management, largely focusing on the potential dementia screening service proposed, encompassing 3 subthemes: service provision, reciprocal communication, and postscreening actions.

XSL•FO
RenderX

Service Provision

Participants discussed who the dementia risk detection service would be provided to in terms of age, family history, and existing health conditions, and at which clinical stage. They suggested that the service might be provided when people present with sleep problems, and that it should be considered an early detection or preventative service. There were mixed feelings regarding the provision of the service to those presenting with memory problems, generally feeling this was too late, although one participant thought it could be provided to people with mild cognitive impairment.

> *One of my initial thoughts was, by the time you've got to the memory clinic, very often that almost seems too late.* [G1P01, female, Newcastle]

Participants also commonly advocated the provision of the sleep mat and service to those with a family history of dementia. They felt that younger people may be more inclined to use the service and make risk-reducing lifestyle changes accordingly, although this may be deterred by the perception that dementia is "for old people" (G1P03, male, Newcastle). Additionally, provisions for middle-aged people and sports players were mentioned as these groups were perceived to have an increased risk of dementia.

Participants also suggested that the sleep mat could be used for additional purposes, such as monitoring sleep in those with concerns, acting as a safety device for people with dementia (eg, detecting falls), as a general well-being device, or as a method to monitor disease progression in dementia.

Reciprocal Communication

The communication of data and results was discussed by participants. Participants wanted to be able to see their own data, while expressing the need to have an expert relay what that data means to them.

> *Well, really, I mean, the common lay person doesn't know what information they're looking for, really. I mean, at the end of the day, it seems, sleep, they don't know the in depths of it, what's good and what's bad. They'll be looking for the GP or the professional to let them know the information that they thought was important.* [G2P02, male, Newcastle]

Participants also expressed the desire to be able to bring results from the sleep mat to the doctor if they were worried before the 3 months were up, or to be able to use the data to communicate abnormalities with clinicians themselves. This reflects the interest in actively engaging with health care services through control of one's own data, rather than passively waiting for the clinician's decision.

Postscreening Actions

Participants expressed the need for clinical support or self-management avenues following sleep-based dementia screening, particularly regarding improving their sleep. Referrals to sleep specialists, talking therapies, and cognitive behavioral therapies were proposed. Some participants expressed willingness to adopt lifestyle changes around sleep if they received a high-risk score or demonstrated poor sleep.

> *"We don't say you're going to have dementia, but we think you're not sleeping very well." Whether I'm going to have dementia or not, I'm going to try and start looking at things that will help me to sleep better.* [G4P02, female, London]

Theme 4: Data Concerns by End Users

Overview

The final theme identified was data concerns, composed of 2 subthemes: data accuracy and management.

Data Accuracy

Participants highlighted multiple factors that could potentially impact sleep and the DRI-SI results, including alcohol, erratic sleep patterns, medications, mental health, daytime sleep outside of the bed, dementia subtypes, and sleep apnea. Additionally, participants outlined concerns regarding characteristics or experiences which might inaccurately be perceived as sleep behaviors relating to dementia risk, such as the influence of bed partners (eg, waking up when partner gets up for the toilet) or incorrectly detecting a bed partner's heart rate as their own including spouses, partners, children and pets; behaviors in the bed besides sleeping such as watching TV or intimate moments; and frequent nighttime toilet use. They were concerned that the microphone features may inaccurately classify white noise or talking as sleep-related noises. Finally, they highlighted that results may be impacted by the accessibility of the device; for example, only collecting and comparing data from those who could afford to use the device. Multiple participants also suggested that end users may change their sleeping behaviors due to a heightened awareness of sleep monitoring.

> *What would be disastrous is if you had this thing and then you stopped doing whatever it is you're doing or trying to change whatever it is, the way you normally do things because you've got this mat.* [G4P02, female, Newcastle]

Data Management

Participants generally expressed the desire to have access to their own sleep data as collected by the device. Some participants considered wider access to their data, such as by researchers, as acceptable if it was positively benefiting wider society, and advocated for the data to be shared across clinical services.

> *So long as it's anonymized, I don't have a problem with the collection of data. Also, provided that it's doing useful research, but also that the research is open, again, I wouldn't mind. I wouldn't want it being sold to the highest bidder… I wouldn't want them being sold to a private company to make a profit off. I'd want any medicine that comes out of it to be open.* [G2P01, male, Newcastle]

Participants questioned who would be processing the sleep data and suggested that it should be processed by the health care services rather than third-party organizations. These perceptions likely reflect wider social anxieties about data misuse and commercial exploitation, and limited awareness of how health

XSL•FO
RenderX

data is often managed through the commissioning of external companies to process tests and support digital infrastructure.

> *But I'm saying that, if you're saying, from a patient point of view, "Where's my data being held and who's processing it?" I would want it to be processed- I don't see why, in the medium to long term- In the short term it's different. But in the medium to long term, why can't that be processed within the auspices of the NHS?* [G4P01, male, London]

Thematic Analysis: Primary Care Physicians

Theme 1: Prospective Acceptability

Overview

Physicians considered what makes the digital sleep mat acceptable to health care professionals, from functionality and validity of the device to clinical feasibility and consequences of dementia risk detection. Two subthemes were identified as follows: (1) feasibility, reliability, and validity and (2) dementia risk detection.

Feasibility, Reliability, and Validity

Regarding the use of the device, physicians considered how feasible and acceptable it would be for use in potential end users. They generally considered it noninvasive and simple, although one mentioned that there may be concerns regarding data privacy. They wanted to understand the benefit of the digital sleep mat in comparison to other familiar digital devices, such as smart watches, particularly as the digital sleep mat may not detect napping behaviors. There were some practical concerns about end users not using it correctly or unplugging the device.

> *I suppose the cables dangling around and could that get in the way? Are people just going to say, "Oh that's in the way," or trip over it and remove the sensor.* [GP4]

Physicians highlighted sleep as a complex, multifactorial behavior, with many different confounding factors for poor sleep quality, including nighttime toileting, partners' sleep behaviors, low mood, chronic pain, heart problems, and sleep apnea. They felt it would be difficult to disentangle these factors from the DRI-SI and required more information on how these confounders would be accounted for. Most physicians agreed that there may be a Hawthorne effect early in the sleep monitoring process, whereby end users would change their sleeping behaviors due to a heightened awareness of being monitored, but that the 3-month period would alleviate this effect.

> *There's so much more about sleep than just… yeah, and I think that would be harder to sell to patients and clinicians. They'd be like, "Well, actually there's so much more to sleep than just memory and the picking up dementia."* [GP2]

> *Whenever a patient knows they're being monitored for something, I suspect what they would do is they would try to be a good, model patient. They'll go to sleep on time and they'll try to make sure they're sleeping above the sensor. But I think the fact that it's over three months means that your initial data might seem quite pure, let's say. But then, later on, maybe after the first few weeks, when the patient has got used to it, they may have forgotten about the sensor. So, then, it becomes a much more natural version of their routine.* [GP1]

Additionally, physicians wanted information about the scientific validity of the device and DRI-SI, including the validity of sleep as a risk marker of dementia, the sensitivity and specificity of the score to detect dementia risk, at which clinical stage or disease subtype, and the measurement error and reliability of the device.

> *And that kind of comes into, is poor sleep a symptom of you're going to develop dementia, or is it a risk factor that causes you to develop dementia?* [GP7]

> *I just want to be knowing how it's working and how accurate it is.* [GP4]

Dementia Risk Detection

Physicians described being familiar with communicating risk scores for other clinical conditions, such as diabetes and heart disease, and generally felt confident that patients understand these concepts. However, they noted that fear and stigma of dementia and ageing stereotypes may reduce patients' desire to know their dementia risk or to understand the role sleep may play in it, although this appears to be shifting for the younger older generation. They noted that some patients may struggle to separate risk from diagnosis and may consider the condition as an inevitability. This may be due to ineffective communication, as explaining risk requires skill and experience.

> *Sometimes people will have experience of dementia and older parents or older relatives, and they'll have almost decided… Well, both my parents had this, you know. So, I'm going to get this. So, I don't know if the score per se would be but in terms of whether they would see that as a modifiable thing, in the same way that they would look at their blood pressure, their cholesterol. I'm not sure.* [GP3]

> *What they understand is the feelings that those numbers trigger off in them. So, in my experience, when I explain to someone that, "You might have a 20% or 30% risk of having a stroke," or whatever, the patient doesn't hear 20% or 30%. What they hear is, "Stroke," so that they hear the thing that they can latch onto, which is the thing which then triggers off an emotional response in them.* [GP6]

To support discussions regarding dementia risk, physicians highlighted that they would need to understand the relationship between sleep and dementia, the components of the risk score, and have guidance on how to explain it to patients, as is the protocol with other common screening processes.

> *I think the one thing that they would want to know is, what is the risk of a sleep disturbance? Or what is it that makes sleep something that puts you at risk of dementia?* [GP1]

Finally, physicians considered the provision of the DRI-SI as acceptable only if there was a consequential positive action to

XSL•FO
RenderX

improve health or reduce and modify risk. Without this, physicians expressed concerns about frightening patients and causing unintended harm by sharing a risk score without a pathway to modification.

> *I wouldn't share it with a patient and frighten them and say that "You're moderate risk of dementia," because I'm sorry until somebody can explain to me the clear evidence for that then I would cause harm to someone by doing that so…* [GP2]

Potential interventions need to be carefully considered and tailored to a patient's individualized response, as this information may support some to make lifestyle changes, but negatively impact others due to emotional connotations and comorbid conditions. Some physicians questioned the need for the DRI-SI based on the current risk reduction evidence, citing primary population-level prevention as a simpler, effective strategy. However, risk modification was not the only considered benefit. Risk detection could also support advanced care planning and trigger safety assessments, such as reviewing driving abilities. Additionally, physicians wanted to know if the DRI-SI could assess intervention effectiveness, with a reduced score showing modified risk.

> *There's a possibility and there's a plausible scenario, given that, in my opinion, a lot of it is driven by emotion triggers, that the people that are least well equipped to be able to actually change their behavior, because their response gets driven by an overwhelming emotional response, then end up not being able to change their behavior, even if they are, in fact, at the greatest risk of getting dementia.* [GP6]

Theme 2: Health Care Provision

Overview

Physicians considered the broader infrastructure and logistical elements required to successfully deploy the digital sleep mat and subsequent DRI-SI within health care, leading to four subthemes: (1) current clinical practice, (2) health care readiness and actionability, (3) service provision, and (4) requirements for implementation.

Current Clinical Practice

Physicians indicated that they often speak to people about sleep problems, usually part of a larger consultation. However, sleep concerns do not usually occur in the context of help-seeking for dementia-related symptoms. Physicians talked about a variety of sleep management techniques they might use, often involving identifying the root cause and trying to make small changes to alleviate the impact. They indicated that they would generally refer people to social prescribers to speak about sleep hygiene, or to websites and apps to encourage lifestyle modifications rather than medical treatment. However, physicians felt that sleep management is variable depending on the clinician and their experience, and generally indicated that sleep is not an area where they have great clinical expertise.

> *Well, I don't have any treatments for poor-quality sleep. And I have asked the powers that be, and I'm not convinced that there's anything that I can really do. So, we talk about sleep hygiene, and exercise, and not eating too late at night, and limiting caffeine intake, particularly in the latter part of the day. Of course, we do all that. We have a speculative idea of what melatonin might do. And many people just go buy it. We avoid benzodiazepines, in the form of hypnotics, very firmly, but we do give them. If there's complete sleeplessness, usually, on a short-term basis. But what's a treatment for sleep disturbance?* [GP5]

> *I don't have any formal training in sleep stuff I suppose like this so I'm coming back to myself.* [GP4]

Physicians also indicated that an increasing number of patients were bringing their own direct-to-consumer devices and outputs relating to sleep, physical activity, and heart rate to a consultation, but there were mixed views on what to do with this data. Some physicians appreciated the role these devices can play in empowering patients and promoting self-advocacy, while others felt that they would not know how to interpret or use the data, and do not allow it to impact clinical decision-making.

> *I think it's a great thing. I think, if people are interested and engaged their health, then that's fantastic, isn't it? But I also think, yeah, it's quite interesting to look through someone's app or their resting heart rate.* [GP6]

> *It wouldn't be like the main point of a consultation if anything… And actually, I might note it down and stuff but it doesn't add much to the history of the condition because I don't then go, "Okay. So, he's had this much REM sleep or this much non-REM sleep."* [GP1]

Health Care Readiness and Actionability

A common area of discussion amongst physicians regarding the implementation of a dementia risk detection service based on the digital sleep mat was a lack of resources and overburden on primary care. Physicians were generally concerned with their lack of time and "the never-ending list of things that the GP does" (GP7). They felt that conducting the proposed dementia risk detection service would remove resources from other critical tasks, such as annual reviews, cognitive assessments, and in-depth conversations about memory concerns. They also discussed how detecting dementia risk might lead to an influx of people being screened, leaving fewer resources for those who require postdiagnostic support and care.

> *Because you haven't got… you've got 10 minutes with someone and I'm looking to see if you've got a risk of dementia. I'm not going to be going on about sleep for 10 minutes, I'll be looking at function and cardiovascular risk and all this else.* [GP2]

> *We already know that many people, when they are diagnosed, experience a high degree of abandonment and not really getting very much post-diagnostic support at all. So, the problem is, quite understandably, many people are really interested in trying to widen the funnel and get more people in at an earlier stage and get something done about it. But*

XSL•FO
RenderX

> *the problem is that that means, unless you have an extremely effective filter and funnel at a relatively early stage in the funnel, you have more people progressing through.* [GP6]

Physicians wanted to know how the service would integrate into current care pathways and have clear guidance on where to refer high-risk individuals.

> *"Here, by the way, here's the risk for dementia, and it's really high," there has to be a, "So what?" a, "So what? It's really high. What can I do that is going to change that?" and in a way which is personalized to the individual, because otherwise referring back to the GP will mean diddly-squat.* [GP6]

Service Provision

Physicians discussed where this sleep-based dementia risk detection service would best fit and which population might benefit the most from it. Generally, they felt it should be commissioned as part of the NHS as opposed to a direct-to-consumer service, citing clinicians' "conscious incompetence" with unfamiliar data, exacerbating health inequalities, and over-investigation due to the uncontrolled provision of the digital sleep mat.

> *So, I think that that kind of digital health revolution is going to create significant problems going forward. The sleep mat isn't going to contribute to that if it's done in a controlled way and it's monitored and it's used in the right people and the right population.* [GP7]

Within the NHS, physicians advocated for the integration of the digital sleep mat into either established health check services or annual reviews, or to consider the DRI-SI as one marker in a clinical toolkit for a dedicated dementia screening service. Regarding the target population, patients with existing risk factors such as diabetes and heart disease were commonly mentioned, alongside people with a family history of dementia, genetic vulnerability, or middle-aged people who chose to be screened due to the need for future planning, such as caregivers for disabled children or partners. Some physicians also suggested using the DRI-SI at a later clinical time point, such as in people with suspected dementia or mild cognitive impairment, and to increase rates of diagnosis within the care home population.

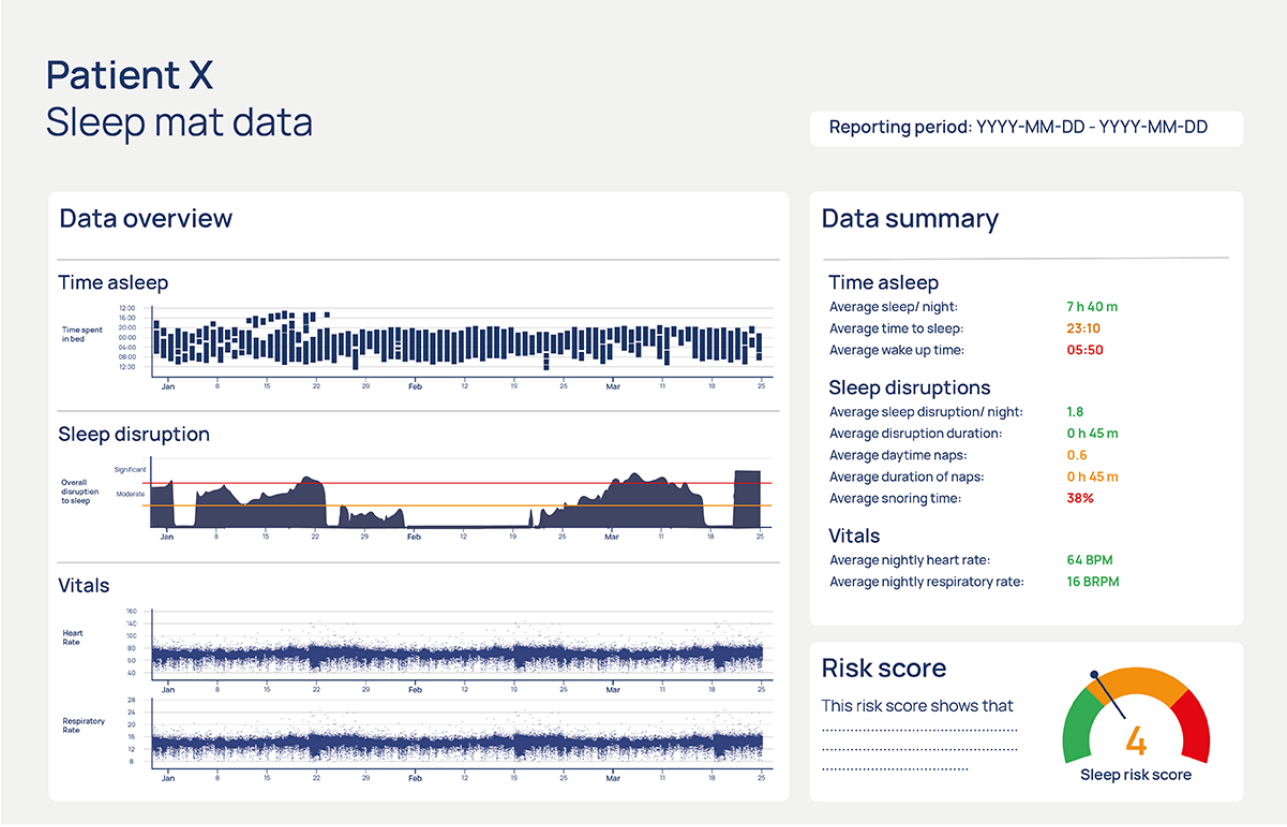
> *You know, everybody who has heart disease, diabetes, that kind of thing they get, you know, anywhere between… sort of… one and thee review appointments a year with the practice nurse. And again, I think the opportunity to have a sleep mat would fit quite nicely into that.* [GP3]

> *If this was part of a wider NHS Dementia Health Check, I think it could certainly fit in and I think that service is massively needed and I think it would be a hugely beneficial use of primary care's time.* [GP7]

Requirements for Implementation

To have this service integrated into the NHS, physicians highlighted the device and DRI-SI to be trustworthy and credible, as evidenced by empirical evidence published in peer-reviewed journals, guidelines from credible sources, such as the National Institute of Clinical Excellence, and appropriate licensing, such as acquiring a CE mark for this use. Additionally, they felt that the cost-benefit must be apparent and that the service would need to be funded with financial incentives for service providers.

> *I think you just find that the reality for any practice would be that unless there was some funding tagged onto it that they could use, they wouldn't.* [GP3]



Theme 3: Practical Considerations

Overview

The final theme focuses on how results will be presented and understood by both patients and physicians, involving two subthemes as follows: (1) digital sleep data report, and (2) clinical interpretation and decision-making. These data were largely derived from discussions with the physicians after presenting them with the prototype clinical report (Figure 1).

XSL•FO
RenderX

Figure 1. Example prototype of the data visualization of the Dementia Research Institute Sleep Index risk score.

Digital Sleep Data Report

Generally, physicians felt the digital sleep data report was "easy to read," "presented nice and clear," "helpfully color coded," and "simpler" than other reports. They tended to be drawn towards the graphs. They compared the report to other clinical reports that they were familiar with, such as echocardiograms, DEXA scans (ie, a bone density test), or QRISK results (ie, a risk score for developing cardiovascular disease), highlighting that these outcomes generally have a standardized summary to aid interpretation and support clinical decision-making. Physicians felt more comfortable with this standardized reporting approach as "you know what is going to come next and you know which bits to focus on" (GP1). They mostly felt comfortable with sharing this report with patients but highlighted that they would need guidance and a "patient decision aid document."

> *But in terms of the presentation, it's very clear in terms of the science for me to understand, but also for me to communicate that to a patient; it's, it's very, very good, I think.* [GP7]

Clinical Interpretation and Decision-Making

Regarding their use of the report to make clinical decisions, physicians highlighted the need for meaningful metrics. They commonly focused on the vital signs in the report, due to their greater familiarity with interpreting and communicating these results. Some tried to interpret the sleep scores, such as sleep disruption, but highlighted the need for training to use such metrics clinically. Physicians also felt that some patient feedback or self-reporting would support their decision-making when considering anomalies in the data. Finally, they wanted a standardized decision-making section within the report to guide them on what actions to take next with the patient.

> *In clinical practice we're less attuned to looking at sleep, the sleep graph, so my immediate attention would be to the vital signs because then that's data that we're more familiar in interpreting.* [GP4]

> *I think a summary by the technician who's reporting this, to say, "These are the things it would be helpful to counsel the patient on," would make our job a lot easier. Because, otherwise, if this is going to be used nationally, you're going to have to train a lot of GPs to be able to determine that. It would take a lot of effort to do that.* [GP1]

Discussion

Principal Results

This is the first study to capture perceptions and attitudes of potential end users and primary care physicians regarding the use of a digital sleep mat to derive a digital sleep biomarker (DRI-SI) for dementia risk detection. Potential end users find both the device and the proposal of dementia risk detection generally acceptable; their concerns focused on the practicality of the device, their trust in technology, and the personal impact of sleep monitoring and dementia risk detection. In contrast,

XSL•FO
RenderX

primary care physicians were reluctant to provide the device or engage in dementia risk detection without clear guidelines, empirical evidence of benefit, and clinical actionability. Findings from this study are informative for the development and implementation of other noninvasive biomarkers for dementia, particularly those using digital methods.

Comparison With Prior Work

End users and primary care physicians differed in their views regarding the acceptability of the use and implementation of the DRI-SI. Potential end users largely focused on the use of the digital sleep mat and the information it could provide, considering how it would fit into their daily lives and how they felt about continuous data monitoring. Regarding dementia risk detection, they believed that dementia risk reduction techniques could be implemented early and effectively, reducing overall health care costs and burden. These findings reflect recent systematic reviews and surveys showing positive attitudes of the general public around dementia risk detection due to beliefs of positive outcomes, such as slowing the disease via lifestyle changes and providing more time to plan for the future [27,28]. Comparatively, primary care physicians were more concerned with the clinical validation and health care system integration of the DRI-SI, requiring a more robust evidence base for implementation of a digital sleep biomarker for dementia. This echoes a recent systematic review, which reported that primary care physicians were reluctant to consider the provision of dementia risk detection, due to a lack of knowledge, skills, and training on dementia, resources to provide the service, and concerns regarding the consequences to patients [29]. While physicians held concerns regarding the accuracy of the DRI-SI to detect dementia risk, they also highlighted the more general issues of limited evidence regarding benefits versus harms of dementia risk detection and for accessible treatments that can slow or stop disease progression [25,38-41]. The complexity of the issue moves beyond the development and validation of the digital biomarker and highlights the need for good-quality evidence on clinical actionability of dementia risk detection and benefit to patients and the wider health care system.

Strengths and Limitations

Strengths of this study include the recruitment of potential end users with a range of ages and experiences related to dementia (ie, care partner, family history, subjective memory concerns), a high representation of males, with ethnic diversity representative of the United Kingdom's 2021 census [42]. Physicians were recruited from across different clinical practices and English regions, providing a greater diversity of professional experiences. Physician-focused interview guides were informed by the end user perspectives, reflecting real-world concerns, and supporting alignment of stakeholder perspectives across the proposed clinical pathway. Finally, throughout this substudy, we have engaged meaningfully with people with lived experience of dementia through our focus groups with potential end users and our partnership with public patient involvement contributors. To address recently reported gaps in meaningful end user engagement in digital health research for neurological populations, we have reported these efforts in adherence to the recommended minimum reporting guidelines [43].

Clinical viewpoints in this study are limited to primary care physicians; this decision was based on the perspectives from end users of where the DRI-SI would best fit. However, this limits our understanding of the broader clinical perspective of those involved in the dementia diagnosis and care pathways, such as old age psychiatrists, geriatricians, and neurologists. Additionally, perspectives are limited to end users and physicians living in England and may differ internationally. For example, in the USA, the American Academy of Neurology and the Alzheimer's Association both recommend annual cognitive screening for older adults [44,45], which may lead to greater willingness to uptake the DRI-SI as a dementia risk detection tool. We also did not collect detailed demographic data on end users, such as education level or socioeconomic status, so it is unclear whether the participants included reflected the established dementia risk factors [3].

Implications for Policy and Practice

Digital biomarker efforts often propose value as population-wide dementia risk detection tools, as they are unobtrusive, objective, usually passive, may reduce health care burden by being conducted remotely, and are speculated to detect dementia risk in "real time" as they continuously monitor changes in physiology and behavior [4,10,22,23,26,46]. However, the reluctance from physicians in this study to use the DRI-SI without its integration in clinical guidelines reflects the wider controversy around dementia risk detection [26,40]. No detection tool, digital or otherwise, has yet to meet the internationally-recognized criteria for population screening, which require an adequate understanding of the latent stages of the condition, an accurate and acceptable tool for both patients and physicians, a target population, provision of an accepted treatment, reasonable facilities for diagnosis and treatment, and economic cost-benefit [8,10]. As such, the UK's National Screening Committee currently recommends against such programs [26]. Many of these criteria go beyond the scope of digital biomarker developers' ambitions and require a comprehensive multidisciplinary team science approach, which would include physicians, health care commissioners, and patient voices. Despite these significant barriers, the physicians in this study felt strongly that, if implemented, the DRI-SI and resulting dementia risk detection service should be integrated into existing clinical pathways with guidance for referral in the national health care services.

To meet this challenge, the emergence of "brain health" clinics in the United Kingdom could offer a potential bridge to continue to gather the required evidence while working with health care providers. Brain health clinics are joint clinical-research services that provide access to high-quality assessments not routinely available to patients under investigation for cognitive impairment and physicians, including biomarkers under investigation [47,48]. Recent reports show that 93.5% of patients consent to the use of their data collected as part of the brain health clinic to be used for research [48]. Brain health clinics are considered a safe and acceptable care model for the conduct of more novel biomarker assessments, and have the resources to implement secondary prevention interventions for high-risk individuals [49]. They also meet the suggestion by both end users and physicians to implement the DRI-SI as part of a wider

XSL•FO
RenderX

clinical toolkit and dedicated service to alleviate burden from primary care, while allowing integration into an already established clinical pathway with actionable endpoints, that is, dissemination of information to clinicians in the memory clinic [29,48]. The term "brain health" can also be less stigmatizing than "dementia" and is preferred by primary care physicians when making referrals [50]. Further work should consider capturing the attitudes and perspectives of brain health clinic staff and associated memory clinics regarding the use of the DRI-SI to support dementia risk detection.

Looking to the Future: Wider Impact for Digital Biomarker Research

Overview

While the optimal application of the DRI-SI, like most digital biomarkers, remains unclear, further work could develop and validate it for a clinical service, as previously proposed, or as a tool to support identification of participants for clinical trials and disease-modifying targets [10,26]. From our findings, we have identified 5 key recommendations that should be considered for all proposed applications for the DRI-SI and are relevant to digital biomarkers more widely, prior to any integration into health care systems.

Clinical Staff Require Training on the Proposed Physiology or Behavior

In both this study and the wider literature, physicians indicated limited knowledge and education on dementia-related risks, particularly the association between sleep and cognitive impairment [29]. This leads to mistrust in the DRI-SI, a lack of confidence in how to explain this link to patients, and heterogeneous intervention strategies. Any digital biomarker will require clear and concise clinical information on the underlying association with dementia, which can be shared with end users.

Digital Technologies Need to Be Usable for All Stakeholders

Both end users and physicians held concerns about the usability of the device. End users were primarily concerned about setting up the device and ensuring its continued maintenance, while physicians felt that setup and maintenance would be beyond their resource abilities. Digital biomarker developers need to develop sustainable models of technical support, should these devices be integrated into clinical services or trials. This should include tailored support for individuals most at risk of digital exclusion, to reduce further exacerbation of health inequities in these groups [30,51-53].

Technical and Clinical Validity Need to Be Clearly Communicated

Both end users and physicians worried about confounding factors influencing data accuracy. Previous research regarding clinical use of artificial intelligence models reports that physicians are more likely to trust these tools if they can readily explain and justify them; this requirement was highlighted by both our stakeholder groups [54]. Digital biomarker developers need to develop adaptive algorithms that account for such factors and communicate clearly with physicians how these algorithms work so that they can answer concerns from end users. Additionally, physicians need access to evidence of clinical validation via credible sources (eg, National Institute of Clinical Excellence guidelines and peer-reviewed journals) to improve confidence in the digital biomarker. Additionally, both stakeholder groups indicated a rise in the desire of patients to manage and advocate for their health and well-being, with an increased ability to continuously monitor relevant outcomes through "wellness" consumer-based products such as smart watches. However, both groups also highlighted a lack of "expert" understanding of these data and the continued need for clinical interpretation to make sense of digital health metrics. While self-management supported through digital means is a key principle of the NHS' 10 Year Health Plan for England [55], there is a disparity between the standards of evidence required for commercial "wellness" devices and those approved for clinical use. Clearer communication of these differences to the general public and clinical bodies is essential to prevent unnecessary anxiety among the "worried well" and to support clinicians with reliable, evidence-based guidance on trusted digital tools.

Outcomes Need to Be Meaningful and Interpretable

End users and physicians wanted to understand and see easily interpretable data with meaningful outcomes, that is, aspects of health that have personal importance for end users [56]. This is not just important to our stakeholders; evidence of meaningfulness of outcomes is now required by regulatory bodies such as the European Medical Association and the Food and Drug Administration for qualification of clinical endpoints [57]. Additionally, patient decision aids and clinical results with standardized advice need to be provided through effective data visualization tools, codeveloped with physicians and end users to ensure effective communication and decision-making, as seen with common screening tools such as the QRISK [58].

Transparency in Data Management and Governance

Aligned with common perspectives on digital technologies, end users indicated that they were concerned with their data management and governance, preferring their data to be held and processed by trusted health services rather than third-party providers [26]. To improve trust in these processes and meet recent ethical guidance, digital biomarker developers should be transparent about who has their data and for what use, with guidance on how physicians can discuss this with end users [59,60].

Conclusions

Overall, this study found contrasting perspectives regarding the acceptability of using a digital sleep biomarker as a dementia risk detection tool, based on the current evidence base and clinical practice. Further work to integrate the DRI-SI in clinical-research pathways may support continued development and improve clinical acceptability and adoptability. Findings from this study support broader recommendations for the development of digital biomarkers for dementia populations, including requirements of further training for clinical staff, development of usable technology and meaningful digital

outcomes, and transparency regarding technical and clinical validation and data governance procedures.

Acknowledgments

The views expressed are those of the authors and not necessarily those of the NHS, the NIHR, or the Department of Health and Social Care. We would like to acknowledge all participants for giving their time to this research and the Public Patient Involvement contributors for supporting the study design and data interpretation.

JMS is a National Institute for Health Research (NIHR) Senior Investigator and acknowledges the support of the NIHR University College London Hospitals Biomedical Research Centre and the UCL Centre of Research Excellence, an initiative funded by British Heart Foundation (RE/24/130013). This work is supported by the UK Dementia Research Institute through UK DRI Ltd, principally funded by the Medical Research Council. He acknowledges grant funding from Alzheimer's Research UK, LifeArc, Brain Research UK, Weston Brain Institute, Medical Research Council, British Heart Foundation, Wolfson Foundation, Brain Research UK and Alzheimer's Association (SG-666374-UK BIRTH COHORT). This work uses data provided by study participants or patients and collected through clinical studies or as part of their care and support.

Abstract

Background: Cognitive decline is a common aspect of aging, and identifying modifiable lifestyle factors, such as physical activity and sleep, is crucial for promoting healthy brain aging. While both are individually linked to cognition, few studies have simultaneously assessed their independent and combined effects using objective wearable-based data, particularly in older Asian populations.

Objective: This study aimed to examine the independent and interactive effects of wearable-assessed sleep and physical activity parameters on memory performance in healthy older adults. We also explored whether age and hippocampal volume moderated these associations.

Methods: This prospective cross-sectional analysis included 88 cognitively healthy community-dwelling adults (≥60 years of age) from the *Integrating Systematic Data of Geriatric Medicine to Explore the Solution for Healthy Aging* cohort in Taiwan.

XSL•FO
RenderX

Participants underwent 12-day wrist-worn actigraphy, brain magnetic resonance imaging, and neuropsychological assessments. Light-intensity physical activity (LPA) and wake after sleep onset (WASO) were selected based on age-adjusted partial correlations with Consortium to Establish a Registry for Alzheimer's Disease Neuropsychological Battery memory scores. Multivariate regressions, age-stratified models (cutoff=72 years), and *PROCESS* moderation and mediation analyses were conducted, adjusting for age, education, daytime sleepiness, and hippocampal volume.

Results: Partial correlation analyses adjusting for age showed that higher LPA (r=0.260; P=.02) and lower WASO (r=–0.251; P=.02) were significantly associated with better memory scores. Age significantly moderated both effects: LPA was beneficial beyond 73.8 years of age, and WASO was detrimental beyond 71.1 years of age. Multivariate regression models confirmed that both WASO (β=–.044; P=.04) and LPA (β=.042; P=.01) were significant predictors of memory. In subgroup analyses (age ≥72 years), both LPA (β=.054; P=.04) and WASO (β=–.111; P=.01) remained significant predictors. Moderated mediation analyses showed that WASO was associated with reduced LPA (β=–.325; P=.03), but the indirect effect on memory via LPA was not significant. Instead, WASO exerted a direct and age-moderated effect on memory performance. Hippocampal volume moderated both associations, supporting the brain reserve hypothesis.

Conclusions: Our findings highlight WASO and LPA, as measured by wearable devices, as modifiable behavioral factors linked to memory function in older adults. The impact of these factors intensifies with advancing age and may be influenced by hippocampal reserve. Promoting daily light physical activity and maintaining sleep continuity may serve as accessible, age-tailored strategies for preserving cognitive health in aging populations.

Introduction

Cognitive decline is a well-recognized physiological aspect of aging. Even in the absence of dementia or mild cognitive impairment, older adults may experience subtle yet measurable decreases in memory performance and other cognitive domains [1]. These cognitive changes often occur alongside physical changes such as reductions in mobility, muscle strength, and endurance, which collectively affect quality of life and functional independence in late life. Among the most common behavioral alterations in aging populations are disrupted sleep patterns—such as changes in sleep timing and reduced sleep quality [2]—and reduced physical activity levels [3]. Growing evidence suggests that lifestyle factors play a critical role in both physical and cognitive health in older adults [4-6]. Given the lack of well-established pharmacological treatments for early-stage cognitive decline, modifiable lifestyle behaviors such as sleep and physical activity are increasingly recognized as vital contributors to cognitive reserve and healthy brain aging.

Many studies have investigated the association between self-reported sleep quality and cognitive function, although the findings have been inconsistent. Some reports have linked longer sleep latency and longer or shorter total sleep duration with poorer cognitive outcomes [7-10], including U-shaped relationships between sleep duration and cognitive performance. Studies using objective sleep measures have further identified associations between poor sleep quality—characterized by increased wake after sleep onset (WASO), prolonged sleep latency, and reduced sleep efficiency—and higher risk of cognitive impairment [11,12].

Physical activity is another important modifiable factor associated with cognitive aging. Observational studies have shown that higher levels of physical activity are linked to better cognitive function in older adults [13,14], whereas sedentary behavior (SB) is associated with poorer outcomes [15]. Interventional trials have also demonstrated cognitive benefits from regular physical exercise [16,17]. Mechanistically, physical activity may promote brain health through the release of muscle-derived myokines, which support neuroplasticity and anti-inflammatory processes [18]. Additionally, sarcopenia has been associated with cognitive decline, highlighting the potential interplay between muscle and brain health [19].

Although a growing body of literature has explored the impact of sleep or physical activity on cognitive functioning, studies that simultaneously examine both factors using objective, device-based methods remain limited, particularly among older adults in Asian populations. Furthermore, little is known about how these associations vary across different age thresholds in older people, despite evidence that the aging process may alter the relative influence of these lifestyle behaviors. In this study, we aimed to investigate the associations between sleep characteristics, physical activity levels, and memory function in healthy, community-dwelling older adults in Taiwan, using actigraphy-based monitoring and age-stratified as well as moderation analyses to explore potential age-related differences.

Methods

Study Population

This study was part of a prospective observational cohort established to create a comprehensive geriatric database for community-dwelling older adults in Taiwan without major physical or psychological disabilities. Community-dwelling adults aged 60 years and older were invited to participate in the *Integrating Systematic Data of Geriatric Medicine to Explore*

XSL•FO
RenderX

the Solution for Healthy Aging (ISDHA) study between September 2019 and October 2020 during annual routine health examinations at Chang Gung Memorial Hospital. Participants were residents of either the Chang Gung Health and Culture Village in Taoyuan or the Songshan District in Taipei, Taiwan. The inclusion criteria were as follows: (1) aged ≥60 years, (2) had visited Chang Gung Memorial Hospital at least once within the past year, and (3) had resided in Taiwan for more than 180 days within the year prior to enrollment. Exclusion criteria included (1) clinical evidence of major organ dysfunction; (2) a history of severe autoimmune disease; (3) ongoing cancer treatment at the time of recruitment; (4) antibiotic use within 1 month prior to enrollment; (5) cognitive impairment, defined as an Ascertain Dementia 8 (AD8) questionnaire score of ≥2 or Mini-Mental State Examination (MMSE) score of ≤26; (6) current follow-up at a cognitive disorder outpatient clinic; (7) depressive symptoms, defined as a Geriatric Depression Scale (GDS) score of ≥5; (8) a prior diagnosis of dementia or major depressive disorder; (9) severe hearing, visual, or cognitive impairment, preventing meaningful participation in interviews; or (10) physical frailty precluding the ability to stand or walk independently.

For this analysis, only participants who completed brain magnetic resonance imaging (MRI) and objective assessments of sleep quality and physical activity using actigraphy were included.

Demographic and Clinical Data Collection

Demographic information, including age, educational attainment, smoking status, and habitual exercise, was obtained through structured interviews. Medical history, such as the presence of hypertension, hyperlipidemia, diabetes mellitus, insomnia, obstructive sleep apnea, peptic ulcer disease, and anxiety, was collected from both electronic medical records and participant self-reports. Vital signs, including systolic and diastolic blood pressure and resting pulse rate, were measured using an automated sphygmomanometer. Body height and weight were measured using standardized procedures, and BMI was calculated as weight in kilograms divided by the square of height in meters (kg/m^2).

Blood Sample Collection and Laboratory Tests

Fasting venous blood samples were collected from all participants following an overnight fast of 8-12 hours. Laboratory tests included a complete blood count, liver and renal function panels, metabolic markers, serum vitamin D and albumin levels, as well as proinflammatory cytokines. All analyses were performed in the central laboratory of Chang Gung Memorial Hospital using standardized protocols.

Body Composition Assessments

Body composition was assessed using bioelectrical impedance analysis, a noninvasive and reliable method based on the electrical conductivity properties of different tissues [20]. Measurements were performed using a multifrequency segmental body composition analyzer (Tanita MC-780 MA; Tanita Corp), following the manufacturer's standard operating procedures. The parameters obtained included fat mass (kg), fat-free mass (kg), percentage of body fat, visceral fat rating, muscle mass (kg), bone mass (kg), total body water (TBW; kg), intracellular water (kg), extracellular water (ECW; kg), and basal metabolic rate (kcal).

Cognitive Function Assessments

Global cognitive status was assessed using the MMSE [21] and the AD8 questionnaire [22]. To specifically evaluate memory function, the Consortium to Establish a Registry for Alzheimer's Disease Neuropsychological Battery (CERAD-NB) was administered following standardized procedures [23]. The CERAD-NB is a widely validated tool for assessing cognitive performance in normal aging and Alzheimer disease [24] and includes several subtests: Verbal Fluency, the Modified Boston Naming Test, MMSE, Word List Memory, and Constructional Praxis [25]. The memory total score of the CERAD-NB was calculated by summing the scores from the 3 trials of the Word List Learning test, Delayed Recall, and Recognition subtests, with a maximum total score of 50 [25].

Subjective Sleep Assessments

Subjective sleep quality and daytime sleepiness were assessed using 2 standardized self-report questionnaires. The Pittsburgh Sleep Quality Index (PSQI) was used to evaluate overall sleep quality over the past month, while the Epworth Sleepiness Scale (ESS) assessed the general level of daytime sleepiness [26]. Both instruments have been widely validated in older adult populations and are commonly used in aging and sleep research.

Actigraphy-Based Monitoring of Physical Activity and Sleep

Objective monitoring of physical activity and sleep was performed using a wrist-worn accelerometer (Actiwatch 2; Philips Respironics), which incorporates a piezoelectric accelerometer to detect movement and a photodiode sensor to measure ambient light (illuminance in lux). The device recorded activity as counts per minute and light exposure at 60-second epochs. Participants were instructed to wear the device on the nondominant wrist for 14 consecutive days. Data from the first and last days were excluded from analysis to avoid partial-day bias. Sleep and wake periods were scored by a trained sleep specialist using Philips Actiware software (version 6.0.9) in conjunction with participants' sleep diaries. Epochs with activity counts below the wake threshold were classified as sleep, while those above the threshold were classified as wake. Circadian rhythm parameters were derived using nonparametric analysis. M10 and L5 were defined as the mean activity counts per minute during the most active 10 consecutive hours and the least active 5 consecutive hours of the day, respectively, reflecting rest-activity patterns [27].

Actigraphy recordings were considered valid if participants wore the device for at least 7 valid days (≥10 hours of daytime wear per day) without prolonged removal. Participants with fewer than 7 valid days (n=1) or who did not complete the actigraphy assessment (n=7) were excluded from the final analysis. The average number of valid actigraphy days before excluding the first and last partial days was 13.6 (SD 1.3; range 9-14) days. After trimming these 2 boundary days to avoid partial-day bias, a continuous 12-day dataset was used for the final analysis. Participants wore the Actiwatch 2 for an average

XSL•FO
RenderX

of 1412 (SD 12.5) minutes per day (~23.5 hours), with all valid recordings exceeding 870 minutes per day (~14.5 hours), indicating high adherence and minimal device removal during monitoring. Most participants (84/88, 95.5%) provided 13-14 days of valid recordings, demonstrating excellent compliance and data completeness.

Physical activity parameters were categorized using validated counts-per-minute thresholds obtained from Actiwatch 2 actigraphy data [28]. SB was defined as activity of <145 counts/minute (corresponding to <1.5 metabolic equivalents of task [METs]), light-intensity physical activity (LPA) as 145-274 counts/minute (~1.5-3 METs), moderate-intensity physical activity (MPA) as 274-597 counts/minute (~3-6 METs), and vigorous-intensity physical activity (VPA) as >597 counts/minute (>6 METs). Wake activity time was calculated as the total time spent in any activity category (SB, LPA, MPA, or VPA) during waking hours. Total activity counts during the wake period were also recorded as an indicator of overall activity level.

Light exposure during the wake period was evaluated using the following measures: wake light illuminance, defined as the average light intensity (lux); wake light time, representing the total duration (minutes) exposed to light; and wake light exposure, calculated as the cumulative product of light intensity and time (lux × minutes).

Sleep-related parameters were also derived from the actigraphy data. These included time in bed (TIB), defined as the duration between bedtime and final wake time; total sleep time (TST), referring to the total number of minutes scored as sleep; sleep onset latency, defined as the time from attempting to sleep to sleep onset; sleep efficiency, calculated as the percentage of time asleep while in bed; and WASO, representing the total number of minutes awake between sleep onset and the final awakening. In addition, light exposure during the sleep period was evaluated, including sleep light illuminance (average light intensity), sleep light time (duration of light exposure during sleep), sleep light exposure (lux × minutes), and sleep total activity (cumulative movement counts during sleep).

Summary statistics of subjective questionnaires and actigraphy-derived parameters, including sleep, physical activity, and light exposure, are presented in Textbox 1.

Textbox 1. Clinical assessments included subjective questionnaires (Pittsburgh Sleep Quality Index [PSQI] and Epworth Sleepiness Scale [ESS]) and actigraphy-derived parameters for sleep, physical activity, and light exposure. The actigraphy-derived parameters were obtained from 12 consecutive days of wrist-worn recordings.

Subjective assessments

- Sleep parameters include (1) PSQI (past 1 month) and (2) ESS (past 1 month).

Objective assessments

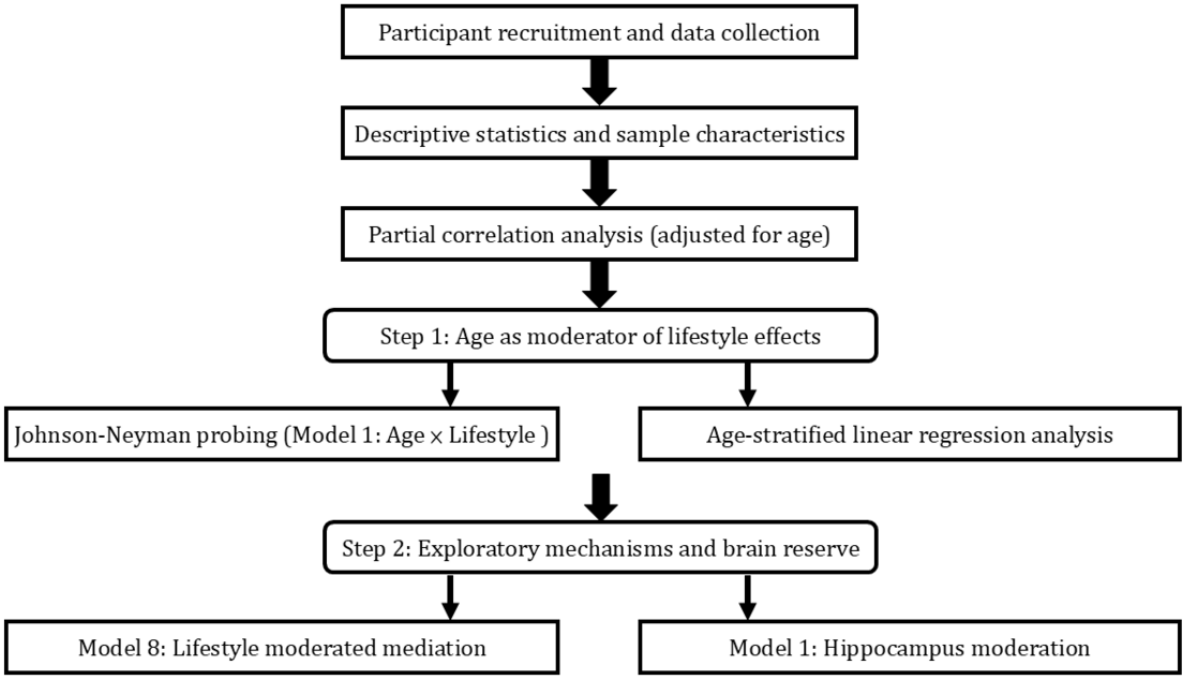
- Actigraphy-derived sleep parameters include (1) time in bed (min), (2) total sleep time (min), (3) onset latency (min), (4) sleep efficiency (%), and (5) wake after sleep onset (min).
- Actigraphy-derived physical activity parameters include (1) M10 (counts/min; indicates the mean activity during the most active 10 consecutive hours), (2) L5 (counts/min; indicates the mean activity during the least active 5 consecutive hours), (3) awaking total activity (counts), (4) sleep total activity (counts), and (5) physical activity time (min), which is further categorized into (i) sedentary behavior time (min), (ii) light-intensity physical activity time (min), (iii) moderate-intensity physical activity time (min), and (iv) vigorous-intensity physical activity time (min).
- Actigraphy-derived light exposure parameters include (1) wake light exposure (lux-min) and (2) sleep light exposure (lux-min).

Brain MRI Acquisition and Analysis

Brain MRI was performed using 3-Tesla scanners (Discovery MR750w and Discovery MR750; GE Healthcare). For each participant, 3 imaging sequences were acquired: a 3D T1-weighted anatomical scan, a 3D T2 fluid-attenuated inversion recovery scan, and diffusion tensor imaging. Gray matter and white matter volumes were estimated from the high-resolution T1-weighted images using the Computational Anatomy Toolbox (version 12.7), implemented within the Statistical Parametric Mapping software (version 12; Wellcome Trust Centre for Neuroimaging).

Statistical Analysis

All statistical analyses were performed using SPSS Statistics software (version 25.0; IBM Corp). Descriptive statistics were used to summarize participant characteristics, including age, education level, sleep and physical activity parameters, and cognitive performance. The normality of continuous variables was assessed using the Kolmogorov-Smirnov test. As most variables did not meet the assumption of normality, nonparametric methods were applied, and between-group comparisons were conducted using the Mann-Whitney *U* test.



To examine the associations between actigraphy-derived sleep and physical activity variables and memory performance, partial correlation analyses adjusted for age were conducted. Based on these results, WASO (r=–0.251; P=.02) and LPA time (r=0.26; P=.02) were identified as candidate modifiable lifestyle factors and selected for further analysis. Subsequently, multivariate linear regression analyses were performed to evaluate the independent contributions of WASO and LPA time to CERAD-NB memory scores, adjusting for relevant covariates, including age, education level, ESS score, and mean hippocampal volume. To investigate whether the effects of lifestyle factors on memory performance were moderated by age, moderation analyses were conducted using the *PROCESS* macro (version 4.2) for SPSS, developed by Andrew F Hayes. Model 1 was used to test interaction effects between age and each lifestyle factor (eg, age × WASO), and the

XSL•FO
RenderX

Johnson-Neyman technique was applied to identify the age threshold at which the interaction became statistically significant. Based on these results, a cutoff age of ≥72 years was established and used for subsequent age-stratified regression analyses.

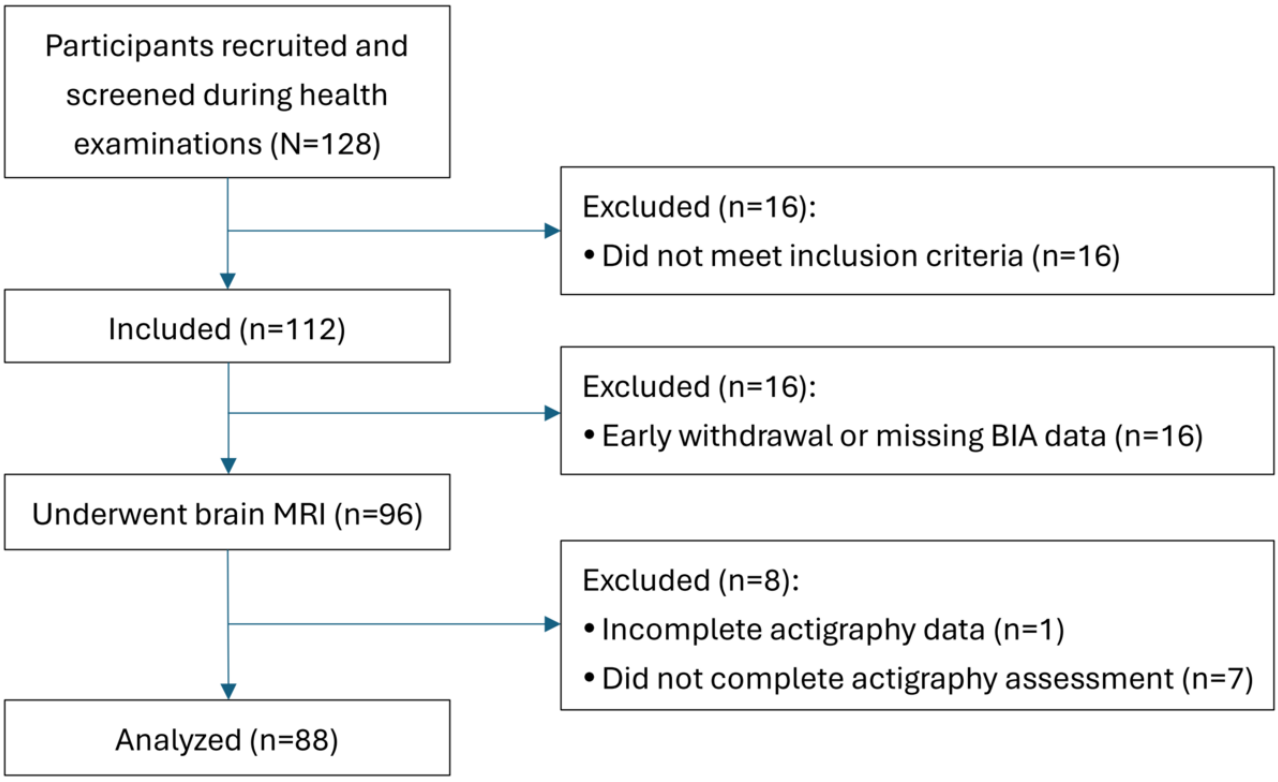
Finally, exploratory analyses were conducted to examine potential mechanisms linking sleep and physical activity to memory performance. This included moderated mediation analyses using Model 8 of the *PROCESS* macro to assess indirect effects and additional moderation analyses (Model 1) evaluating the role of hippocampal volume as a potential moderator, in alignment with the brain reserve hypothesis. All statistical tests were 2-tailed, with *P* values of <.05 considered statistically significant. For moderation and mediation models, bias-corrected bootstrap 95% CIs based on 5000 resamples were used to assess the robustness of indirect and interaction effects. The overall analytic framework is illustrated in Figure 1.

Figure 1. Analysis flowchart of the study design.

This diagram illustrates the sequential analytic framework used to investigate the associations between lifestyle factors and memory performance in older adults. After participant recruitment and descriptive analysis, partial correlation analysis (adjusted for age) was conducted to identify candidate actigraphy-derived lifestyle parameters. Step 1 examined whether age moderated the relationship between these lifestyle variables and memory performance, using Johnson-Neyman probing (*PROCESS* Model 1) and age-stratified linear regression. Step 2 further explored potential mechanisms and the brain reserve hypothesis through lifestyle-moderated mediation analysis (Model 8) and mean hippocampal volume moderation (Model 1).

Ethical Considerations

The study was approved by the Institutional Review Board of Chang Gung Medical Foundation, Taiwan (approval number 201900702A3). Written informed consent was obtained from all participants. To ensure privacy and confidentiality, all data were deidentified using unique study codes, with no personally identifiable information stored with research data. Participants received NT $100 (US $3.10) for nutritional supplementation and NT $200 (US $6.20) for transportation for each visit involving additional blood sampling or questionnaire-based assessments.



Results

Participants' Characteristics

Of the 128 individuals initially enrolled in the study, 112 met the inclusion criteria. Participants who did not complete the body composition assessment (bioelectrical impedance analysis), brain MRI, or valid actigraphy recordings were excluded. After these exclusions, a total of 88 participants were included in the final analysis (flow diagram in Figure 2). Their demographic characteristics, cognitive performance, subjective sleep assessments, and actigraphy-derived sleep and physical activity parameters are summarized in the total column of Table 1.

XSL•FO
RenderX

Figure 2. Flow diagram of the inclusion process. BIA: bioelectrical impedance analysis; MRI: magnetic resonance imaging.

The mean age of participants was 73.5 (SD 7) years, and 55.7% (49/88) were female. Educational attainment was distributed as follows: 8% (7/88) had completed primary school, 23.9% (21/88) had completed junior or senior high school (including vocational programs), 52.3% (46/88) had attended college or university, and 15.9% (14/88) held a graduate degree. The mean BMI was 23.7 (SD 3.4) kg/m^2, and the average systolic and diastolic blood pressures were 138.4 (SD 17) mm Hg and 75 (SD 9.6) mm Hg, respectively. Regarding habitual exercise, 75% (66/88) of participants reported engaging in regular physical activity exceeding 150 minutes per week, 19.3% (17/88) exercised less than 150 minutes per week, and only 5.7% (5/88) reported no regular exercise habit.

The average CERAD-NB memory score was 37 (SD 5.7). In terms of subjective sleep assessments, the mean scores were 6.4 (SD 3.8) for the PSQI and 3.7 (SD 3.7) for the ESS.

Actigraphy-derived sleep parameters revealed an average TIB of 468 (SD 81.2) minutes and TST of 391.5 (SD 80.7) minutes. The mean sleep onset latency was 11.6 (SD 13.4) minutes, sleep efficiency was 83.6% (SD 8.2%), and WASO averaged 56.2 (SD 25.6) minutes. In terms of physical activity, participants showed an average M10 activity of 267 (SD 97.2) counts/minute and L5 activity of 21.7 (SD 15.6) counts/minute. Daily activity distributions included a mean LPA time of 141.5 (SD 33.2) minutes, MPA of 236.2 (SD 67.6) minutes, and VPA of 141.3 (SD 88.5) minutes. Average wake light exposure was 136576.4 (SD 129264.3) lux-minute, and sleep light exposure was 497.9 (SD 1103.9) lux-minute. A comprehensive summary of subjective and actigraphy-derived sleep and activity parameters is provided in Textbox 1.

Correlation Between Sleep, Physical Activity, and Memory Performance

Partial correlation analyses adjusted for age were conducted to examine the associations between actigraphy-derived parameters and memory performance, as measured by the CERAD-NB memory score (Table 2).

Among sleep-related variables, WASO showed a significant negative correlation with memory performance (r=–0.251; P=.02), indicating that greater sleep fragmentation was associated with lower memory scores. Other sleep parameters, such as TIB (r=–0.199; P=.07), sleep efficiency (r=0.152; P=.16), and onset latency (r=–0.119; P=.28), did not reach statistical significance.

Table 2. Partial correlations between actigraphy parameters and Consortium to Establish a Registry for Alzheimer's Disease Neuropsychological Battery memory score.

Actigraphy variables	Values (adjusted for age)	
	r	*P* value
Sleep		
Time in bed (min)	–0.199	.07
Total sleep time (min)	–0.082	.45
Onset latency (min)	–0.119	.28
Sleep efficiency (%)	0.152	.16
Wake after sleep onset (min)	–0.251	.02
Physical activity		
M10[a] (counts/min)	0.216	.046
L5[b] (counts/min)	–0.098	.37
Awaking total activity (counts)	0.166	.13
Sleep total activity (counts)	–0.160	.14
Physical activity time (min)	0.196	.07
SB[c] time (min)	–0.132	.23
LPA[d] time (min)	0.260	.02
MPA[e] time (min)	0.170	.12
VPA[f] time (min)	0.120	.27
Light exposure		
Wake light exposure (lux-min)	–0.144	.19
Sleep light exposure (lux-min)	–0.167	.12

[a]M10 indicates the mean activity (counts/min) during the most active 10 consecutive hours.

[b]L5 indicates the mean activity (counts/min) during the least active 5 consecutive hours.

[c]SB: sedentary behavior.

[d]LPA: light-intensity physical activity.

[e]MPA: moderate-intensity physical activity.

[f]VPA: vigorous-intensity physical activity.

Regarding physical activity, several metrics showed modest positive correlations with memory. Notably, LPA time was significantly associated with better memory scores (r=0.260; P=.02). Additionally, M10—the mean activity (counts/min) during the most active 10 consecutive hours—was also significantly correlated with memory scores (r=0.216; P=.046). However, LPA was prioritized for subsequent multivariate and moderation analyses because it represents a clearly defined, low-intensity, and modifiable behavioral category, whereas M10 reflects a composite index of total daytime movement combining multiple activity intensities. Thus, LPA provided a more interpretable and intervention-relevant indicator for

XSL•FO
RenderX

modeling behavioral effects on memory. Total physical activity time (r=0.196; P=.07) and MPA (r=0.170; P=.12) showed nonsignificant trends in the expected direction. No significant associations were observed for sedentary time, VPA, or nighttime sleep activity.

Light exposure variables, including wake light exposure and sleep light exposure, also did not show significant correlations with memory performance (P>.10). Taken together, WASO and LPA time emerged as the 2 behavioral parameters showing statistically significant and physiologically meaningful associations with memory and were therefore selected for subsequent regression and moderation models to examine their independent and age-dependent effects on cognitive performance.

Age as a Moderator of the Association Between Lifestyle Factors and Memory

To determine whether age moderated the relationship between modifiable lifestyle factors and memory performance, moderation analyses were conducted using *PROCESS* Model 1 with the Johnson-Neyman technique. As illustrated in Figure 3, age significantly moderated both associations of LPA time and WASO with CERAD-NB memory scores. In contrast, no significant moderating effects of age were observed for MPA, VPA, or combined moderate to vigorous physical activity (MVPA) on memory performance (Figure S1 in Multimedia Appendix 1).

Figure 3. Interaction effects of age with light-intensity physical activity (LPA) time and wake after sleep onset (WASO) on Consortium to Establish a Registry for Alzheimer's Disease Neuropsychological Battery (CERAD-NB) memory performance. (A) Interaction between LPA time and age on CERAD-NB memory scores. (B) Johnson-Neyman plot showing the age-dependent significance threshold for the association between LPA time and memory. (C) Interaction between WASO and age on CERAD-NB memory scores. (D) Johnson-Neyman plot showing the age-dependent significance threshold for the association between WASO and memory.

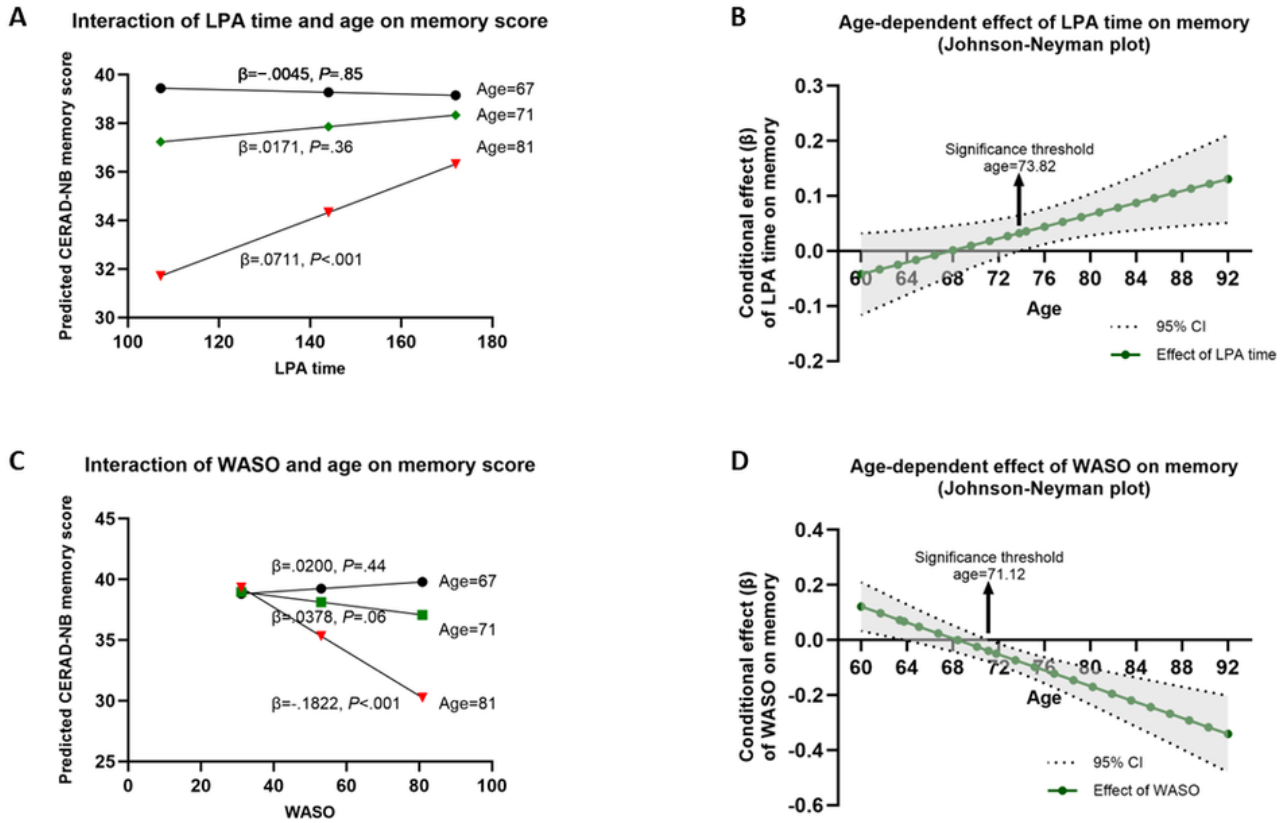

Figure 3A illustrates the interaction between LPA time and age on CERAD-NB memory scores. While no significant association was found in younger adults (eg, aged 67 or 71 years), higher LPA time was significantly associated with better memory performance at older ages (eg, 81 years; β=.0711; P<.001). Figure 3B shows the Johnson-Neyman plot, indicating that the association between LPA time and memory became statistically significant at age 73.82 years onward.

Figure 3C depicts the interaction between WASO and age. While WASO was not significantly associated with memory among younger individuals, it showed a significant negative relationship at older ages (eg, 81 years; β=–.1822; P<.001). The Johnson-Neyman plot in Figure 3D indicates a significance threshold at age 71.12 years, after which increased WASO was associated with worse memory performance.

All models were tested using the *PROCESS* macro Model 1 (moderation analysis), examining the interaction between age and each lifestyle factor.

For LPA time, the conditional effect on memory became statistically significant at age 73.82 years, above which greater LPA time was associated with higher memory scores. Conversely, for WASO, the association with memory became significantly negative starting from age 71.12 years, indicating that sleep fragmentation had a more detrimental impact on

XSL•FO
RenderX

memory among older participants. Based on these results, we stratified participants into 2 groups using an age cutoff of 72 years for subsequent subgroup analyses.

Compared to younger participants, older adults (aged ≥72 years), as shown in the age-stratified columns of Table 1, had significantly lower CERAD-NB memory scores (35.4, SD 6.5 minutes vs 38.7, SD 4.2; *P*=.02), longer TIB (491.8, SD 87.2 minutes vs 444.3, SD 67.6 minutes; *P*=.006), and greater TST (412.5, SD 83.2 minutes vs 370.5, SD 73.1 minutes; *P*=.02). However, no significant age differences were observed in sleep onset latency, sleep efficiency, or WASO.

In terms of physical activity, participants aged ≥72 years had significantly lower M10 activity (237.1, SD 85.4 counts/min vs 296.9, SD 99.9 counts/min; *P*=.006), shorter VPA time (108.2, SD 61.6 minutes vs 174.4, SD 99.1 minutes; *P*<.001), and reduced awake total activity and sleep total activity counts (*P*<.01). They also exhibited significantly lower wake light exposure (*P*<.001).

Further comparisons in Table S1 in Multimedia Appendix 1 revealed significant age-related physiological and structural differences. Older participants had slower gait speed, lower estimated glomerular filtration rate, and smaller hippocampal volume, including both right and left hippocampi (*P*<.001). Additionally, significant age-related differences were observed in visceral fat rating, ECW and TBW ratio, and regional brain structure volumes (eg, anterior cingulate cortex), consistent with expected patterns of biological aging. Moreover, among the inflammatory markers assessed, only interleukin-8 showed a significant increase with age (*P*=.02), whereas other cytokines (interleukin-1β, interleukin-6, interleukin-10, tumor necrosis factor-alpha) did not differ significantly between groups, suggesting mild low-grade inflammation in this otherwise healthy cohort.

Together, these findings support the use of age-stratified analyses to further explore how sleep and activity factors impact memory differently across the aging continuum.

Multivariate Models and Brain-Based Mechanisms

To assess the independent contributions of LPA time and WASO to memory performance, multivariate linear regression analyses were conducted, adjusting for age, education level, ESS scores, and mean hippocampal volume. As shown in Table 3, both LPA time (β=.042; *P*=.01) and WASO (β=–.044; *P*=.04) remained significant predictors of CERAD-NB memory scores in the overall sample. Increasing age was independently associated with lower memory scores (β=–.318; *P*=.003), whereas education level, ESS, and hippocampal volume did not show significant contributions in the total model. Among participants aged ≥72 years, the effects of LPA time (β=.054; *P*=.04) and WASO (β=–.111; *P*=.01) on memory remained statistically significant, suggesting that these modifiable lifestyle factors exert a stronger influence in later age.

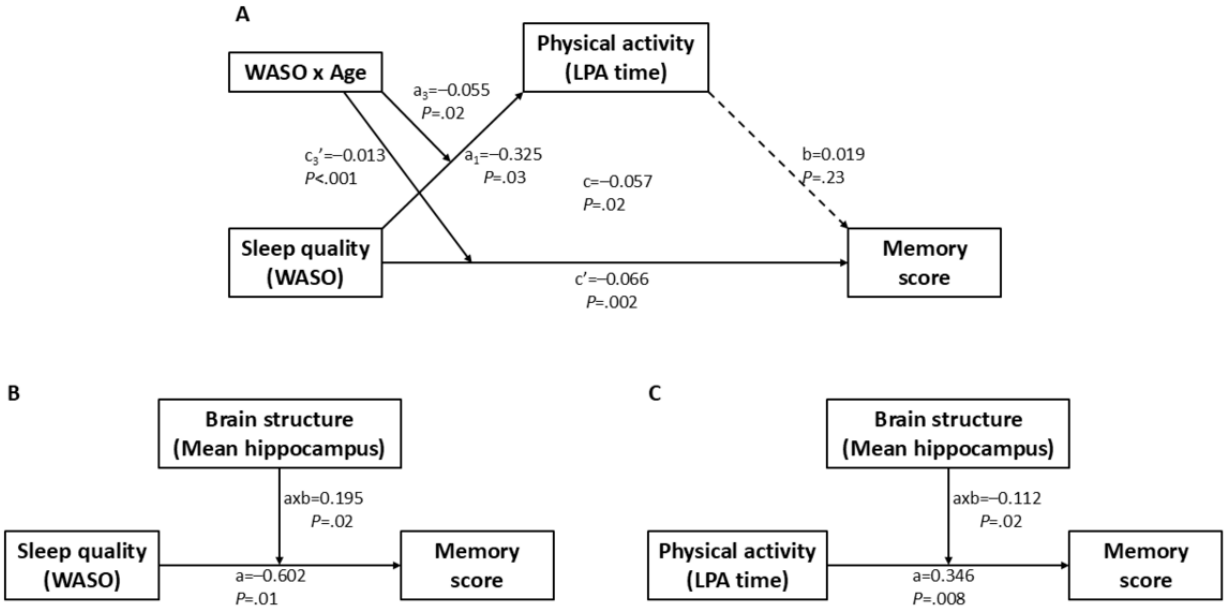

Table 3. Multivariate linear regression models examining associations of light-intensity physical activity (LPA) time and wake after sleep onset (WASO) with Consortium to Establish a Registry for Alzheimer's Disease Neuropsychological Battery memory scores. Two adjusted models are presented: the left column reports results for the full sample, and the right column reports results for participants aged ≥72 years. Both overall models were statistically significant (*P*<.001). All models were adjusted for age, education level, Epworth Sleepiness Scale score, and mean hippocampal volume. Regression coefficients (β) and corresponding *P* values are reported.

Factors	Models (total)		Models (age ≥72 years)	
	β	*P* value	β	*P* value
Age	–.318	.003	–.268	.15
Education	1.144	.09	.886	.39
Epworth Sleepiness Scale	–.207	.17	–.257	.25
Mean hippocampal volume	.054	.98	6.053	.09
LPA time	.042	.01	.054	.04
WASO	–.044	.04	–.111	.01

To further explore the potential mechanisms linking sleep fragmentation, physical activity, and memory decline, 2 exploratory models were tested using the *PROCESS* macro (Figure 4A). A moderated mediation model (Model 8) showed that higher WASO was associated with lower LPA time (a_1=–0.325; *P*=.03), and this relationship was significantly moderated by age (a_3=–0.055; *P*=.02), suggesting that sleep disruption more strongly reduced activity levels in older adults. However, LPA itself was not a significant predictor of memory performance (b=0.019; *P*=.23), and the indirect effect of WASO on memory via LPA was not statistically significant. Instead, WASO exerted a direct effect on memory performance (c'=–0.066; *P*=.002) that was also moderated by age (c_3'=–0.013; *P*<.001), supporting an age-dependent vulnerability to sleep fragmentation on cognitive function.

XSL•FO
RenderX

Figure 4. Exploratory models examining potential mechanisms linking sleep fragmentation, physical activity, and memory performance in older adults. (A) Moderated mediation model examining whether the association between wake after sleep onset (WASO) and memory performance is mediated by light-intensity physical activity (LPA) time and moderated by age. (B) Moderation model testing whether mean hippocampal volume moderates the association between WASO and memory performance. (C) Moderation model testing whether mean hippocampal volume moderates the association between LPA time and memory performance.

In Figure 4A, a moderated mediation model (*PROCESS* Model 8) was used to examine whether the relationship between sleep fragmentation (measured by WASO) and memory performance was mediated by LPA time and whether age moderated these behavioral pathways. Higher WASO was associated with reduced LPA (a_1=–0.325; *P*=.03), and this effect was moderated by age (a_3=–0.055; *P*=.02), indicating a stronger negative effect of sleep disruption on physical activity in older individuals. However, LPA was not a significant predictor of memory performance (b=0.019; *P*=.23), and the indirect path from WASO to memory via LPA was not statistically significant. In contrast, the direct effect of WASO on memory remained significant after accounting for LPA (c'=–0.066; *P*=.002), and this effect was also moderated by age (c_3'=–0.013; *P*<.001), indicating that the negative impact of WASO on memory increased with advancing age.

In addition, moderation analyses (*PROCESS* Model 1) were used to test the brain reserve hypothesis by examining hippocampal volume as a moderator of the LPA-memory and WASO-memory associations (Figures 4B and 4C). For WASO, hippocampal volume significantly moderated the association with memory (interaction effect: a×b=0.195; *P*=.02), suggesting that individuals with greater hippocampal volume were less affected by sleep fragmentation. Similarly, for LPA, the moderation effect was significant (a×b=–0.112; *P*=.02), indicating that low hippocampal reserve amplified the cognitive impact of reduced physical activity.

These findings provide evidence for both behavioral (activity-mediated) and structural (hippocampal-modulated) pathways linking modifiable lifestyle factors to memory outcomes in older adults.

In Figure 4B, moderation models (*PROCESS* Model 1) examined whether mean hippocampal volume moderated the effects of WASO and LPA on memory, consistent with the brain reserve hypothesis. These models showed that mean hippocampal volume significantly moderated the relationships between both WASO (a=–0.602; *P*=.01; a×b=0.195; *P*=.02) and LPA (a=0.346; *P*=.008; a×b=–0.112; *P*=.02) with memory scores. These findings support the idea that greater structural brain reserve may buffer the negative impact of sleep disruption and low activity on cognitive outcomes in aging.

These findings underscore WASO as a direct and age-sensitive predictor of memory performance, with its negative impact particularly evident in older individuals and those with lower hippocampal reserve. Although LPA did not mediate the sleep-memory relationship, it remained an independent modifiable factor, also moderated by brain reserve. Together, sleep continuity and light physical activity represent key behavioral targets for cognitive preservation in aging.

Discussion

Principal Findings

In this study, using wearable device–based monitoring, we identified 2 objectively measured lifestyle factors—LPA time and WASO—that were significantly associated with memory performance in community-dwelling older adults. Higher LPA time was linked to better memory scores, while greater WASO was associated with poor memory. These associations remained

XSL•FO
RenderX

robust after adjusting for age, education, daytime sleepiness, and hippocampal volume. Importantly, age moderated both effects, with LPA showing a protective role from age 73.8 years onward, and WASO exerting a detrimental influence from age 71.1 years onward. Subgroup regression analyses confirmed that both LPA (β=.054; *P*=.04) and WASO (β=–0.111; *P*=.01) were stronger predictors of memory among older participants (≥72 years of age). Moreover, hippocampal volume moderated these associations, consistent with the brain reserve hypothesis.

Beyond these primary findings, this study contributes novel insights in 3 ways. First, it simultaneously examined sleep and physical activity using objective wearable-based monitoring, rather than focusing on one lifestyle factor in isolation. Second, it integrated these measures with validated neuropsychological testing and structural brain imaging, providing a multimodal framework to explore behavioral and neural determinants of cognitive health. Third, by testing age and hippocampal reserve as moderators, it highlights how the effects of lifestyle factors intensify with advancing age and reduced neural reserve. Taken together, this work advances understanding of how modifiable lifestyle behaviors interact with biological aging processes to influence memory in older adults, particularly within an underrepresented Asian population.

This study highlights LPA and sleep continuity (measured as WASO) as key modifiable lifestyle factors associated with memory performance in community-dwelling older adults. Our findings on the correlation between sleep and memory function align with those of other studies. Actigraphy-based research has identified links between sleep disturbances, prolonged sleep duration, and poorer cognitive performance [6,12,20,29]. Recent evidence from an accelerometer-based study in *JMIR Aging* further demonstrated that greater night-to-night variability in sleep efficiency was associated with poorer cognitive performance in older adults [30], reinforcing the role of objective sleep fragmentation in cognitive aging. Consistently, wearable-derived rhythm metrics, such as interdaily stability and sleep-wake fragmentation measured by the myRhythmWatch platform, have been linked to cognitive impairment among community-dwelling elders [31], supporting the concept that circadian rhythm disruption contributes to cognitive vulnerability. Similarly, good sleep quality, as objectively measured by polysomnography, has been shown to correlate with enhanced cognitive performance in older adults [11]. Various potential mechanisms have been proposed to explain how sleep influences cognition in older people. Sleep disturbances might negatively impact synaptic plasticity by disrupting neuronal and glial signaling pathways [32]. Inadequate sleep could promote neuroinflammation and impair neurogenesis, potentially leading to neurodegeneration in the hippocampus [33]. Furthermore, increased sleep fragmentation, often due to sleep-disordered breathing, could induce neuron apoptosis and brain atrophy through inflammatory and oxidative pathways [34]. A polysomnography-based study also highlighted the relationship between sleep and glymphatic function, which, in turn, was associated with neuropsychological function [35] and gray matter volumes [36].

Numerous studies have identified physical activity as a crucial, modifiable lifestyle factor influencing cognitive and memory function in aging populations [14,37]. However, the optimal duration, frequency, and intensity of physical activity necessary to mitigate cognitive decline in older adults remain uncertain. Several mechanisms have been proposed to explain the cognitive benefits of physical activity. One key hypothesis centers on its impact on brain structure; that is, MRI-based studies have shown that regular activity is associated with preserved brain microstructure and reduced hippocampal atrophy [38,39]. At the molecular level, exercise stimulates the release of myokines from skeletal muscle, promoting the production of neurotrophic factors such as brain-derived neurotrophic factor and insulin-like growth factor-1 [18]. These neurotrophic mediators support synaptic plasticity, neurogenesis, and angiogenesis in regions critical to memory, including the hippocampus [40-44]. This interaction between muscle and brain could account for the observed benefits of physical activity on cognitive function in older people. Reports suggest that higher intensity and variability in physical activity are linked to a reduced risk of dementia [45,46]. While MVPA is often the focus of public health recommendations, our findings indicate that even low-intensity movement, particularly LPA, plays a meaningful role in supporting cognitive health. Interestingly, in our relatively healthy older adult sample, 75% (66/88 participants) reported having regular exercise habits exceeding 150 minutes per week, and accelerometry data showed that MPA time was substantially higher than LPA time (mean MPA 236.2, SD 67.6 minutes/day vs mean LPA: 141.5, SD 33.2 minutes/day). The absence of a significant association between MPA and memory in our data may partly reflect a ceiling effect, as most participants already met or exceeded recommended activity levels. However, this explanation remains speculative and was not directly tested. Future studies with broader variability in physical activity levels are warranted to verify this interpretation. In contrast, LPA, which includes incidental movement such as light walking, standing, or household activities, showed greater interindividual variation and a stronger correlation with cognitive function. Consistent with this interpretation, supplementary analyses (Figure S1 in Multimedia Appendix 1) demonstrated that neither MPA, VPA, nor their combined MVPA time showed significant age-moderated associations with memory performance, further supporting that low-intensity, sustained movement may be a more sensitive behavioral indicator of cognitive health in highly active older adults.

Our findings extend the emerging evidence supporting incidental light physical activity as a health-promoting behavior. A recent large-scale study [47] demonstrated that incidental light physical activity was associated with a dose-dependent reduction in cardiovascular events and all-cause mortality, even in populations not engaging in structured exercise. Building on these results, our study provides novel evidence that LPA is also beneficial for brain health, particularly memory performance in older adults. Additionally, physical activity may contribute uniquely to cognition through nonfatiguing, sustained movement that stabilizes cerebral perfusion, minimizes sleep disruption, and potentially supports glymphatic clearance. Recent evidence suggests that long-term exercise can enhance brain waste removal via glymphatic and meningeal lymphatic pathways [48], providing a novel mechanism linking physical activity with cognitive health. Taken together, these findings

XSL•FO
RenderX

suggest that while maintaining structured exercise remains important [49], encouraging older adults to stay consistently active throughout the day, even at low intensity, may be an equally vital strategy for preserving memory and cognitive function.

Our findings indicate that age significantly moderates the impact of lifestyle factors on memory performance. Using Johnson-Neyman analysis, we identified distinct age thresholds—73.8 years for LPA and 71.1 years for WASO—beyond which the cognitive effects of these modifiable behaviors became statistically significant. While both LPA and WASO were significant predictors of memory performance in the overall sample, subgroup regression analyses showed that their predictive effects were even stronger among participants aged ≥72 years. This observation aligns with emerging evidence that aging is not a uniform or linear process but one marked by biological inflection points across the lifespan. For instance, a large-scale proteomic study [50] revealed 3 major age-related transitions in the human plasma proteome—around ages 34, 60, and 78 years—indicating phase-like shifts in biological aging trajectories. Similarly, a recent multiomics analysis [51] showed cliff-like drops in functional integrity occurring around ages 44 and 60 years, supporting a model of nonlinear, stepwise aging rather than gradual decline. While our study does not directly assess molecular aging, our results extend this nonlinear perspective by showing that the cognitive impact of behavioral factors such as physical activity and sleep continuity intensifies with advancing age. These findings carry important clinical implications. They suggest that behavioral risks are not static across age but rather become more influential in late life, even in otherwise healthy older adults. This emphasizes the importance of early and consistent engagement in health-promoting behaviors throughout adulthood, while also recognizing that targeted interventions in older age may yield greater benefits. Age-stratified strategies that prioritize sleep consolidation and daily activity may help optimize cognitive preservation throughout aging.

Our exploratory analyses suggest that the relationship between sleep and memory is not only behavioral but also shaped by neurobiological and age-related factors. Although sleep fragmentation (WASO) was associated with reduced LPA in older adults, this behavioral pathway did not significantly mediate memory outcomes. Instead, WASO exerted a robust and direct negative influence on memory, with the effect strengthening significantly with increasing age. The absence of a significant indirect pathway suggests that sleep fragmentation may impair memory primarily through direct neurophysiological mechanisms—such as disrupted synaptic homeostasis or impaired glymphatic clearance—rather than solely through behavioral reductions in activity. This interpretation aligns with prior evidence linking sleep continuity to neural restoration and waste clearance processes. In parallel, hippocampal volume moderated the associations of both WASO and LPA with memory performance. Participants with larger hippocampi showed relative resilience to the adverse effects of poor sleep and low activity, whereas those with smaller hippocampal volume demonstrated stronger behavior-cognition associations. These findings support the brain reserve hypothesis, which posits that individuals with greater structural brain integrity are more capable of withstanding behavioral and pathological insults without manifesting cognitive decline. While hippocampal volume has previously been linked to cognitive resilience in the context of neuropathology, depression, and sleep disorders [52-54], our results extend this model to modifiable lifestyle factors measured objectively via wearable technologies in cognitively healthy older adults.

To explore the reasons behind the varying correlation patterns between sleep, physical activity, and memory function in participants older than 72 years, we compared several physical, laboratory, and imaging parameters between participants younger and older than this age threshold. Significant differences were observed in some variables, such as pulse rate, visceral fat rating, the ratio of ECW to TBW, indicators of muscle function, and hippocampal volume, but not in the appendicular skeletal muscle mass index between the 2 groups. Previous studies have indicated that higher levels of body fat negatively affect brain volume and contribute to memory decline [55]. Furthermore, higher ratios of ECW to TBW have been linked to poorer cognition [56]. Whether these differences in body composition are responsible for diminishing the effects of physical activity on memory function in individuals aged 72 years or older requires further investigation.

In addition to these physiological factors, systemic inflammation may also play a role in mediating age-related differences. Inflammatory markers, including interleukin-1β, interleukin-6, interleukin-10, and tumor necrosis factor-alpha, were assessed in this study (Table S1 in Multimedia Appendix 1). Among these, only interleukin-8 levels were significantly higher in older adults, while other cytokines showed no marked differences. This pattern suggests that low-grade inflammation may exist but remains relatively mild in this healthy, community-dwelling sample. The modest change in IL-8 could reflect early immune activation associated with aging and sleep disruption, consistent with prior evidence linking chronic sleep fragmentation to subtle increases in inflammatory signaling [57-59]. Future studies incorporating oxidative stress and glial activation markers could help clarify whether inflammatory processes mediate the observed age-specific behavioral and cognitive effects.

In this study, we used the Actiwatch 2 accelerometer to objectively assess physical activity and estimate sleep quality and duration. As a lightweight and easy-to-wear device, actigraphy enables continuous monitoring over multiple days or weeks [60], thereby capturing behavioral patterns that more closely reflect individuals' habitual, real-world lifestyles. While actigraphy is known to overestimate TST and underestimate nocturnal awakenings when compared to polysomnography [60], it remains a practical and scalable tool in population-based and longitudinal research [61]. In an era of increasingly accessible wearable technology, actigraphy offers valuable insight into daily lifestyle rhythms and provides meaningful, ecologically valid data to inform behavioral recommendations and health interventions, especially in community and aging populations where in-laboratory polysomnography is often not feasible.

XSL•FO
RenderX

Our findings contribute new insights by integrating wearable-derived behavioral data, validated neuropsychological memory outcomes, and structural brain imaging into a unified analytic model. The demonstration that sleep and activity behaviors interact with age and hippocampal reserve to influence memory performance underscores the complexity and heterogeneity of cognitive aging. Importantly, these results suggest that individuals with lower hippocampal volume—who may be at higher risk of future cognitive decline—could particularly benefit from targeted interventions that improve sleep continuity and promote consistent physical activity. This highlights the potential value of combining lifestyle-based strategies with brain-based risk stratification in the design of personalized cognitive health programs for older adults.

From a translational perspective, these findings underscore the potential of promoting incidental, low-intensity movement, such as walking, household activities, and standing breaks, as realistic behavioral goals for older adults who may find structured exercise challenging. Public health strategies emphasizing total daily movement, rather than only moderate to vigorous exercise, may therefore be particularly beneficial in aging populations.

This study has several notable strengths. First, we used objective, wearable-based monitoring to assess both sleep and physical activity over an extended period in a real-world setting, avoiding the biases associated with self-reported lifestyle data. Second, by focusing on memory-specific cognitive outcomes, rather than global cognition, we provide a more targeted understanding of functional decline in aging. Third, we incorporated structural neuroimaging data to test how brain reserve, operationalized as hippocampal volume, interacts with behavioral risk factors. To our knowledge, this is one of the few studies to examine the joint impact of objectively measured lifestyle factors and neural reserve on memory performance in healthy older adults, using advanced moderation and mediation models to capture complex interactions between age, behavior, and brain structure.

Despite these strengths, several limitations should be acknowledged. First, although this was a prospectively designed cross-sectional study, the absence of longitudinal follow-up limits our ability to infer causal relationships between physical activity, sleep, and memory function. Future longitudinal or interventional studies are warranted to verify the temporal and causal pathways suggested by our findings. Second, participants were recruited from a single hospital-based health examination program in northern Taiwan, which may introduce selection bias and limit external validity. Third, our sample consisted primarily of relatively healthy, community-dwelling older adults with generally high physical activity levels. While this ensured sample homogeneity and reduced confounding, it also excluded high-risk individuals, such as those with cognitive impairment or major chronic diseases, thus limiting the generalizability of our results to more clinically vulnerable populations. Fourth, participants were aware that their activity and sleep were being monitored, which may have temporarily increased activity levels and slightly reduced the accuracy of habitual behavior estimates. Fifth, although actigraphy is not the gold standard for evaluating sleep architecture or activity intensity, it remains a US Food and Drug Administration–approved, user-friendly tool that enables unobtrusive and ecologically valid data collection under free-living conditions. In an era of widespread wearable technology use [62], actigraphy offers scalable and meaningful behavioral data for aging research. Sixth, polysomnography data were collected as part of the broader ISDHA cohort but were not included in this analysis because this study focused on wearable-based lifestyle measures to capture real-world behavior; polysomnography findings will be reported separately. Seventh, we did not account for other potentially influential factors, such as diet, socioeconomic status, or social engagement, that may also modulate cognitive outcomes. Finally, although hippocampal volume was examined as a moderator, other neural or molecular mechanisms (eg, functional connectivity or serum neurotrophic and inflammatory markers) were not analyzed. While basic inflammatory cytokines were assessed, more specific biomarkers of oxidative stress or neuroinflammation (eg, glial or endothelial activation indices) should be incorporated in future studies to clarify underlying biological pathways. Additionally, the proposed ceiling effect for moderate physical activity should be interpreted cautiously, as it was not formally tested. Collectively, these limitations highlight the need for longitudinal, multisite studies integrating multimodal biomarkers to validate and expand our findings. Nonetheless, this study provides an essential foundation for identifying modifiable behavioral factors and developing age- and brain-based strategies to preserve cognitive health in older adults.

Conclusions

In this study of cognitively healthy older adults, we demonstrated that 2 modifiable lifestyle factors—sleep continuity and LPA, objectively measured via wearable devices—were significantly associated with memory performance. These associations were further shaped by age and hippocampal volume, emphasizing the interplay between behavioral and neurobiological factors in cognitive aging. Our findings provide empirical support for the brain reserve hypothesis and highlight that the cognitive impact of lifestyle behaviors becomes more pronounced in later life and among individuals with lower neural reserve. Encouraging consistent, light-intensity activity throughout the day, together with maintaining sleep continuity, may represent a practical, scalable, and age-tailored strategy to support cognitive health in older adults. Future longitudinal and intervention studies are warranted to validate these pathways and inform personalized behavioral approaches for preserving memory function across aging populations.

Abstract

Background: With the growing number of older adults in the Norwegian population and the associated rapid rise in dementia and cognitive impairment, novel and more efficient methodologies are needed to facilitate research, improve diagnostic triage, and deliver effective brain health interventions in the community. Platform for Research Online to Investigate Genetics and Cognition in Ageing Norge (PROTECT Norge) is a web-based, remote research platform on the aging brain, culturally adapted from the UK PROTECT study, incorporating a Norwegian cohort of adults aged 50 years and older, where participants complete study activities via a dedicated website. Data were collected through study activities, which included self-reported questionnaires and a computerized neuropsychological test battery.

Objective: The study aimed to assess associations between dementia risk factors, including obesity, hypertension, smoking, and hearing loss, and cognition using baseline data from the PROTECT Norge study.

Methods: Data from the PROTECT Norge study were used to assess associations between dementia risk factors and cognition. These associations were assessed using independent-sample *t* tests for each of the cognitive tests, which included paired associate learning, self-ordered search, digit span, and verbal reasoning tasks.

Results: During the first 2 years of data collection, records from 3214 participants were obtained. Associations between established risk factors and cognitive performance were found, with significant detriments to cognitive performance on the computerized neuropsychological test battery. In the PROTECT Norge cohort, consisting of 74.5% females, the mean age was 64.1 (SD 7.7), and 94% of participants provided consent for contact regarding future research.

Conclusions: These data show the associations between dementia risk factors and cognition and attest to the excellent feasibility of the PROTECT Norge cohort, with over 3000 participants included over a period of 2 years and accessibility for people with early cognitive impairment. This, combined with the cohort's willingness to participate in future studies (94%), positions PROTECT Norge as a tremendous opportunity for cost-efficient, large-scale brain health research and potentially for clinical digital cognitive health programs.

Introduction

With an aging population, developing new approaches to improve brain health and prevent cognitive decline is essential to empower the community and mitigate against a potential "dementia epidemic." For example, there are already more than 50 million people worldwide living with dementia, and this is projected to rise rapidly over the next 30 years [1]. Aging is the single biggest risk factor for dementia [2]. In addition, genetic predispositions contribute significantly to dementia risk, both of which are factors with limited potential for mitigation. However, within the domains of lifestyle, mental health, and physical health, there exists a spectrum of potential modifiable risk factors for dementia [3], which are thought to account for 40% of the total dementia risk. With no cure for dementia,

XSL•FO
RenderX

addressing these potentially modifiable risk factors through proactive management and preventative interventions is proposed as a key strategy going forward. This approach aims to maintain and improve cognitive health in aging and slow the onset or progression of dementia, to address the expected increase of dementia cases in the population [3,4]. As populations worldwide grow older, the urgency of dementia prevention becomes increasingly evident. In Norway, this trend is reflected in a projected 30.1% increase in those aged 50 years and older from 2024 to 2050 [5], with rural municipalities seeing the greatest impact, where individuals aged 70 years and older could make up a third of the population [6]. Digital technologies show promise in supporting health promotion and disease prevention, with adults aged 50 years and older increasingly integrating them into their daily lives for this purpose [7].

In the United Kingdom, a web-based aging cohort was set up in 2014 to address these challenges. The Platform for Research Online to investigate Cognition and Genetics in Ageing- United Kingdom (PROTECT-UK [8-10]) study aimed to collate large-scale health and cognitive data from older adults to provide novel insights into cognitive trajectory in aging and the risk factors associated with decline. PROTECT-UK (University of Exeter) was built on emerging strengths in digital technologies and the rapid increase in engagement with the internet, computers, and smartphone devices by people in mid and later life. PROTECT-UK demonstrated the enormous potential for this approach to longitudinal research, enabling rapid recruitment of 20,000 participants within the first year, with strong year-on-year retention, for a fraction of the cost of traditional in-person cohort methodologies. Norway was the first country outside the United Kingdom to adopt the PROTECT model, contributing to its international expansion, with Canada later implementing a similar approach [11]. By providing large-scale, standardized cognitive data across multiple countries, PROTECT enables cross-national comparisons and enhances global understanding of dementia risk factors.

Platform for Research Online to Investigate Genetics and Cognition in Ageing Norge (PROTECT Norge) builds upon the PROTECT-UK infrastructure but is tailored to the Norwegian context. PROTECT Norge was launched in September 2020 and has already collected data on more than 5000 participants [12]. The PROTECT infrastructure has enabled large-scale collection of longitudinal data on a range of lifestyle, physical health, mental health, and well-being, in addition to robust, well-validated computerized neuropsychology data in the Norwegian population, providing an accessible, engaging, and cost-efficient approach to cognitive health research using a web-based, remote methodology, which combines computerized cognitive tests and health questionnaires on a dedicated web-based platform with remote genetic testing. The platform provides the opportunity to engage people at scale with epidemiological studies, genomic and biomarker research, and clinical trials. Upon registration, potential participants are given the option to voluntarily consent to being recontacted for future studies, which will enable us to capitalize on their participation in clinical trials relevant to cognition, health, and well-being. For example, this will be an important vehicle to increase the proportion of people who are offered participation in clinical studies, contributing to reach the Government's action plan and the national target of including 5% of the patient population in Norwegian hospitals by 2025.

The need for such digital initiatives like PROTECT Norge is underscored by the introduction of antiamyloid antibodies for dementia, whose effectiveness depends on early diagnosis. However, this remains a major challenge, as only 1 in 3 dementia cases in the Norwegian community are diagnosed, and diagnosis often occurs in late stages of the condition when irreversible cognitive decline has already led to pronounced functional impairments in daily life and an increased need for care [13].

PROTECT Norge is the only study of this scale incorporating remote data collection, including longitudinal cognitive testing in Norway. The platform is uniquely situated to optimize approaches for the early identification of people with progressive cognitive decline and provide a potential opportunity to evolve as a primary care and community health delivery pathway and resource. While PROTECT Norge is tailored to the Norwegian context, its findings contribute to the wider understanding of cognitive aging and dementia risk factors, supporting ongoing research efforts in dementia prevention and early detection.

This study presents information regarding the baseline characteristics, neuropsychological performance, and risk factors for dementia in the PROTECT Norge cohort with the objective of assessing associations between previously identified dementia risk factors and cognition.

Methods

Design

This is a cross-sectional analysis of data collected through PROTECT Norge, a web-based observational cohort study focusing on the aging brain of individuals aged 50 years and older living in the community in Norway. All data are collected remotely via the PROTECT Norge study website. The reporting of the study follows the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) [14] guidelines and the Checklist for Reporting Results of Internet E-Surveys (CHERRIES) [15] (the CHERRIES checklist is provided in Checklist 1).

Cross-Cultural Adaptation of PROTECT Norge

All questionnaires without an existing Norwegian translation, along with cognitive tests, underwent a thorough translation process [16]. Two native Norwegian speakers independently translated each measure, 1 familiar with the content and 1 unfamiliar. They then collaborated to create a consensus version. This was back-translated by 2 bilingual translators, preferably native English speakers. Where this was not feasible, Norwegians fluent in English with relevant academic or professional experience were used. An expert committee, including translators from all stages and PROTECT Norge working group members, reviewed all versions and finalized the Norwegian adaptations. For medical and mental health-related questionnaires, additional domain experts and professional translators contributed to quality assurance.

XSL•FO
RenderX

The PROTECT Norge platform underwent multiple rounds of user acceptance testing (UAT). Initial alpha and beta testing of an unscripted manner was conducted by PROTECT-UK and PROTECT Norge personnel. A scripted UAT was then carried out with 30 participants, including end users, user representatives, researchers, and PROTECT Norge personnel. This allowed for simultaneous platform testing and translation validation, ensuring clarity and usability [17].

Participants

Participants fulfill the inclusion criteria for PROTECT Norge, with all participants aged 50 years or older, residing in Norway, without a diagnosis of dementia, and with a good understanding of the Norwegian language. Participants must also have access to a computer or tablet with an internet connection. The vast majority of people over the age of 50 years in Norway are eligible, thus providing an opportunity for the whole community within this age group to participate in research. Participation is entirely remote and can be completed at home.

Recruitment

Participants were recruited to PROTECT Norge through publicity in national and regional broadcasting channels, newspaper coverage, placement of written materials in health care facilities, and oral presentations. However, social media, particularly Facebook, served as a primary recruitment channel through both nontargeted posts and targeted advertisements, the latter applying demographic filters based on the inclusion criteria (age 50 years and older and residing in Norway). The participants register, confirm eligibility, and provide consent through an ethically approved, validated web-based procedure, which includes voluntary consents for contact for future research and consent for providing saliva for genetic sampling. Following registration, participants provide demographic information and then receive email reminders for assessments and study activities. Participants complete an annual assessment of validated questionnaires and assessments on the PROTECT Norge platform.

Cognitive Assessments

Participants complete an annual cognitive assessment using a validated computerized cognitive assessment system. This analysis presents data from 4 widely used and well-validated cognitive tests that were in use on the platform from 2020 to 2022, including tests of spatial working memory (Paired Associate Learning [18], Self-Ordered Search [19]), numerical working memory (Digit Span [20]), and executive function (Verbal Reasoning [21]). The Trail-making B test was also included to enable benchmarking against well-established cognitive norms [22]. Mild cognitive impairment (MCI) was identified based on established thresholds [23].

Although not presented in this paper, it is important to note that in 2022, the cognitive assessment protocol was updated to the FLAME (Factors of Longitudinal Attention, Memory, and Executive Function; University of Exeter) cognitive test battery which includes the 4 original tests in addition to 3 tests of reaction time and attention, and 1 of attention and episodic memory. The FLAME battery is well validated [23], showing good discrimination between different levels of cognitive impairment, good sensitivity to change, and good concurrent validity with functional change. Importantly, the battery is validated for self-test in their own home [10].

Health Questionnaire Assessments

Participants complete annual questionnaire assessments to capture key risk and cognitive association factors. Participants provide information regarding current and past medical conditions through a tick-box selection of key conditions, including hypertension and hearing loss, free-text capture of prescribed medications, and height and weight to enable BMI calculation. Participants also complete a comprehensive questionnaire set to capture lifestyle and modifiable risk factors, including questions on smoking status (current-, ever-, and nonsmoker). Where participants have voluntarily nominated an informant, the informant is invited to complete adapted versions of specific questionnaires pertaining to the participant. Although not evaluated as part of the current paper, the other assessments undertaken are summarized in Textbox 1 for information.

XSL•FO
RenderX

Textbox 1. Other assessments completed in PROTECT Norge (Platform for Research Online to Investigate Genetics and Cognition in Ageing Norge).

The text box lists other study assessments undertaken by participants in PROTECT Norge:

- Health Questionnaire: captures Medical conditions and prescribed medications, sensory impairments, pain, and history of traumatic brain injury
- Family history of neurodegenerative disease questionnaire
- The Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE): self and informant questionnaire
- Mild Behavior Impairment (MBI) scale: measures neuropsychiatric symptoms; available as self and informant questionnaire
- Instrumental Activities of Daily Living questionnaire
- Lifestyle questionnaire: includes items capturing use of technology, cognitive training, alcohol use, caffeine intake, dietary supplement use, use of cognitively stimulating activities, and the number of languages spoken, physical activity, including CHAMPS (Community Healthy Activities Model Program for Seniors), physical activity questionnaire for older adults. This contains adaptive questioning, whereby certain items are conditionally displayed based on previous responses
- Composite mental health questionnaire: Patient Health Questionnaire (PHQ-9) and General Anxiety Disorder (GAD-7) scales as assessments of depression and anxiety, history of mental health disorder, items from the World Health Organization (WHO) composite international diagnostic interview psychosis and manic modules, addictions, including Alcohol Use Disorder Identification Test (AUDIT), questions relating to self-harm, suicidality, well-being, and experiences in adult life and childhood. Items exploring neurodivergent symptoms from childhood. This questionnaire is voluntary in its entirety, and participants may choose “prefer not to answer” for any item. It also uses adaptive questioning
- Sleep: St. Mary’s Sleep Questionnaire, Insomnia Severity Index, Bergen Insomnia Scale, and Epworth Sleepiness Scale
- Awareness of age-related change-10 SF: assesses perceived gains and losses with aging
- University of California, Los Angeles Three-Item Loneliness Scale (UCLA-3)
- ASK (Aging, Social Dynamics, and Knowledge) questionnaire: captures information about living situations, social interactions, technology use, travel habits, future housing preferences, and views on future care models

For all questionnaires, respondents can review and modify their responses at any time before final submission.

Patient and Public Involvement

User involvement is paramount in all health research and aligns with the mission of the Ministry of Health and Care Services to regional health authorities and has been the core value in all activities at the Centre for Age-Related Medicine - SESAM since its establishment in 2010. PROTECT Norge is supported by 2 designated user representatives who have been actively engaged since the start of PROTECT Norge. They are part of the steering group, have been represented in seminars, and have been actively involved in the translation of material from PROTECT-UK.

Statistical Analysis

Categorical variables were described using count and percentage. Continuous variables were described using mean (SD) if symmetrically distributed and median with IQR if otherwise. For each test, the average value of all scores over the number of times it was completed (from 1 to 3 at each testing time point) was used as a final score.

For each cognitive test score and each potential medical risk factor (Hypertension–present or absent, smoking ever, or nonsmoker), BMI (<30 v>30), hearing loss—present or absent—identified as risk factors from the Lancet commission meta-analysis [3], we performed a 2-tailed independent sample *t* test for each of the cognitive tests (df=3212). Two-tailed *P* values <.05 were considered significant; no adjustments for confounders and no correction for multiple testing were done. All statistical analyses were undertaken using SPSS (version 29; IBM Corp).

Ethical Considerations

This study uses data from the PROTECT Norge Study [12], launched in September 2020 and approved by the Regional Committee for Medical and Health Research Ethics, West (2019/478), and the study has been approved by the Stavanger University hospital. Informed consent was obtained through a validated web-based procedure, and data are stored in compliance with the General Data Protection Regulation (GDPR) and Stavanger University Hospital’s data security policy [24]. To protect privacy, data were pseudonymized before analysis. No compensation was provided for participants, except for gaining access to brain training games on the PROTECT Norge platform.

Results

Cohort Characteristics

During the first 2 years of the data collection period, 3214 participants completed the baseline assessment. The average age of the cohort was 64 years, of whom 74.5% (n=2393) were female and nearly 80% (n=2503) had a higher education degree. The majority (n=2289, 71.7%) of the participants were either widowed, divorced, or single, and 50% reported that they were working either part- or full-time. Of all the participants (n=3214), 58 had MCI. The full cohort characteristics are shown in Table 1.

The majority of participants (74.4%) reported hearing about PROTECT Norge through social media. Additional sources included friends and acquaintances (10.3%), traditional media (TV, radio, and newspapers; 4.4%), other study participants (4.2%), other sources (5.8%), and courses or conferences (0.9%).

XSL•FO
RenderX

Consent for contact for future research was provided by 94% of the participants in PROTECT Norge.

Table . Characteristics of PROTECT Norge[a] cohort participants.

Characteristics (n=3214)[b]	Values
Age (years), mean (SD), min/max	64.1 (7.7), 50.0/89.2
Female, n (%)	2393 (74.5)

[b]This table presents the demographic and health-related characteristics of the participants in the PROTECT Norge cohort study.

Cognitive Profile of the Cohort

The mean scores for each of the neuropsychological tests undertaken are described and compared between participants with and without MCI, showing that performance was significantly more impaired on the 4 PROTECT tasks in people with MCI compared with those with normal cognition (Table 2).

Table . Neuropsychological test scores and comparison of cognitive performance between people with MCI[a] and healthy cognition.

Test[b]	Mean (SD)	MCI vs normal cognition	
		t test (*df*)	*P* value
Digit Span Memory Test	6.3 (2.5)	6.7 (3212)	<.001
Paired Associate Learning	3.6 (1.0)	3.3 (3212)	<.001
Verbal Reasoning task	24.5 (10.1)	8.8 (3212)	<.001
Self-Ordered Search task	33.9 (14.4)	6.3 (3212)	<.001

[a]MCI: mild cognitive impairment.

[b]This table presents the mean scores (SD) on neuropsychological tests among individuals with mild cognitive impairment (MCI) compared to those with normal cognition. The statistical comparison between the MCI group and the normal cognition group is shown with corresponding *t* values (df=3212) and *P* values.

Association of Medical Risk Factors With Cognitive Performance

A consistent pattern of mainly significant associations was seen between the Lancet commission risk factors for dementia examined (hypertension, smoking, hearing loss, and BMI>30) [3] and the neuropsychological test battery scores. The full results are shown in Table 3.

XSL•FO

Discussion

Principal Findings

This study reports the baseline characteristics of the first 3214 participants in the PROTECT Norge digital cohort study of people aged 50 years and older. We found a consistent pattern of mainly significant associations between the Lancet Commission risk factors for dementia [3], including hypertension, smoking, hearing loss, and BMI>30, and lower cognitive performance on the neuropsychological test battery scores.

Comparison to Previous Work

Established risk factors for dementia (BMI, smoking, hypertension, and hearing loss) were all significantly associated with lower cognitive performance on the computerized neuropsychological tests, which is important for several reasons. First, it acts as a validation of the PROTECT Norge cohort, demonstrating the same pattern of risk associations that have been identified in other international studies [3]. Second, the work builds on this by demonstrating that in addition to the longer-term risks for dementia identified in other studies, these risk factors are associated with subtle but measurable cognitive impairments in individuals who are cognitively healthy but with an increased future risk of dementia. This also highlights the opportunities to improve cognitive health through intervention studies in the Norwegian population. Hearing loss is a relatively newly identified risk factor for dementia, and it is therefore of particular note that a strong association was seen between hearing loss and cognitive test performance. Emerging work also suggests that the risk can be mitigated by wearing hearing aids [25,26], with important potential public health implications.

Strengths and Limitations

First, a strength of the PROTECT Norge study is its fully digitalized study design, which has enabled the inclusion of over 3000 Norwegian individuals over a period of 2 years, during which high-quality data, including computerized neuropsychology, validated questionnaires collecting health, mental health, and lifestyle data were successfully collected. In addition, 94% of the cohort has consented to be contacted for future research. Second, the computerized neuropsychology cognitive test battery is objectively measured, demonstrates good discrimination between different levels of cognitive impairment, and has been validated for self-testing in a home setting [10]. However, other health assessments used in this study rely on self-reported data, which may introduce potential biases such as recall errors and misestimation. Third, it should be acknowledged that the findings reported in this study are based on cross-sectional data, meaning causality cannot be inferred.

Fourth, the cohort is predominantly Caucasian, female, and well-educated, in line with other digital health studies, and the self-selection recruitment strategy and a heavy reliance on Facebook for outreach have likely contributed to this imbalance, as women in this age group are more engaged on this platform [24,27]. Finally, although it is encouraging that participants with MCI successfully completed study assessments, only 58 of 3214 participants had MCI, well below population estimates and the proportion seen in PROTECT UK.

Future Direction

In 2030, for the first time in Norway, there will be more people over 65 years than 19 years and younger [6] and the number of people with dementia will increase from 101,118 in 2020 to almost 235,000 in 2050 [28], along with a reduction in the ratio of people working to those who are retired. These numbers are even more dramatic in rural districts [6]. Better brain health and improved initiatives to diagnose early cognitive impairment and prevent dementia will be imperative. Lifestyle and cognitive training interventions have been found to improve brain health and prevent cognitive decline [29,30], and the PROTECT infrastructure is well placed to deliver large-scale interventions to the Norwegian population. Digitalized research and health care platforms will be an essential part of improving the brain health of older people in our society.

This study demonstrates the feasibility of the PROTECT model, highlighting the tremendous opportunity for this approach to contribute significantly to large-scale, cost-effective brain health research and service delivery as we move forward. In addition, despite the current demographic limitations seen in PROTECT Norge, this study still provides valuable insights into how these risk factors influence cognition within a large cohort, contributing to the understanding of cognitive health at a population level. However, future efforts are warranted, specifically to improve demographic diversity in the cohort and increase the representation of individuals with early cognitive

XSL•FO
RenderX

impairment. Moving this forward could be done by specifically targeting underrepresented demographic groups on social media platforms, whilst simultaneously expanding outreach beyond social media to relevant interest groups or organizations and collaboration with primary care providers.

Conclusion

In summary, our study using PROTECT Norge data reveals significant associations between established dementia risk factors, including obesity, hypertension, smoking, and hearing loss, and lower cognitive performance, even among individuals who are cognitively healthy but at increased future risk of dementia. These findings support the validity of the PROTECT model and highlight its potential to detect early cognitive changes in at-risk populations. The successful collection of large-scale, remotely administered data further demonstrates the feasibility of this digital approach. PROTECT Norge offers a unique and cost-effective opportunity to scale brain health research and interventions across Norway, particularly by targeting individuals with modifiable risk factors.

However, to improve cohort representativeness, more targeted recruitment strategies are needed to reduce selection bias and enhance demographic diversity. Future efforts should focus on expanding outreach channels and optimizing participant engagement to improve the inclusion of underrepresented demographic groups, including individuals with MCI.

Acknowledgments

The PROTECT Norge (Platform for Research Online to Investigate Genetics and Cognition in Ageing Norge) study received funding from the National Collaboration Group for Health Research in the Specialist Health Care Services (Nasjonal samarbeidsgruppe for helseforskning i spesialisthelsetjenesten), Stavanger Health Trust and from the Western Norway Regional Health Authority. We extend our gratitude to Adam Hampshire for providing the cognitive tests for the study. We also thank the study participants from PROTECT Norge, as well as the patient and public involvement representatives, Pamela Cranner and Tor Cranner, organized through WiseAge.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to data governance restrictions, but may be accessed on reasonable request. Applications for access to the PROTECT Norge data must be submitted, and this process is initiated by contacting the corresponding author.

Abstract

Background: Cognitive impairment in older adults reduces independence and raises health care costs but can be mitigated through stimulating activities. Based on network theory, intricate relationships within and between clusters of instrumental activities of daily living (IADLs) and cognitive domains suggest the existence of central IADLs and cognitive domains, as well as bridge IADLs. Modifying these can significantly enhance daily living activities and cognitive functions holistically.

Objective: This study aims to identify central IADLs (key activities within the IADL network), central cognitive domains (key domains within the cognitive network), and bridge IADLs (linking IADL and cognitive networks). These insights will inform targeted interventions to effectively improve IADL and cognitive well-being in older adults.

Methods: A cross-sectional analysis of adults aged 65 years and older in the United States focused on 5 IADLs and 6 cognitive domains from the National Health and Aging Trends Study (NHATS). Network analysis identified central and bridge variables. Nonparametric and case-dropping bootstrap methods checked network stability. Network comparison tests assessed sex differences with Benjamini-Hochberg adjustments.

Results: Of the 2239 participants, 56.4% were female (n=976). We computed and tested 3 networks: IADL, cognition, and bridge-with correlation stability coefficients of 0.67, 0.75, and 0.44, respectively (all>0.25). Meal preparation was identified as the central IADL, with a centrality index of 3.87, which was significantly higher than that of other IADLs (all P<.05). Visual attention emerged as the central cognition domain, with a centrality index of 0.86, which was significantly higher than that of other cognition domains (all P<.05). Shopping was determined to be the bridge IADL, with a centrality index of 0.41, which was significantly higher than that of other IADLs (all P<.05). Notably, gender differences emerged in the IADL network, with stronger associations between laundry and meal preparation in females (1.69 vs males: 0.74; P=.001) and higher centrality in meal preparation among females (difference=1.99; P=.007).

Conclusions: While broad enhancements in all IADL and cognitive domains are beneficial, targeting meal preparation, visual attention, and shopping may leverage their within-network influence to yield a more pronounced improvement in holistic IADL, holistic cognition, and holistic cognition function through IADL interventions among older adults. Notably, meal preparation interventions may be less effective in males, requiring tailored approaches.

Introduction

Cognitive function encompasses mental processes such as acquiring knowledge, manipulating information, and reasoning, including perception, memory, learning, attention, decision-making, and language abilities [1]. Globally, cognitive impairment in older adults has a prevalence ranging from 5.1% to 41%, with incidence rates around 53.97 per 1000 person-years [2]. This impairment not only predicts older adults' future incidence of dementia, but also significantly reduces functional independence and quality of life [2]. Beyond the individual level, economically, cognitive impairment incurs 44% higher direct medical costs and significantly increases the need for

XSL•FO
RenderX

informal care [3]. Given these consequences, early detection and proactive management are essential to mitigate impacts and prevent progression to more severe conditions and greater health care burdens.

Instrumental activities of daily living (IADLs) encompass complex tasks necessary for independent living, such as cooking, cleaning, transportation, laundry, and financial management [4]. These activities assessment sometime adjusted by country or age will include driving or medication management [5,6] and demand cognitive skills like planning, memory, and problem-solving, linking their performance closely to cognitive well-being [4]. In performing these tasks, individuals engage in practical cognitive training that builds cognitive reserve and supports overall brain health. Furthermore, regularly performing IADLs provides ongoing cognitive training that builds "cognitive reserve," a concept suggesting that mentally stimulating tasks strengthen neural connections, thereby enhancing brain resilience [7]. Although other pursuits, such as employment or volunteering, also require high-level cognition, IADLs foster daily independence in older adults, and their everyday, repetitive occurrence makes them an ideal approach for continuous cognitive training. However, current interventions usually target specific IADL domains, such as shopping or meal preparation, highlighting the challenges and resource demands of broad IADL interventions [8].

A significant research gap exists in identifying the most impactful IADL component that can efficiently enhance global cognitive function, particularly crucial in resource-limited settings. This need is supported by complex interactions between IADLs and cognition [9-12], correlations within individual IADL domains (eg, between laundry and meal preparation due to similar cognitive and physical demands) [13], and relationships within cognition domains (between psychomotor function and visual attention stemming from their joint role in tasks requiring quick coordination and responses) [14]. Notably, the cognitive demands of specific IADLs vary; for instance, shopping necessitates skills in navigation, selection, and financial transactions, whereas meal preparation involves planning, execution, and presentation. Such distinctions suggest the existence of certain IADLs that are more closely linked to multiple cognitive domains. Traditional analytic methods, which often isolate relationships or assume predictor independence, may overlook the nuanced, simultaneous interactions among nodes. In contrast, network analysis captures these complex dynamics by representing variables as nodes interconnected by edges [15]. This approach not only elucidates direct interactions but also reveals broader network structures, thereby identifying "central" nodes-those exerting significant within-group influence-and "bridge" nodes that connect disparate networks [15]. Specifically, within our framework, a central IADL is defined as the activity with the highest connectivity within the IADL network, while central cognition refers to the cognitive domain with the most extensive links. A bridge IADL, by linking the IADL and cognitive networks, may have an outsized impact on overall function when its performance changes. Such insights can inform target interventions and strategic resource allocation aimed at enhancing both daily living activities and cognitive function [15]. Furthermore, gender-specific differences in cognitive decline and IADL performance further complicate this landscape. Women generally demonstrate superior executive function and memory; however, their executive function appears to decline more rapidly than that of men, while memory trajectories remain similar between sexes. In contrast, difficulties in financial management and medication adherence are more predictive of dementia in men, whereas transportation challenges serve as stronger indicators in women [16,17]. Consequently, a nuanced exploration of these differences is critical for developing targeted intervention strategies.

This study aimed to identify the central IADL and cognition domains within their respective networks, pinpoint the bridge IADL most substantially linked to overall cognitive function, and examine sex differences in these variables. We hypothesized the existence of central, bridge variables and sex-based differences affecting them. The findings are expected to reveal network dynamics, pinpoint key intervention targets for effectively enhancing holistic IADL and cognitive functions in the elderly, and indicate the necessity of sex-specific interventions.

Methods

Study Design and Data Source

This cross-sectional analysis used waves 11 and 12 (2021 - 2022) of the National Health and Aging Trends Study (NHATS), a nationally representative longitudinal database of Medicare beneficiaries aged 65 years and older. Waves 11 and 12 of NHATS were chosen for their comprehensive 6-domain cognitive assessment, unlike earlier waves that measured only episodic memory, executive function, and orientation. Data were gathered during in-home interviews by NHATS interviewers. For those included in both waves, only data from wave 12 were retained to ensure the latest cognitive assessments were used. The reporting of this study followed the CHERRIES checklist [18].

Participants and Sample Size Calculation

Eligible participants were cognitively intact individuals aged 65 years and older, not residing in nursing homes, and without signs of cognitive impairment. Cognitive intactness was determined by absence of potential or probable dementia. According to previous NHATS literature, potential dementia was defined by scores≤1.5SDs below the mean in one cognitive domain, while probable dementia was indicated by similar scores in at least two domains, meeting AD8 criteria, or having a clinical dementia diagnosis [19]. To ensure adequate statistical power, our network analysis of 11 nodes and 55 edges required a minimum of 165 participants, adhering to the 3-participants-per-parameter rule [20].

Measures

Cognitive performance was assessed across six domains: (1) Episodic memory, scored 0 - 20 from immediate and delayed recall of 10 words; (2) executive function, scored 0 - 5 by the clock drawing test; (3) orientation, scored 0 - 8 from knowledge of the current date and names of the president or vice president; (4) psychomotor function, measured by reaction speed in log-transformed milliseconds from the cogstate detection task,

XSL•FO
RenderX

where participants respond when a card turns face up; (5) visual attention, assessed by reaction speed for correct responses in log-transformed milliseconds from the cogstate identification task, where participants decide if a card is red or black; and (6) working memory, evaluated by accuracy in the cogstate one card back task, asking participants to remember if they have seen a card before. Cogstate, a tablet-based test used since wave 11 in NHATS, includes card detection, identification, and one card back activities, expanding cognitive assessments beyond traditional tests. This computerized assessment has been validated against traditional paper-based cognitive tests, demonstrating adequate reliability and validity in differentiating adults with cognitive impairment from those without [21]. Further details are available in the NHATS Cogstate user guide [22].

IADLs were assessed via self-reports on managing medication, laundry, shopping, meal preparation, and banking. Participants reported performance over the past month using 5 options: “1” Did not do by self last month; “2” Did by self last month with no difficulty; “3” Did by self last month with difficulty; “4” -Don’t know or refuse, with no difficulty; and “5” Don’t know or refuse, with difficulty. We dichotomized responses rather than using a Likert scale because the options do not form a natural continuum, but instead distinguish independent performance from any difficulty. Participants with no difficulty (responses “2” or “4”) were classified as “no difficulty,” while those with difficulty or inability (responses “1,” “3,” or “5”) were classified as “difficulty.” This binary approach preserves the key distinction in functional independence and aligns with previous research [23].

Sociodemographic variables included age (70 - 74, 75 - 79, 80 - 84, 85 - 89, and 90+ years), sex (female or male), living arrangement (alone, with others), race (Hispanic, non-Hispanic Black, non-Hispanic White, and other non-Hispanic), income status (poverty, low income, and normal), and self-rated health (poor, fair, good, very good, and excellent). Income status was defined according to federal guidelines from the Office of the Assistant Secretary for Planning and Evaluation at the US Department of Health and Human Services (ASPE HHS, 2024 version) as follows:≤100% Federal Poverty Level (FPL), >100% to≤200% FPL, and>200% FPL, replacing the previous labels of “poverty,” “low income,” and “normal.” Self-rated health was measured using a single 5-point Likert-scale item (1=poor, 5=excellent): “Would you say that, in general, your health is poor, fair, good, very good, or excellent?”

Statistical Analysis

Data were organized in a Microsoft Excel database and subjected to rigorous quality control checks. The analysis was carried out using R statistical software (version 4.1.1; R Core Team). Descriptive statistics summarized participant demographics and performance in IADLs and cognitive functions. Continuous variables were checked for normality with P-P plots and described using mean and SD; categorical variables were presented as frequencies and percentages. To maintain consistency across all nodes within the IADL and cognition networks, necessary reverse coding adjustments were made to ensure that higher scores consistently indicate diminished capabilities. Network analysis proceeded through 5 phases: evaluating topological overlap, estimating the network, assessing network stability, calculating centrality and bridge centrality indices, and conducting network comparison tests.

Checking Topological Overlap

We used the R package *network tools*’ goldbricker function to identify unique variables and avoid artificial relationships from symptom similarity in our network analysis. A significance threshold of 0.25 and a *P* value<.01 determined statistical significance [24].

Network Estimation

We developed 3 networks for our study: an IADL network for all 5 IADL domains, a cognitive network for all 6 cognitive domains, and a bridge network linking both. Each network consisted of nodes (items within each domain) and edges (relationships between items). For the cognition network with continuous data, we applied the EBICglasso method, which used the Extended Bayesian Information Criterion (EBIC) with the least absolute shrinkage and selection operator (LASSO) for partial correlation analysis, reducing confounding by shrinking coefficients and zeroing smaller correlations. The IADL network, based on binary data, was analyzed using the IsingFit method, which used logistic regression to adjust node states and determine conditional probabilities. The bridge network was assessed using the “mgm” method, designed for mixed data types, using conditional independence tests tailored to heterogeneous data. Network visualization was performed using R packages *bootnet* and *qgraph*, where edge thickness represented association strength—blue for positive and red for negative associations [25].

Network Stability

The *bootnet* package was used to assess edge and centrality stability in each network [25]. Edge stability was evaluated through nonparametric bootstrap, with 95% CIs reflecting accuracy; narrower CIs indicate higher network reliability [25]. Centrality stability was measured with a case-dropping subset bootstrap, as reflected by the correlation stability coefficient (CS-C); values above 0.25, ideally over 0.5, denote optimal stability [25].

Central Node, Centrality, Bridge Node, and Bridge Centrality

A central node in a network has substantial influence due to its extensive connections with other nodes [26]. Bridge nodes connect different communities or clusters within a network, facilitating interactions that would otherwise not occur [27]. Centrality measures in network analysis typically include strength, betweenness, closeness, and expected influence; however, due to the instability of betweenness and closeness, and because strength ignores negative edges (summing only absolute values), we exclusively used expected influence for central nodes and bridge expected influence for bridge nodes [28]. The expected influence index, which accounts for both positive and negative edge values, was calculated using the *qgraph* package in R [26,27]. Similarly, the top bridge node was identified through the highest bridge expected influence (1-step) index, which sums the edge values connecting the node

XSL•FO
RenderX

to those outside its community, determined by the *networktools* package in R [26,27]. Differences in node centrality were analyzed using Wilcoxon tests with 1000 bootstrapped indices from the bootnet package in R, applying Benjamini-Hochberg corrections for multiple comparisons [29].

Network Comparison Test

To analyze gender differences across 3 networks, we used the *network comparison test* package in R. This involved performing both a network invariance test, which identified significant variations in edges among subgroup networks, and a global strength invariance test, which evaluated the total weighted sum of all edges to measure the connection strength among network variables. Should the network invariance test yield significant results, we then conducted an edge invariance test to pinpoint specific edge pairs that varied between subgroups. In addition, we compared node centrality between men and women. To adjust for multiple comparisons at the level of individual edges and centralities, the Benjamini-Hochberg correction method was used.

Ethical Considerations

This secondary analysis of the NHATS dataset relies on publicly available data. The original data collection, which obtained informed consent from all participants, was approved by the Johns Hopkins University IRB. As no restricted data were used, further IRB review was not required.

Results

Sample Characteristics and Descriptions of IADL and Cognitive Domains

Of the 2239 participants (1194 from wave 12 and 245 from wave 11), 1263 were female (56.41%), and 1720 (76.82%) were White. The predominant age group was 75‐79 years, representing 748 participants (33.41%). Detailed sociodemographic data, as well as descriptions and abbreviations of the IADL items and cognitive domains, are provided in Table 1.

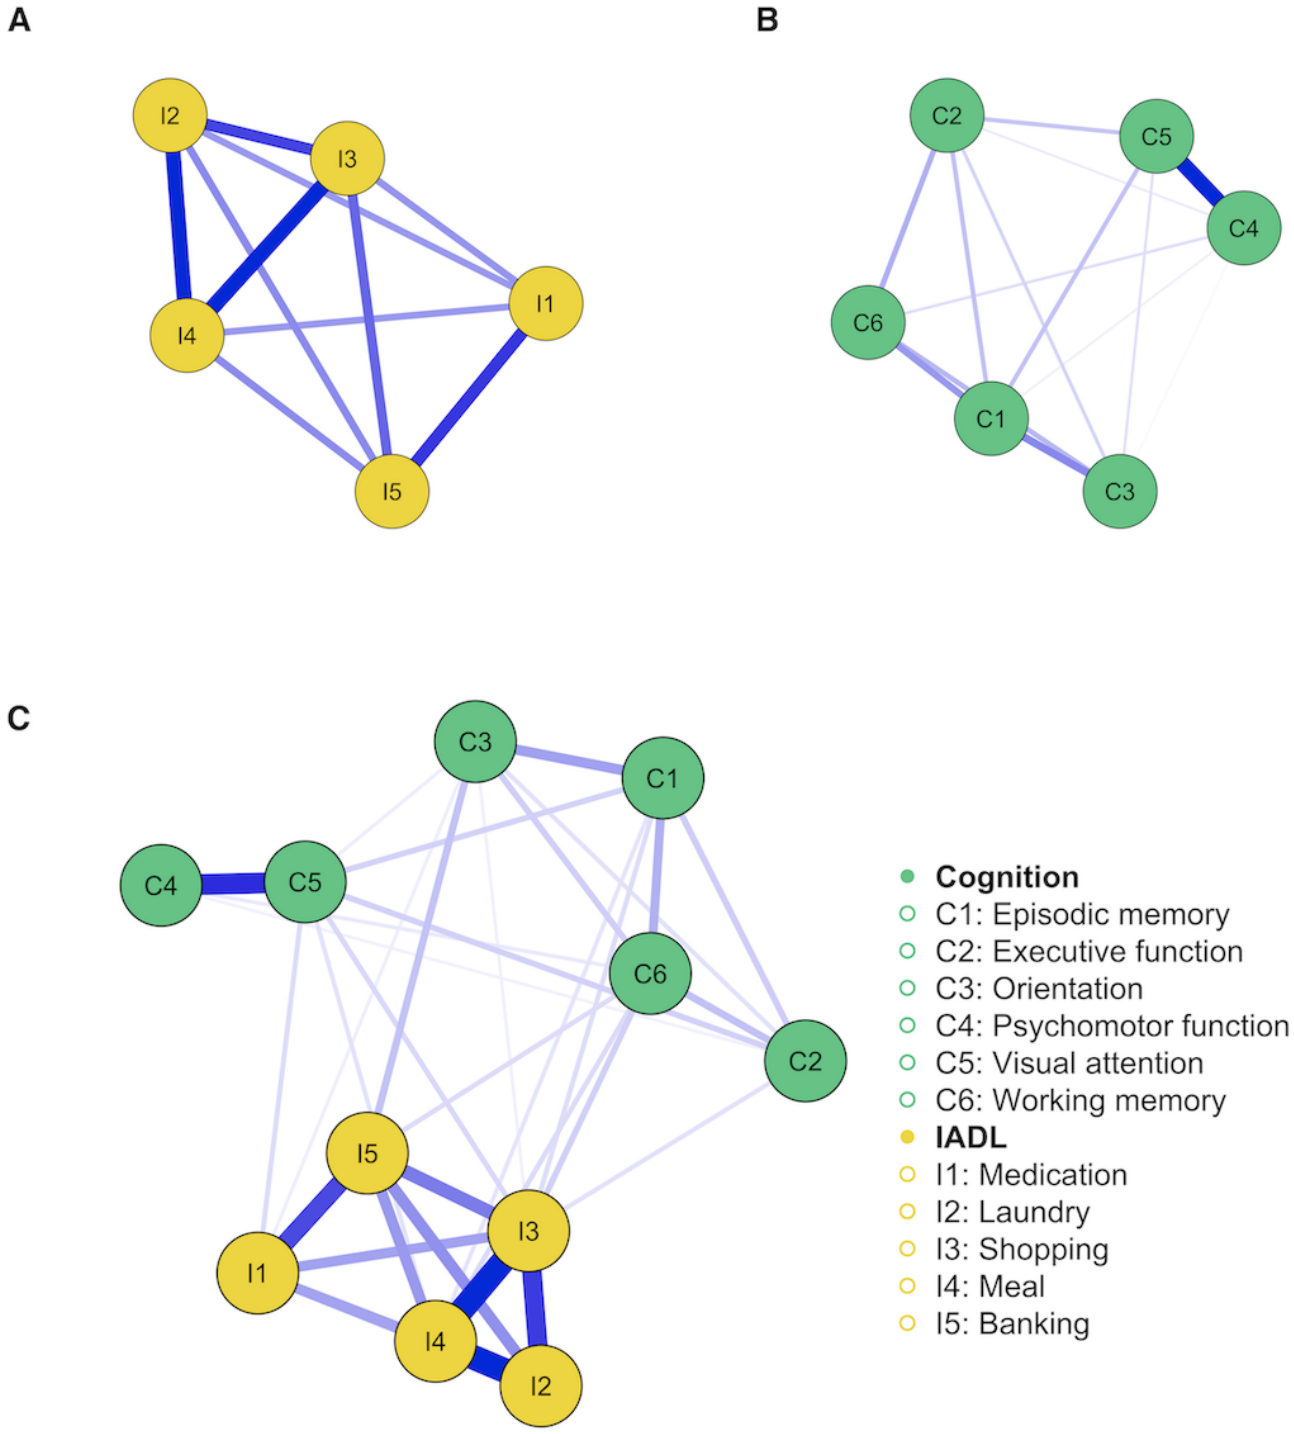
Items Remained After Redundancy Check

The Goldbricker analysis confirmed no redundancy in the IADL and cognitive domains, thus all items were retained.

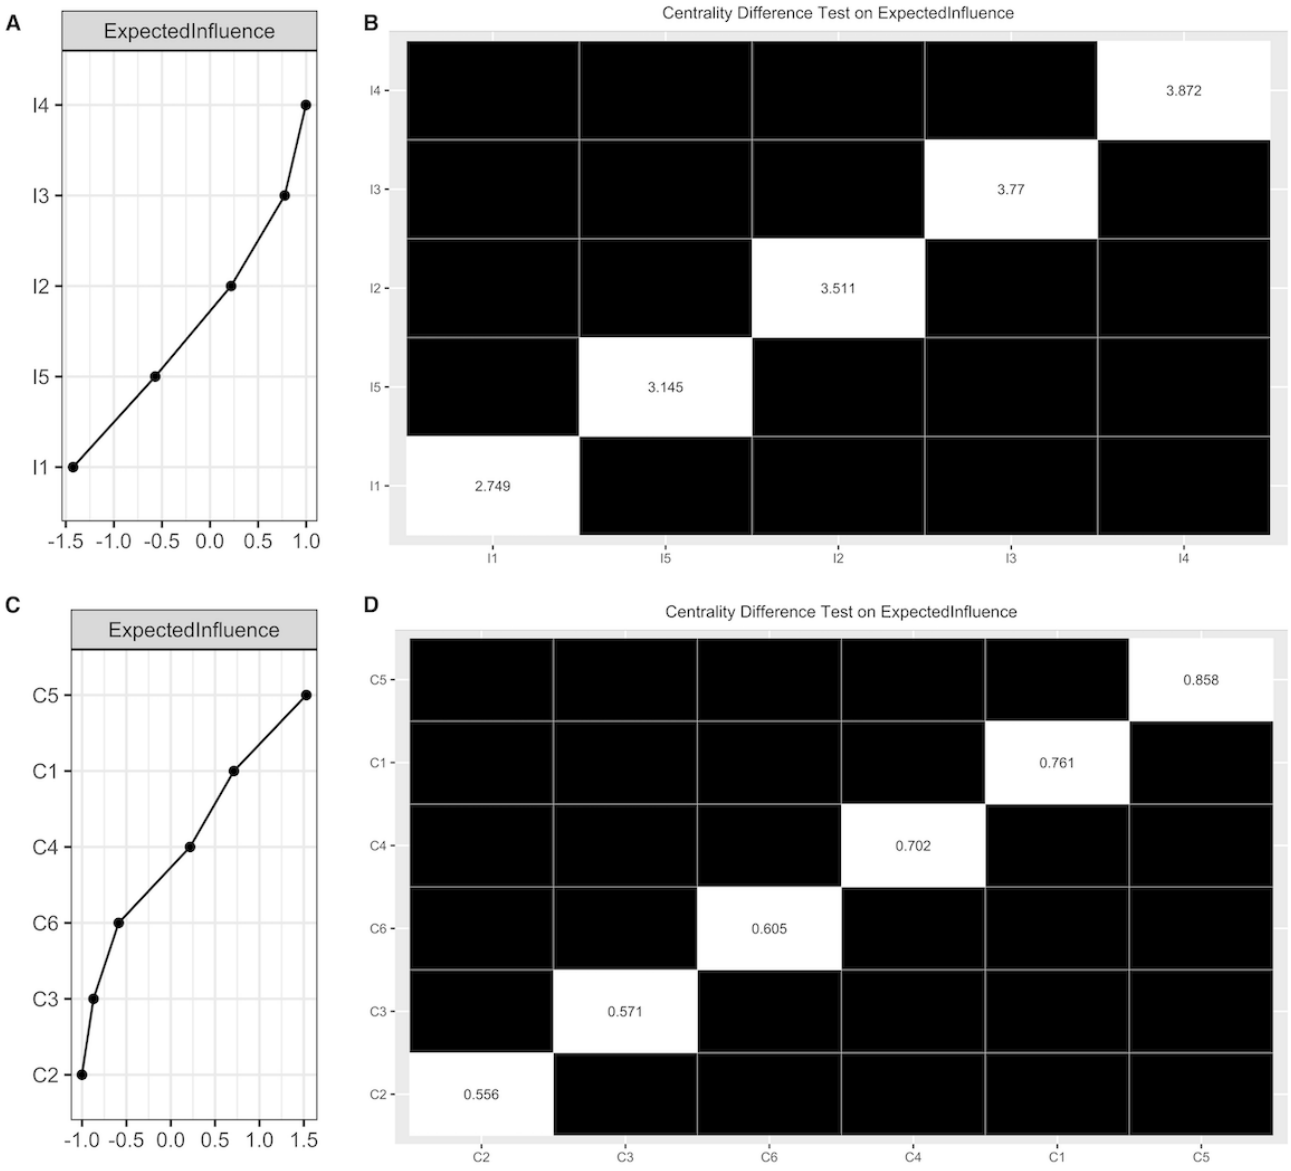
Stability of IADLs, Cognition, and the Bridge Networks



The bootstrapped 95% CI analysis revealed narrow CIs across all 3 networks (IADL, cognition, and bridge), indicating precise edge-weight estimates (Figures S1, S3, and S5 in Multimedia Appendix 1). In addition, CS-C values for the IADL, cognition, and bridge networks were 0.67, 0.75, and 0.44, respectively, all surpassing the recommended threshold of 0.25, confirming the networks' interpretability and reliability (Figures S2, S4, and S6 in Multimedia Appendix 1).

IADL Network

Figure 1A illustrates the IADL network, with all edges (10/10, 100%) nonzero, indicating strong connectivity among nodes. The most robust connections were between I3 and I4 (I3: shopping-I4:meal, edge weight 1.38), I2 and I4 (I2: laundry-I4:meal, 1.33), and I1 and I5 (I1: medication- I5: banking, 1.08). Logistic regression coefficients for other edges are detailed in Table S1 in Multimedia Appendix 1. Figure 2A shows that node I4 (meal) had the highest expected influence of 3.87. Figure 2B's centrality bootstrapped difference test highlights I4's (meal's) significantly higher influence (all $P<.05$ after Benjamini-Hochberg corrections), underscoring its central role in the network.



XSL•FO
RenderX

Figure 1. Network structure of instrumental activities of daily living (IADL) network, cognition network, and the bridge network.

XSL•FO
RenderX

Figure 2. Expected influence centrality index and centrality bootstrapped difference tests for variables in the IADL network (Pane A and Panel B) and the cognition network (Panel C and Panel D). Gray boxes indicate variables that do not significantly differ from one-another. Black boxes represent variables that differ significantly from one another (α=.05). White boxes show the values of bridge expected influence. I1: difficulty in managing medication; I2: difficulty in managing laundry; I3: difficulty in managing shopping; I4: difficulty in managing meals; I5: difficulty in managing banking; C1: episodic memory; C2: executive function; C3: orientation; C4: psychomotor function; C5: visual attention; C6: working memory.

Cognition Network

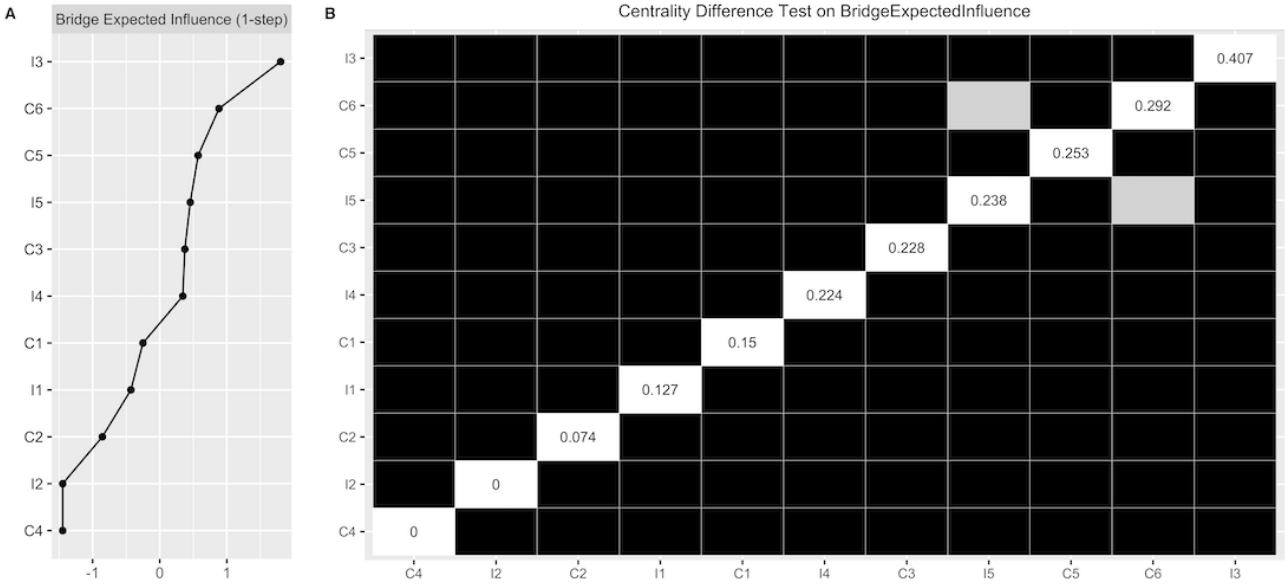


Figure 1B shows the cognition network structure, with 14/15 edges (93.33%) nonzero, reflecting strong connectivity among nodes. The strongest connections were C4-C5 (C4: psychomotor function-C5: visual attention; edge weight 0.54), C1-C3 (C1: episodic memory-C3: orientation, 0.25), and C1-C6 (C1: episodic memory-C6: working memory, 0.22). The partial correlation matrix for other edges is in Table S2 in Multimedia Appendix 1. Figure 2C displays the expected influence index for all nodes, with C5 (visual attention) having the highest at 0.86. Figure 2D's centrality bootstrapped difference test underscores C5's (visual attention's) significant influence within the cognitive domains (all P<.05 after Benjamini-Hochberg corrections).

Bridge Network

Figure 1C shows the bridge network between IADL and cognition, with 34/55 edges (61.82%) nonzero, indicating strong connectivity. Details on all edges are in Table 3 in Multimedia Appendix 1. Figure 3A highlights the bridge expected influence index, with I3 (shopping) recording the highest at 0.41, followed by I5 (banking, 0.24) and I4 (meal, 0.22). Significant bridge edges include I3-C6 (I3: shopping-C6: working memory, edge weight: 0.12), I5-C3 (I5: banking-C3: orientation, edge weight: 0.15), and I4-C6 (I4: meal-C6: working memory, edge weight: 0.09). Figure 3B's centrality bootstrapped difference test confirms I3's (shopping's) prominent role in connecting IADL and cognitive domains (all P<.05 after Benjamini-Hochberg corrections).

XSL•FO
RenderX

Figure 3. Bridge expected influence centrality index (Panel A) and centrality bootstrapped difference tests (Panel B) for variables in the bridge network. Gray boxes indicate variables that do not significantly differ from one-another. Black boxes represent variables that differ significantly from one another (α=.05). White boxes show the values of bridge expected influence. I1: difficulty in managing medication; I2: difficulty in managing laundry; I3: difficulty in managing shopping; I4: difficulty in managing meals; I5: difficulty in managing banking; C1: episodic memory; C2: executive function; C3: orientation; C4: psychomotor function; C5: visual attention; C6: working memory.

Sex Differences in Networks

Network invariance and global strength tests revealed no significant sex differences in the cognition network (*M*=0.07, *P*=.64; *S*=0.10, *P*=.21). Conversely, significant sex differences were evident in the IADL and bridge networks, confirmed by network invariance tests (IADL: *M*=0.95; *P*=.005 and bridge: *M*=0.49; *P*=.002) and global strength tests (IADL: *S*=1.94; *P*=.001 and bridge: *S*=1.79; *P*=.002). Following these findings, further edge and centrality invariance tests were conducted for the IADL and bridge networks between sexes. In the IADL network, edge invariance tests identified significant sex disparities between I2 (laundry) and I4 (meal), with females demonstrating stronger associations (female 1.69, male 0.74; *P*=.001) and greater centrality in I4 (meal: difference=1.99; *P*=.007). However, in the bridge network, no significant sex differences were detected through further edge and centrality invariance tests (all *P*>.05 after Benjamini–Hochberg corrections).

Discussion

Principal Findings

Using network analysis, the main findings of this study elucidates the detailed interactions within and between IADL and cognitive domains in older adults, identifying 3 key variables as predictive markers and potential intervention targets for enhancing global IADL and cognitive function, while also noting sex differences. First, meal preparation difficulty and visual attention are central nodes within their respective IADL and cognition networks, with higher levels predictive of better functionality; targeted modifications could significantly improve overall functionality. Secondly, shopping difficulty within the IADL network has the strongest association with global cognition. Given the cause-and-effect relationship between IADL and cognitive function, early interventions targeting shopping difficulties could effectively boost global cognition. Finally, a sex difference was observed, with meal preparation exerting a greater influence in the IADL network among females than males, suggesting its higher predictive relevance and intervention efficacy for females.

Within the IADL network, the biggest 3 connections include those between shopping and meal preparation, laundry and meal preparation, and medication management and banking. The strong link between shopping and meal preparation is due to their shared planning, organization, and physical demands necessary for food tasks [30-32]. Likewise, laundry and meal preparation share organizational and physical demands [13]. The link between medication management and banking stems from their reliance on the same executive functions and working memory [33,34]. Importantly, meal preparation is central in the IADL network, perhaps due to impacts on other domains like medication, shopping, and banking owning to necessary executive skills such as multitasking and planning [35,36]. Data from our cross-sectional analysis indicate that meal preparation is the most central node within the IADL network. This finding suggests that same unite improvement in meal preparation ability can yield the largest overall enhancement in IADL performance relative to other tasks. Therefore, targeted interventions—such as the integration of assistive kitchen technologies or cognitive orthoses—may be especially effective in promoting independent cooking and, by extension, broader functional independence [37,38].

In the cognition network, the strongest connections are between psychomotor function and visual attention, and between episodic memory, orientation, and working memory. The link between psychomotor and visual attention is due to their roles in coordinated, rapid response tasks [14]. Significant correlations also exist between episodic memory and gray matter volume in the bilateral hippocampus and parahippocampal gyrus, which are key for orientation [39]. Furthermore, the association

XSL•FO
RenderX

between episodic memory and working memory is supported by evidence that working memory capacity and prefrontal cortex executive functions are essential for episodic memory formation and retrieval [40]. Importantly, visual attention, the most central node in the cognitive network, is crucial for selective focus necessary for advanced cognitive processes like reasoning and problem-solving [41], and it enhances complex task execution through interactions with working memory [42]. Studies show that enhancing visual attention can lead to sustained improvements in cognitive performance [43,44], supporting its pivotal role in overall cognition and highlighting the need for targeted interventions to enhance focus and processing of visual stimuli. Potential interventions include computer-based training programs, video games, mindfulness exercises, and virtual reality applications specifically designed for visual tracking tasks, all of which may contribute to enhanced cognitive function [45-48].

In the bridge network, which integrates both IADLs and cognition, connectivity is notably high, with 61.82% (34/55) of edges being nonzero. This finding indicates a robust interconnection among multiple cognitive domains and IADLs, suggesting that daily tasks rely on a synergy of cognitive processes rather than on any single discrete skill [49,50]. Such an observation aligns with mounting evidence that real-life cognition operates as an integrated set of processes-often termed functional cognition [51,52]. While traditional neuropsychological models emphasize isolated cognitive constructs, functional cognition highlights how domains such as attention, executive function, and memory converge to support everyday activities [53]. By adopting this framework, our findings on the specific links ("edges") between each cognitive domain and each IADL can offer theoretical guidance for real-world functional cognition rehabilitation or training aimed at improving IADL performance. Importantly, the prominent bridge edge was identified between shopping and working memory. When considering the overall impact on global cognition, shopping ranked first as the bridge IADL, followed by banking and meal preparation. These latter activities are also highly demanding cognitively and should be targeted in interventions. However, if resources are limited, prioritizing shopping may yield the greatest benefits in enhancing overall cognitive function. Notably, shopping functions as a bridge IADL because it draws on a broad range of cognitive skills: episodic memory for recalling past purchases and layouts; executive function for planning and budgeting; spatial orientation for navigation; psychomotor skills for handling products and carts; visual attention for identifying items; and working memory for tracking purchases and costs [33,54-57]. To leverage its bridge position, shopping tasks could be integrated into routine cognitive assessments, and regular shopping activities could be encouraged to maintain cognitive function. Virtual reality simulations of shopping tasks, artificial intelligence-powered service robotics, and the use of audio recorders as assistive technology to enhance shopping independence among older adults [58,59], can leverage the bridge IADL role of shopping to effectively improve global cognitive function.

Sex differences within the IADL network show females with a stronger association between laundry and meal preparation and a higher centrality of meal preparation. These patterns likely result from societal norms assigning women more IADL responsibilities, especially laundry and meal preparation [17,60,61]. The elevated centrality of meal preparation in women's IADL networks suggests a ripple effect where challenges in meal preparation deplete time management, mental energy, and physical resources, reducing efficiency in other tasks. This ripple effect also explains the stronger association between meal preparation and laundry among women compared with men. Previous studies indicate that IADLs do not measure equivalently for men and women [61]; our study finds that meal preparation has a lower predictive value for overall IADL function in males than in females. Interventions to improve IADL performance through meal preparation should be tailored with an awareness that these activities vary in importance and difficulty between sexes.

Limitations

Several limitations are worth mentioning. First, the assessment of IADL relied on self-reported data, which, while expedient, may compromise reliability and necessitate cautious interpretation of the findings. Future research should use more objective measures to validate these results. Second, the cross-sectional design precludes the establishment of causality and does not capture the temporal dynamics between IADL capabilities and cognitive function, underscoring the need for longitudinal approaches. Third, we excluded older adults with dementia, as dementia-related deficits may mask subtle variations in both cognition and IADL performance, which is critical for identifying central or bridge nodes in network analysis. Consequently, our findings should be interpreted primarily for community-dwelling older adults with relatively preserved cognitive function. Future research should incorporate participants with more severe cognitive impairments to validate whether our findings remain consistent. Fourth, although we set eligibility at ≥65 years, all final participants were aged 70+ years, likely because those aged 65 - 69 years in earlier waves either dropped out or turned 70 years old by Waves 11 - 12. This may limit the generalizability of our findings to younger older adults. Fifth, our study relies on the NHATS dataset, which limits the assessment to a select set of IADL and cognitive domains. Sixth, one limitation of our study is that the network analysis did not adjust for external confounders (eg, age and cultural background). Network models focus solely on the relationships among the included nodes and do not account for factors outside the network. Future research might address this limitation by residualizing each node on confounders before constructing the network, or by using subgroup or multigroup analyses to examine how these factors influence network structure. While these measures capture key aspects of functioning, we acknowledge that not including additional, more nuanced domains may affect the generalizability of our findings. Finally, the generalizability of our findings is limited to the American population studied; it remains unclear if these results can be generalized to populations with differing cultural, economic, or health system backgrounds. Further studies should

XSL•FO
RenderX

expand the demographic scope to determine if these findings hold across diverse populations.

Conclusions

The central IADL, central cognitive domain, and bridge IADL connecting global cognition were meal preparation, visual attention, and shopping, respectively, underscoring the need for targeted interventions to maximize resource efficiency and effectiveness. Specifically, enhancing meal preparation in older adults may significantly boost holistic IADL capabilities through interventions such as cooking classes, nutritional education, and tailored tools, along with support services such as interdisciplinary collaboration, caregiver training, and smart appliances. Similarly, focusing on visual attention training through methods such as computer-based programs, neurofeedback, and mindfulness exercises may substantially improve global cognitive function. Given the link between IADL performance and cognitive function, interventions centered on shopping are expected to be highly effective. This can be achieved by integrating shopping tasks into cognitive assessments and promoting regular shopping activities. Technological aids such as GPS, virtual reality simulations, and caregiver education on the cognitive benefits of shopping can further support elderly care and quality of life. In addition, observed sex differences suggest that meal preparation interventions may vary in effectiveness, with potentially lower efficacy among males, highlighting the need for tailored strategies to maximize outcomes.

Abstract

Background: Cognitive training for older adults is crucial before cognitive impairment emerges. During periods of social distancing like the COVID-19 pandemic, cognitive stimuli are lacking. Online dual-task training is proposed as a solution to address these needs.

Objective: We aimed to explore the feasibility, acceptance, and potential effects of online group-based dual-task training as an intervention for enhancing cognitive function among community-dwelling older adults.

Methods: A randomized controlled feasibility study was conducted with 76 participants in Hong Kong, randomly assigned to the intervention and attention control groups in a ratio of 2:1 (n=50, 66% and n=26, 34%, respectively). The intervention group underwent 60-minute online dual-task training sessions twice a week for 12 weeks, incorporating cognitive components (upper limb and finger movement, arithmetic operation, and verbal fluency) and physical components (chair-based exercises) developed through a co-design approach. The attention control group received online health talks. Outcomes related to feasibility and acceptance included class attendance and self-reported satisfaction. Main outcomes related to potential effects included the Memory Inventory in Chinese and the Montreal Cognitive Assessment 5 Minutes (Hong Kong Version) at baseline, 6 weeks (midintervention), 12 weeks (postintervention) and 18 weeks (follow-up). Descriptive statistics and linear mixed effects models were used. Effect size was described with Cohen *d*. Qualitative feedback was collected from 12 informants and analyzed by thematic analysis.

Results: About 72% (36/50) of the participants in the intervention group and 62% (16/26) in the control group attended over 75% of the classes. In total, 44 (88%) participants from the intervention group provided acceptance feedback; 82% (36/44) were satisfied and 84% (37/44) would recommend the training to others. Improvement in the Memory Inventory in Chinese score in the intervention group was observed at midintervention, postintervention, and follow-up, with a medium-to-large effect size (d=0.65, 0.43 and 0.85, respectively). Adjusting for baseline values, the between-group differences in the Montreal Cognitive Assessment 5 Minutes (Hong Kong Version) score attained a small-to-medium effect size at midintervention (d=0.34) and postintervention (d=0.23). Qualitative feedback highlighted the timesaving and convenient aspects of online dual-task training, with participants finding the sessions challenging and enjoyable, and reporting benefits across cognitive, physical, and psychosocial domains. However, a preference for traditional in-person training was noted among the older adults despite the advantages of online training.

Conclusions: Online dual-task training is a feasible intervention accepted by the older adults, with potential benefits in cognitive abilities. Online training may complement in-person sessions. Further investigation in a full-scale randomized controlled trial is warranted to comprehensively explore its effects and address areas for improvement.

Introduction

Cognitive Decline

The cognitive health of older people is critical to aging in place. Even among healthy older adults, about one-third may experience cognitive decline within 18 months [1], impacting decision-making and daily activities like managing finances, medications, transportation, and meal preparation [2]. Cognitive decline is also linked to decreased physical performance and psychosocial issues, such as loneliness and depression [3]. The health care burden may thus increase in the long run [3].

Existing Dual-Task Interventions

Interventions to enhance cognitive function or to prevent decline are essential for healthy aging. When older adults have limited capacity in performing both functional tasks and cognitive tasks, they tend to prioritize the former over the latter because of the lower chance of being injured [4]. Dual-task training, which involves combining cognitive and physical training components, has been shown to improve physical and cognitive performance, including, but not limited to, gait, balance, and memory and cognitive function [5]. Compared with training with single components, dual-task training tends to have potentially greater benefits [6,7]. Dual-task training has been widely applied among populations with clinical conditions, such as stroke, Parkinson disease, and cognitive impairment. A systematic review of 13 randomized controlled trials (RCTs) on stroke survivors reported that dual-task training could improve walking and balance function [8]. A recent meta-analysis of 14 RCTs estimated a small-to-moderate effect in improving cognitive function among stroke survivors [9]. Meanwhile, a meta-analysis of 17 RCTs on people with Parkinson disease revealed positive effects in physical performance, such as gait and balance, with effect size varying from small to large [10], and a narrative review of 3 studies reported potential improvements in cognitive function among this group, although statistical significance was not always achieved [11]. A 2022 network meta-analysis concluded that dual-task training was promising for addressing the cognitive and motor symptoms of patients with Parkinson disease [12]. The benefits of dual-task training for cognitive function were commonly investigated among cognitively impaired people. A review of 18 RCTs on those with dementia or mild cognitive impairment reported improvements in overall cognitive function, attention, and functional mobility [7]. Another meta-analysis of 21 RCTs reported small-to-moderate effects in global cognitive function, memory, executive function, and attention in cognitively impaired people [13]. A recent meta-analysis of 20 RCTs also reported benefits for global cognition, executive function, and working memory with effect sizes that were moderate, small to moderate, and moderate to large, respectively [14]. There is growing literature on studies targeting cognitively healthy older people. A meta-analysis of 8 controlled trials on cognitively healthy older adults reported improvement in cognitive functions, such as global cognition, working memory, and executive function [15]. The same review also reported no statistically significant difference in efficacy between cognitively healthy older adults and those with mild cognitive impairment [15].

Service Gaps

In practice, motivating healthy older adults to engage in cognitive training can be challenging, especially when they perceive no immediate risk of decline. Presenting interventions as recreational and stimulating can enhance participation. Compared with solely cognitive training, dual-task training may address this need. Meanwhile, when there was social distancing, such as during the COVID-19 pandemic, older adults lost their opportunity to exercise and interact with others. Reductions in physical activity and social interaction not only challenged their physical and psychological health but also challenged their cognitive performance. Although group-based dual-task training could be beneficial, existing dual-task training programs have been conducted face-to-face, which limits their application during times of social distancing, prompting the exploration of online delivery methods. As the participants could join the training in their own homes, the training components had to be specially designed to simultaneously ensure safety, enjoyment, and efficacy. Hence, as an initial step, the feasibility, acceptability, and potential effects of the proposed intervention had to be investigated through a feasibility study.

Aim and Objectives

This study aimed to explore the feasibility, acceptance, and potential effects of online group-based dual-task training as an intervention for enhancing cognitive function among community-dwelling older adults. To accomplish this aim, we had three objectives: (1) to develop the intervention through a co-design approach, (2) to explore its feasibility and acceptance among older adults, and (3) to examine its potential effects in terms of the cognitive, physical, and psychosocial status of the intervention group before and after the intervention and in comparison with the control group. We hypothesized that online based dual-task training would be feasible for healthy older adults.

Methods

Study Design

This was a randomized controlled feasibility study with 2 parallel arms. The trial was registered at ClinicalTrials.gov (NCT05573646).

XSL•FO
RenderX

Ethical Considerations

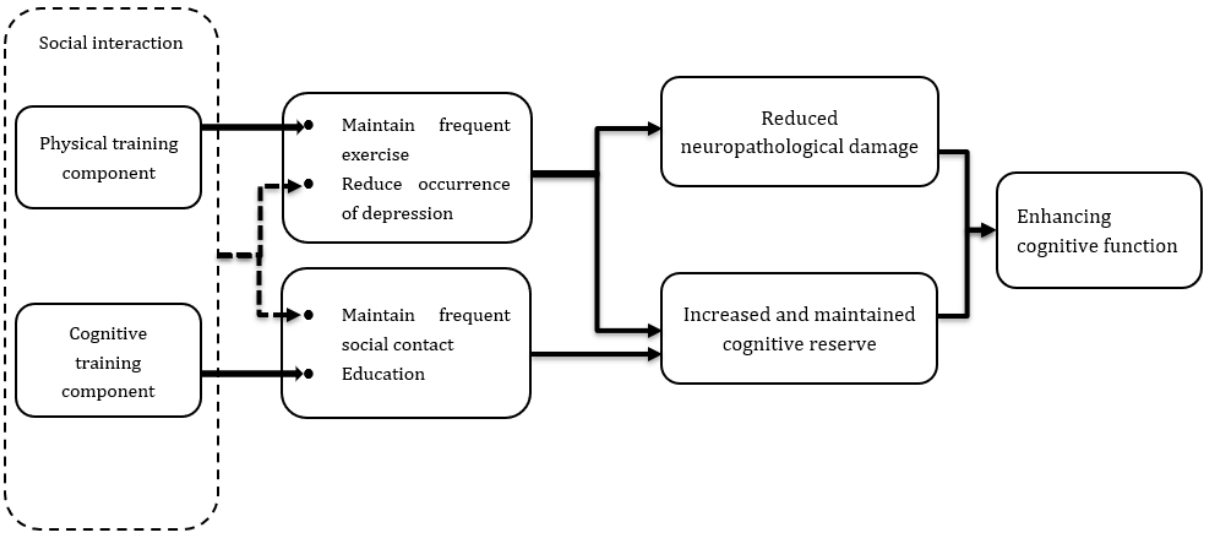
Ethics approval was obtained from The University of Hong Kong/Hospital Authority Hong Kong West Cluster Institutional Review Board (UW22-038).

Setting

This study was conducted in both online and community settings across Hong Kong. Data collection was conducted at older adults community centers, an older adult educational center, and a university campus, and the intervention was delivered online.

Target Population and Sample

The target population comprised community-dwelling older adults. The inclusion criteria were (1) age ≥65 years, (2) no communication problems, and (3) ability to use an online meeting platform. The exclusion criteria were (1) contraindications to chair-based exercises and (2) engagement in any kind of cognitive training 3 months before the study or during the study period.



According to the literature, for a main trial designed with 80% power and 2-sided 5% significance to detect a small-to-medium effect (Cohen *d* between 0.1 and 0.3), a sample size of at least 20 per treatment arm is needed for a pilot study [16]. Meanwhile, to allow the sample to detect a medium within-group effect size in the intervention group (d=0.5) with 80% power and 2-sided 5% significance, a sample size of 34 was required for the intervention group. Taking both scenarios and 20% attrition into account, 50 participants in the intervention group and 25 participants in the control group were required.

Intervention: Online Group-Based Dual-Task Training

Participants in the intervention group received a 1-hour online group-based dual-task training session twice a week for 12 weeks, resulting in a total intervention time of 24 hours. Such frequency and duration were within the range of 4 to 25 weeks and 30 to 240 minutes per week, as used in previous dual-task training programs for healthy older adults [6].

Figure 1 shows the conceptual framework underpinning the development of the intervention based on the 2020 Report of the Lancet Commission on dementia prevention, intervention, and care [17]. The framework proposed that modifiable risk factors prevent dementia through reduction of neuropathological damage and increase and maintenance of a cognitive reserve. Among these factors, maintenance of frequent exercise and reduction of depression act on both paths, while maintenance of frequent social contact and education act on the cognitive reserve path. In our intervention, the physical training components helped to maintain frequent exercise (at least twice weekly) and the cognitive training component mimicked the education effect. The social interaction via group Zoom (Zoom Communications, Inc) classes maintained frequent social contact for at least twice a week and thus could help to relieve depression symptoms.

Figure 1. Conceptual framework.

In the development of the cognitive training component, various factors were considered, including the lower education level of the local older adults, the online delivery format of the intervention, the cultural appeal to the local older population, and the effectiveness and safety of the training. A diverse set of training components were incorporated, such as upper limb and finger movements, arithmetic operations, and verbal fluency exercises, based on their proven efficacy in previous dual-task training studies [18,19]. A co-design approach was adopted to develop the dual-task training components. In total, 9 participants from the target population were invited to a trial run to provide feedback on their interests, challenges, and suggestions for tasks they preferred. The suggested tasks were then reviewed by the project team to assess their intensity and potential impact on training outcomes. Considering what would be acceptable and effective, 18 upper limb and finger movement games, 22 arithmetic operation games, and 6 verbal fluency training components were finalized (Textbox 1). During the 1-hour training session, participants engaged in different tasks according to a predefined schedule (Table 1). Specifically, participants spent 12 minutes on upper limb and finger movement exercises, 15 minutes on arithmetic operations, and 15 minutes on verbal fluency tasks. Each game started at the easiest level, with the facilitator adjusting the cognitive demand

XSL•FO
RenderX

as participants progressed. For each game, the facilitator would start with the easiest level first. To sustain motivation and enjoyment, the difficulty level of each component increased when participants demonstrated mastery, typically indicated by 3 consecutive rounds without losing a game.

Textbox 1. Examples of cognitive training components.

Upper limb and finger movements

- Goal-directed finger movements, such as counting and reverse counting with the fingers and making motions in different directions with different hands
- Forming patterns in the air

Arithmetic operation

- Counting
- Reverse counting
- Counting or reverse counting with subtraction or addition
- Clapping at specific numbers or multiples

Verbal fluency

- "Jie Long" (a well-known Chinese word chain game)
- Naming games (particularly on Chinese cultural concepts, such as Chinese dim sum and greetings in the Chinese new year)
- Memory games (participants needed to recap the previous terms presented by others and then add their own)

Table 1. Dual-task training schedule for each 60-minute session.

Time (minutes)	Dual-task training	
	Physical components (chair-based)	Cognitive components
5	Warm-up exercise	Safety reminder or casual chit-chat
3	Toes raises	Upper limb and finger movement 1
3	Heel raises	Upper limb and finger movement 2
3	Toes raises	Upper limb and finger movement 3
3	Heel raises	Upper limb and finger movement 4
3	Break	Break
3	Stepping	Arithmetic operation 1
3	Rest	Arithmetic operation 2
3	Stepping	Arithmetic operation 3
3	Rest	Arithmetic operation 4
3	Stepping	Arithmetic operation 5
3	Break	Break
3	Stepping	Verbal fluency 1
3	Clam exercise	Verbal fluency 2
3	Stepping	Verbal fluency 3
3	Clam exercise	Verbal fluency 4
3	Stepping	Verbal fluency 5
3	Clam exercise	Verbal fluency 6
4	Cool-down exercise	Safety reminder

For the physical training component, we selected chair-based exercises, which were chosen due to their suitability for the limited space available in most local households. Chair-based exercises offer various benefits, such as improving mood and well-being, enhancing certain activities of daily living, promoting social interaction, and increasing muscle strength [20]. Alongside the cognitive training games, participants engaged in exercises like toe or heel raises on alternate sides,

XSL•FO
RenderX

stepping, and clam exercises (Table 1). The exercises were performed at a low frequency, such as 60 steps per minute. To ensure safety, participants were permitted to use their hands for balance support during stepping or clam exercises. Therefore, when upper limb and finger movement tasks were involved, only toe or heels raise were performed.

A group-based training approach was adopted as group-based cognitive training might yield greater interaction and cognitive benefits than individual-based training [21]. Group-based exercise was also reported as having the additional advantage of creating a social support environment that could enhance psychosocial well-being [22]. Moreover, group-based interventions tend to have higher adherence rates than general exercise programs due to the motivational support provided by group dynamics [23]. To encourage interaction among participants and enable close monitoring by the facilitator, a group size of less than 10 people was used.

Zoom was selected as the training platform due to its widespread use and familiarity among local older adults. Throughout the session, participants were instructed to sit on a sturdy chair with a back rest in front of a desktop computer, laptop, tablet, or mobile phone securely placed on a table. Mobile device users were provided with stands for better posture (all participants received the stand as a souvenir). To allow enough space for movement, the chair and table needed to be positioned 60 cm apart. Participants were encouraged to turn on their cameras during the session to facilitate interaction with one another. They were also asked to keep their audio on to actively participate in the cognitive tasks by verbalizing their answers.

The sessions were led by a trained facilitator. The facilitator did not need to be health professional, but they were required to undergo necessary training to ensure they had the knowledge and skills to effectively work with older adults [20]. A written manual with all the rules and regulations of the training was provided. During the initial sessions of the intervention, the project lead provided on-site supervision of the facilitator to ensure that the intervention was delivered according to the protocol. In addition, random spot checks were conducted by the project lead to ensure strict adherence to the protocol.

Attention Control: Interactive Health Talks

In line with recommendations for attention control groups [24], participants in the control group underwent 8 one-hour online group-based interactive health talks on food label knowledge and its practical applications. These sessions were led by a facilitator with nutrition training.

Outcome Measures

The primary outcomes were related to feasibility and acceptance. Feasibility was reflected by class attendance. Reasons for absence were documented when available. There was no consensus on the definition of high attendance [25]. We took 75% attendance as high attendance, as a review reported 3 of 11 studies on exercise interventions adopted this definition [25]. The proportion of participants with high attendance was calculated using the number of participants randomized to the group as denominator. A review of group exercise interventions for older adults reported that in 4 of 6 studies, 65% to 67% of participants adhered to the program [22]. Hence, our study considered over 65% of participants completing at least 75% of the classes as feasible.

Acceptance was reflected by 5-point Likert scale questions on the level of satisfaction with the intervention (“Are you satisfied with this training?”) and the level of likeliness of recommending the intervention to other people (“Would you recommend this training to friends and family”), with answers collected at the end of the intervention via instant text messaging. The proportion of respondents providing a positive response was calculated. As a conservative estimate, another proportion was calculated by assuming those who did not provide feedback as not being satisfied and not likely to recommend the intervention, with the number of participants randomized to the group as the denominator.

The secondary outcomes were related to potential effects, which included subjective memory complaints, cognitive status, working memory, executive function, physical function, instrumental activities of daily living, happiness, and social networks.

Subjective memory complaints were assessed using the Memory Inventory in Chinese (MIC) [26]. This scale consists of 27 items on memory concerns related to daily activities in the past month. Responses are rated on a scale from 0 (none) to 4 (once or more per day or continuously), with scores totaling between 0 and 108. A higher score indicates a greater frequency of memory concerns.

Cognitive status was assessed using the validated Montreal Cognitive Assessment 5 Minutes (Hong Kong Version) (HK-MoCA 5-Min), which covers 4 domains, namely, attention, executive functions or language, orientation, and memory [27]. The total score ranges from 0 to 30, with a higher score indicating better cognitive status.

Working memory was assessed by Digit Span Test [28]. Participants were required to repeat progressively longer series of digits. The test began with 2 digits and increased in length, with a maximum of 8 digits for the forward test and 7 digits for the backward test. The participant’s ability to recall the longest digit series in forward and backward order was recorded as the forward and backward scores, respectively. A higher score indicated a better working memory capacity.

Executive function was assessed by the Chinese version of the Victoria Stroop Test [29]. The test consisted of 3 parts, each presenting different stimuli: colored dots, common words unrelated to color, and color words. Participants were required to name the color in which the stimuli were printed. Inference scores were calculated based on the difference in completion time between the word or color test and the dot test, with a longer completion time indicating a poorer condition.

Lower-limb muscle strength was assessed by the 5-time chair stand task [30]. Participants were timed on how long it took them to complete the task, with a longer time indicating poorer performance. If participants were unable to finish the task within 1 minute, the test was stopped, and a time of 60 seconds was imputed for analysis purposes.

XSL•FO
RenderX

Instrumental activities of daily living were assessed by Lawton's 8 selected tasks, which include telephone use, shopping, food preparation, housekeeping, laundry, transportation, medicine use, and handling finances [31]. Participants rated their level of dependence in performing each task on a 5-point Likert scale. The score was the sum of all items, ranging from 0 to 8, with a higher score indicating greater independence.

Happiness was assessed by the Chinese version of the validated 4-item Subjective Happiness Scale [32]. Participants rated their responses on a 7-point Likert scale. The score was the average of the 4 items, ranging from 1 to 7, with a higher score indicating a higher level of happiness.

Depressive symptoms were assessed by the Patient Health Questionnaire-9 (PHQ-9) [33]. PHQ-9 was validated as a reliable tool for evaluating depression among older adults. The scale ranged from 0 to 27, with a higher score indicating a higher level of depressive symptoms.

Social networks were assessed by the Chinese version of the 6-item Lubben Social Network Scale [34]. Participants rated their responses on a 5-point Likert scale. The total score ranged from 0 to 30, with a higher score indicating a stronger social network.

All effect-related outcomes were assessed at recruitment (T0, baseline), 6 weeks after baseline (T1, midintervention assessment), 12 weeks after baseline (T2, postintervention assessment), and 18 weeks after baseline (T3, follow-up assessment). Demographic, medical and lifestyle information, such as age, gender, education level, exercise habits (measured by the International Physical Activity Questionnaire-Short Form), frailty status (measured by the FRAIL scale, which consists of 5 items, namely, fatigue, resistance, ambulation, illnesses, and loss of weight) and comorbidity (coexistence of 2 or more chronic illnesses) were collected at baseline. For participants who could not undergo face-to-face assessment for reasons such as quarantine or sickness, the 5-time chair stand task was not administered and was regarded as missing data.

Qualitative feedback was collected from a purposive sample at the end of the follow-up period through phone interviews. A semistructured interview guide was used to explore reasons for participating in the intervention, perceived difficulties encountered, logistical aspects of the intervention, and strengths and limitations perceived by participants. Prompts were provided as appropriate. Participants who exhibited varying degrees of change in the MIC score were invited to ensure diverse perspectives. Data saturation was achieved with 12 informants.

Procedure

Participants were recruited through social media and nongovernmental organizations in Hong Kong. They were randomly assigned to the intervention or control groups at a ratio of 2:1. As a strategy to enhance recruitment, a ratio of 2:1 was proposed for the number of people in the intervention and control groups, such that less participants would be disappointed with the allocation to the control group. A face-to-face orientation session was conducted to guide participants on using the Zoom platform and provide them with mobile device stands. Furthermore, for intervention group participants, demonstrations of the chair-based exercises were provided as they were unable to observe lower-limb movements on Zoom.

Randomization and Concealment

Block randomization with varying block sizes was used to generate the allocation sequence. An independent research assistant generated the sequence using an online platform and prepared sequentially numbered opaque sealed envelopes. These envelopes were opened in front of the participants immediately after obtaining informed consent.

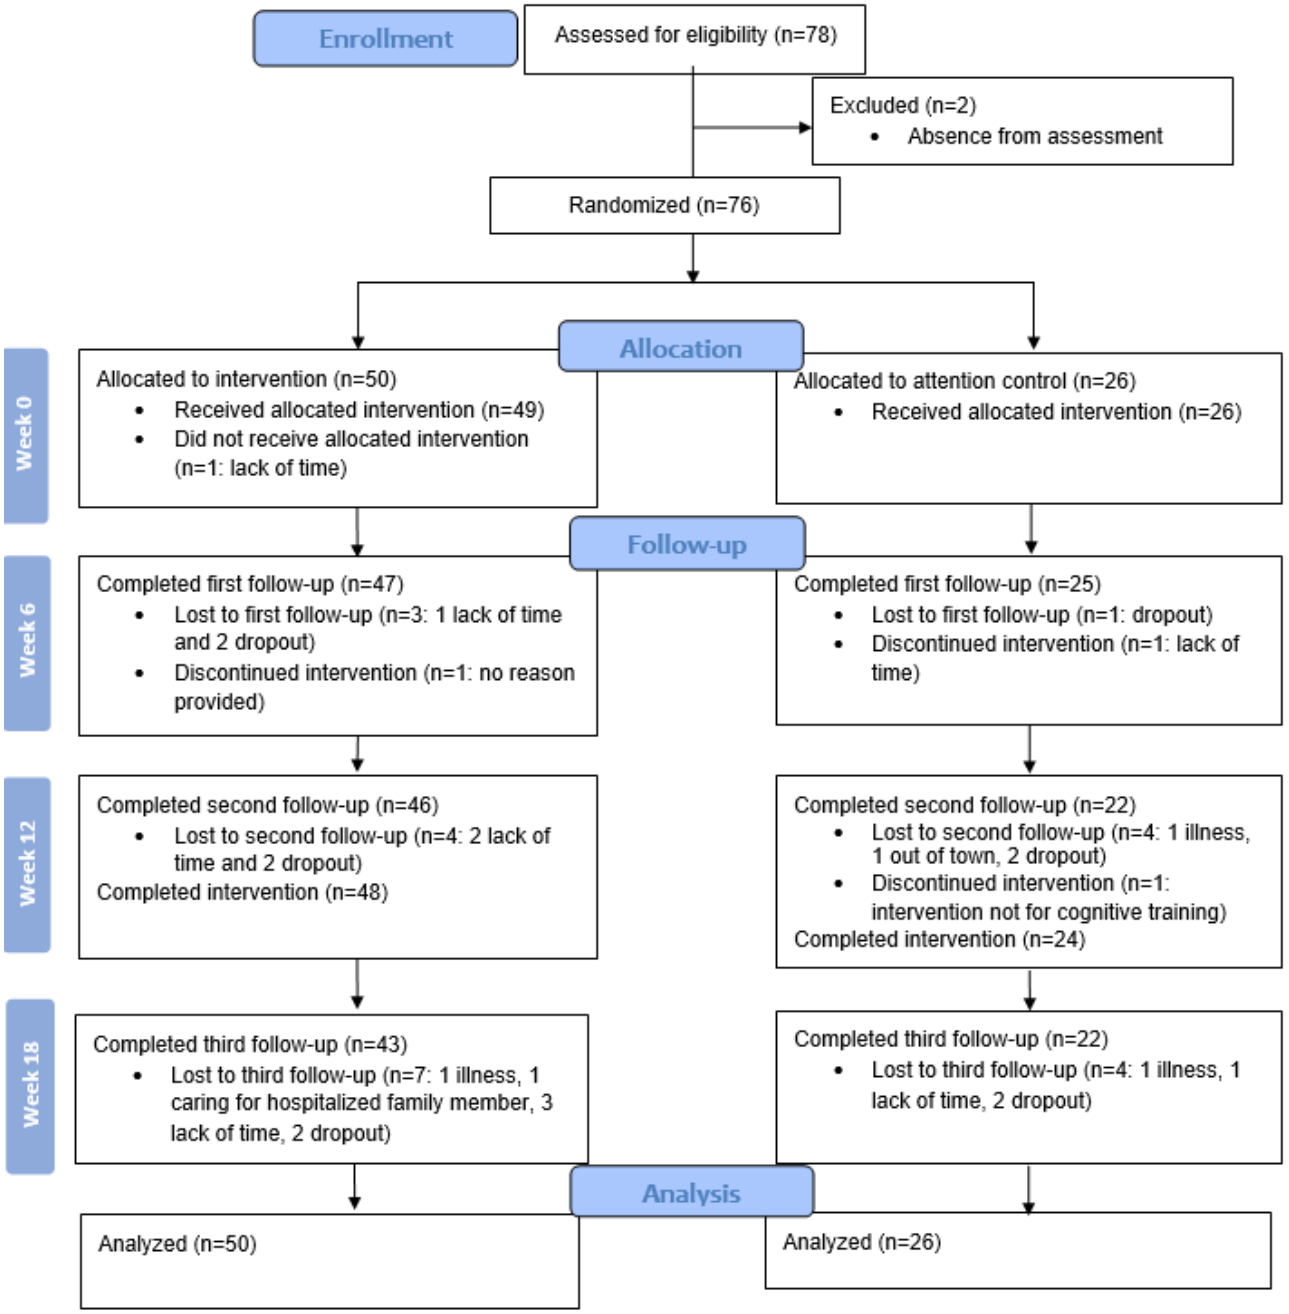
Blinding

This was a single-blinded study as participants and interventionists could not be blinded. Trained research assistants involved in assessing outcomes related to potential effects were blinded to the allocation.

Data Analysis

The participants' characteristics were summarized using descriptive statistics. Attendance statistics, regarding the percentage of scheduled classes attended, were calculated. The percentage of participants satisfied with the intervention and those who would recommend it to others were also calculated. Adopting intent-to-treat, linear mixed effects models were used to analyze effect-related outcomes, adjusting for sociodemographic characteristics, medical history, and lifestyle patterns. A significance level of 5% was used. However, given the small sample size, focus was placed on effect size with the corresponding 95% CI. A Cohen *d* of 0.2 was considered clinically meaningful [35]. Missing outcome measures were not imputed as the linear mixed effects models could handle missing data. Statistical analyses were performed using SPSS version 28.

As for the qualitative interview, the audio recordings were transcribed verbatim for thematic analysis [36]. First, 2 researchers read the transcripts several times and conducted the systematic coding independently. They proceeded to generate the initial codes and the recurrent pattern within the data and identify and name the themes and subthemes according to the underlying meaning. Then, a third researcher checked for the consensus on the themes and subthemes and discussed with the team accordingly. They also worked together to identify the common threads that extend across the interviews of the participants. Analyses were performed manually without the aid of software.



Results

Overview

In total, 76 participants were recruited from October 2022 to May 2023 (Figure 2). To manage class sizes, the 50 participants in the intervention group were divided into 8 subgroups, each with 24 classes, and the 26 participants in the attention control group were divided into 2 subgroups, each with 8 classes. Overall, 48 (96%) participants from the intervention group and 24 (92%) from the control group completed the assigned intervention.

XSL•FO
RenderX

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) diagram.

The mean ages of the participants in the intervention and the control groups were 71.5 (SD 5.2) and 71.1 (SD 6.0) years, respectively. There were 64% (32/50) female participants in the intervention group and 88% (23/26) in the control group. One-fifth (15/76, 20%) of the participants had a primary level of education or below. About 44% (22/50) of the participants in the intervention group and 54% (14/26) in the control group had multimorbidity. Most participants in both groups (30/50, 60% and 16/26, 61%) had low levels of physical activity. Prefrailty was observed in about 38% (19/50) of intervention-group participants and 50% (13/26) of control-group participants. Table 2 shows the characteristics of the participants.

XSL•FO
RenderX

Table 2. Baseline characteristics of participants (N=76).

Characteristics	Intervention (n=50)	Control (n=26)
Age (y), mean (SD)	71.5 (5.2)	71.1 (6.0)
Sex, n (%)		
Male	18 (36)	3 (11)
Female	32 (64)	23 (89)
Education level, n (%)		
Primary or below	10 (20)	5 (19)
Secondary	27 (54)	14 (54)
Tertiary or above	13 (26)	7 (27)
Multimorbidity[a], n (%)		
No	28 (56)	12 (46)
Yes	22 (44)	14 (54)
Physical activity level (measured by IPAQ[b]), n (%)		
Low	30 (60)	16 (61)
Moderate	15 (30)	9 (35)
High	5 (10)	1 (4)
Frailty status (measured by FRAIL[c] scale), n (%)		
Robust	31 (62)	13 (50)
Prefrail	19 (38)	13 (50)

[a]Multimorbidity is defined as the co-existence of at least 2 of the following long-term health conditions: hypertension, heart disease, high cholesterol, cancer, osteoporosis, and other chronic illnesses, as reported by the participants.

[b]IPAQ: International Physical Activity Questionnaire.

[c]FRAIL: Fatigue, Resistance, Ambulation, Illnesses, and Loss of weight.

Feasibility

In the intervention group, 36 (72%) participants attended over 75% of the 24 classes. For the attention control group, 16 participants (61%) attended over 75% of the 8 classes. Common reasons for absence in both groups included time clashes with medical appointments, illness, or other prior commitments.

Acceptability

Among 44 participants who provided acceptance feedback on the intervention, 82% (36/44) expressed being very satisfied or satisfied with the intervention, and 84% (37/44) indicated they would be very likely or likely to recommend the intervention to others. Assuming that those who did not provide feedback were not satisfied and were not likely to recommend the intervention, the satisfaction rate was 72% (36/50) and the recommendation rate was 74% (37/50).

Potential Effects

Regarding the effect-related outcomes, owing to the pilot nature of the trial, statistical significance was not the primary focus, instead, the effect size was noted. Within-group changes were explored and are presented in Multimedia Appendix 1. For the intervention group, the effect size of the MIC improvements at midintervention, postintervention, and follow-up compared to baseline were 0.65, 0.43 and 0.85, whereas the estimates for the control group were 0.51, 0.37 and 0.78, respectively. Similarly, both groups experienced an increase in HK-MoCA 5-Min score with moderate to large effect sizes. However, changes in working memory, as assessed by the Digit Span Test, did not consistently show the same direction in both groups. The intervention group showed a moderate improvement in executive function, as shown by the inference score for color from the Victoria Stroop Test, while the control group showed a small-to-large improvement in the inference score for words. Improvement was not observed for other outcomes in both groups.

Between-group differences, adjusting for the baseline differences, were explored and are presented in Multimedia Appendix 1. The intervention group did not outperform the control group in the MIC, but it showed better performance in the HK-MoCA 5-Min at the midintervention and the postintervention assessments (effect size 0.34 and 0.23, respectively). Meanwhile, a medium effect size was observed for between-group difference in the Digit Span Test at the follow-up. However, the findings for the Victoria Stroop Test were inconsistent. Details on other outcomes are presented in Multimedia Appendix 1.

Comparing the effect-related outcomes between participants with high attendance (≥75% of class) and low attendance in the intervention group (Multimedia Appendix 1), those with high attendance had fewer subjective memory complaints than those

XSL•FO
RenderX

with low attendance at midintervention and postintervention, with effect sizes of 1.18 and 1.53, respectively. At the follow-up assessment, the between-group difference was observed to be in favor of the high-attendance group in the Digit Span Test, inference score for color, and PHQ-9 score.

Qualitative Feedback

Table 3 shows the demographic characteristics of the 12 informants. Table 4 shows the 5 identified themes and the corresponding subthemes derived from the qualitative feedback, along with the significant quotes. The themes are summarized as presented in Textbox 2.

Table 3. Characteristics of the 12 informants providing qualitative feedback.

Informant	Sex	Age group (y)	Education level
A	Female	65-74	Primary
B	Female	65-74	Secondary
C	Male	≥75	Primary
D	Female	65-74	Secondary
E	Female	65-74	Secondary
F	Female	65-74	Tertiary
G	Female	≥75	Secondary
H	Female	65-74	Secondary
I	Female	65-74	Secondary
J	Male	65-74	Tertiary
K	Male	65-74	Primary
L	Male	65-74	Tertiary

XSL•FO
RenderX

Table 4. Five identified themes and the corresponding subthemes from the qualitative feedback and the significant quotes.

Themes and subthemes	Significant quotes by informants
Perceived strength of the training (before participation)	
Arousing curiosity and motivation to join	• "I heard an introduction at the elderly community center, and I want to learn more." [Informant A] • "Curious about online dual task training." [Informant B]
Giving them hope to slow down cognitive decline	• "I am taking precautions because I don't know if I will have cognitive impairment in the future. I just want to prevent it. Early prevention is better." [Informant D] • "I want to maintain, not improve, cognitive ability." [Informant L]
Offering opportunity for social interaction	• "I want to make new friends." [Informant C]
Save travel time	• "No need to spend time going back and forth; you can stay at home. Nowadays, we mostly go to centers to learn things. In-person is much better, but it takes more time to get there and back." [Informant E] • "But overall, I think online is good for participants, as it saves travel time." [Informant J]
Positive experience from the training	
Comprehensive training	• "I think the course is quite good and comprehensive; it does not just focus on those with cognitive impairment." [Informant I]
Challenging training	• "There is some difficulty; sometimes I forget, like moving a hand or getting distracted and forgetting to do the stepping. You need to stay focused to complete it." [Informant B] • "At the beginning, I feel a bit frustrated when playing. However, it has its benefits. If everything were easy, there would be no need for training." [Informant G] • "If you have to move both your foot and hand, you often end up neglecting one. Sometimes, you also have to keep track of numbers, so you need to pay attention to what the other participants are saying." [Informant K]
Engaging facilitator	• "The host guided us with patience." [Informant A] • "Overall, I think the team is very dedicated. Sometimes when we can't hear, she [the facilitator] reminds us. Or when we can't think of an answer, she gives us hints at the right time. I think the whole process is very smooth." [Informant I]
Peer support and encouragement during the training	• "We encourage each other during the training." [Informant L]
Enjoy the convenience at home environment	• "I can start the training right after breakfast. When we have breaks, we can go to the washroom and drink water at home. After the session ends, we can prepare lunch ourselves." [Informant A]
Challenges encountered with online training	
Constrained supervision and intensity of training	• "At least with Zoom, the camera cannot capture my feet, so you cannot tell if participants are doing stepping. I think in-person is ultimately more useful because you can see everyone's movements." [Informant B] • "Because in-person, you can immediately see everyone's performance." [Informant D]
Harder to follow the sequence if the training involved taking turns	• "Because it is online and most participants are women, it is hard for me to know that it is my turn unless there is a man preceding my turn. But after a few sessions, everyone starts to get familiar with each other, and we build up rapport about the sequence." [Informant J]
Less concentrated and less cordial	• "During training, some might not be able to concentrate, for example, if there are things happening at home." [Informant A] • "It's not as easy to get distracted if it is in-person." [Informant D]
Class atmosphere not comparable to in-person class	• "But in-person is more enjoyable, with more group interactions, which makes it more fun." [Informant G]
Technical issues encountered	• "The display is limited in size, and there might be some lag time." [Informant J] • "The problem is that some resource-limited families don't have Wi-Fi at home, so they have to go to the center to access it, which is less convenient." [Informant K]

Themes and subthemes	Significant quotes by informants
Perceived benefits of the training	
Improved cognitive ability (including attention and concentration)	• "Initially, I felt very unfamiliar with it, but after a few more sessions, I absorbed new knowledge and it made my mind more agile." [Informant G] • "I think I can use my brain more, as I usually don't use it much." [Informant H] • "My memory has been maintained without much decline." [Informant L]
Improved coordination and physical flexibility	• "After participating, my knowledge has broadened, and both my hands and mind have become more agile." [Informant C] • "I find that after training, the coordination of my hands and feet has become a bit more agile compared to before." [Informant L]
Improved communication skills	• "It can train an older person to handle different communication demands." [Informant J]
Promotion of positive mood and social interactions	• "Someone accompanies you. I also find it fun and enjoyable." [Informant F]
Learn new skills for self-practice in future	• "I have not experienced this kind of hand-eye coordination, but now I do. Sometimes, when I'm alone, I practise the movements." [Informant E] • "I'll go back and practise it myself." [Informant K]
Increased self-efficacy and self-confidence	• "My brain is now willing to exercise and let me do calculations." [Informant F] • "I actually feel quite happy and it gives a sense of accomplishment because you can achieve your goals and meet the training requirements, so there is a sense of success." [Informant J]
Self-explanation of less benefit from "cheating"	• "I do not feel like I have gained much. Maybe I prepare the answers in advance. For example, knowing that the next lesson will involve 'clapping on 7,' I will prepare the answers beforehand. But if it is in-person, it is harder to cheat." [Informant I]
Suggestions for improvements	
Continue the training (beyond 12 weeks)	• "I think I need to keep doing it consistently to see improvement. But I understand it is difficult if resources are lacking. Once the training stops, like now, I have forgotten a lot." [Informant K]
Booster training	• "Suggest to add online virtual courses. Each session would be half an hour, allowing students to choose their own study times." [Informant K] • "If possible, it would be best to have a booster session once a month to refresh what we have learned." [Informant L]
Consider in-person mode (but reduced frequency to accommodate time and venue constraints)	• "I think in-person sessions are ultimately more useful because you can see everyone's movements. In-person sessions could be held once a week, not too frequently, since not everyone can attend twice a week, and the center might not be able to provide the space for two days of training." [Informant B]

Textbox 2. Summary of the themes and subthemes derived from qualitative feedback.

- Perceived strength of the training (before participation): informants found dual-task training to be a novel approach, which interested them and motivated them to participate. They expected the training would help to slow down cognitive decline. The online format of the training saved them travel time but could still offer social interaction.
- Positive experience from the training: informants described the training comprehensive and challenging. The engaging facilitator increased their adherence. The group training enabled peer support, enhancing their training experience. Informants also found having the training at home very convenient.
- Challenges encountered with online training: supervision and the intensity of training was limited by the online format. Some informants found it harder to follow the sequence if the training involved taking turns. Some found the home environment made them less concentrated and the class atmosphere was not comparable to in-person class. The quality of the experience was also influenced by the display size of their device, Wi-Fi speed, and more importantly accessibility to a stable internet connection.
- Perceived benefits after the training: informants perceived benefits in cognitive ability, coordination, physical flexibility, communication skills, positive moods, and social interactions. Some valued acquiring new skills that could enable future self-practice. Some mentioned increased self-efficacy and self-confidence. Meanwhile, one mentioned the use of a cheat sheet as related to the negligible improvement.
- Suggestions for improvements: informants expressed a desire to continue the training by either extending the training period or offering regular booster sessions. However, informants generally preferred in-person training, although they acknowledged limitations regarding time and venue.

Discussion

Principal Findings

This study demonstrated feasibility and explored potential effects of an online dual-task training for community-dwelling older adults. The innovative aspects of the online dual-task training included (1) the delivery mode, allowing for uninterrupted training even during a pandemic, (2) chair-based exercises suitable for home-based practice, (3) cognitive training tailored to the needs of Chinese older adults with lower education levels, and (4) a co-design approach that considered the preferences and interests of the participants when designing the training components.

This study was launched at the end of 2022 when the COVID-19 pandemic was still ongoing. While there was no citywide quarantine policy in place, there was still a home quarantine policy for those who were infected and their close contacts. Older adults tended to limit their outings to reduce the risk of infection, as well as chance of becoming close contacts. The older population had experienced a lack of activities for a prolonged period, potentially leading to a faster decline in cognitive performance. The group-based online dual-task training addressed this gap by offering training that the participants could participate in at home.

The findings of our pilot study showed the intervention was highly feasible, as 72% (36/50) of the participants in the intervention group attended over three-quarters of the classes, which was above the target of 65%. The intervention was also well received by the participants; 82% (36/44) of the participants were satisfied with the intervention and 84% (37/44) would recommend the intervention to others. Even adopting the most conservative approach, such figures remained high at 72% (36/50) and 74 (37/50), respectively. The dual-task training successfully attracted some relatively cognitively healthy participants to join and could be continued irrespective of the pandemic situation. This initiative addressed the existing gap in services by providing online cognitive training for community-dwelling older adults.

Within-group improvement was observed in subjective memory complaints and cognitive function in the intervention group. Such improvements became evident at midintervention and persisted until the final follow-up, showing a medium-to-large effect size. Despite the qualitative feedback indicating self-perceived benefits, other outcomes did not consistently favor the intervention. Controlled for the baseline outcomes, small-to-medium effects ranging from 0.23 to 0.34 were observed in cognitive function for the between-group difference in midintervention and postintervention assessments. These findings are consistent with previous literature reporting small effects of 0.22 to 0.29 for dual-task training over control groups [37,38]. Nevertheless, inconsistent results were reported for other outcomes. Moreover, the fluctuation in the magnitude of the improvement was unexpected. Although possible self-practicing of the dual-task training after the intervention period might explain the increase in within-group improvement at the follow-up, the drop at the postintervention assessment was unexpected. There were factors that might have affected the evaluation. For example, engagement in the environment might influence achievement in relation to the effects of cognitive training [39], but the social context of the participants was not assessed. Another possibility might be COVID-19 infection, which might influence the performance of the participants not only during the infection period but afterward [40]. Moreover, some assessments could not be performed face-to-face but were conducted via Zoom; the different modes of data collection might have also influenced their performance. After the pandemic, a proper RCT should be conducted.

Meanwhile, within-group improvement was observed for the attention control group. The attention control condition consisted of a series of interactive health talks focusing on nutrition and food labeling. Participants memorized the contents delivered in each talk so they could answer the instructors' questions. Moreover, some participants had to learn to operate the Zoom platform as it was new to them. The learning process might also be beneficial to the participants, as some calculation was involved in comparing food labels using different units. In future trials, usual care control may be adopted.

Qualitative feedback highlighted the strength of the training regarding convenience, innovation, and comprehensiveness. In contrast, participants expressed a preference for in-person interactions. Hence, online training could be considered as a potential alternative or complement to traditional in-person training. Participants engaged in the training before receiving a cognitive impairment diagnosis, indicating that dual-task training could motivate early engagement in cognitive training. The facilitator leading the training does not necessarily be a health professional [20], and it is the engaging nature of the training, as revealed from the feedback, that the participants highly valued. This makes implementation of the intervention more feasible. Apart from the cognitive training, the participants also treasured social interactions and peer support during the class, and these further support the need to organize group-based training.

Implications

Dual-task training offers sufficient challenges to community-dwelling older adults; they found it interesting and reported that it boosted their motivation to participate in cognitive training. The contents of the training were comprehensive, covering motion, arithmetic operations, and verbal fluency. The training was conducted in a stimulating and recreational atmosphere, which was well received by the participants.

Online training offers the advantage of saving time and being convenient. However, it is not intended to replace traditional in-person training, as older adults generally prefer face-to-face interactions. Nonetheless, online training can be viewed as an alternative or complement to in-person sessions. Participants highlighted that organizing training twice a week in-person would be challenging, indicating a potential solution of combining one day of in-person training with one day of online training to maintain a twice-weekly training frequency. As older adults become more accustomed to online training, it can serve as a viable option during situations like a pandemic, enabling

XSL•FO
RenderX

training to continue even when older adult community centers are closed or during citywide quarantine measures.

When considering the implementation of in-person or hybrid mode training, it is essential to conduct research studies to assess their effectiveness. If in-person dual-task training is to be provided, incorporating more physical components could be beneficial. Similarly, any modified training approaches should undergo evaluation before being integrated into routine services. Future research studies could involve including a usual care control group or a waitlist control group to accurately determine the true impact of the training, building upon the improvement areas identified in this study. For instance, potential strategies for future interventions may involve implementing a 6-week intervention period, as some participants in the outcome evaluations exhibited positive effects as early as 6 weeks after the intervention; combining both in-person and online training modalities; and incorporating booster sessions. The exclusion criterion regarding engagement in any form of cognitive training 3 months before or during the study period may pose challenges once activities return to normal after the pandemic. Therefore, future trials should take a pragmatic approach, ensuring that any benefits derived from the intervention are in addition to participants' existing daily lifestyle routines.

Strengths and Limitations

The strength of this study included the integration of both quantitative and qualitative outcomes, which would reflect the feasibility and perceived benefits more holistically. The multiple outcome domains also helped to examine the potential effects more comprehensively. The multiple assessment points (4 time points) would facilitate the exploration of potential effects relative to the dosage of the intervention. The innovation components of the interventions were not restricted to the local context but could largely be applied to other regions.

Nevertheless, there were some limitations. The use of an attention control group might have limited the examination of potential effects from the intervention. Moreover, COVID-19 infection among the participants or their family members and the overall social environment during the study period were not documented, limiting the ability to control for the influences from these factors on the study outcomes. The cognitive domains assessed were limited to attention, verbal fluency, orientation, working memory, and executive function. Other cognitive domains, such as perceptual-motor control and social cognition, that might benefit from the intervention were not evaluated. User satisfaction was based on a self-developed question, and a validated scale could be considered in future. Owing to the nature of the feasibility study, the sample size was small, and a proper trial is needed in the future involving larger sample size.

Conclusions

Online dual-task training was shown to be a feasible intervention and was well received by older adults during the pandemic. Within-group improvement was observed in subjective memory complaints and cognitive function, with a medium-to-large effect size in the intervention group. Further investigation in a full-scale RCT is required to fully explore the intervention's potential effects.

Acknowledgments

This project was supported by the Health and Medical Research Fund (19200991) under the Food and Health Bureau of the government of the Hong Kong Special Administrative Region. The authors would like to thank the New Territories West Elder Academies Cluster and Hong Kong Sheng Kung Hui Welfare Council for their support and the older adults for their participation.

Authors' Contributions

All authors were responsible for conceptualization, funding acquisition, methodology, and writing−review and editing. PHC was responsible for formal analysis, project administration, and writing−original draft.

Conflicts of Interest

PHC is an Associate Editor for JMIR Aging.

Abstract

Background: Elective surgeries for older adults are increasing. Machine learning could enhance risk assessment, influencing surgical planning and postoperative care. Preoperative cognitive assessment may facilitate early detection and management of postoperative delirium (POD).

Objective: This study aims to assess machine learning models' predictive ability for POD, focusing on the added predictive value of the neuropsychological assessments before elective surgery.

Methods: This retrospective cohort study analyzed data from the multicenter PAWEL (Patient safety, Efficiency and Life quality in elective surgery) and PAWEL-R (risk) studies, encompassing older patients (≥70 y) undergoing elective surgeries from July 2017 to April 2019. A total of 1624 patients (52.3% male, N=850; age: mean 77.9, SD 4.9 years) were included, with a POD diagnosis made before discharge. Sociodemographic, clinical, surgical, and neuropsychological features were collected pre- and intraoperatively by care providers. Machine learning models' performance was evaluated using the area under the receiver operating characteristic curve (AUC), with permutation testing for significance, and Shapley Additive Explanations to identify effective neuropsychological assessments.

Results: Predicting POD before surgery with a random forest model achieved an AUC of 0.760. Incorporating all pre- and intraoperative features into the model yielded a slightly higher AUC of 0.783, with no statistically significant difference observed (P=.24). While cognitive factors alone were not strong predictors (AUC=0.617), specific tests within neuropsychological assessments, such as the Montreal Cognitive Assessment and Trail Making Tests, showed high feature attribution and played a crucial role in further enhancing prediction before surgery.

Conclusions: Preoperative risk prediction for POD can increase risk awareness in presurgical assessment and improve perioperative management in older patients at a high risk for delirium.

postoperative delirium; predictive model; preoperative cognition; geriatrics; elective surgery

Introduction

In an aging society, there is a rising demand for elective surgeries due to the changing health care needs of older people [1-3]. However, this increase in elective surgeries raises concerns about additional adverse outcomes, particularly given the unique challenges posed by aging, such as pre-existing health conditions, disease sequelae, and diminished physiological reserves [4,5]. Meeting the growing demand for elective surgeries among older adults requires a comprehensive strategy, including thorough preoperative assessments, personalized care plans, and continuous postoperative support [6-8].

Postoperative delirium (POD), characterized by acute and fluctuating inattention with alterations in thinking or consciousness after surgery, affects 12% to 51% of older patients, with incidence varying by surgical procedures and regions [9]. POD in older patients is linked to heightened rehospitalization rates, persistent postoperative cognitive dysfunction, increased incidence of dementia, and elevated mortality [10-12]. Some studies have shown significant associations between POD and factors collected before or during surgery (pre- or intraoperatively) [13,14]. These factors could aid in predicting the POD [15,16]. However, different pre- and intraoperative feature categories may vary in their importance for POD risk prediction. Sociodemographic factors, such as age and sex, are critical for assessing POD risk [17-24]. Clinical data, including blood samples and chronic disease medication, is also predictive [25-27]. The type and duration of surgery and anesthesia have been shown to be indispensable for POD prediction [18,28]. Although preoperative neuropsychological assessments, like the Mini-Mental State Examination (MMSE) and others [29-31], help identify at-risk patients for early risk mitigation [32-34], these evaluations are not yet incorporated into clinical routine despite experts' recommendations [35]. The early identification of POD predictors enables clinicians to proactively assess risks to mitigate the occurrence of POD [36] and might affect patients' decisions before nonemergent surgery. Therefore, identifying preoperative predictors for POD is crucial in facilitating personalized surgical risk assessment before surgery [37,38]. Moreover, examining POD risks remains challenging due to its multifactorial origins [18,22,39]. The precise categories of preoperative and intraoperative features with superior predictive capabilities for POD remain unknown and unvalidated [40].

In this study, we (1) predict POD by using machine learning approaches using diverse pre- and intraoperative features from a large multicenter cohort of older patients and (2) conduct a comparative analysis of independent models using various predictor categories, including sociodemographic, clinical, surgical, and neuropsychological features. By featuring one of the largest cohorts to date, this multicenter study provides an extensive assessment of POD predictors in both cardiac and noncardiac surgeries through machine learning techniques. This approach can enhance presurgical risk assessment and perioperative management in older patients.

Methods

Participants

Building on previous research [13,41,42], this study comprehensively investigates the predictive capabilities of various feature categories of the entire cohort from the PAWEL (Patientensicherheit, Wirtschaftlichkeit und Lebensqualität bei elektiven Operationen, English: Patient safety, Efficiency and Life quality in elective surgery) study, originally recruited between November 21, 2017, and April 12, 2019. In addition, it also includes additional participants from the add-on PAWEL-R study (R for risk estimation), which extended the recruitment period from July 11, 2017, to January 15, 2019. By incorporating both datasets, our study expanded the cohort size, strengthening the predictive model's reliability. Machine learning models were used to predict POD, departing from original statistical non–cross-validated methods in the previous reports [13]. Patients were recruited from 5 major medical institutions in Germany (3 university hospitals: Tübingen, Freiburg, and Ulm, and 2 tertiary medical centers: Stuttgart and Karlsruhe). The study adheres to CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) [43] and STROBE (Strengthening the Reporting of Observational studies in Epidemiology) [44] guidelines (the CONSORT-EHEALTH checklist is provided in Checklist 1). This study was approved by ethical votes under the PAWEL-R study, and ethical approval (Ethical Committee 233/2017BO1) was provided by the Ethical Committee of Tübingen University Hospitals, Tübingen, Germany on June 6, 2017.

Participants included patients aged 70 years and older undergoing elective surgery (joint, spine, vessels, heart, lung, abdomen, urogenital system, and other organs) with an expected surgical duration exceeding 60 minutes. Exclusion criteria covered patients unable to communicate effectively in German, those undergoing emergency surgery, severe dementia with MMSE <15 or Montreal Cognitive Assessment (MoCA) <8, or an estimated survival time of less than 15 months. A stepped-wedge cluster randomized design was used for equitable intervention group allocation [41,42]. The study, initially including 1631 patients, conducted thorough postoperative assessments within 1 week after surgery but before discharge. To ensure accuracy in predicting POD diagnosis, patients without sufficient information for POD diagnosis before discharge (N=7) were excluded, resulting in 1624 patients included in prediction models (Figure S1). The study reported 23.1% of patients diagnosed with POD, with detailed between-group comparisons available in Tables S1 and S2.

Measures

The PAWEL and PAWEL-R studies extensively evaluated elective surgery patients to identify risk factors and outcomes related to POD. Diagnosis involved the Confusion Assessment Method (I-CAM) algorithm and chart review within the first postoperative week or until discharge. Features were categorized

XSL•FO
RenderX

into 4 feature groups: sociodemographic, neuropsychological, clinical, and surgical information.

Sociodemographic data, including age, sex, education, alcohol and smoking habits, living arrangements, and hospital location, were collected preoperatively. Neuropsychological assessments such as MoCA, Trail Making Test (TMT) parts A and B, digit span backward, Subjective Memory Impairment (SMI), and Patient Health Questionnaire-4 (PHQ-4) were conducted during admission. Clinical profiles included blood samples, past medical histories (including pre-existing mild or moderate dementia and previous delirium history), preoperative and intraoperative medication dose (including benzodiazepine, neuroleptics, opiates, and propofol), polypharmacy, multimorbidity, the mininutritional assessment, American Society of Anesthesiologists (ASA) physical status classification system, Charlson comorbidity index, Barthel index, clinical frailty scale, and sensory impairments (auditory, visual, and others). Surgical information covered types and duration of surgery and anesthesia, cardiopulmonary bypass, and intraoperative physiological changes. Preoperative and intraoperative features were defined to assess predictive performance achieved at 2 distinct time points: before and during surgery. Additional details can also be found in Table S1.

To identify effective predictors for POD diagnosis, the specific and combined predictive capacity of sociodemographic, clinical, and surgical features before (preoperative) and during surgery (intraoperative) were analyzed. Models were developed and tested with both features and preoperative features alone. In addition, models were compared with and without neuropsychological assessments to examine their contribution to predictive performance.

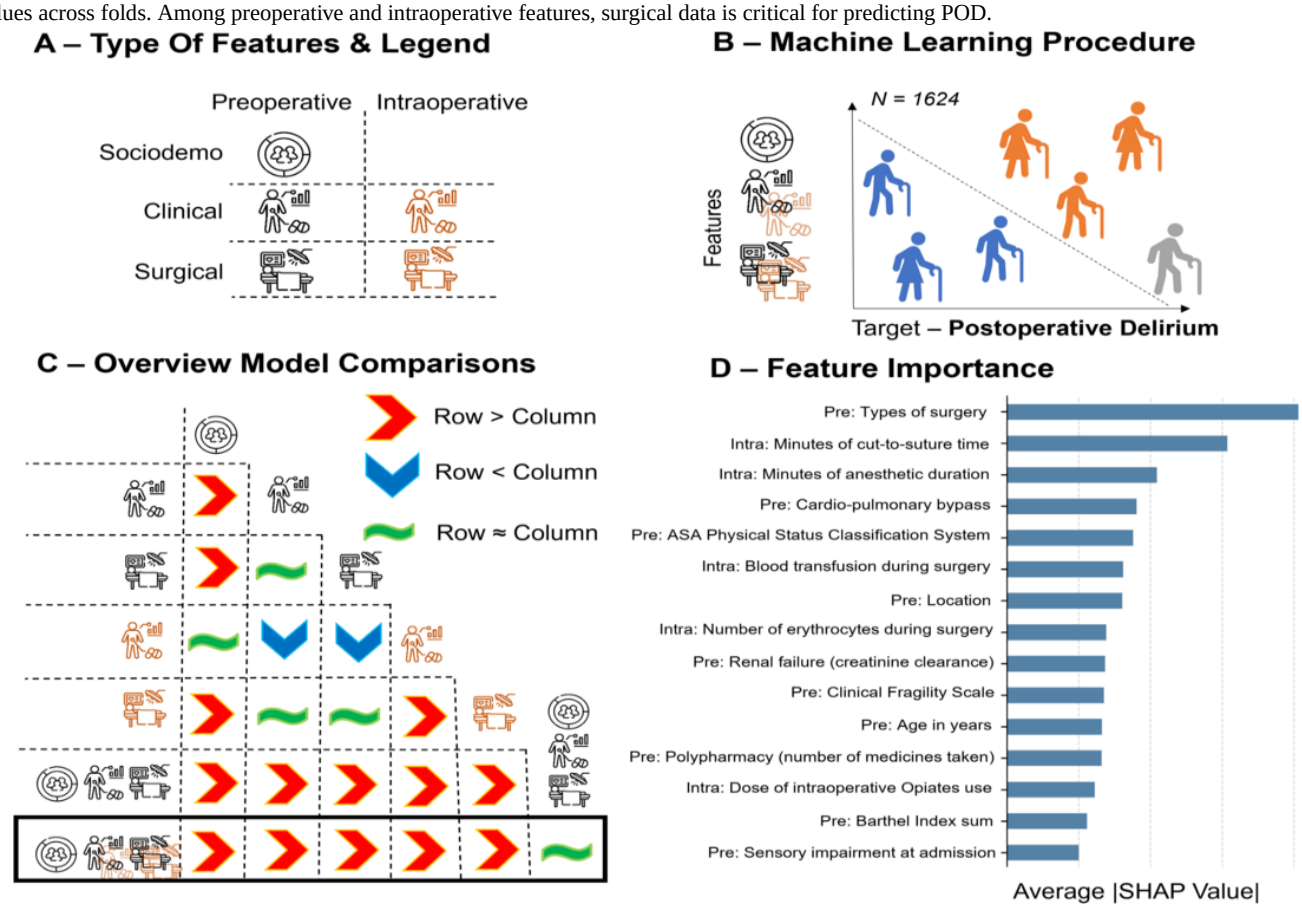
Preprocessing, Imputation, and Features

Two features with excessive missingness were excluded, namely, albumin level (979/1624, 60.28%) and depth of anesthesia (1224/1624, 75.37%) were excluded [16]. Information about missing values is available in Table S3. Data imputation involved using multiple imputation (IterativeImputer) for continuous variables and random sampling from the original probability distribution for discrete and binary variables within cross-validation folds for all models, except for gradient boosting, which does not require imputation [45]. Continuous and discrete variables were scaled within cross-validation folds for all models. Potential outliers or data entry errors in clinical assessments were identified when a data point exceeded 5 SD from the mean and were subsequently imputed using the above method.

Blood samples, including hemoglobin, sodium levels, and C-reactive protein (CRP), were interpreted and discretized following clinical guidelines from Harrison's Principles of Internal Medicine, 20th version, in line with standard practice [46]. Specifically, hemoglobin levels of less than 12 g/dL were considered indicative of anemia, while values of 12 g/dL or higher were considered normal. Serum sodium levels were categorized as hyponatremia if below 135 mmol/L and hypernatremia if above 145 mmol/L, with values within this range considered normal. Similarly, CRP levels greater than 3 mg/L indicated elevated levels in adults aged 65 years and older [47], while values within the normal range were not considered clinically significant. Redundant features with a perfect correlation were excluded; therefore, use of heart-lung machine was excluded for its perfect correlation with cardiopulmonary bypass. Nonbinary categorical features, including location, SMI, types of anesthesia and surgery, and transformed blood samples were one-hot encoded because they had no natural ordinal relationship among their categories, and assigning numerical labels to them could introduce bias or incorrect assumptions in the model.

Fifty-nine features were used, divided into preoperative (48 features) and intraoperative (11 features) categories. Preoperative features encompassed sociodemographic (7 features), clinical (20 features), surgical categories (6 features), and neuropsychological assessments (15 features). Intraoperative features included clinical (4 features) and surgical (7 features) categories. Different combinations of features were compared, including preoperative only, preoperative and intraoperative, and each category of preoperative features. The study evaluated model performance, feature category effectiveness, and the additional benefits of preoperative neuropsychological assessments.

The study aimed to develop a prediction model in a naturalistic setting. Information regarding interventions was included only as a sensitivity analysis to demonstrate its potential impact on the prediction model. The potential imbalance of the dataset for all models was tested by oversampling with the Synthetic Minority Oversampling Technique [48]. Given that the overall sex distribution in the cohort was fairly balanced (774/1624, 47.66% female), we did not apply additional rebalancing for sex to avoid potential bias. In addition, no significant age differences were observed between patients with and without POD. Various sensitivity analyses described were performed.



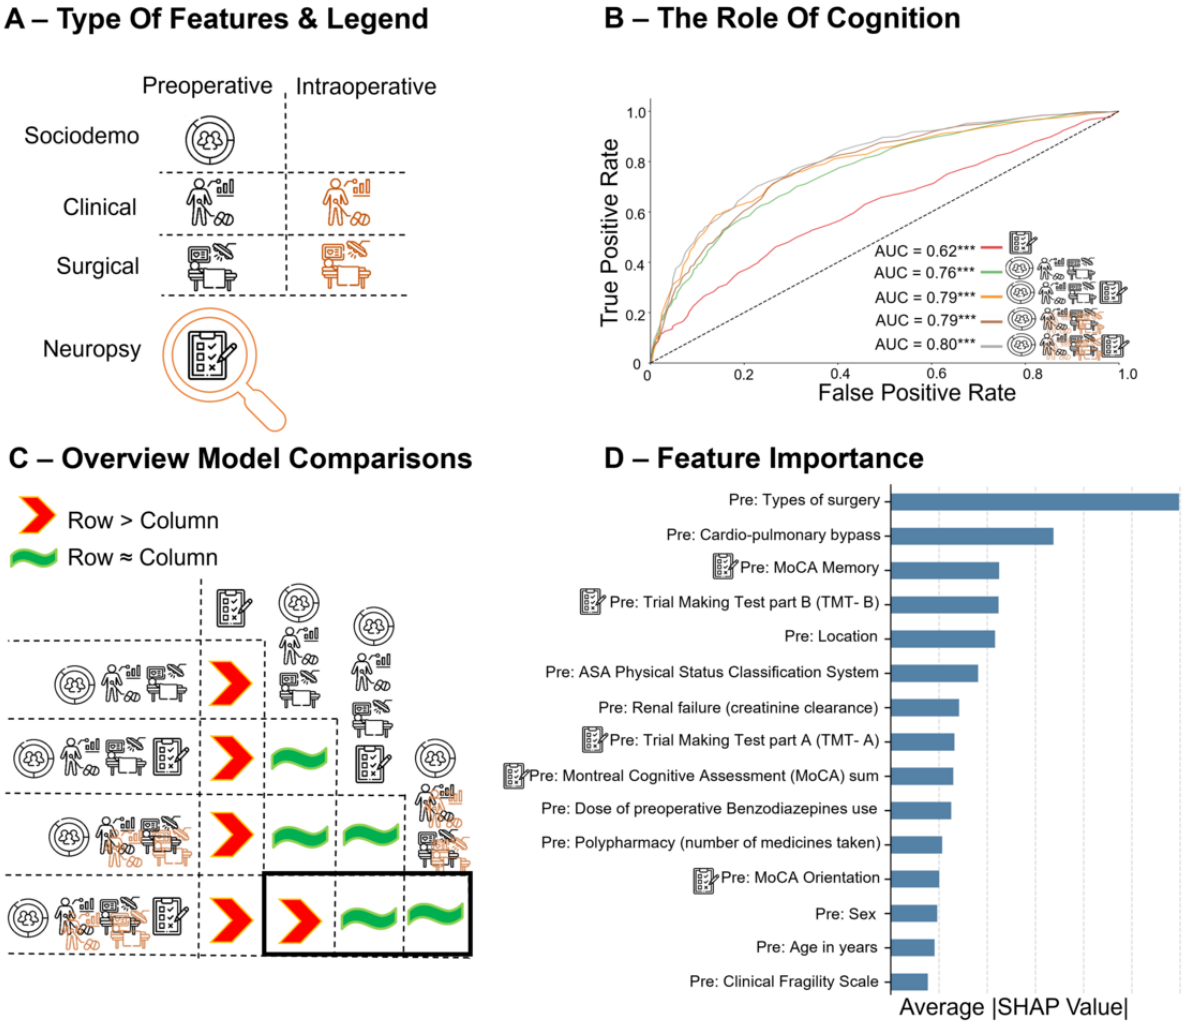
Machine Learning Models, Performance Evaluation, and Feature Importance

Machine learning models were used to predict POD, including logistic regression, support vector machines, random forest, and gradient boosting without hyperparameter tuning using the scikit-learn library version 1.2.2 [49] and the Xgboost library version (1.7.3) [50]. Independent variables were feature variables, while the dependent variable was POD diagnosis, as illustrated in Figure 1B. Feature selection was performed using the SelectFromModel function from scikit-learn, leveraging model-based feature selection, to retain the most predictive variables. Given the sample size relative to the complexity of the models, we did not anticipate substantial improvements from hyperparameter tuning. However, we conducted additional sensitivity analyses to assess its impact on model performance via nested cross-validation (Tables S12-S15 in Multimedia Appendix 1). To ensure model stability and interpretability, we used default parameters from the software for the primary analysis (Table S11 in Multimedia Appendix 1). 5-fold cross-validation, with balanced labels across folds, measured model performance at testing using the area under the receiver operating characteristic curve (AUC) as the primary metric. In order to robustly evaluate model performance against chance and between models, permutation testing was used to assess

XSL•FO
RenderX

whether the AUC of each model was significantly greater than expected by chance. Specifically, POD diagnostic labels were randomly shuffled, and AUC values were recalculated 1000 times to generate a null distribution. The *P* value was derived by comparing the observed AUC to this null distribution (Table S4 in Multimedia Appendix 1). Furthermore, to compare AUC differences between models, permutation testing was also used to generate a null distribution of AUC differences by randomly permuting the labels 1000 times while preserving data dependencies. The *P* value for model comparison was computed based on the observed difference relative to this null distribution [51,52]. Lastly, to obtain a robust measure of variability in model performance, 95% CI for AUC using bootstrapping with 1000 resamples was estimated. Additional metrics included precision, recall, sensitivity, specificity, balanced accuracy, and area under the precision-recall curve presented in Table S5 in Multimedia Appendix 1.

Figure 1. Individual feature categories perform worse than combined feature categories pre-, intraoperatively, and postoperative delirium (POD) can effectively be predicted prior to surgery (see back box). (**A**) The symbols are consistently used in this study and represent the different types of features. (**B**) A random forest classifier with 5-fold cross-validation was used to forecast POD onset in 1624 older individuals. Among them, 23.1% experienced POD. Orange indicates patients with POD, blue represents those without POD, and gray signifies patients predicted to have POD by the algorithm. (**C**) A comparative analysis of different feature combinations based on their respective area under the receiver operating characteristic curve (AUC) values, calculated over 1000 permutations was conducted. Combined feature sets consistently outperformed individual feature types. (**D**) Shapley Additive Explanations (SHAP) was used to assess feature importance. The feature importance was based on the average absolute value of the aggregated SHAP values across folds. Among preoperative and intraoperative features, surgical data is critical for predicting POD.



The Shapley Additive Explanations (SHAP) values were used to assess feature importance. Positive SHAP values increased the probability of POD, while negative values decreased it. SHAP values were computed across all cross-validation folds and aggregated over 5-fold cross-validation with 5 shuffles to ensure stability and robustness in feature importance rankings. To facilitate explanation of the main models, we presented the top 15 features contributing to model performance and complete feature attributions in major feature sets: preoperative features with and without neuropsychological assessments, and combined preoperative and intraoperative features with and without neuropsychological assessments (Figures 1D and 2D, Figure S2 in Multimedia Appendix 1, and Tables S7-S10 in Multimedia Appendix 1). The SHAP library version 0.41.0 in Python was used [53]. To evaluate the calibration of our models, calibration plots were generated (applying Platt scaling if needed), and the number of patients with high-confidence positive predictions (>0.9) and high-confidence negative predictions (<0.1) was calculated for each model. This analysis was conducted across different feature sets to assess whether the addition of features affected the model's probability estimates.

All preprocessing steps and analyses are available on GitHub upon publication from Sharma forked to our laboratory's page, and data can be requested by addressing the PAWEL consortium as indicated in the data availability section.

XSL•FO
RenderX

Figure 2. Cognition, in isolation, demonstrates limited predictive power. However, when combined with preoperative features, the performance matches that of all pre- and intraoperative features (see back box). (**A**) The predictive capability of preoperative neuropsychological tests was assessed for postoperative delirium (POD) individually and in combination with other features. (**B**) Our analysis, as depicted in the receiver operating characteristic curve, demonstrated the successful prediction of POD by preoperative neuropsychological tests. However, when combined with pre- and intraoperative data, the performance gains were only marginal. Asterisks (*) denote the Area Under the receiver operating characteristic Curve (AUC) values, which were assessed against chance permutation testing, revealing a significance (**$P \leq .001$). (**C**) The AUC values of neuropsychological tests were compared to those integrated into the pre- and intraoperative features. Adding preoperative neuropsychological tests to the preoperative model improves POD prediction to a level comparable to the best-performing model, similar to the effect of incorporating intraoperative features. In contrast, using preoperative features alone without neuropsychological tests results in lower performance. (**D**) Specific neuropsychological tests, such as the Montreal Cognitive Assessment (MoCA) and Trail Making Tests (TMTs), were particularly influential in POD prediction.

Ethical Considerations

This study was approved by the Ethics Commission of the Faculty of Medicine of the University of Tübingen (233/2017BO1, October 12, 2017) and the Ethics Commission of the University of Potsdam (38/2017, December 11, 2017), and was registered in the German Clinical Trials Register (DRKS00012797, July 2017).

All participants provided written informed consent for participation and for the publication of any potentially identifiable data. Data were pseudonymized, stored securely, and handled in accordance with applicable privacy and confidentiality regulations. Participants were not financially compensated but were reimbursed for travel expenses when applicable.

Results

Predicting POD With Combined, Pre-, and Intraoperative Features

The models incorporating combined and independent pre- and intraoperative features exhibited robust performance, as evidenced by AUC values surpassing chance levels, all with $P<.002$ (Table S4 in Multimedia Appendix 1) and Table S5 in Multimedia Appendix 1 displays the performance of these models through receiver operating characteristic curves with the random forest. The combined model using only preoperative features (Pre-Op) achieved an AUC of 0.760, comparable to a model incorporating both pre- and intraoperative features (Pre- and Intra-Op) with an AUC of 0.783, showing no statistically significant difference (Figure 1C and Table S6 in Multimedia

XSL•FO
RenderX

Appendix 1). Independent models exclusively using preoperative clinical, preoperative surgical, or intraoperative surgical features also demonstrated high AUC values (0.691, 0.664, and 0.670, respectively) without statistically significant difference. Notably, key predictors of POD included surgery type and cardiopulmonary bypass (preoperative surgical; recruiting hospital and age (preoperative sociodemographic); ASA status, Clinical Frailty Scale, Barthel Index, polypharmacy, and creatinine clearance (preoperative clinical); cut-to-suture time, anesthesia duration, and blood loss (intraoperative surgical) shown in Figure 1D and Figure S2-A in Multimedia Appendix 1. Further details, including all pairwise model comparisons and *P* values for differences in AUC values, can be found in Table S6 in Multimedia Appendix 1. A detailed list of the feature importance can be found in Tables S7-S8 in Multimedia Appendix 1.

Addition of Preoperative Neuropsychological Assessments

The model using preoperative neuropsychological assessments exclusively exhibited AUC values of 0.617. Integrating neuropsychological assessments into the model, using both pre- and intraoperative features (Pre- and Intra-Op+NeuroPsy), led to a slight improvement in the AUC, reaching 0.803 (Figure 2B and Table S6 in Multimedia Appendix 1). Adding neuropsychological assessments to the preoperative model (Pre-Op+ NeuroPsy) improved the AUC from 0.760 to 0.787, which resulted in a model that matched the above best-performing model (Figure 2C and Table S6 in Multimedia Appendix 1). Specifically, the MoCA scores and TMTs before surgery were important for predicting POD, as illustrated in Figure 2D and Figure S2-B in Multimedia Appendix 1. For detailed pairwise comparisons of AUC values and corresponding *P* values, please refer to Table S6 in Multimedia Appendix 1. A detailed list of the feature importance can be found in Tables S9-S10 in Multimedia Appendix 1.

Robustness of Predictive Models in Performance Evaluation

Evaluating the performance of 4 classifiers with tuned hyperparameters revealed comparable results (Tables S12-S15 in Multimedia Appendix 1). The random forest model, demonstrating marginally better performance in AUC values in models with combined features, was highlighted above. In addition, random forest models demonstrated good calibration, as indicated by a consistent distribution of high-confidence predictions across different feature sets. The inclusion of intraoperative and neuropsychological information did not compromise calibration, ensuring the model's reliability in distinguishing high- and low-risk patients (Figure S3 in Multimedia Appendix 1).

Including intervention allocation information had no discernible impact on predictive performance (Tables S5 and S16 in Multimedia Appendix 1). Finally, there was no statistically significant difference in AUC between models with and without oversampling (Table S17 in Multimedia Appendix 1).

Discussion

Principal Findings

Leveraging machine learning, we predicted the occurrence of POD after elective surgeries through a combination of preoperative and intraoperative features with a large multicenter cohort, achieving an AUC above 0.8. This performance exceeds that of traditional scoring systems such as the Delirium Risk Assessment Tool, Delirium Risk Assessment Score, and Delirium Elderly At-Risk, which have demonstrated AUC values between 0.5 and 0.7 in a large cohort [54-56]. Surgical information both before and during the surgery was critical in predicting POD. Integrating neuropsychological tests into preoperative features enhanced the AUC to a level comparable to the best-performing model, effectively replacing intraoperative features for predicting POD before surgery. This improvement was primarily driven by MoCA and TMTs A and B, as elucidated by model explanations. This integrated analysis improves conventional clinical risk profiling, furnishing superior predictive capacity with promising implications for surgical planning in the era of machine learning-assisted health care and empowering the prioritization of pivotal features in future work.

Critical Surgical Information

Surgical features, both preoperative and intraoperative, emerged as good solo predictors category for POD (Figure 1C). While baseline clinical profiles, including ASA physical status, renal function, frailty, and polypharmacy, are important, intraoperative surgical features such as individual surgery and anesthesia duration and factors related to blood loss were particularly important for predicting POD (Figure 1D and Figure S2-A in Multimedia Appendix 1). In addition, preoperative surgical information such as types of surgery and use of cardiopulmonary bypass were also associated with a higher risk of POD, aligning with a higher overall incidence of cardiac surgery in patients with POD relative to those without POD (206/375, 54.9% vs 264/1249, 21.1% as indicated in Table S1 in Multimedia Appendix 1). Consistent with our findings, a 30-minute increase in surgery duration corresponded to a 6% rise in POD risk [28], and this risk is further elevated in prolonged cardiac surgeries using cardiopulmonary bypass [57], potentially leading to hypoperfusion or microembolism [58]. This suggests a potential cumulative effect, particularly in patients with poor preoperative clinical profiles. Overall, our findings highlight the critical importance of cardiovascular surgical risk measures in POD prediction.

Looking ahead, the integration of real-time predictive technology into surgical workflows holds promise. This advancement could potentially facilitate on-the-fly predictions during surgery, enabling timely adjustments to medication or nonpharmacological intervention to mitigate potential adverse outcomes associated with surgical interventions. Our study emphasizes the substantial value of information gleaned from measures taken during surgery, shedding light on their crucial role in enhancing our understanding and prediction of POD.

XSL•FO
RenderX

Enhanced POD Prediction Before Elective Surgery Through Neuropsychological Assessments

With a larger cohort and a more comprehensive battery of preoperative neuropsychological assessments, this study demonstrated slightly improved predictive performance compared to a previous model that used a smaller sample and a limited neuropsychological assessment (MoCA) [37]. Consistent with prior research [16], our results indicate that preoperative models can achieve comparable performance to those incorporating intraoperative features in predicting POD. Although incorporating intraoperative data slightly improved POD predictions, they do not diminish the value of neuropsychological testing for early risk stratification, especially in elective surgeries where timing allows for actionable planning. A key limitation of intraoperative data prevents surgical planning and decision-making beforehand, allowing only adjustments in real time. These findings are particularly relevant to older patients undergoing elective surgery, as they have sufficient preoperative time for noninvasive neuropsychological assessments and for adjusting surgical strategies accordingly. Therefore, augmenting the predictive performance by incorporating data that can be gathered before a surgical procedure is important, as it allows for potential prehabilitation strategies, integrated surgical planning, and informed decision making prior to any invasive or surgical procedure.

In our study, preoperative neuropsychological assessments were predictive above chance (Figure 2B). To achieve performance comparable to the model combining all available features, adding neuropsychological tests to the preoperative model can effectively replace intraoperative features to predict POD before surgery (Figure 2C), which is critical given that surgical and postoperative management could be optimized. Preoperative models with neuropsychological tests effectively predicted POD before surgery substantiating previous observations [13,29,59]. This could be attributed to preoperative neuropsychological tests revealing subtle cognitive deficits that are not captured by dementia or delirium history. Fewer than 2% of patients in this cohort reported a diagnosis of mild or moderate dementia before elective surgery (Table S1 in Multimedia Appendix 1), and neither dementia nor delirium history was influential predictors with consistently almost zero feature attributions (Tables S7-S10 in Multimedia Appendix 1). These subtle deficits may progress into POD. In line with this explanation, timely preoperative cognitive interventions can mitigate the risk of POD and long-term cognitive dysfunction after cardiac surgeries [60,61]. In addition, patients with pre-existing cognitive decline face increased risks of other postoperative complications [62,63]. Consequently, baseline neuropsychological assessments are valuable for improving the prediction of POD beyond what clinical history alone can offer.

Selecting suitable neuropsychological assessments for clinical use is crucial. Our study identified the MoCA and TMTs as effectively indicated by their average absolute SHAP values (Figure 2D and Figure S2-B in Multimedia Appendix 1). Low scores on the MoCA and longer test times on the TMT indicate poor cognitive performance and executive dysfunction. These tests are crucial for predicting POD risk, as demonstrated in a previous prediction study [15]. Our findings, while focused on prediction [64], can complement previous etiological studies that show patients with mild cognitive impairment at baseline are more likely to develop POD [26], while good preoperative cognitive performance is protective against POD [18]. Previous studies have often used the MMSE [29,32,65], Clock-Drawing Test [20], or MoCA score as preoperative risk factors [66]. Critically, we replicated the strong association between baseline MoCA and POD risk in the previous theory-driven etiological PAWEL-R study with a larger and extended cohort [13]. These findings offer a thorough understanding of the efficacy of individual preoperative neuropsychological tests in predicting POD. By conducting comprehensive assessments of predictors for pre-existing risks, we may unlock new avenues for optimizing surgical planning and postoperative management. Our study underscores the added, albeit moderate, advantage of evaluating cognition, emphasizing its importance and advocating for its inclusion in future developments aimed at refining preoperative risk assessments.

Limitations and Recommendations

The study exhibits several limitations that require consideration. First, interpreting and using SHAP values warrants caution [67], as is generally the case for methods using model explanations in medicine [68,69]. Unstable explanations are not uncommon for complex models trained on large datasets [70,71]. While the ranking of importance may fluctuate, features with higher mean absolute SHAP values generally maintain consistent attributions. To enhance stability and reduce dependence on specific cohort segments, we aggregated SHAP values across multiple folds with shuffling, ensuring a more reliable assessment of feature importance (Tables S7-S10 in Multimedia Appendix 1). Second, although permutation is a robust statistical method, its conservative nature means nonsignificance does not always indicate the absence of a difference. Third, to minimize temporal bias and avoid causal leakage, we excluded perioperative features whose timing could not be clearly verified to precede the onset of delirium. While such features may have clinical relevance, their inclusion risks introducing postoutcome information. We recommend future research explore causal-learning approaches to better define temporal relationships, though limitations of observational data must be considered [72]. Fourth, we harnessed cognitive data derived from standardized assessments. However, it is crucial to note that these procedures, while standardized, often remain nondigitalized. This presents significant untapped potential for future advancements in the realm of risk prediction before surgical procedures. Fifth, while our study included a wide range of preoperative neuropsychological assessments, it is not an exhaustive list. As neuropsychological assessments are time-consuming and require training for assessors to conduct accurate tests and interpret results. Therefore, incorporating semiautomatic assessments of cognition [73] may prove advantageous and a relevant direction for future research.

Conclusion and Relevance

This study highlights the feasibility of predicting POD before elective surgery in adults aged 70 years and older by using a diverse set of features, including neuropsychological

XSL•FO
RenderX

assessments. Our research advances the understanding of POD predictors, enabling a more targeted approach to POD risk prediction in clinical practice. The findings offer crucial insights into predictive features for POD, underscoring the importance of integrating these predictors into the digital transformation of preoperative risk assessment.

This work was supported by the BMBF-funded de.NBI Cloud within the German Network for Bioinformatics Infrastructure (de.NBI) (031A532B, 031A533A, 031A533B, 031A534A, 031A535A, 031A537A, 031A537B, 031A537C, 031A537D, 031A538A).

We would like to thank the PAWEL (Patientensicherheit, Wirtschaftlichkeit und Lebensqualität bei elektiven Operationen) and PAWEL-R (Patientensicherheit, Wirtschaftlichkeit und Lebensqualität bei elektiven Operationen–Risk) Study group and the patients' participation in this study, making the work possible.

"PAWEL Study Group" includes members: Florian Metzger, Department of Psychiatry and Psychotherapy, University Hospital Tübingen; Andreas Straub, Department of Anesthesiology, University Hospital Tübingen; Tobias Krüger, Department of Heart Surgery, University Hospital TübingenFelix Bausenhart, Department of Orthopedics, University Hospital Tübingen; Petra Renz, Nursing Department, University Hospital Tübingen; Andreas Walther, Department of Anaesthesiology and Intensive Care, Katharinen Hospital, Klinikum Stuttgart; Carola Bruns, Department of Old Age Psychiatry and Psychotherapy, Klinikum Stuttgart; Juliane Spank, Department of Old Age Psychiatry and Psychotherapy, Klinikum Stuttgart; Patricia Sabbah, Department of Old Age Psychiatry and Psychotherapy, Klinikum Stuttgart; Andreas Häusler, Department of Social and Preventive Medicine, University of Potsdam; Bernd Förstner, Department of Social and Preventive Medicine, University of Potsdam; Susanne Schulze, Department of Social and Preventive Medicine, University of Potsdam; Markus Martin, Department of Neurology and Neurophysiology, University of Freiburg; Bernhard Heimbach, Sebastian Voigt-Radloff, Center for Geriatric Medicine and Gerontology (ZGGF), University of Freiburg; Heiko Reichel, Department of Orthopedics, University Hospital Ulm; Andreas Liebold, Department of Cardiothoracic and Vascular Surgery, University Hospital Ulm; Simone Brefka, Agaplesion Bethesda Clinic, Geriatric Medicine, Ulm University and Geriatric Center Ulm; Stephan Kirschner, Department of Orthopedics, ViDia Christian Clinics Karlsruhe; Nina Stober, Geriatric Center Karlsruhe, ViDia Christian Clinics Karlsruhe; Uwe Mehlhorn, Helios Clinic for Cardiac Surgery, Study Center in KarlsruheJürgen Wasem, Institute for Healthcare Management and Research, University Duisburg-Essen; Anja Neumann, Institute for Healthcare Management and Research, University Duisburg-Essen

Data Availability

All preprocessing steps and analyses are available on GitHub [74] upon publication. The dataset analyzed during this study is available from the PAWEL study consortium on reasonable request.

Conflicts of Interest

CT received honoraria from serving on the scientific advisory board of Roche, a research grant from the gemeinsame Bundesausschuß der Krankenkassen and has received funding for travel and speaker honoraria from several hospitals for scientific education. GWE has nothing to disclosure. CAFvA received honoraria from serving on the scientific advisory board of Biogen, Roche, Novo Nordisk, Biontech, MindAhead UG, Lilly and Dr. Willmar Schwabe GmbH &Co. KG and has received funding for travel and speaker honoraria from Lilly, Biogen, Roche diagnostics AG, Novartis, Medical Tribune Verlagsgesellschaft mbH, Landesvereinigung für Gesundheit und Akademie für Sozialmedizin Niedersachsen e. V., FomF GmbH | Forum für medizinische Fortbildung and Dr. Willmar Schwabe GmbH &Co. KG and has received research support from Roche diagnostics AG.

Abstract

Background: There is a lack of research on the trajectories of cognitive functioning in older people with hypertension, as well as possible contributing factors and correlations between cognitive functioning and mental health.

Objective: This study aimed to conduct a secondary longitudinal analysis to examine cognitive functioning trajectories and their associated factors in older people with hypertension.

Methods: The data used in our study were retrieved from the Chinese Longitudinal Healthy Longevity Survey. The Chinese version of the Mini-Mental State Examination was used to assess cognitive functioning. The trajectories of cognitive functioning of older individuals with hypertension were determined by using group-based trajectory modeling. The binary logistic regression analyses were performed to examine how participant factors affected the trajectories of cognitive functioning in older individuals with hypertension. The relationships between cognitive functioning and mental health were investigated using multivariable linear regression models. Data were analyzed using SPSS (version 20.0; SPSS Inc) and Stata (version 16.0; StataCorp LLC).

Results: A total of 642 older people with hypertension were included. Cognitive functioning was categorized into 2 trajectories according to group-based trajectory modeling: “rapid decline” (48/642, 7.9%) and “slow decline” (594/642, 92.1%). Binary logistic regression results showed that older adults with hypertension aged equal to or greater than 80 years had an elevated risk of rapid decline in cognitive functioning (odds ratio 5.484, 95% CI 2.365 - 12.719), and higher score in mental health was the protector of rapid decline in cognitive functioning during the following 13 years (odds ratio 0.918, 95% CI 0.852 - 0.988). In the unadjusted model, mental health was positively associated with cognitive functioning (β=.246, 95% CI 0.125 - 0.234, *P*<.001), and this association was maintained after partial or complete adjustment for covariates (β=.159, 95% CI 0.059 - 0.174, *P*<.001; β=.138, 95% CI 0.043 - 0.158, *P*=.001). Subgroup analyses by age showed that this positive correlation was only seen in the 60 - 69 years age group (β=.183, 95% CI 0.036 - 0.193, *P*=.004), while subgroup analyses by sex revealed that the association between these 2 indicators was no longer presented among males in the fully adjusted model (β=.082, 95% CI −0.024 to 0.119, *P*=.19), and BMI fully stratification demonstrated this association persisted in the healthy weight group (β=.125, 95% CI 0.039 - 0.210, *P*=.004).

Conclusions: Our research showed that the decline in cognitive functioning is associated with lower mental health and occurs more rapidly in older adults with hypertension who are older than 80 years.

Introduction

According to the summary of the China Cardiovascular Health and Illness Report 2022, there will be 245 million individuals with hypertension in China, and the prevalence of cardiovascular illness is expected to continue rising. Currently, cardiovascular disease ranks first among all causes of death for Chinese citizens living in both urban and rural areas. Patients with hypertension account for 50% of deaths from coronary heart disease and stroke, and the disease has increased the burden on society and the populace [1]. One of the main chronic illnesses in China that has a significant impact on health care costs is hypertension, which also poses the greatest risk of stroke, heart disease, and renal disease [2].

XSL•FO
RenderX

Hypertension is well established as a key risk factor that raises the likelihood of vascular cognitive impairment and Alzheimer disease, which affects a considerable fraction of the adult and geriatric population [3]. Due to its disruption of the cerebral circulation's structural and functional integrity, hypertension primarily affects cerebral blood supply by causing vascular thinning and dysfunction as well as neurovascular uncoupling. Furthermore, because it compromises the blood-brain barrier, hypertension also increases the risk of neuroinflammation and amyloidosis. In addition, age worsens the body's ability to recover from cellular stress and maintain homeostasis, which exacerbates the negative consequences of hypertension on the cerebral vasculature [4]. Cognitive decline is closely associated with all of these factors.

There may also be a connection between poor mental health and cognitive deterioration in hypertension. According to recent research, there is evidence linking mental illnesses with hypertension, and chronic stress is acknowledged as a common but underappreciated risk factor for cardiovascular disease [5,6]. Another significant risk factor for cognitive deterioration that has been identified is depression. Studies have indicated a link between chronic depressed symptoms and decreased cognitive functioning in late middle age [7], and that depression is a risk factor for developing Alzheimer disease [8]. The link between the development of cardiovascular disease, cognitive decline, and poorer mental health is uncertain and needs to be researched in depth.

In light of the high incidence and unfavorable effects of hypertension, it is critical to investigate how the disease may affect cognitive trajectories and its connections to mental health, all of which may aid in the early detection and management of hypertension. By extracting pertinent data from the Chinese Longitudinal Healthy Longevity Survey (CLHLS), the study aimed to investigate the cognitive functioning trajectories, potential affecting factors, and link with mental health in older persons with hypertension.

Methods

Ethical Considerations

The CLHLS study was approved by the Research Ethics Committee of Peking University (IRB00001052-13074), and all written informed consent had been obtained from participants or their proxy respondents and the participants' privacy was protected. All data were fully anonymized to ensure participant confidentiality.

Study Design and Population

Data included in the study were retrieved from 5 waves of the CLHLS from 2005 to 2018. The CLHLS, initiated in 1998, is a prospective cohort designed to investigate factors influencing longevity among older adults. It uses a nationally representative sample drawn from 22 of China's 34 provinces. The study uses a multistage, nonequal target random sampling strategy: approximately half of all counties, county-level cities, and municipal districts within the participating provinces were randomly chosen as survey sites. These selected administrative areas were further stratified into "large sample" and "small sample" categories for data collection purposes. Qualified interviewers, centrally trained and assessed for competency, conducted the surveys. Data gathering involved direct interviews with surviving participants (older adults) and proxy interviews with the adult children of decedent participants. For more information on the sampling design and data quality assessment, readers can refer to this literature [9].

Participants in the wave of 2005 as baseline involved 15,638 older people, and we excluded those who lacked necessary information on cognitive functioning and blood pressure in the following CLHLS 2008, 2011, 2014, and 2018 waves (n=14,404). This study focused only on older adults with hypertension. Therefore, of the 1234 participants who remained, we further excluded those who did not satisfy the diagnostic criteria of hypertension previously established in the literature (n=531), who missed the information on covariates (n=12), and those with unreliable data (n=49). Ultimately, a total of 642 participants were included in the analysis. The adequacy of our sample size (N=642) was rigorously evaluated using Green's power-based framework for regression analyses with 12 predictors [10]: for multivariable linear regression examining mental health-cognition associations, detecting medium effect sizes (f^2=0.15) required ≥128 participants for overall model significance ($N \geq L/f^2$), while testing individual coefficients (partial correlations) needed ≥65 participants ($N \geq 8/f^2+(m-1)$). As for binary logistic regression analyzing cognitive trajectory predictors, the Peduzzi criterion (10 events per predictor) necessitated ≥600 participants ($N \geq 10 \times m/p$). Our sample size of 642 substantially surpassed all these thresholds, providing over 99% power to detect medium effects at α of .05 (calculated via Cohen tables). Our fullest model (k=12 covariates) required n ≥116, well below our analytic sample. Therefore, the current sample size provides adequate statistical power for the core objectives. Based on the literature [11], hypertension in this study was defined as systolic blood pressure ≥140 mmHg or diastolic blood pressure ≥90 mmHg or self-reported diagnosis of hypertension in the hospital prior to enrollment.

Cognitive Functioning

Cognitive functioning was measured by the Chinese version of the Mini-Mental State Examination (C-MMSE), which evaluated 4 aspects of cognitive functioning, including orientation, calculation, recall, and language [12]. The C-MMSE comprised 13 questions with total scores ranging from 0 to 30. A higher score indicated better cognitive functioning. The psychometrics of the C-MMSE have been verified in previous studies [13,14].

Covariates

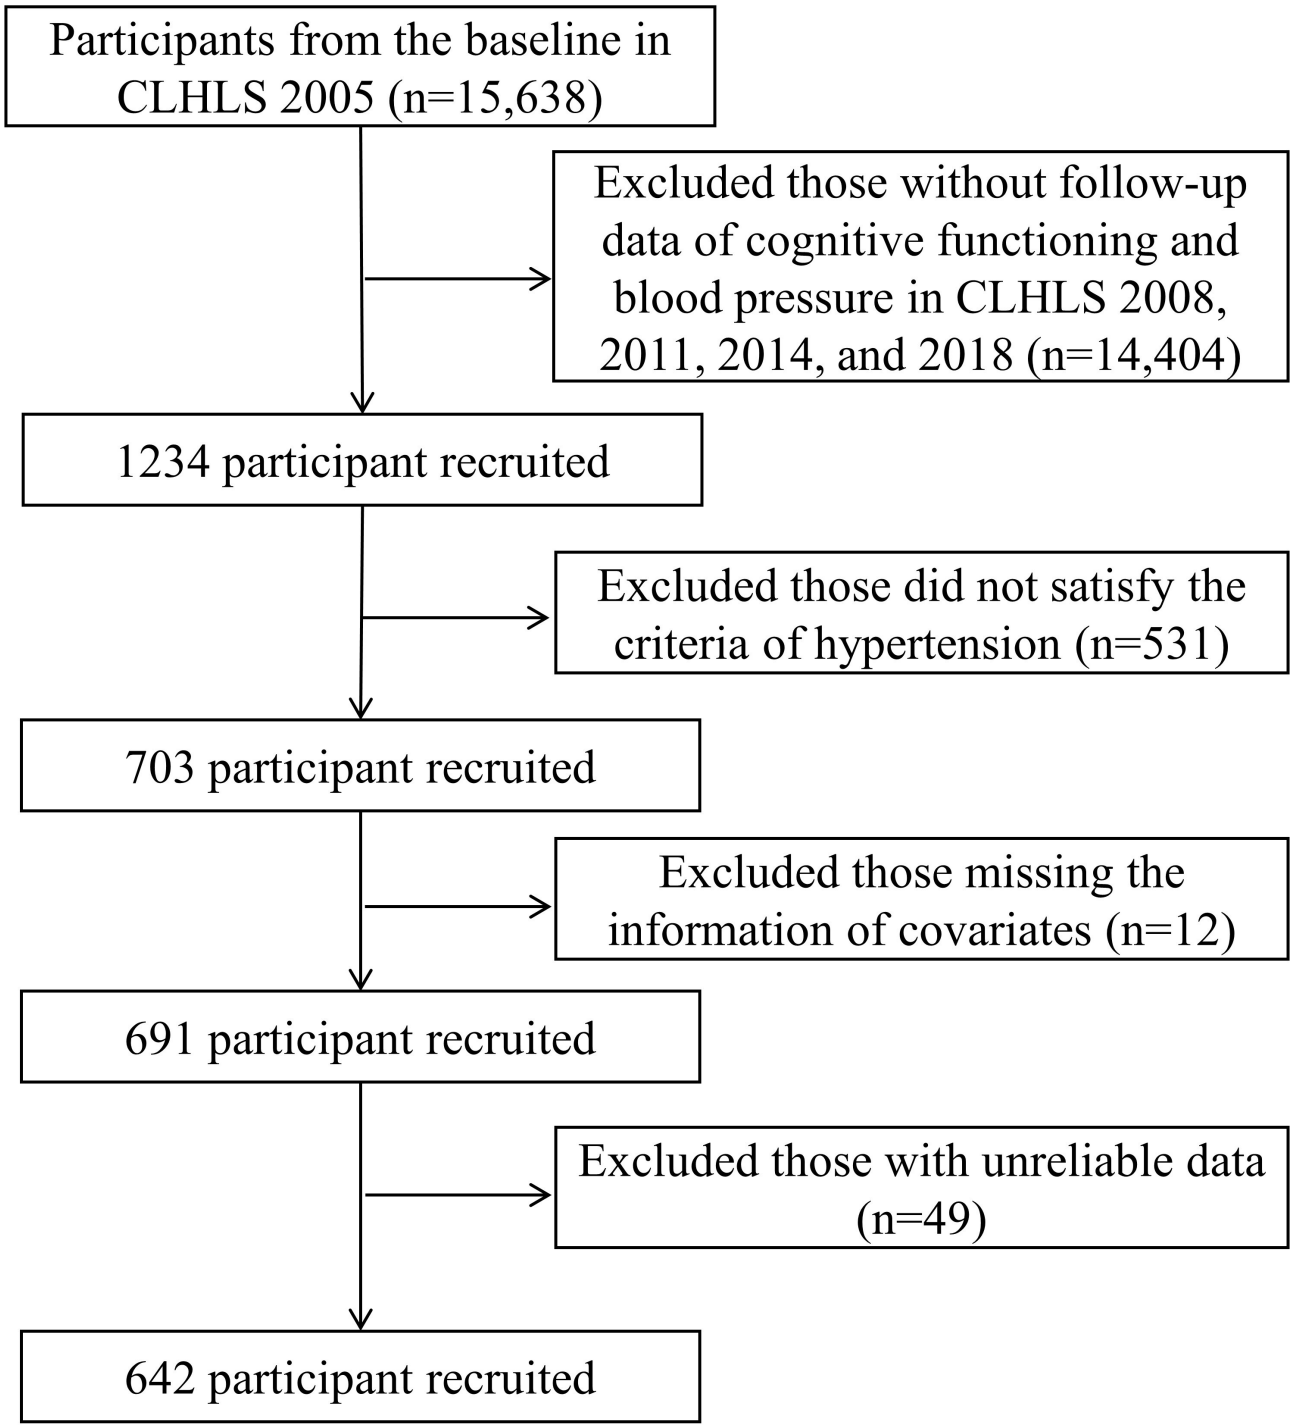
The selection of covariates was guided by established gerontological and epidemiological frameworks, aiming to control for potential confounding factors and capture key dimensions influencing health outcomes in older adults, particularly cognitive functioning [15]. The covariates included in this study were as indicated below: age category (60-69 y, 70-79 y, and ≥80 y), sex (male or female), smoking status (current, previous, and never), drinking status (current, previous, and never), exercise (current, previous, and never), educational level (zero year of schooling, 1-6 y of schooling, and ≥7 y of

XSL•FO
RenderX

schooling), marital status (married and living with spouse, separated/divorced/widowed/never married), BMI (<18.5 as underweight, 18.5-23.9 as healthy weight, 24-27.9 as overweight, and ≥28 as obesity), and quality of sleep (bad, general, and good). Among these, smoking, drinking, and exercise were self-reported by participants, who could report their current, previous, or never status for each factor. Social participation was evaluated by 10 activities in the CLHLS questionnaire according to the previous study [16]. Activities of daily living (ADL) were measured by 6 items including bathing, dressing, toileting, indoor transferring, continence, and feeding, and instrumental activities of daily living (IADL) were assessed by 8 items including going out to visit neighbors, shopping, making food, washing clothes, walking 1 kilometer, carrying 5 kg weight, crouching and standing 3 times, and taking public transport [16]. Mental health was examined by 7 items, such as "look on the bright side of thing," "keep my belongings neat and clean," "feel fearful or anxious," "feel lonely and isolated," "make own decision," "feel useless with age," and "be happy as younger." The negative-oriented items were coded reversely. The maximum score is 28, and a higher score indicates a greater degree of mental health [17].

Statistical Analysis

The data analyses were administered by using the SPSS (version 20.0; SPSS Inc) for general statistical analyses. Stata (version 16.0; StataCorp LLC) was used for group-based trajectory modeling (GBTM) to identify the trajectories of cognitive functioning in older adults with hypertension from 2005 to 2018. The normally and abnormally distributed continuous data were manifested as the mean (SD) and median (IQR), respectively. The categorical data were expressed as a number (%). The *t* test was used to compare continuous variables with a normal distribution; otherwise, the Mann-Whitney *U* rank sum test was used. Pearson chi-square or Fisher exact test was applied to compare categorical variables. The best-fitting model was determined based on the following parameters and principles [18,19]: (1) the Bayesian Information Criterion closer to 0; (2) lower Akaike Information Criterion values; (3) the odds of correct classification higher than 5 for each group; (4) the entropy values closer to 1; (5) the average posterior probabilities of group membership greater than 0.7 for each group; and (6) the presence of sufficient number of individuals in each group (at least 5%). After confirming the optimal number of trajectory groups and appropriate trajectory shapes, we visually delineated the trajectories of cognitive functioning. Binary logistic regression analyses (Forward: LR) were conducted to analyze the influence of participants' characteristics on the trajectories of cognitive functioning of older adults with hypertension. Multivariable linear regression models were applied to examine the associations between mental health and cognitive functioning. Model 1 was crudely adjusted (unadjusted); model 2 was adjusted for age, sex, drinking status, smoking status, exercise, educational level, marital status, BMI, and quality of sleep; and model 3 was additionally adjusted for social participation, ADL, and IADL. Subgroup analyses stratified by either age or sex were performed with all covariates except those adjusted. $P<.05$ was considered statistically significant differences.



Results

Baseline Characteristics of Study Population

A total of 642 older adults with hypertension were included in this study (Figure 1). Of the included participants, 292 (45.48%) participants were men, and 350 (54.52%) participants were women (as seen in Table 1). The age distribution of older adults aged 60-69, 70-79, and ≥80 years was 41.12% (n=264), 45.95% (n=295), and 12.93% (n=83), respectively. For BMI, participants categorized as underweight, healthy weight, overweight, and obesity were 171 (26.64%), 346 (53.89%), 93 (14.49%), and 32 (4.98%), respectively. The median of social participation, ADL, IADL, and mental health was 17 (14-20), 12 (12-12), 16 (15-16), and 20 (17-23), respectively. In terms of blood pressure, the median of systolic blood pressure and diastolic blood pressure was 130 (120-130) and 80 (80-85) mmHg, respectively. From the cognitive perspective, participants rated a median score of 29 (27-30) in the baseline assessment (the cohort of 2005).

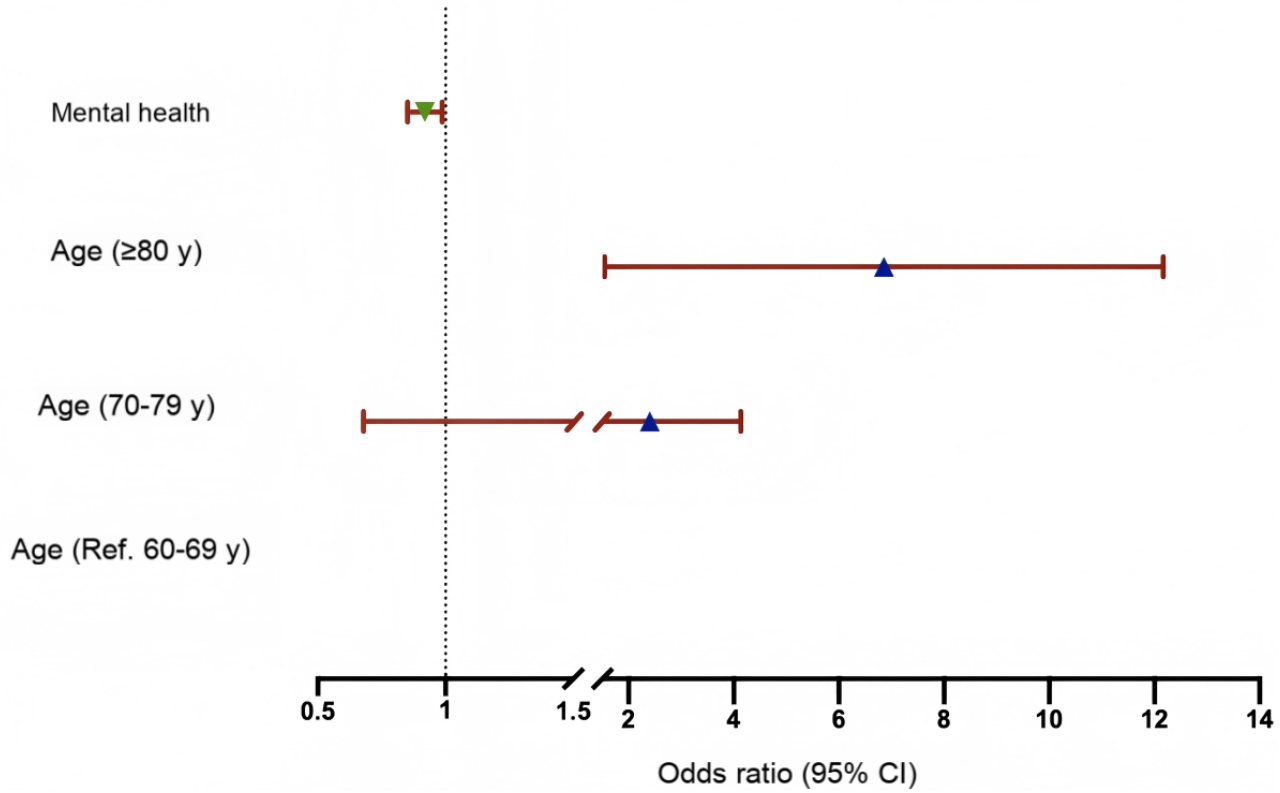
Trajectories of Cognitive Performance for Older People With Hypertension

According to GBTM, the cognitive functioning was divided into 2 trajectories. As shown in Figure 2, the trajectory of group 1 comprised 48 (7.9%) older adults with hypertension and was defined as “rapid decline”. The second group was estimated to include 594 (92.1%) older people with hypertension labeled as “slow decline.”

Figure 2. Trajectories of cognitive functioning for older people with hypertension.

The average posterior probabilities for these 2 trajectory groups were 0.91 and 0.99, respectively, which were higher than the recommended cut-off of 0.70. The odds of correct classification values were 114.58 for group 1 and 6.82 for group 2, with the lower value (6.82) surpassing the recommended threshold of 5. Model fit indices further supported this solution: the Bayesian Information Criterion was –8107.51, the Akaike Information Criterion was –8089.65, and entropy was 0.937.

Comparison of Cognitive Functioning Trajectory Groups



As demonstrated in Table 1, there were significant differences between the cognitive functioning trajectory groups in age (χ^2_2=21.901, *P*<.001), educational level (χ^2_2=5.979, *P*=.04), and IADL (*z*=−2.544, *P*=.01). Compared with group 1, the median of mental health was significantly higher (*z*=−2.691, *P*=.007). However, no statistically significant difference was found between groups in sex (χ^2_1=0.427, *P*=.51), BMI (χ^2_3=4.227, *P*=.22), smoking status (χ^2_2=0.297, *P*=.86), drinking status (χ^2_2=0.112, *P*=.95), exercise (χ^2_2=1.527, *P*=.47), marital status (χ^2_1=2.335, *P*=.13), quality of sleep (χ^2_2=0.411, *P*=.81), social participation (*z*=−1.363, *P*=.17), and ADL (*z*=−1.113, *P*=.27).

Factors Influencing the Cognitive Functioning Trajectories

Figure 3 presented the results of binary logistic regressions between group 1 and group 2. Older adults with hypertension aged 80 years or older had an elevated risk of rapid decline in cognitive functioning (odds ratio 5.484, 95% CI 2.365 - 12.719). However, a higher score in mental health was the protector of rapid decline in cognitive functioning during the following 13 years (odds ratio 0.918, 95% CI 0.852 - 0.988).

XSL•FO
RenderX

Figure 3. Logistic regression forest plot of the factors associated with the cognitive functioning trajectory groups.

Association Between Mental Health and Cognitive Functioning

As shown in Table 2, the multivariable linear regression model was used to examine the association between mental health and cognitive functioning in older people with hypertension. In the unadjusted model, mental health was positively associated with cognitive functioning (β=.246, 95% CI 0.125 - 0.234, *P*<.001). After adjusting the covariates partially (model 2) or fully (model 3), the positive relationship also remained unchanged (β=.159, 95% CI 0.059 - 0.174, *P*<.001; β=.138, 95% CI 0.043 - 0.158, *P*=.001).

XSL•FO
RenderX

Table . Association between mental health and cognitive functioning.

Mental health with cognitive functioning	Model 1		Model 2		Model 3	
	β (95% CI)	*P* value	β (95% CI)	*P* value	β (95% CI)	*P* value
Overall	0.246 (0.125 to 0.234)	<.001	0.159 (0.059 to 0.174)	<.001	0.138 (0.043 to 0.158)	.001
Stratified by age (years)						
60-69	0.255 (0.086 to 0.233)	<.001	0.199 (0.046 to 0.202)	.002	0.183 (0.036 to 0.193)	.004
70-79	0.197 (0.062 to 0.228)	.001	0.119 (−0.001 to 0.176)	.05	0.106 (−0.012 to 0.168)	.09
≥80	0.322 (0.102 to 0.480)	.003	0.239 (−0.020 to 0.452)	.07	0.107 (−0.127 to 0.319)	.39
Stratified by sex						
Male	0.215 (0.059 to 0.190)	<.001	0.128 (0.002 to 0.146)	.04	0.082 (−0.024 to 0.119)	.19
Female	0.238 (0.110 to 0.275)	<.001	0.179 (0.058 to 0.231)	.001	0.165 (0.047 to 0.219)	.002
Stratified by BMI (kg/m²)						
<18.5 as underweight	0.186 (0.081 to 0.292)	.001	0.126 (0.015 to 0.237)	.03	0.108 (−0.04 to 0.220)	.06
18.5-23.9 as healthy weight	0.184 (0.100 to 0.269)	<.001	0.142 (0.054 to 0.230)	.002	0.125 (0.039 to 0.210)	.004
24-27.9 as overweight	0.068 (−0.037 to 0.132)	.20	0.053 (−0.060 to 0.166)	.36	0.067 (−0.052 to 0.186)	.26
≥28 as obesity	0.052 (−0.127 to 0.231)	.56	0.061 (−0.180 to 0.303)	.60	−0.017 (−0.261 to 0.228)	.89

Subgroup analysis stratified by age, sex, and BMI was conducted to further evaluate the relationship between mental health and cognitive functioning. After adjusting for all confounders except for age, subgroup analysis by age showed that the positive association between these 2 variables was merely in the age group of 60-69 years (β=.183, 95% CI 0.036 - 0.193, *P*=.004). Meanwhile, subgroup analysis by sex revealed that although the positive relationship between these 2 indicators was shown in model 1 and model 2 for both males and females, the association was no longer presented in model 3 for males (β=.082, 95% CI −0.024 to 0.119, *P*=.19). Additionally, subgroup analysis by BMI demonstrated that in the partially adjusted model, mental health was significantly associated with cognitive functioning in underweight (β=.126, 95% CI 0.015 - 0.237, *P*=.03) and healthy weight groups (β=.142, 95% CI 0.054 - 0.230, *P*=.002). After full adjustment, this association persisted only in the healthy weight group (β=.125, 95% CI 0.039 - 0.210, *P*=.004), but not in underweight, overweight, or obesity groups.

Discussion

Principal Findings

This longitudinal study identified 2 distinct cognitive trajectories among Chinese older adults with hypertension using GBTM: a rapid decline trajectory (7.9%) and a predominant slow decline trajectory (92.1%). Key factors significantly differentiating these trajectories included age, education level, IADL, and mental health. Notably, age of 80 years or older emerged as a critical risk factor for rapid decline. Furthermore, the protective association between mental health and cognitive functioning was found to be significantly moderated by BMI, remaining robust only in normal-weight individuals after comprehensive adjustment for confounders.

Trajectory Classification and Risk Profiles

As far as research on the cognitive functioning trajectories of older persons with hypertension, possible contributing factors, and their connection to mental health is concerned, this is the first longitudinal survey of its kind. A total of 642 older adults with hypertension were included in our study. We distinguished between 2 categories of cognitive trajectories of patients with hypertension based on GBTM analysis: “rapid decline” (7.9%) and “slow decline” (92.1%). These 2 groups differed significantly in terms of age, education, and IADL, and the group with higher mental health scores showed a trend towards slow decline. According to one study, having hypertension was linked to worse cognitive trajectories, while treating and controlling the condition was linked to improved cognitive trajectories [20]. In a different study, Zhang et al [21] identified trajectory categories of executive functioning and situational memory in cognitive functioning. Their findings showed that patients with hypertension who had higher education levels,

XSL•FO
RenderX

moderate sleep at night, fewer depressive symptoms, and at least one alcoholic beverage per month were more likely to be in the optimal group for stabilized executive functioning; as time went on, participants with higher BMI, adequate daytime naps, and higher education levels were also more likely to be in the optimal group for stabilized executive functioning. Individuals with stable situational memory over time [21]. This is in keeping with our findings, which showed variations in age and education level between those who saw a quick and slow decrease.

Stratified Effects in Key Subgroups

We additionally propose possible causes for this interparticipant variability based on the binary logistic regression results. Stratified by age, we found that patients with hypertension aged 80 years or older had a higher risk of rapid cognitive decline compared with other age groups. Hypertension is known to affect a large portion of the adult and older population and is an important risk factor for vascular cognitive impairment and dementia in later life. Hypertension impairs cognitive functioning by altering or destroying the structural and functional integrity of the cerebral circulation, which in turn is exacerbated by aging [22]. This suggests that the age factor plays an important role in the risk of cognitive decline in patients with hypertension. As we can see from the logistic regression forest plot of the factors associated with cognitive functioning, higher mental health scores emerged as a protective factor against cognitive functioning decline. This illustrates the link between cognitive decline in hypertension and poor mental health. The study by Bai et al [23] confirmed that interventions targeting depression have the potential to alleviate the deterioration of cognitive symptoms. This corroborates the results obtained in our study and provides a theoretical basis for identifying risk factors and alleviating cognitive functioning decline.

We used multivariate linear regression models to examine the association between the trajectories of cognitive ability and mental health. According to our research, there is a positive correlation between mental health and cognitive capacity. This correlation persists even after controlling for confounders either fully (model 3) or partially (model 2). We performed age-, gender-, and BMI-stratified subgroup analyses to examine the connection between mental health and cognitive functioning in more detail. Age-specific subgroup analysis revealed that only the 60 - 69 years age group had a positive correlation between the 2, even after controlling for all other variables save age. Gender subgroup analysis revealed that in models 1 and 2, there were positive correlations between the 2 indicators for both males and females, but in model 3, there were no longer any for males. BMI subgroup analysis also revealed that mental health's cognitive protection was consistently significant only in normal-weight individuals. Effects attenuated in underweight and disappeared in overweight/obese groups, suggesting metabolic factors may override psychological benefits when BMI exceeds 23.9 kg/m^2. Clinically, mental health interventions should prioritize normal-weight elders with hypertension, while weight management precedes psychological therapies in higher BMI groups. This is in line with a study by Zhou et al [24] that found a negative correlation between serious depressive symptoms and lower cognitive function in an older Chinese community population. Guo et al [25] showed a substantial correlation between cognitive deterioration and older women with depression. Yeom et al [26] also revealed that the relationship between depressive symptoms and cognitive function is related to BMI. In summary, our findings indicate that the relationship between mental health and cognitive ability is significantly influenced by BMI and age, with normal-weight individuals and specific age groups showing stronger correlations even after controlling for confounders.

Conclusions

In summary, this population-based longitudinal study's data indicated that the cognitive trajectories of older Chinese persons with hypertension can be divided into 2 categories: rapid decline and moderate decline. Age was a significant factor, with hypertension patients older than 80 years having a larger chance of experiencing rapid cognitive decline than patients in other age groups; rapid cognitive decline was indicated by lower mental health scores. To determine the causal association between mental health and cognitive trajectory in older persons with hypertension, further longitudinal cohort studies should be carried out.

Strengths and Limitations

There are significant advantages to our study. As the first longitudinal study using trajectory analysis to examine older Chinese adults with hypertension, our work first clarifies changes in trajectories of cognitive ability, examines potential causes, and identifies correlations between trajectories of cognitive ability and mental health in this population. Second, we performed a thorough examination of cognitive functioning while keeping track of a sizable sample of middle-aged and older Chinese adults that was nationally representative. In order to better understand the fundamental causes of cognitive loss, we also fit the trajectory of cognitive aging using a cutting-edge statistical model (GBTM). It is crucial to acknowledge that this study has several limitations. First of all, it is challenging to explain causality in this observational study due to the cross-sectional methodology. Another limitation is the reliance on secondary data from the CLHLS. The variables and measurements were limited by the original survey design, potentially omitting unmeasured confounding factors. Moreover, we used a set of cognitive tests and questionnaires for cognitive assessment. These tools might not fully capture the complexity of cognitive functions or subtle variations in cognitive functioning. Finally, the reliance on self-reported measures may introduce recall bias and social desirability bias, particularly among older adults with cognitive impairment whose self-assessment accuracy could be compromised.

Abstract

Background: The utility of aging metrics that incorporate cognitive and physical function is not fully understood.

Objective: We aim to compare the predictive capacities of 3 distinct aging metrics—motoric cognitive risk syndrome (MCR), physio-cognitive decline syndrome (PCDS), and cognitive frailty (CF)—for incident dementia and all-cause mortality among community-dwelling older adults.

Methods: We used longitudinal data from waves 10-15 of the Health and Retirement Study. Cox proportional hazards regression analysis was employed to evaluate the effects of MCR, PCDS, and CF on incident all-cause dementia and mortality, controlling for socioeconomic and lifestyle factors, as well as medical comorbidities. Discrimination analysis was conducted to assess and compare the predictive accuracy of the 3 aging metrics.

Results: A total of 2367 older individuals aged 65 years and older, with no baseline prevalence of dementia or disability, were ultimately included. The prevalence rates of MCR, PCDS, and CF were 5.4%, 6.3%, and 1.3%, respectively. Over a decade-long follow-up period, 341 cases of dementia and 573 deaths were recorded. All 3 metrics were predictive of incident all-cause dementia and mortality when adjusting for multiple confounders, with variations in the strength of their associations (incident dementia: MCR odds ratio [OR] 1.90, 95% CI 1.30 - 2.78; CF 5.06, 95% CI 2.87 - 8.92; PCDS 3.35, 95% CI 2.44 - 4.58; mortality: MCR 1.60, 95% CI 1.17 - 2.19; CF 3.26, 95% CI 1.99 - 5.33; and PCDS 1.58, 95% CI 1.17 - 2.13). The C-index indicated that PCDS and MCR had the highest discriminatory accuracy for all-cause dementia and mortality, respectively.

Conclusions: Despite the inherent differences among the aging metrics that integrate cognitive and physical functions, they consistently identified risks of dementia and mortality. This underscores the importance of implementing targeted preventive strategies and intervention programs based on these metrics to enhance the overall quality of life and reduce premature deaths in aging populations.

Introduction

The aging process encompasses various physiological declines across multiple systems. As the global population ages, the prevalence of dementia is rising, expected to reach 131 million individuals by 2050. This increase poses a significant economic challenge, potentially equating to 1.1% of the global gross domestic product by 2030 [1]. The lack of curative treatments for dementia and its substantial public health impact underscore the necessity for early detection to mitigate or delay its onset. Given dementia's heterogeneous and lengthy preclinical phase, early screening and diagnosis in at-risk individuals are vital for disease management and caregiver preparedness [2].

Cognitive and physical declines with age often occur simultaneously, suggesting shared underlying mechanisms [3]. Researchers have developed metrics across molecular, phenotypic, and functional areas [4] to reflect the complex nature of aging accurately. Cognitive deterioration typically

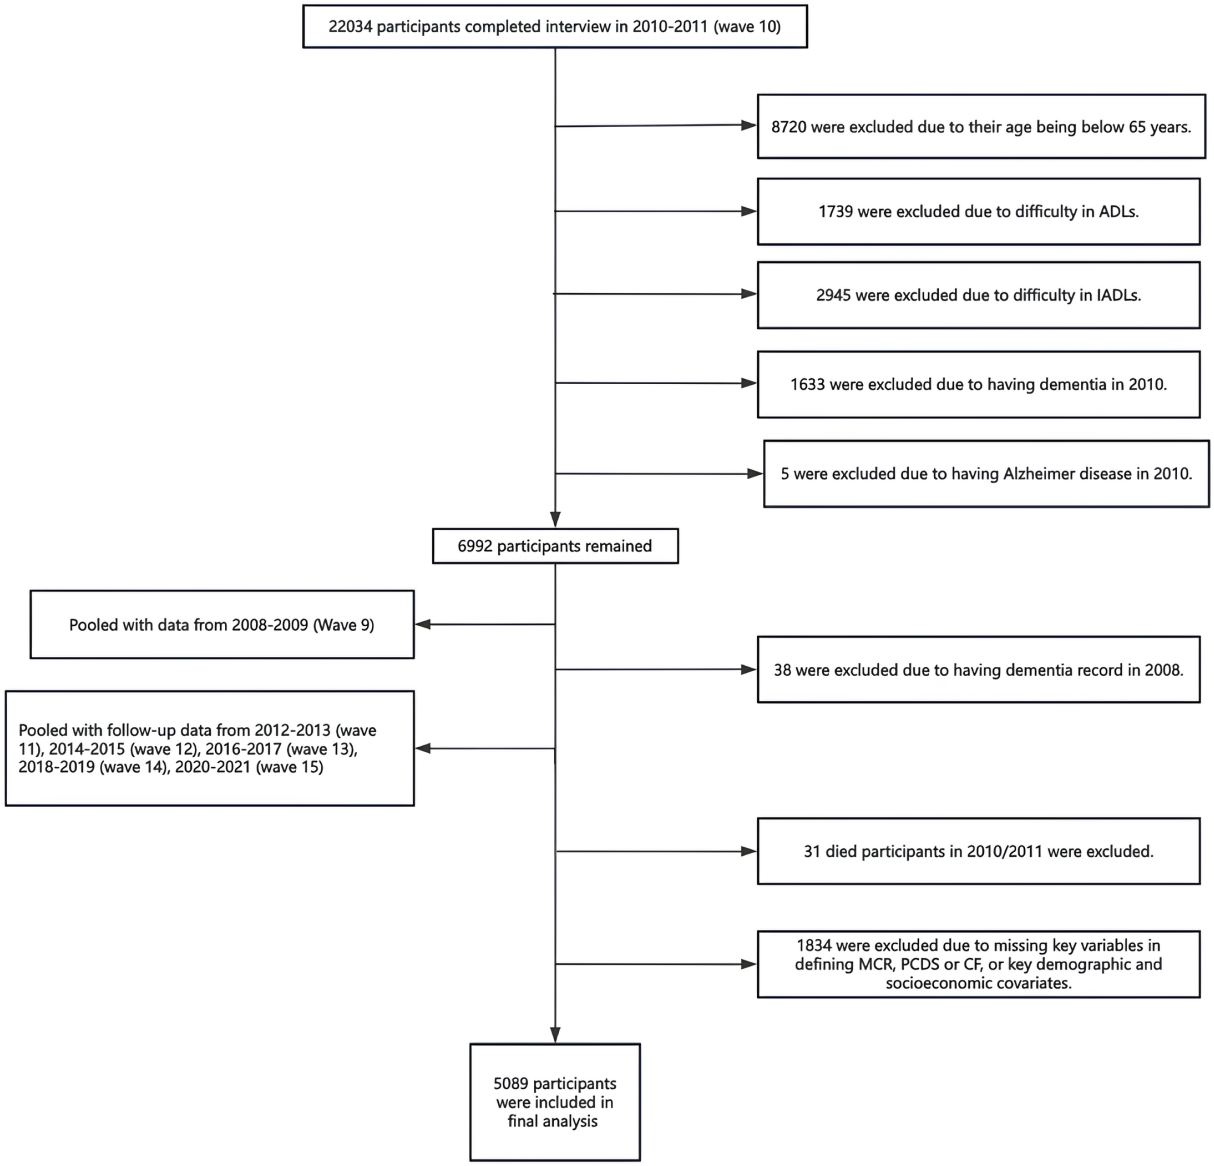
XSL•FO
RenderX

precedes dementia by several years, with evidence indicating that motor decline, especially in walking speed, can precede cognitive decline by over a decade [5,6]. Thus, composite aging metrics, encompassing both physical and cognitive functions, offer a promising method to gauge the functional status of the aging population. A meta-analysis highlighted an increased dementia risk in individuals with both physical frailty and cognitive impairment compared to those with cognitive impairment alone [7]. Therefore, composite aging metrics may serve as focal points for interventions aimed at preventing or delaying disability onset and enhancing the healthy lifespan of the elderly [8,9].

An ideal dementia screening tool for primary care should be brief, easily administered, acceptable to older individuals, and exhibit high sensitivity and specificity. Research on aging metrics that incorporate both cognitive and physical functions is gaining traction in gerontological studies due to their strong predictive power for adverse health outcomes. Various metrics have been introduced, such as cognitive frailty (CF) [10], motoric cognitive risk syndrome (MCR) [11], and physio-cognitive decline syndrome (PCDS) [12]. Despite their conceptual similarities, detailed assessments of their definitions and attributes are scarce, hindering their application in research and clinical settings.

Research has shown an increased incidence of concurrent gait and cognitive impairments in older adults susceptible to dementia [5]; however, the specific clinical traits of those experiencing both declines are not well-defined, and direct comparisons between different aging metrics have not been made. Additionally, the effectiveness of these metrics in identifying at-risk individuals and assessing the risk of adverse health events within the same population is not well understood. This lack of knowledge is clinically important for effectively categorizing older adults and identifying potentially reversible conditions in individuals with concurrent declines, thereby informing targeted strategies to slow dementia progression or reduce mortality rates. Consequently, our study seeks to fill these voids by comparing the risk of future dementia and all-cause mortality across 3 aging metrics and examining the predictive abilities of MCR, PCDS, and CF for adverse events among community-dwelling older adults without dementia at baseline, employing data from a broad population-based cohort.

Methods



Sample

This study analyzes data from waves 10 - 15 of the Health and Retirement Study (HRS), the most extensive longitudinal study examining the aging experiences of Americans aged 51 and older. The HRS uses multi-stage probability sampling of U.S. households to obtain a nationally representative sample of adults in this age group [13]. It collects self-reported data on demographics, chronic health conditions, daily activities, disability status, and other health determinants at baseline and every 2 years thereafter. In 2006, the HRS began conducting enhanced face-to-face interviews that included physical performance assessments, biomarker collections, and a leave-behind questionnaire on psychosocial topics. Half of the households were chosen randomly for the enhanced interview in 2006, with the remainder selected in 2008, a process that continues in subsequent waves. Further information on the HRS's recruitment strategies and design is detailed in previous literature [13].

The baseline for this analysis combined data from the 2008 - 2009 (wave 9) and 2010 - 2011 (wave 10) waves, marking the initial occasion respondents were asked about diagnoses of Alzheimer disease or dementia, instead of a "memory-related disease." Mortality data has been available since 2011. A total of 22,034 individuals completed wave 10 and were followed biennially through to 2020 - 2021 (wave 15). This study is a secondary analysis of the de-identified HRS public data, and the original HRS was approved by the University of Michigan Institutional Review Board. All participants signed the informed consent at the time of participation. Our final sample consisted of 2372 individuals who (1) were 65 years or older, (2) had complete baseline data on MCR, PCDS, and CF measures, (3) reported no difficulty with any activities of daily living and instrumental activities of daily living at baseline, (4) did not have Alzheimer disease or dementia at baseline, and (5) were alive in 2010 and 2011. Figure 1 shows the participant flow through each selection stage according to the inclusion criteria.

Measures

Cognitive Function

Biennial cognitive function tests were administered by trained HRS interviewers either in-person or via telephone using the Modified Telephone Interview for Cognitive Status (TICS-m), a global cognition test modeled on the Mini-Mental State Examination. The TICS-m comprises immediate and delayed 10-noun free recall tests (score range: 0 - 10 for each), a serial 7 subtraction test (score range: 0 - 5), and a test of counting backward from 20 (score range: 0 - 2). Higher scores denote better cognitive performance. During each assessment, HRS participants were categorized into normal cognition, mild cognitive impairment (MCI), or dementia based on established thresholds and comprehensive evaluations, including expert clinician adjudication from the Aging, Demographics, and Memory Study, a dementia sub-study within the HRS framework. Cognitive status was categorized into 3 distinct groups based on continuous scores [14], where scores from 12 to 27 indicated no impairment; scores between 7 and 11 signified cognitive impairment without dementia or MCI; and scores from 0 to 6 suggested dementia [15].

Motoric Cognitive Risk Syndrome

MCR was defined by subjective cognitive complaints coupled with slow gait in older adults who did not have a mobility disability or dementia [16]. In the HRS, gait speed (measured in meters per second) was determined from the time taken (in seconds) to walk a 2.5-meter course at a normal pace within participants' homes. A slow gait was defined as performance ≥1 SD below the mean for the participant's age and sex, a criterion previously used in HRS to identify MCR [17].

Subjective cognitive complaints were assessed using 2 questions: 1. "How would you rate your memory at the present time? Would you say it is excellent, very good, good, fair, or poor?" and 2. "Compared with the previous interview, would you say your memory is better now, about the same, or worse now than it was then?" Responses of 'fair' or 'poor' to the first question,

XSL•FO
RenderX

or 'worse' to the second, were considered indicative of cognitive complaints.

Cognitive Frailty

CF was defined as the co-occurrence of physical frailty and MCI [18]. The concept of frailty was identified using the 5 criteria outlined by Fried et al [19] in the Cardiovascular Health Study: unintended weight loss, physical inactivity, exhaustion, weakness, and reduced speed. Unintended weight loss is recognized as either a 10% or greater reduction in BMI since the last measurement in 2008 or a current BMI less than 18.5 kg/m^2. Physical activity levels were quantified by averaging the frequencies of activities at 3 levels of intensity—mild, moderate, and vigorous—weighted by the average metabolic equivalent of task (MET) scores for each intensity level: mild (1 - 3 MET), moderate (4 - 6 MET), and vigorous (7 - 10 MET). Participants were deemed physically inactive if their average physical activity fell within the lowest 20%. Exhaustion was determined based on responses to 2 questions from the Center for Epidemiologic Studies Depression scale [20], including, "I could not get going" and "I felt that everything I did was an effort." Muscle strength was assessed through the average of 2 grip strength measurements using a dynamometer on the dominant hand. Weakness was determined by grip strength falling below thresholds adjusted for BMI and gender, as established in the CHS. Reduced speed or slowness was defined as a speed <0.762 m/s for women taller than 159 cm or men taller than 173 cm and as <0.653 m/s for women 159 cm tall or less or men 173 cm tall or less, measured on a 2.5-m course [19,21]. Participants were considered to have missing data for physical measures if they were unable to perform the assessments due to the absence of suitable facilities or equipment or recent surgery. The diagnosis of frailty was based on the number of these criteria fulfilled, with those meeting 3-5 criteria classified as frail.

Physio-Cognitive Decline Syndrome

PCDS was defined as slowness or weakness (using cutoffs from the 2019 consensus update by the Asian Working Group for Sarcopenia), accompanied by cognitive performance that is at least 1.5 standard deviations below the mean for age-, sex-, and education-matched controls across all cognitive domains [12,22]. This assessment is based on comprehensive objective neuropsychological tests.

All-Cause Dementia and Mortality

The diagnosis of dementia was based on physician-diagnosed dementia and TICS scores ranging from 0 to 6. Mortality data were recorded, including the year and month of death, obtained from an exit interview or a spouse or partner's core interview.

Covariates

Covariates included sociodemographic factors, clinical characteristics, and health-related lifestyle behaviors, all of which were assessed at baseline. Sociodemographic characteristics included age (in years), sex (male or female), educational background (primary school or below, high school or equivalent, college and above), and marital status (married vs unmarried). Health-related lifestyle behaviors included excessive drinking, defined as more than 14 drinks per week for men and more than 7 drinks per week for women. Alcohol consumption was calculated by multiplying the number of days per week that alcohol (drink liquor or beer or wine or rice) was consumed by the number of drinks (liang or bottles or mugs) per day. Clinical characteristics included history of hypertension, diabetes, and heart disease. Hypertension was defined as systolic blood pressure ≥140 mm Hg, diastolic blood pressure ≥90 mm Hg, physical diagnosis, or antihypertensive medication use [23,24]. Diabetes was defined as having a diabetes diagnosis by a physician, being on treatment for diabetes, and having a fasting glucose level greater than or equal to 126 mg/dL and HbA_{1c} >6.5%. The presence of heart disease was determined via a physician's diagnosis obtained through an in-person visit with study personnel via a questionnaire.

Statistical Analysis

The incidence rates of all-cause dementia and mortality were calculated as the number of incident cases divided by the number of person-years of follow-up within the observation year (from 2008 to 2021). Differences between the MCR and non-MCR groups, PCDS and non-PCDS groups, and CF and non-CF groups were assessed using a 2-sided, independent *t*-test and the χ^2 test. To evaluate the impact of MCR, PCDS, and CF on the occurrence of all-cause dementia and mortality, we employed Cox proportional hazards regression analysis. The observation period extended from the index date to the earliest of the following: onset of dementia, death, or the conclusion of the observation period (December 31, 2018). Adjusted hazard ratios (AHRs) for MCR, PCDS, and CF in predicting the onset of dementia and all-cause mortality were calculated, accounting for covariates in an initially unadjusted model. Subsequent adjustments for covariates were made in 2 stages: Model 1 adjusted for age and gender; Model 2 further incorporated socioeconomic (education level and marital status), lifestyle (excessive drinking), and medical conditions (hypertension, diabetes, heart disease, and stroke). To assess and compare the predictive accuracy of all models, discrimination, defined by the model's ability to differentiate between individuals who develop dementia and those who do not, was quantified using Harrell C-statistic, taking survival into account.

Several sensitivity analyses were conducted to verify the stability of our findings. First, to focus on new cases and reduce reverse causation bias, individuals diagnosed with dementia or who died within 2 years of follow-up (sensitivity analysis I) were excluded. Second, to address the competing risk of death for dementia occurrences, Fine and Gray competing risk models were used [25], comparing these to the results from Cox proportional hazards regression models (sensitivity analysis II). The sub-distribution hazard function, defined at time *t*, represents the immediate risk of event *k* among individuals not previously experiencing event *k*. Third, to minimize selection bias, associations within individual samples with complete data on MCR, PCDS, and CF were analyzed separately (sensitivity analysis III). Statistical analyses were performed using 2-tailed tests with a significance level of $P<.05$ and 95% CIs, employing Stata (version 17) for all statistical procedures.

Ethical Considerations

This investigation has been conducted in accordance with the ethical standards of the Declaration of Helsinki, as well as national and international guidelines. The study has been approved by the Institutional Review Board at the University of Michigan (approval number: HUM00061128). All participants were provided with detailed information about the study, including its purpose, procedures, potential risks and benefits, and their rights to withdraw at any time. Written informed consent was obtained from all participants prior to their involvement in the study. To ensure privacy and confidentiality, all data collected were anonymized and deidentified. No identifying information was retained or published. Protective measures were in place to safeguard participant information, including secure storage of data and restricted access to study records. Participants were not compensated for their involvement in this study. The research was conducted on a voluntary basis, and no financial or other incentives were provided.

Results

Baseline Characteristics

The study participants' baseline characteristics are outlined in Table 1. The initial cohort comprised 2367 individuals, featuring prevalence rates for MCR, PCDS, and CF at 5.4% (n=121), 6.3% (n=140), and 1.3% (n=31), respectively. Among these, CF patients were the oldest on average (75.7, SD 6.1 years), with the distribution of men being 52.89% (64/121) in the MCR group, 47.14% (66/140) in the PCDS group, and 58.06% (10/31) in the CF group. During the follow-up, 573 (24.2%) patients died. The proportions of all-cause dementia for MCR, PCDS, and CF were 24.8% (30/121), 33.6% (47/140), and 41.9% (13/31), respectively.

Relationships of MCR, PCDS, and CF With Incident Dementia and All-Cause Mortality

Overall, there were 341 incident dementia cases during follow-up, for an overall incidence rate of 19.52 (95% CI 17.56-21.71) per 1000 person-years. There were 573 cases that died during follow-up, for an overall incidence rate of 30.14 (95% CI 27.77-32.71) per 1000 person-years (Table 2). The incidence rates of all-cause dementia among MCR, CF, and PCDS patients were 38.04, 108.11, and 55.80 per 1000 person-years, respectively—significantly higher than those observed in the relatively healthy control group. Similarly, the incidence rates of all-cause mortality were 47.99, 100.79, and 44.70 per 1000 person-years for MCR, CF, and PCDS patients, respectively—again, markedly higher than in the healthy controls. Table 2 also demonstrates significant associations of the 3 conditions with increased risks of incident dementia and all-cause mortality in various models (all *P* values <.001). CF had the highest AHR for both outcomes (5.06; 95% CI 2.87-8.92 for dementia, and 3.26; 95% CI 1.99 - 5.33 for mortality). Participants with dual decline experienced a two to threefold increased risk of dementia progression (AHR: 1.90 - 2.22 in the MCR group; 3.21 - 3.35 in the PCDS group) compared with those without dual decline. The AHR for all-cause mortality ranged from 1.60 to 1.84 in the MCR group and from 1.56 to 1.63 in the PCDS group. The trend was consistent across models: AHRs for dementia and mortality increased from the unadjusted model to adjusted model 1, then decreased upon further adjustment for covariates, including socioeconomic status, lifestyle factors, and medical comorbidities. Sensitivity analyses I (Table S1 in Multimedia Appendix 1) and III (Table S2 in Multimedia Appendix 1) consistently showed an elevated risk of dementia and mortality for MCR, CF, and PCDS. However, in sensitivity analysis II, the standardized hazard ratios for MCR and CF were not statistically significant post-adjustment (Table S3 in Multimedia Appendix 1).

Discriminations of MCR, PCDS, and CF for All Outcomes

The discrimination abilities of MCR, PCDS, and CF regarding all-cause dementia and mortality are detailed in Table 3. The C-index for PCDS in identifying all-cause dementia was 0.732 (95% CI 0.703-0.760), outperforming the C-indices for MCR and CF (PCDS vs MCR: 0.012, 95% CI −0.001 to 0.025; *P*=.08; CF vs MCR: 0.005, 95% CI −0.004 to 0.013; *P*=.35). In contrast, MCR's C-index for identifying all-cause mortality was the highest among the 3, at 0.727 (95% CI 0.706-0.748). Similar to the case with incident dementia, the differences in discrimination ability among MCR, PCDS, and CF for all-cause mortality were not statistically significant.

Discussion

Principal Findings

Analyzing data from a large-scale cohort in the United States, this study is the first to illustrate that MCR, PCDS, and CF have significant associations with incident dementia and all-cause mortality within the same population, despite the inherent heterogeneity of these metrics. Among them, CF emerged as the highest-risk group for both dementia and mortality, with markedly elevated incidence rates and the highest AHRs (5.06 for dementia and 3.26 for mortality), identifying CF as the most vulnerable subgroup. These findings offer valuable insights into the future health trajectories of frail individuals with cognitive impairments and highlight the need for targeted interventions and early health education to mitigate dementia and mortality risks in later life at lower costs. While PCDS showed the strongest predictive ability for dementia and MCR for mortality, the differences in predictive accuracy were not statistically significant. Implementing appropriate management strategies can help alleviate the health care burden for individuals with varying cognitive and physical conditions.

To forestall unhealthy aging, health care systems need to identify individuals at risk of functional declines that are still preventable or reversible. Our results are in line with prior studies, indicating that MCR syndrome is linked with a 90% increased risk of incident dementia and a 60% higher risk of mortality, even after adjustments for demographics, SES, and cardiovascular comorbidities (hypertension, diabetes, and heart disease). Consistent with research from Chung et al, the prevalence of hypertension and heart disease was significantly higher in the MCR group, highlighting the importance of regular screening to manage cardiovascular risk factors and delay dementia onset [26,27]. These observations further emphasize the potential neurodegenerative nature of MCR pathologic changes [28].

CF has been associated with an increased risk of dementia and mortality, as demonstrated by a meta-analysis revealing that older adults with CF face higher mortality and dementia risks than their healthier counterparts [29]. However, the absence of a standardized assessment tool for CF hampers its use in widespread epidemiological studies. Using the frailty phenotype alongside the MMSE, although common, proves to be time-intensive and presents challenges for deployment in community and hospital settings [30]. Furthermore, the lower prevalence of CF compared to other measures (1.31% for CF vs 5.91% for PCDS vs 5.11% for MCR) in the community-dwelling older adult cohort indicates difficulties in identifying a substantial number of at-risk individuals for interventions in similar groups.

In contrast to CF, PCDS, with its precise definition encompassing physical decline and cognitive impairment, provides a more targeted approach. By focusing on the mobility aspects of frailty linked to worse cognitive outcomes and increased mortality risk, researchers can more accurately identify the target population, concentrating on specific causal mechanisms [31,32]. PCDS serves as an advantageous focus for multidomain interventions, integrating physical activity, cognitive training, nutritional counseling, and disease management education to improve the condition of vulnerable but potentially reversible older individuals [33]. A recent Singapore study that used a 12-week dual-task exercise program to examine the potential reversibility of CF, MCR, and PCDS also found clinical improvements in PCDS, but the longer-term effects remain uncertain [34]. Nonetheless, Lee et al [35] demonstrated that PCDS was related to a 6-year, but not 3-year, incidence of dementia, even when using inverse probability weighting analysis to account for bias from missing data. This finding implies a latency period for the development of dementia, highlighting this interval as potentially crucial for preventive interventions.

While PCDS demonstrated the best predictive performance for incident dementia, MCR emerged as a superior predictor for all-cause mortality. The choice between these 2 metrics may depend on practical considerations, with MCR offering several unique advantages for clinical use. MCR is simpler and more efficient to assess, unaffected by education levels or learning effects, which enhances its credibility and reliability as a screening tool. In contrast, the comprehensive cognitive assessments required for PCDS diagnosis can be labor-intensive and require specific skills, which may limit their use in community or primary care settings. Given MCR's higher predictive accuracy for all-cause mortality and its ease of implementation, it is well-suited for use in routine health care assessments, particularly in primary health care settings. Additionally, research suggests that while handgrip strength declines earlier in aging, walking speed in later life is a stronger predictor of mortality [36]. This further supports MCR's higher predictive accuracy for all-cause mortality.

Despite representing a prodromal phenotype of accelerated aging, MCR remains an important target for intervention to prevent poor outcomes in older adults. MCR offers incremental validity in predicting dementia beyond what is provided by MCI subtypes [16] and individual components such as subjective cognitive complaints or slow gait [16,37]. Our findings suggest that MCR could serve as a simpler, more efficient tool to identify individuals at higher risk for dementia, especially given its independence from educational background or learning effects. The motor components of MCR, such as the time-up-and-go test or one-leg-standing test, are reliable and valid methods for quantifying motor function, making MCR an easily implementable screening tool in various health care settings. However, one study has shown that the MCR subtype defined by the 5-times-sit-to-stand test, which also includes a balance component, was less effective in predicting cognitive decline compared to MCR defined by slow gait [38]. Further research is needed to determine how different gait and balance assessments influence the identification of individuals at risk for dementia, and whether integrating MCR into routine geriatric assessments could enhance early intervention strategies in aging populations.

Early and appropriate intervention might postpone the onset of dementia or reduce its risk, particularly given the lengthy incubation period associated with the development of dementia. Our results could aid clinicians in the early implementation of screening and prevention strategies and inform government decisions on community health prevention. The strength of this

XSL•FO
RenderX

study lies in its extensive, well-delineated cohort, featuring longitudinal assessments, uniform measures, and verified outcomes. To our knowledge, this is the first study to assess the predictive accuracy of MCR, PCDS, and CF regarding dementia incidence and all-cause mortality within the same cohort. The reliability and consistency of our findings, supported by sensitivity analyses, bolster the study's validity. Nonetheless, several limitations should be acknowledged. First, the study lacked objective neuropsychological testing [39] and did not account for some potential confounding factors, such as *APOE* genotype or imaging biomarkers [40,41]. However, our sensitivity analysis—excluding participants diagnosed with dementia or those who died within 2 years of the index date—strengthened the robustness of our conclusions. Second, while we used data from a large longitudinal cohort, the final sample size of 2372 individuals may limit the representativeness of our findings. Additionally, the prevalence rates of MCR (5.4%), PCDS (6.3%), and CF (1.3%) in our sample may be higher than those in the general older population, introducing potential selection bias. To address this, sensitivity analyses were conducted within individual subgroups with complete data on MCR, PCDS, and CF. These analyses included larger sample sizes and showed lower prevalence rates for the 3 conditions, aligning more closely with those observed in the general population. The robustness of these results further confirmed our conclusions, enhancing their validity and generalizability while mitigating potential selection bias. Future research could benefit from larger, more diverse, and representative samples to enhance generalizability. Third, the potential influence of mortality on dementia risk assessment must be considered. Individuals who died during follow-up could bias dementia outcome evaluations. To address this competing risk, we employed Fine and Gray competing risk models and compared the results with those from Cox proportional hazards regression models as part of our sensitivity analysis. This approach ensured that our findings remained robust and accounted for the impact of mortality on dementia risk associations. Finally, variations in syndrome definitions and differences in the prevalence of the 3 aging metrics within the population could affect their predictive power for adverse outcomes. This variability may limit the generalizability of our results to other populations. To mitigate this, sensitivity analyses within subgroups with complete data on MCR, PCDS, and CF were conducted, reinforcing the reliability of the associations between these aging metrics and adverse health outcomes.

Conclusions

The integration of cognitive and physical functions into aging metrics consistently indicates risks for incident dementia and all-cause mortality, despite their significant differences, underscoring their utility for effective risk stratification in research and clinical settings. Patients with CF represent the most vulnerable subgroup, highlighting the need for prioritized preventive strategies and interventions. Meanwhile, MCR emerged as a particularly efficient and accurate screening tool for both dementia and mortality. These findings emphasize the importance of implementing targeted prevention and intervention programs based on these metrics to enhance quality of life and reduce premature mortality among aging populations. Further research on the longitudinal dynamics of these aging metrics in relation to dementia, mortality, and other outcomes is essential for a deeper understanding of their long-term impact.

Abstract

Background: The number of centenarians worldwide is expected to increase dramatically, reaching 3.4 million by 2050 and >25 million by 2100. Despite these projections, depression remains a prevalent yet underdiagnosed and undertreated condition among this population that carries significant health risks.

Objective: This study aimed to identify and achieve consensus on the most representative signs and symptoms of depression in near-centenarians and centenarians (aged ≥95 years) through an e-Delphi study with an international and interdisciplinary panel of experts. Ultimately, the outcomes of this study might help create a screening instrument that is specifically designed for this unique population.

Methods: A modified e-Delphi study was carried out to achieve expert consensus on depressive symptoms in near-centenarians and centenarians. A panel of 28 international experts was recruited. Consensus was defined as 70% agreement on the relevance of each item. Data were collected through a web-based questionnaire over 3 rounds. Experts rated 104 items that were divided into 24 dimensions and 80 criteria to identify the most representative signs and symptoms of depression in this age group.

Results: The panel consisted of experts from various countries, including physicians with experience in old age psychiatry or geriatrics as well as nurses and psychologists. The response rate remained consistent over the rounds (20/28, 71% to 21/28, 75%). In total, 4 new dimensions and 8 new criteria were proposed by the experts, and consensus was reached on 86% (24/28) of the dimensions and 80% (70/88) of the criteria. The most consensual potentially relevant dimensions were *lack of hope* (21/21, 100%), *loss of interest* (27/28, 96%), *lack of reactivity to pleasant events* (27/28, 96%), *depressed mood* (26/28, 93%), and *previous episodes of depression or diagnosed depression* (19/21, 90%). In addition, the most consensual potentially relevant criteria were *despondency, gloom, and despair* (25/25, 100%); *depressed* (27/27, 100%); *lack of reactivity to pleasant events or circumstances* (28/28, 100%); *suicidal ideation* (28/28, 100%); *suicide attempt(s)* (28/28, 100%); *ruminations* (27/28, 96%); *recurrent thoughts of death or suicide* (27/28, 96%); *feelings of worthlessness* (25/26, 96%); *critical life events* (20/21, 95%); *anhedonia* (20/21, 95%); *loss of interest in activities* (26/28, 93%); *loss of pleasure in activities* (26/28, 93%); and *sadness* (24/26, 92%). Moreover, when assessing depression in very old age, the duration, number, frequency, and severity of signs and symptoms should also be considered, as evidenced by the high expert agreement.

XSL•FO
RenderX

Conclusions: The classification of most elements as *relevant* highlights the importance of a multidimensional approach for optimal depression screening among individuals of very old age. This study offers a first step toward improving depression assessment in near-centenarians and centenarians. The development of a more adapted screening tool could improve early detection and intervention, enhancing the quality of mental health care for this population.

Introduction

Background

The centenarian population is growing significantly and is projected to increase sharply in the coming decades. As of 2024, there were approximately 722,000 centenarians worldwide, with Japan, the United States, and China having the highest numbers [1]. This figure is expected to rise to 3.4 million by 2050 and exceed 25 million by 2100 [2,3]. In Europe, notable examples include France, Italy, and Greece, each with >20 centenarians per 100,000 inhabitants registered already in 2011. Portugal also stands out with a density of 14.4 centenarians per 100,000 inhabitants that same year, ranking it among the top 15 in Europe [4]. In Switzerland, the centenarian population more than doubled from 787 in 2000 to 1948 in 2022, reaching a noteworthy prevalence of 22.1 per 100,000 inhabitants [5].

Amid extreme longevity, individuals' health experiences vary significantly, from robust health to substantial declines [6-8]. Depression, a prevalent mood disorder among older adults [9], emerges as a major public health concern [10]. The *International Classification of Diseases, 11th Revision* characterizes a depressive episode as "a period of depressed mood or diminished interest in activities occurring most of the day, nearly every day during a period lasting at least two weeks accompanied by other symptoms such as difficulty concentrating, feelings of worthlessness or excessive or inappropriate guilt, hopelessness, recurrent thoughts of death or suicide, changes in appetite or sleep, psychomotor agitation or retardation, and reduced energy or fatigue" [6]. However, this definition broadly encompasses the general population and may not fully address the possible difference and heterogeneity of depressive symptomatology in older adults, potentially leading to diagnostic imprecision.

Accurate diagnosis is crucial as depression should not be misconstrued as an inherent aspect of aging even in very advanced age [11,12]. A systematic literature review reported substantial variations in depression prevalence among near-centenarians and centenarians across countries, such as 12.8% in Italy, 13.5% in Australia, 20% in the United States, and 29% in Mexico [13]. These differences may reflect cultural, health care, and socioeconomic influences as well as methodological variations in study conduct [13,14]. Interestingly, comparisons between centenarian cohorts and younger groups have shown inconsistent findings, with half of the studies reporting higher rates of depressive symptoms among centenarians [13]. This highlights the diversity of aging experiences and suggests that mental health may not necessarily worsen with age. Particularly noteworthy are the findings from Sweden, where near-centenarians and centenarians exhibited almost double the depression rates of older adults aged 85 years at 32.3% versus 16.8%, respectively. These statistics highlight the need not only for careful mental health evaluations among individuals of very old age but also for prompt discussion on tailored approaches to support mental well-being in this population [13,15].

Depression can lead to severe physical, cognitive, and psychological effects. Physically, it can cause malnutrition, falls, delirium, functional decline, and increased mortality [13,16-20]. Cognitively, depression has been connected to cognitive decline and dementia [21-25]. Psychologically, it has been associated with anxiety and suicidal ideation [26,27]. Furthermore, depression places a significant burden on caregivers and health care systems [16-18,28,29], increasing costs and resource demands. These consequences underscore the critical need for early detection and intervention. Therefore, proactive measures such as regular mental health screenings are essential to prevent the severe impact of depression on individuals' quality of life and alleviate its wider societal effects [11]; however, these are not part of the current practice in most countries worldwide.

Addressing this gap in care is difficult as depression in older adults frequently remains underdiagnosed and undertreated, in part because its manifestations are often misinterpreted as natural aspects of aging [18,19,30,31]. Studies have estimated that approximately half of depression cases are not identified by frontline health care providers [16,18], and of those detected, approximately half do not receive adequate treatment [16]. The challenge in detecting late-life depression (LLD) stems from its sometimes subtle, hidden, or atypical signs and symptoms [30,32]. Physical manifestations such as weight loss, psychomotor retardation, and exhaustion, as well as emotional manifestations such as loss of interest in activities, heightened anxiety, or irritability, might overshadow the typical sadness often associated with depression [9,18]. This complexity requires greater clinical vigilance. Moreover, the possible overlap of symptoms between depression and dementia adds another layer of diagnostic difficulty as both conditions can present with symptoms such as memory impairment, psychomotor retardation, and reduced motivation [9]. Beyond dementia, several other medical conditions can mimic or exacerbate depressive symptoms. Chronic pain, thyroid dysfunction, Parkinson disease, stroke, and medication side effects—particularly in polymedicated individuals—can contribute to *depression-like* symptoms, including fatigue, apathy, functional dependence, memory impairment, and

XSL•FO
RenderX

disturbances in mood and sleep [33-38]. These overlapping symptoms underscore the need for a comprehensive assessment to distinguish LLD from other conditions, aiming for an accurate differential diagnosis. The wide range of signs and symptoms associated with LLD can extend beyond the conventional diagnostic criteria for depressive disorders. Symptom clusters not fully meeting the diagnostic criteria for depression may still carry significant clinical importance due to their link to reduced quality of life and increased disability [9,18].

Objectives

Given the prevalence of depression among individuals of very old age, better detection of early signs and symptoms is crucial. However, despite the availability of various screening tools, to the best of our knowledge, none have been specifically validated for near-centenarians and centenarians (aged ≥95 years). Therefore, our study aimed to compile a comprehensive range of potentially relevant depressive features that have been documented in scientific literature. These features were then submitted to an international panel of experts to achieve consensus on the most representative signs and symptoms of depression in individuals of very old age. The outcomes of this approach are 2-fold. First, by systematically examining and integrating diverse diagnostic criteria and screening tools, this study aimed to contribute to the ongoing debate about the complexities and challenges of effectively diagnosing depression in individuals of very old age. Second, achieving expert consensus is central to developing a new screening instrument specifically tailored to this unique population. This effort might be an important first step toward early detection and effective intervention, which might lead to better outcomes and enhanced general well-being for this age group, and seeks to contribute to promoting mental health and supporting optimal care for individuals of very old age.

Methods

Study Design

We conducted a modified e-Delphi study to systematically combine expert opinions and achieve an informed group consensus on the symptomatology of depression in very old age. The Delphi technique is an established approach in which a panel of experts is asked to provide their opinions on a given issue over the course of several rounds [39]. In each round, the questions are informed by the findings of the previous one, allowing the study to evolve over time based on the collected data [39].

Given the prevalence of depression among older adults and the complexities of its diagnosis, the Delphi technique is particularly useful for gathering expert consensus on this issue. In our study, we used an e-Delphi approach to involve experts from different locations and facilitate efficient data collection through electronic communication methods. To adapt the traditional Delphi approach to the specific requirements of our study, we implemented several modifications (referred to as a *modified e-Delphi study*). To keep the focus on the items rather than on the degree of agreement, experts were informed at the start of each new round about which items had reached consensus without being given the precise consensus rates. In addition, for items on which consensus had already been reached, experts were unable to review their previous responses. This decision was made to avoid revisiting settled issues and manage the large number of items efficiently, ensuring the stability of agreed-upon elements. An additional aspect of our modified methodology was a final evaluation of open issues by the steering committee. This last step took place to discuss the items that had not achieved consensus over the e-Delphi rounds, ensuring a thorough examination of these elements.

The materials presented to the e-Delphi panel were based on a comprehensive analysis of the existing literature on depression in very old age (personal communication by Gomes da Rocha et al, 2023). This ensured that the expert panel's input was based on a thorough understanding of the relevant literature, thereby enhancing the validity of the final consensus, which may be seen as a lever to encourage scientific debate and foster new developments toward an effective diagnosis of depression in very old age [40].

This study adhered to the Conducting and Reporting Delphi Studies guidelines [41,42].

Steering Committee

The steering committee for this e-Delphi study based in Western Switzerland comprised 4 members: 2 physicians who are old age psychiatrists and senior researchers (AvG and PV), 1 clinical nurse specialist in geriatric care and a senior researcher skilled in the e-Delphi technique (HV), and 1 clinical nurse specialist in geriatric care who is also a junior researcher (CGdR). The committee was responsible for overseeing the study design, ensuring ethical compliance, and guiding the iterative process of questionnaire refinement and consensus building. Meetings were held monthly, with methodological decisions made based on discussion. The committee played a crucial role in maintaining the study's rigor, managing data collection and analysis, and addressing any lack of consensus among panelists.

Selection of Experts

In the Delphi approach, nonprobability sampling methods are used through the purposive selection of an expert panel. However, clear selection criteria were applied to limit researcher bias based on a five-step procedure [43]:

1. *Identifying the most appropriate categories of experts for the panel:* we identified experts from 3 main professional categories—physicians, nurses, and psychologists—each with a minimum of 5 years of professional experience and competencies in LLD. These professionals were selected for their specific work experience or contact with individuals of very old age in clinical, research, or teaching domains within the fields of old age psychiatry or geriatrics. In addition, our recruitment strategy aimed for a broad geographical representation by including experts from various continents (ie, Asia, Australia, Europe, and North America) to enrich the panel with diverse perspectives and, thereby, enhance the global view on depression screening among individuals of very old age.
2. *Identifying experts:* names were compiled from various sources, including previous research involvement, publications on the subject, professional email lists,

XSL•FO
RenderX

professional associations or societies, and boards of professional organizations. This method aimed to create a list of potential panelists recognized for their expertise and contributions to the field that was as comprehensive as possible.

3. *Contacting some readily reachable experts from each professional category to nominate other experts:* initial contact was made with experts who were easily accessible. These experts were then asked to nominate additional professionals whom they believed could contribute valuable insights to the study, thereby using a snowball sampling technique to ensure a wide and diverse pool of expertise.
4. *Creating sublists for each professional category and ranking experts based on specific criteria:* experts were organized into sublists by professional category and ranked according to their representation of professional role or specialty and their field of practice. This was a strategic approach intended to foster a diverse and balanced panel that reflects a broad spectrum of experiences and viewpoints, contributing to the robustness and credibility of the consensus process.
5. *Inviting the experts.*

The Delphi method offers no consensus on an ideal sample size as the focus is on qualitative depth and the use of expert judgment for a comprehensive exploration of specific topics rather than on statistical representativeness [44]. Usually, a panel comprises 7 to 15 experts to facilitate effective information processing and decision-making; however, some studies may involve up to 30 experts for broader perspectives [44]. For our study, we aimed to assemble a convenience sample of at least 20 experts from various countries.

Recruitment Procedure

On the basis of the predefined selection of potential panelists, we emailed invitation letters to a total of 84 experts. These letters outlined the study's objectives, described the e-Delphi context, detailed the questionnaire (eg, language, type of questions, and estimated completion time), and clarified what was expected from the participants, ensuring that they understood the significance of their contributions to the study. Interested parties could access the questionnaire through a direct URL to the survey. Anticipating a 25% to 30% response rate for the first-round questionnaire, we expected approximately 20 to 25 experts to participate. We aimed to retain these experts across all subsequent rounds, planning for a maximum of 4 rounds.

Data Collection Procedures

The SurveyMonkey tool (SurveyMonkey Inc) was used as the survey software as it facilitates secure and efficient data collection. In accordance with literature recommendations [43], each e-Delphi round remained open for a minimum of 4 weeks, during which up to 3 automatic reminder emails were dispatched to nonrespondents. At the start of each new round, experts were provided access to the overall results from the previous round, including a list of items for which consensus was either *achieved* (≥70% agreement) or *not achieved* (<70% agreement) [43]. The items that did not reach consensus were integrated into the current round for further deliberation, along with any new items that emerged from panel suggestions through open-ended questions.

Measures

The questionnaire was divided into 3 sections.

e-Delphi Section

This section aimed to achieve consensus on the topic under study and consisted of 104 items. These were divided into 24 dimensions (eg, *impaired concentration* and *lack of hope*) and 80 criteria (eg, *impaired ability to think or concentrate* and *hopelessness*), which experts rated according to their relevance using a Likert scale from 1 (*Not relevant*) to 4 (*Very relevant*). Experts also had the possibility to comment on their answers and suggest additional items that they considered relevant to the topic for subsequent rounds.

In addition to rating the relevance of each item, experts were asked to indicate the most suitable type of assessment for each criterion: self-assessment, hetero-assessment, or both. This was intended to identify preferred methods of assessing potential depressive signs and symptoms. The aim was not to achieve a stringent consensus of 70% as with the relevance ratings but to capture a broad spectrum of expert opinions on assessment approaches.

The initial selection of 104 items was based on a comprehensive review of existing instruments widely used in research to screen for and evaluate depressive signs and symptoms among near-centenarians and centenarians [13] supplemented by additional insights from recent analysis (personal communication by Gomes da Rocha et al, 2023). We started with all items available in these measures to be as comprehensive as possible. These instruments included self-assessment tools such as the Geriatric Depression Scale–30 [45], the Center for Epidemiologic Studies Depression Scale [46], the depression-related items from the Brief Symptom Inventory [47], and the Hospital Anxiety and Depression Scale [48], as well as the Montgomery-Åsberg Depression Rating Scale [49], which is administered by a professional rater. Furthermore, given the significant prevalence of neurocognitive disorders in our aging population and the need for reliable assessment of depressive symptoms in individuals with cognitive impairments, we also considered instruments specifically designed for such assessments: the Cornell Scale for Depression in Dementia [50,51] and the depression section of the Neuropsychiatric Inventory [52,53]. In addition, we included the *International Classification of Diseases, 11th Revision* and the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* diagnostic criteria to anchor our selections in the gold standards for depression diagnosis [6,54]. To complete the pool of items, the Depression Rating Scale from the Resident Assessment Instrument was also retained given its widespread use among adults of old and very old age in diverse settings, such as private homes (Resident Assessment Instrument–Home Care) or long-term care facilities (Resident Assessment Instrument–Long-Term Care Facilities) [17,55-57]. After compiling all items from the selected instruments, we checked for overlap and excluded identical items, which led to the final selection of 104 items. For instance, items such as "Do you feel

XSL•FO
RenderX

that your situation is hopeless?" from the Geriatric Depression Scale–30 and "Feeling hopeless about the future" from the Brief Symptom Inventory necessitated thematic grouping under a unified dimension (*Lack of Hope* in this example). This process enabled us to construct more general items designated as *dimensions* that reflected the essence of the criteria within each group, thereby streamlining the questionnaire without compromising the depth of depressive symptom screening. The list of all selected instruments and original items can be found in Multimedia Appendix 1.

In summary, this strategic selection of items aimed to cover a broad spectrum of relevant criteria for the screening of depressive signs and symptoms, ensuring the questionnaire's comprehensive scope and its applicability to adults of very old age with varying levels of cognitive functioning.

Sociodemographic and Professional Characteristics

This section included questions designed to capture the sociodemographic and professional characteristics of the panelists in round 1, including age, gender, nationality, profession, years of professional experience, and their country and field of practice. In subsequent rounds, only essential information (age, gender, nationality, and profession) was collected to ensure continuity and to accurately link responses from the same panelists across all rounds.

Contact With Individuals of Very Old Age

Although this could be considered part of professional characterization, this section specifically gathered information on the frequency of the panelists' experiences or interactions with individuals of very old age (aged ≥85 and ≥95 years). It was specific to the first round, aiming to inform the context of their responses. While this study's target population was defined as near-centenarians and centenarians (≥95 years), there is only a limited number of experts focusing on this exact population. However, most experts working with individuals aged ≥85 years have regular contact with near-centenarians and centenarians. Thus, these experts were also invited provided that they felt confident in drawing on their experiences and perceptions relevant to the population aged ≥95 years.

Pretest

Before launching round 1, the questionnaire was pretested with a small purposive sample of 5 professionals (nurses, psychologists, and a physician) to verify its clarity and comprehensibility, with only a minor adjustment made based on 1 expert's suggestion to include specific examples for certain items. Despite the positive outcomes of the pretest, experts were invited to rate the questionnaire at the end of round 1 for comprehensiveness, readability, and clarity.

Overall, 93% (26/28) of the experts participating in round 1 rated the questionnaire as *Comprehensive* or *Very comprehensive*, and 86% (24/28) found it *Easy* or *Very easy* to read and understand. Due to this positive feedback, no further structural adjustments were implemented before proceeding to the subsequent rounds.

Data Analysis

Data collected via SurveyMonkey were transferred to a Microsoft Excel spreadsheet (Microsoft Corp) and examined for any potential errors or missing data. They were then imported into the SPSS Statistics software (version 29.0; IBM Corp) for analysis [58]. Descriptive statistics were computed to characterize the panel from a sociodemographic and professional perspective using means and SDs as well as medians and interquartile ranges for quantitative variables and frequency distributions and percentages for qualitative variables. The level of agreement among experts required to achieve consensus on a given item was set at 70% for each round. This threshold is commonly used in Delphi studies [59-61] as it allows for the inclusion of minority viewpoints in the early rounds, ensuring that diverse perspectives are considered before achieving final consensus. This is particularly relevant in the context of depressive symptom screening given the challenges associated with detecting LLD, as previously mentioned. Hence, this consensus rate is considered acceptable for preserving methodological rigor, as supported by the literature [43], which indicates that such a threshold aligns with norms for ensuring reliability and validity in the context of an iterative, consensus-building approach. The consensus rate for each item was calculated using a 4-level Likert scale (1=*Not relevant*, 2=*Somewhat relevant*, 3=*Relevant*, and 4=*Very relevant*). In the first step, these responses were recoded into 2 levels: values of 1 and 2 were recoded as "0" (*Overall not relevant*), and values of 3 and 4 were recoded as "1" (*Overall relevant*). Next, we aggregated the recoded responses for each item to determine consensus, which was achieved when the percentage of experts identifying an item as *Overall relevant* or *Overall not relevant* met or exceeded the predefined threshold of 70%.

After the first e-Delphi round, items that did not reach the consensus level were carried forward to the subsequent round. At the beginning of each subsequent round, experts were given the opportunity to review the general outcomes from the previous round (ie, *consensus achieved* or *consensus not achieved* for each evaluated item). Items that achieved consensus were not included again in subsequent rounds. After conducting 3 rounds with the participating panel and observing only limited changes in the consensus rate after the third round, we decided to proceed with the last round, which involved a final evaluation of unresolved aspects by the steering committee. This last step aimed to gain a deeper understanding of the reasoning behind the outcomes and further refine the consensus process. Items that still did not achieve consensus after the 3 e-Delphi rounds were thoroughly examined during this phase.

Ethical Considerations

The Ethics Commission on Human Research of the Canton of Vaud was consulted and confirmed that this project fell outside the scope of the Swiss Human Research Act (Req-2023-00844; Multimedia Appendix 2) as the study did not involve the collection of health-related personal data or biological material.

All participants received detailed information about the study, including its aim and relevance, what to expect, a description of the questionnaire, instructions for participation, and contact information for the main researcher, along with the invitation

XSL•FO
RenderX

email. The questionnaires for all rounds (1, 2, and 3) included an introductory section emphasizing the voluntary nature of participation in the study, as well as specific information regarding confidentiality, data protection, risks, and benefits and a statement on ethical considerations. Participants were explicitly informed that, by answering the questionnaire, they were implicitly providing consent to take part in the study. They did not receive any compensation for their participation. Each participant received a survey link for accessing the questionnaire, and their IP addresses were not recorded to ensure confidentiality. The collected data were deidentified, with no personal identifiers retained. Responses stored on SurveyMonkey were deleted after transferring the data to the Microsoft Excel spreadsheet. All data are securely stored on a password-protected institutional server to comply with Swiss data protection regulations and will be definitively deleted after 5 years.

Results

Expert Participation and Sociodemographic and Professional Characteristics

A total of 84 experts were invited to this modified e-Delphi study. Of these 84 experts, 28 (33%) participated in the first round, forming the baseline panel. This group (n=28) was consequently invited to the second and third rounds, for which the participation rates were 75% (21/28) and 71% (20/28), respectively.

The panel exhibited sociodemographic and professional diversity, including different nationalities, professions, and fields of practice. The average age ranged slightly between 44.1 (SD 10.6) and 46.7 (SD 11.4) years over the rounds. A majority of women participated in the first and second rounds (17/28, 61% and 13/21, 62%, respectively), whereas men were more prevalent in the third round (11/20, 55%). Swiss and Portuguese nationalities were the most represented (12/20, 60% to 18/28, 64%), with the nursing profession being predominant (9/20, 45% to 12/21, 57%), followed by the medical profession (5/21, 24% to 8/20, 40%). The average professional experience was 19.4 (SD 8-9) years, with nearly 80% (22/28, 79%) of the experts being engaged in purely clinical activities or a combination of clinical and academic activities, among others (eg, service organization). More than 80% (23/28, 82%) reported having regular or very regular contact (daily, weekly, or monthly) with individuals aged ≥85 years, and 75% (21/28) reported having regular or very regular contact with individuals aged ≥95 years (Table 1).

Questionnaire Completion Times

The completion dates and the mean time taken for participants to complete the questionnaires in each round are summarized in Table 2. Globally, the e-Delphi rounds took place between August 2023 and February 2024, with an overall weighted mean completion time of 16 minutes and 40 seconds (SD 11 min and 27 s).

Table 2. Summary of overall consensus achievements across e-Delphi rounds regarding potential dimensions and criteria for depression screening.

Overall Consensus Achievements

A consensus threshold of ≥70% was established for both dimensions and criteria, as previously described.

Depression Screening: Potentially Relevant Dimensions

In round 1, experts assessed 24 dimensions, reaching consensus on 13 (54%). In addition, 4 new dimensions were suggested by the experts and incorporated in round 2: *underlying cognitive disorder* (dimension 25), *previous episodes of depression or diagnosed depression* (dimension 26), *personal care (eg, poor hygiene)* (dimension 27), and *language/speech (eg, poor speech)* (dimension 28). Thus, 15 dimensions (n=11, 73% without consensus and n=4, 27% new proposals) were reassessed in round 2, with consensus achieved on 10 (67%). In round 3, a total of 5 dimensions were revisited, with consensus reached on only 1 (20%; Table 2).

Table 3 summarizes the consensus rates for the 28 dimensions assessed across the 3 e-Delphi rounds. A total of 14% (4/28) of the dimensions failed to reach the ≥70% consensus threshold: memory problems (dimension 21), mood-congruent delusions (dimension 22), reduced adaptation capacity (dimension 24), and language/speech (eg, poor speech) (dimension 28)—the only newly suggested dimension without consensus. Of the dimensions on which consensus was achieved, all were considered relevant for screening for depression in individuals aged ≥95 years except for increased appetite (dimension 8), which was deemed not relevant. Notably, several relevant dimensions reached ≥90% consensus: lack of hope (dimension 20; 21/21, 100%), loss of interest (dimension 4; 27/28, 96%), lack of reactivity to pleasant events (dimension 5; 27/28, 96%), depressed mood (dimension 1; 26/28, 93%), and previous episodes of depression or diagnosed depression (dimension 26; 19/21, 90%).

Figure S1 in Multimedia Appendix 3 provides an overview of the consensus rates for the potentially relevant dimensions for depression screening.

Depression Screening: Potentially Relevant Criteria

In round 1, a total of 80 criteria were assessed, with consensus reached on 49 (61%). In addition, 8 new criteria emerged from suggestions by the panel and were incorporated in round 2: *critical life events (eg, loss of a child or another loved one)* (criterion 81), *emotional indifference* (criterion 82), *anhedonia* (criterion 83), *afraid of being alone* (criterion 84), *resurfacing of "old wounds" (eg, long-standing conflicts with children)* (criterion 85), *feeling of accomplishment throughout life* (criterion 86), *closeness with family and significant others* (criterion 87), and *subjective health* (criterion 88). As a result, 39 criteria (n=31, 79% without consensus and n=8, 21% new proposals) were reassessed in round 2, with consensus achieved on 12 (31%). In round 3, a total of 27 criteria were revisited, with consensus reached on 9 (33%; Table 2).

The consensus rates for the 88 criteria assessed across the 3 e-Delphi rounds are presented in Multimedia Appendix 4. In total, 20% (18/88) of the criteria failed to reach the ≥70% consensus threshold: *easily annoyed* (criterion 20); *short-tempered* (criterion 21); *staying home instead of going out and doing new things* (criterion 26); *psychomotor agitation* (criterion 29); *significant unintentional weight gain (more than 5% in a month)* (criterion 33); *restless sleep* (criterion 35); *full of energy* (criterion 42); *feels as good as other people* (criterion 51); *pessimism* (criterion 52); *thinks most people are better off than him/her* (criterion 56); *finding life exciting, wonderful, and enjoyable* (criterion 58); *getting bored often* (criterion 62); *feeling fearful* (criterion 64); *feeling that people are unfriendly or dislike him/her* (criterion 66); *memory problems* (criterion 69); *the mind is as clear as it used to be* (criterion 70); *having a sense of direction and purpose in life* (criterion 79); and *afraid of being alone* (criterion 84)—the only newly suggested criterion without consensus. Of the criteria on which consensus was achieved, all were considered *relevant* for screening for depression in individuals aged ≥95 years except for *hard to get started on new projects* (criterion 28), *fear of dying* (criterion 75), and *sufficient financial resources* (criterion 77), which were considered *not relevant*. Notably, several *relevant* criteria reached a ≥90% consensus: *despondency, gloom, and despair* (criterion 5; 25/25, 100%); *depressed* (criterion 6; 27/27, 100%); *lack of reactivity to pleasant events or circumstances* (criterion 25; 28/28, 100%); *suicidal ideation* (criterion 45; 28/28, 100%); *suicide attempt(s)* (criterion 46; 28/28, 100%); *ruminations* (criterion 14; 27/28, 96%); *recurrent thoughts of death or suicide* (criterion 43; 27/28, 96%); *feelings of worthlessness* (criterion 47; 25/26, 96%); *critical life events* (criterion 81; 20/21, 95%); *anhedonia* (criterion 83; 20/21, 95%); *loss of interest in activities* (criterion 23; 26/28, 93%); *loss of pleasure in activities* (criterion 24; 26/28, 93%); and *sadness* (criterion 4; 24/26, 92%).

Figure S2 in Multimedia Appendix 3 provides an overview of the consensus rates for the potentially relevant criteria for depression screening.

Signs and Symptoms of Depression: Duration, Number, Frequency, and Severity

In round 1, experts (n=28) were asked about the importance of considering the duration of depressive signs or symptoms in addition to their presence. It is important to note that, for the purpose of this assessment, they were instructed not to consider *suicidal thoughts or ideation* as these require immediate attention and, thus, were deliberately excluded from the duration criteria. All participants (28/28, 100%) agreed on its importance. When specifically asked about the minimum duration for considering these signs or symptoms as clinically significant, 25 experts provided their insights—21 (84%) suggested a range from *a few days* (1 to 3) to *4 weeks*, with *2 weeks* being the most cited (n=9, 36%).

In addition, 7% (2/28) of the experts suggested differentiating the duration of signs or symptoms between recurrent episodes in chronic depression and new-onset cases. For this reason, a question addressing this specificity was introduced in round 2 (n=21), with 62% (13/21) supporting the distinction. For recurrent episodes, most experts favored a minimum duration

XSL•FO
RenderX

of *2 weeks* (9/13, 69%), whereas for a new onset, opinions varied, with "4 weeks" (5/13, 38%) being the most cited.

In round 2 (n=21), 62% (13/21) emphasized the importance of considering the number of signs or symptoms during screening. Of the 12 experts who specified a threshold, 7 (58%) favored a minimum of 3 symptoms.

Regarding sign or symptom frequency, all experts who provided an opinion in round 2 (20/20, 100%) considered it relevant. Of these 20 experts, 19 (95%) specified a particular frequency, of whom 9 (47%) suggested a frequency of *several times per day*, 3 (16%) suggested a frequency of *nearly daily*, and 6 (32%) suggested a frequency of *several times per week*.

For severity, 90% (18/20) considered it an important factor. Moreover, on a severity scale from 0 to 10 (with 10 being the most severe), the average threshold for clinical concern was 4.9 (SD 1.4), with a median of 5.0 (IQR 2.0).

Further details regarding the results described previously can be found in Multimedia Appendix 5.

Steering Committee's Decision on Dimensions and Criteria Lacking Consensus After 3 e-Delphi Rounds

The steering committee conducted 2 additional rounds of discussion to decide on the relevance of the 4 dimensions and 18 criteria that did not reach a consensus of ≥70% among the panelists during the 3 e-Delphi rounds.

In the first round of discussion, committee members reviewed the panelists' comments and agreement levels for each dimension and criterion, analyzing potential reasons for the lack of consensus and considering the clinical implications. Each member shared their perspectives drawing on their clinical expertise. In the second round, the committee revisited the dimensions and criteria after reflecting on the insights from the first round, aiming to resolve any remaining uncertainties and reach a collective decision. Consensus was prioritized, with majority voting used when necessary.

A summary of the committee's final determinations is provided in Multimedia Appendix 6, where the rationale behind the inclusion or exclusion of each dimension and criterion is detailed.

Table 4 presents an overview of the consensus levels reached in each e-Delphi round and the final decisions made by the steering committee.

Types of Assessment for Potential Depression Criteria: Self-Assessment, Hetero-Assessment, or Both?

In addition to assessing the relevance of each criterion, the panel provided opinions on the preferred assessment method (self-assessment, hetero-assessment, or both). Rather than seeking strict consensus, the goal was to identify general trends. Using a 50% threshold as an example, 35% (28/80) of the criteria were deemed suitable for *self-assessment* only, 4% (3/80) of the criteria were deemed suitable for *hetero-assessment* only, and 40% (32/80) of the criteria were deemed suitable for both methods. Detailed information is available in Multimedia Appendix 7, whereas Figure S3 in Multimedia Appendix 3 provides an overview of the consensus rates for these assessment methods.

Discussion

Principal Findings

This modified e-Delphi study aimed to identify and achieve consensus on the most representative signs and symptoms of depression in very old age, focusing on near-centenarians and centenarians.

Our results revealed that most of the items proposed—86% (24/28) of the dimensions and 80% (70/88) of the criteria—which had been assembled based on a literature review, were considered *relevant* for depression screening in very old age. This highlights the importance of a multidimensional approach and acknowledges the complexity of accurately diagnosing depression in this population.

Most Consensual Potentially Relevant Depressive Signs and Symptoms

Focusing on items with the highest consensus rates (≥90%), some overlap between dimensions and criteria was observed, which was expected as dimensions grouped related criteria.

For example, the *depressed mood* dimension was widely considered *relevant*, aligning with criteria such as *depressed*; *sadness*; and *despondency, gloom, and despair*, which reflect the emotional core of depressive disorders [6,54]. Similarly, *loss of interest in activities*, *loss of pleasure in activities*, *lack of reactivity to pleasant events or circumstances*, and *anhedonia* also achieved broad consensus as critical indicators of depression [6,54,62-64]. Collectively, these signs and symptoms highlight the significant impact of depression on a person's capacity for joy and engagement with life, underscoring their relevance in depression screening.

Criteria such as *ruminations* and *feelings of worthlessness* equally achieved a strong consensus due to their role in the negative cognitive and emotional patterns of depression. Previous research has shown that *ruminations* exacerbate psychopathology, including depression, by intensifying and extending negative mood states, thus interfering with problem-solving and perpetuating physiological stress responses [65]. Similarly, *feelings of worthlessness* are strongly linked to self-blame, lack of hope, and an increased suicide risk even after depressive episodes remit [66,67]. Building on this, the *lack ofhope* dimension achieved unanimous consensus (21/21, 100%) as a relevant element, reflecting its importance as a significant predictor of psychological well-being [68]. Within this broader dimension, the *hopelessness* and *hopeful about the future* criteria also showed high consensus (24/27, 89% and 16/21, 76%, respectively), emphasizing their important role in depression screening in individuals of very old age whether as a negative indicator or a positive resource.

Furthermore, *previous episodes of depression or diagnosed depression* were also identified as relevant, highlighting the importance of considering an individual's psychiatric history as past experiences with depression increase the risk of recurrence [69]. In addition, *critical life events* perceived as negative were recognized for their significant association with higher levels of depressive symptoms in a recent meta-analysis [70].

Finally, the strong agreement on severe criteria such as *recurrent thoughts of death or suicide*, *suicidal ideation*, and past *suicide attempt(s)* underscores the critical need to address these factors due to their immediate risk to individuals' safety [26].

Most Consensual Potentially Relevant Depressive Signs and Symptoms in the Context of Old Age

Having established the most consensual depressive features, it is essential to explore how these characteristics manifest specifically in older adults as unique age-related factors may shape their expression and impact.

As individuals age, they may face different challenges, some of which are particularly relevant to LLD. These include agism; loss of income; the death of loved ones; and the risk of isolation, functional limitations, multimorbidity, cognitive decline, and institutionalization [71]. Such multidimensional challenges can impact well-being and mental health, contributing to reduced aging satisfaction and increased loneliness, including near-centenarians and centenarians [71,72]. While the cumulative effect of these difficulties can increase the risk of LLD, it is important to note that experiencing them does not necessarily lead to the development of a depressive state [72].

The dimensions and criteria that achieved high consensus, as previously discussed, clearly represent central elements in depression screening across all age groups, aligning with current diagnostic standards [6,54]. Our findings confirm their importance for accurate diagnosis in individuals of very old age, underscoring their transversality across generations and relevance even in the final stages of life. While depression in very old age may have unique aspects, some of the core signs and symptoms of the disorder remain consistent and should not be overlooked, including in near-centenarians and centenarians. However, these signs and symptoms may carry additional significance due to the unique psychosocial and physical challenges faced by these individuals [72].

For instance, *loss of interest in activities*, *loss of pleasure in activities*, *lack of reactivity to pleasant events or circumstances*, and *anhedonia* may highlight a deeper disengagement from life that can be difficult to detect in older adults. These symptoms are often masked by typical aging challenges such as physical decline, social isolation, or even cognitive issues, complexifying their identification. In addition, *feelings of worthlessness* and

XSL•FO
RenderX

the negative impact of *critical life events* may be particularly relevant in late-life contexts, where significant life changes and losses are common [67,73]. As highlighted in a meta-synthesis [74], older adults often experience declines in physical and cognitive abilities, leading to feelings of disconnection and a perception of being unneeded by their communities. This sense of being unneeded can foster feelings of isolation and insignificance, thereby triggering or exacerbating depressive symptoms. Moreover, societal changes and loss of social roles further deepen these feelings of worthlessness, underscoring the importance of addressing these issues in older populations [74].

While the high consensus on many classic criteria suggests their continued relevance across the life cycle, our findings also point to unique aspects of depression in very old age that may not be fully captured by current approaches. For example, the unanimous agreement on the relevance of *lack ofhope* highlights its particular significance in this age group. Unlike other factors typically associated with normal aging processes, low levels of hope have been identified as a significant risk factor in older adults, reflecting a deeper sense of despair with potentially serious consequences. A systematic review [75] underscored that lack of hope is closely linked to negative outcomes in older populations, including an increased risk of depression and poorer overall health outcomes.

Moreover, the strong agreement on severe symptoms such as *recurrent thoughts of death or suicide*, *suicidal ideation*, and past *suicide attempt(s)* underscores the importance of also addressing these factors in very old age, where such topics often remain taboo [76]. Reluctance to discuss or acknowledge these symptoms may lead to underdiagnosis and inadequate treatment, emphasizing the need for sensitive and proactive approaches in this age group. Recent qualitative research [76] has revealed that suicidal thoughts in later life are often subtly expressed and normalized in everyday conversations, making them difficult to detect. However, the extent to which this applies to centenarians is unclear. Previous research suggests that only a minority of centenarians express a wish to die [77,78], making explicit suicidal thoughts likely rare and not always linked to depressive states. Nonetheless, feelings of life being *completed and no longer worth living* reflect a deeper disconnection from life, characterized by aching loneliness, feelings of not mattering, and a physical and mental tiredness [79]. Creating safe spaces for informal—yet meaningful—discussions is essential, alongside strategies for timely recognition and management of these symptoms [76].

Potentially Not Relevant Depressive Signs and Symptoms in the Context of Old Age

The *increased appetite* dimension may have been considered *not relevant* as it can result from situational factors such as attending a day center or moving to a nursing home, where tailored meals and social dining often enhance the willingness to eat, contributing to an increased appetite. Similarly, the *significant unintentional weight gain* criterion was likely deemed *not relevant* for related reasons as previous research has found no association between weight gain and incident depressive symptoms in older adults [80].

Certain cognitive dimensions such as *memory problems* and *language/speech (eg, poor speech)* were also classified as *not relevant*, likely due to their overlap with nondepressive phenomena commonly observed in older adults. This highlights the need for tailored screening protocols that can effectively differentiate between depression and cognitive impairment, conditions that often coexist in individuals of very old age and require distinct therapeutic strategies [81,82]. The criterion *the mind is as clear as it used to be* was likely deemed *not relevant* for the same reasons.

Criteria such as *hard to get started on new projects*; *staying home instead of going out and doing new things*; *finding life exciting, wonderful, and enjoyable*; *easily annoyed*; and *getting bored often* may be more closely related to motivational factors, social involvement, social support, or underlying health conditions rather than directly indicating a depressive state [83,84]. Similarly, criteria such as *thinks most people are better off than him/her*, *feeling that people are unfriendly or dislike him/her*, and *feels as good as other people* may reflect personality traits, which are relatively stable over the life span and may not necessarily reflect a change in mental health status [85].

Symptoms such as *psychomotor agitation* illustrate the challenge in differentiating between depression-related symptoms and those arising from other geriatric conditions such as dementia or delirium [86], suggesting that certain depressive features may be less applicable or not sufficient for individuals of very old age [87]. In addition, the *full of energy* criterion, typically seen as a positive indicator, was not deemed relevant, possibly because it is rare for a near-centenarian or centenarian without depression to report feeling full of energy. This likely reflects their overall physical condition rather than a depressive state, and the absence of this criterion may often be confounded with physical exhaustion linked to frailty [88].

The *fear of dying* criterion was also classified as *not relevant*. Although it might be assumed that individuals in the final stage of life would fear death, previous research suggests that death anxiety is generally low among older adults, who are more often concerned with the dying process rather than death itself [89]. Similarly, *sufficient financial resources* was deemed *not relevant*. While financial difficulties can impact mental health, their link to psychological distress in older adults appears to be more influenced by underlying factors such as mastery and self-esteem rather than acting as a direct indicator of depression [90].

The Specificity of Near-Centenarians and Centenarians

Research on near-centenarians and centenarians has predominantly focused on physical, cognitive, and social health, with less attention paid to psychiatric aspects [13]. Studies on depression in this population often rely on overall assessment scores from standardized instruments rather than detailed analysis of individual items [72,87,91-94]. This gap, alongside the variety of existing tools for screening for depression in very old age, also motivated this study.

Notably, one study conducted a detailed item-level analysis using a 14-item version of the Geriatric Depression Scale in

XSL•FO
RenderX

Portuguese centenarians [88] and found that 51.4% reported *feelings of worthlessness*, supporting the relevance of this specific criterion in our e-Delphi study. In addition, only 12.3% reported having more *memory problems*, 43.3% expressed a preference for *staying home instead of going out and doing new things*, 39.8% reported *getting bored often*, and 33.3% agreed with the statement *thinks most people are better off than they are* [88]. Globally, these findings align with our results, where these criteria were considered not relevant in this age group.

While these findings suggest reduced presence of symptoms established for younger populations, it remains unclear whether depression in near-centenarians and centenarians significantly differs from that in other older individuals, such as octogenarians; the key features of depression may not vary meaningfully. Therefore, it is worth questioning whether the development of a tool specifically designed for very old age, including the near-centenarian and centenarian population, is truly necessary. Nevertheless, psychological resources such as resilience appear to be particularly strong in near-centenarians and centenarians [77,95]. These protective characteristics may lead traditional depression screening tools to overlook subtle signs of depression that are masked by these strengths. A tool specifically designed for this age group could better capture the subtle differences and specific needs, enhancing the accuracy and effectiveness of depression screening.

Duration, Number, Frequency, and Severity of Depressive Signs and Symptoms and Type of Assessment

Our findings emphasize the importance of considering the duration, number, frequency, and severity of depressive signs and symptoms in near-centenarians and centenarians. Notably, experts differentiated between chronic and new-onset depression, advocating for a nuanced approach that may significantly impact clinical assessments and interventions. This aligns with existing literature documenting distinct clinical profiles for persistent and nonchronic depressive disorders in adults aged 18 to 79 years [96,97], with persistent cases often involving earlier onset, more severe symptoms, and greater treatment resistance [96]. While these findings are based on younger individuals, they reinforce the necessity of a personalized life span approach that includes rigorous screening and comprehensive clinical strategies for the oldest age groups.

Furthermore, experts in our study highlighted the potential value of combining self- and hetero-assessment techniques to screen for depressive signs and symptoms in very old age. However, this approach may require further consideration. Cognitive limitations at this age may affect the reliability of self-reports, complicating the integration with caregiver observations. Developing strategies to reconcile these differing perspectives—such as guidelines for interpreting discrepancies—could ensure that assessments are accurate and sensitive to the unique challenges faced by individuals of very old age. Flexible, combined approaches remain relevant as research suggests that they enhance diagnostic accuracy and patient engagement [98].

Further Considerations

Given the findings of our study, a more comprehensive approach to depression screening in near-centenarians and centenarians may be advantageous. The high consensus among experts regarding certain depressive features highlights their relevance and significance for this particular age group. Importantly, the diagnosis of LLD in adults of very old age can be particularly complex due to overlapping symptoms with other mental or somatic conditions, as previously outlined. This overlap necessitates a differential diagnostic approach that integrates a broader perspective. This emphasizes the need for screening tools that are both comprehensive and sensitive to the unique experiences and needs of individuals of very old age. Implementing such tailored screening methods could contribute to improved mental health outcomes within this population.

Our work extends existing literature by providing a comprehensive overview of a wider range of depressive features, including considerations of their duration, number, frequency, and severity—factors that are less considered in standard depression screenings. This highlights the complexity of diagnosing depression in adults of very old age and confirms the necessity of incorporating these specific aspects into the screening process.

While the e-Delphi method was valuable for identifying key elements in detecting depressive signs and symptoms in those of very old age, a separate validation study is necessary to confirm whether the extended screening process would be more effective compared to current tools. Nonetheless, this study hopefully represents a meaningful step forward in improving the detection of depressive signs and symptoms in this population.

Limitations

We acknowledge several limitations. First, despite the international and professional diversity of the expert panel, it may not have captured the full spectrum of clinical practices or cultural perceptions related to aging and depression. The relative overrepresentation of nurses among the panelists in rounds 1 and 2 may have introduced a bias toward nursing-specific priorities, such as a stronger focus on the practical applicability of screening criteria in daily care. However, this also reflects their pivotal role in direct care for individuals of very old age, making their insights particularly relevant for developing pragmatic screening criteria. Given this, a *groupthink* effect in which the dominant profession influenced the consensus cannot be excluded. In addition, our panel lacked experts from Asian countries despite notable recruitment efforts even though these regions have some of the highest proportions of centenarians worldwide. This absence may have introduced a bias toward Western perspectives. At the same time, the concept of depression in very old age may be less clearly defined in some Asian cultures due to cultural background. Second, the selection of a 70% consensus threshold may have influenced the interpretation of the results as it reflects a compromise between inclusivity and stringency, subtly shaping the scope of the consensus achieved. Third, the structured nature of the e-Delphi process may have limited the exploration of nuanced symptoms critical to understanding depression in individuals of very old

XSL•FO
RenderX

age, a population whose cognitive decline may complicate symptom presentation. Fourth, some overlap between dimensions and criteria was observed, which may be perceived as a limitation to some extent. However, the steering committee was aware of this overlap and intentionally decided to retain it to confirm certain trends in consensus on specific items.

Despite these challenges, this study's insights have the potential to stimulate discussions on improving mental health strategies for older populations, especially those of very old age. The diverse and interdisciplinary composition of the panel further contributes to the generalizability of the findings, offering valuable insights to health care professionals and researchers worldwide.

Future research should aim to develop and validate a screening tool specifically designed for depressive signs and symptoms in very old age, including near-centenarians and centenarians. A validation study comparing the extended method with established tools or a *gold standard* diagnostic reference is crucial to determining its efficacy. In addition, it is important to assess the tool's effectiveness across different cultural contexts to ensure its broad applicability. The incorporation of Patient-Reported Experience Measures in future developments would also be beneficial in capturing the lived experiences and perceptions of this age group.

Conclusions

This expert consensus could significantly contribute to enhancing early detection and intervention for depression in individuals of very old age, notably by informing the creation of a new screening tool. The findings have the potential to improve diagnostic accuracy and, consequently, allow for the personalization of treatment plans tailored to the unique needs of individuals of very old age.

In conclusion, this study used expert consensus to establish a foundational step toward enhancing the detection and treatment of depression among individuals of very old age, including near-centenarians and centenarians. This study emphasizes the need for cautious, multidimensional, and multidisciplinary approaches to depression screening in this age group, advocating for the continuous refinement of screening tools to address the complex nature of very old age effectively.

Acknowledgments

This work was supported by the Swiss National Science Foundation through the Sinergia grant CRSII5_186239/1 (SWISS100). The authors gratefully acknowledge the contributions of all the experts who participated in this study. They recognize those who agreed to be publicly acknowledged: Alcina Matos Queirós, Department of Health and Social Welfare, Canton of Vaud, Switzerland; Carina Santos, Riviera-Chablais Hospital, Switzerland; Christophe Nakamura, Lausanne University Hospital, Switzerland; Eivind Aakhus, the Norwegian National Centre for Ageing and Health, Vestfold Hospital Trust, Norway; Filipa Pereira, School of Health Sciences, University of Applied Sciences and Arts Western Switzerland Valais-Wallis, Switzerland; Jean Roche, Lille University Hospital, France; Kim Uittenhove, Swiss Federal Institute of Technology in Lausanne, Switzerland; Nancy A Pachana, the University of Queensland, Australia; Oscar Ribeiro, University of Aveiro, Portugal; Raquel Neves, Almoosa Rehabilitation Hospital, Kingdom of Saudi Arabia; Sofia Fernandes, School of Health Sciences, University of Applied Sciences and Arts Western Switzerland Valais-Wallis, Switzerland; Sylvain Nguyen, Riviera-Chablais Hospital, Switzerland; Sylvie Bonin-Guillaume, Aix-Marseille University, University Hospital of Marseille, France; and Tiago Ferreira, Lausanne University Hospital, Switzerland. The authors also extend their sincere appreciation to the experts who preferred to remain anonymous. Their equally valuable contributions were central in shaping this study's outcomes.

Authors' Contributions

CGdR, AvG, and HV contributed to the conceptualization of the study. AvG, PV, and HV provided methodological input. AvG, PV, DSJ, OR, and HV contributed scientific input. CGdR was responsible for data collection, data analysis, and writing the original draft. CGdR, AvG, PV, DSJ, OR, and HV reviewed and edited the manuscript. AvG and HV supervised the study.

Abstract

Background: Cyberchondria is the compulsive searching for health information online that continues despite harmful effects. It leads to increased health anxiety and lower health-related quality of life (HRQOL). Older adults face higher risks of cyberchondria due to their limited digital literacy skills and more frequent health concerns. However, researchers have not thoroughly studied how cyberchondria affects this age group.

Objective: This study aimed to explore cyberchondria in the older population and investigate its relationship with cognitive fusion (ie, the tendency to become entangled with thoughts and perceive them as literal truths that dictate behavior), HRQOL, and mental well-being.

Methods: A web-based, cross-sectional survey was conducted in May 2024 with a sample of 638 participants from China aged ≥60 years recruited through the online panel of a survey company. The participants completed questionnaires assessing cyberchondria (using the Cyberchondria Severity Scale-12 [CSS-12]), cognitive fusion, HRQOL, and mental well-being. Structural equation modeling (SEM) was used to assess the hypothesized mediation model, and standardized estimates and their 95% CIs were calculated for all structural paths.

Results: Participants had a mean CSS-12 score of 40 (SD 8.5), suggesting a fairly high level of cyberchondria in this sample. Participants with a higher socioeconomic status tended to report lower levels of cyberchondria. The SEM showed that cyberchondria was positively associated with cognitive fusion (β=0.505, *P*<.001 for both models) and negatively associated with HRQOL (β=–0.221, *P*<.001) and mental well-being (β=–0.212, *P*<.001). The mediation model showed a good fit and demonstrated that cognitive fusion fully mediated the total effect of cyberchondria on HRQOL and mental well-being.

Conclusions: Cyberchondria may be more prominent in older Chinese adults, especially those residing in rural areas and with a lower socioeconomic status. Additionally, cyberchondria can enhance cognitive fusion, contributing to poor HRQOL and mental well-being. Interventions focused on “defusing” cyberchondria-relevant thoughts may help reduce maladaptive behaviors associated with cyberchondria and improve the overall well-being of older populations.

Introduction

Background

The internet can amplify health anxiety by creating an environment in which distinguishing credible online health information from that derived from unreliable sources may be difficult, often leading to confusion and fear [1,2]. Cyberchondria refers to excessive or repeated online health information seeking that persists despite negative consequences and is associated with increased health anxiety [3] and decreased health-related quality of life (HRQOL) [4,5], with its toll including diminished well-being and compromised daily functioning. Cyberchondria and health anxiety are closely intertwined, and studying this link is crucial to address the growing impact of cyberchondria. The rise of cyberchondria is intimately linked to the digital revolution, and online misinformation and worst-case scenarios often lead to catastrophic interpretations that exacerbate anxiety. The internet also facilitates confirmation bias, allowing individuals to seek information that aligns with their existing fears, reinforcing anxiety. Easy access to information facilitates compulsive checking behaviors, which provide temporary relief but ultimately perpetuate anxiety. This creates a vicious cycle, in which increased anxiety leads to more compulsive online health information seeking [4,6,7].

Cyberchondria in Older Adults

Older adults face heightened vulnerability to cyberchondria. Their vulnerability stems not only from lower digital literacy and more frequent health concerns [8,9] but also from their generation's unique beliefs and life experiences [10]. Older adults, particularly those from generations that emphasized deference to authority figures, may uncritically accept health-related information presented in an authoritative tone, even from unreliable online sources [11]. This attitude, coupled with passive health information-seeking habits developed in an era of limited access to medical knowledge, heightens susceptibility to misinformation and catastrophic health interpretations.

Moreover, older age brings an expectation of decline, a psychological state shaped by imminent health risks, accumulated losses, and direct experiences with chronic illness [12]. These experiences may foster hypervigilance toward bodily changes, prompting compulsive online searches that reinforce anxiety through confirmation bias. The interplay of factors, such as cohort beliefs, anticipatory health anxiety, and cumulative adversity, may create a unique pathway for cyberchondria in older adults, distinct from younger populations. Despite these risks, limited research has focused on cyberchondria in this age group, even as studies highlight their frequent use of the internet for health information, which may increase their anxiety and distress [12-14].

HRQOL and Cyberchondria

HRQOL is a multidimensional construct that encompasses an individual's physical health, mental health, social functioning, and role functioning [15]. HRQOL is particularly affected by cyberchondria, as the anxiety and stress from constant health-related searches have a negative impact on emotional well-being. This anxiety can also manifest as psychosomatic symptoms, affecting physical health and daily functioning.

Unravelling the mechanisms linking cyberchondria to HRQOL is essential, as individual differences in coping strategies, digital literacy, and pre-existing health conditions interact dynamically with the aforementioned specific vulnerabilities in older adults. As cyberchondria becomes more prevalent [16], targeted interventions must address not only the skill gaps but also the ingrained cognitive and emotional patterns that predispose older adults to its harms, ultimately safeguarding their well-being in an increasingly digital health landscape.

Mental Well-Being and Cyberchondria

Mental well-being and HRQOL are distinct concepts that address different dimensions of human experience. Unlike HRQOL, which quantifies the impact of health on physical, social, and role functioning, mental well-being focuses on emotional and psychological states and encompasses positive aspects such as happiness, life satisfaction, resilience, and a sense of purpose [17]. Rooted in frameworks like positive psychology, mental well-being relates to the presence of flourishing mental states (eg, optimism, self-acceptance) and absence of psychological distress (eg, anxiety, depression). Cyberchondria can jeopardize mental well-being by heightening anxiety about one's health [18]. It can also destabilize emotional health, trigger obsessive thought patterns, and impair resilience, ultimately eroding the core components of mental well-being and leaving individuals trapped in a cycle of distress and hypervigilance [19].

Elucidating the mechanisms connecting cyberchondria to mental well-being is vital, especially for older adults who face unique risks due to diminished digital literacy, heightened health concerns, and reduced adaptability to stress [20]. Factors such as pre-existing anxiety, limited ability to critically evaluate online content, and a propensity for catastrophic thinking can intensify cyberchondria's impact, making older adults particularly susceptible to its psychological toll [21]. With the growing prevalence of digital health-seeking behaviors, research must prioritize these interactions to inform robust, tailored interventions, combining enhanced digital education with cognitive-behavioral strategies, to break the cycle of anxiety and safeguard mental well-being in this vulnerable population [22].

Cognitive Fusion and Cyberchondria

Cognitive fusion refers to the tendency for behavior to be overly regulated and influenced by cognition. Cognitive fusion occurs when individuals get overly entangled with their thoughts, treating them as literal truths rather than just mental phenomena [23]. Although cognitive fusion is primarily a state phenomenon, some individuals may experience it more persistently, leading to patterns that resemble a trait. This means that certain people might be more prone to cognitive fusion across various situations, making it appear as a stable, trait-like characteristic [24]. Studies have shown that cognitive fusion is strongly associated with health care avoidance and weight stigma [25] and that higher levels of cognitive fusion are associated with

XSL•FO
RenderX

increased anxiety and depression and poorer HRQOL [26,27]. Cognitive fusion is also related to rumination, shame, and reduced self-compassion [28]. Cognitive fusion involving anxious thoughts can exacerbate anxiety-related maladaptive behaviors, such as avoidance, checking, and reassurance seeking. The inability to distance oneself from such thoughts perpetuates the anxiety cycle and strengthens the perceived validity of the thoughts [29].

Previous studies have shown an association between cyberchondria and metacognitive beliefs [30,31], a concept potentially linked to cognitive fusion. Although metacognitive beliefs refer to ways of appraising one's thoughts and other cognitive functions, cognitive fusion is about a strong attachment to one's thoughts and their perceived truth. Compared with cognitive fusion, metacognitive beliefs reflect a broader construct, can be either positive or negative, and lack an element of attachment to one's own thoughts, regardless of the nature of these thoughts. Both constructs influence how individuals experience and respond to their thoughts, but considering the potential role that cognitive fusion can play in psychopathology, it has not received sufficient attention from researchers in the context of cyberchondria.

Although cognitive fusion can affect people of all ages, older adults may be more severely impacted than their younger counterparts, given their thoughts about numerous life transitions, including retirement, loss of loved ones, high risks of social isolation, and declining health [32]. Cognitive fusion may amplify health-related anxiety of older adults by making it difficult for them to separate their concerning health-related thoughts from the reality about their health. However, limited empirical evidence exists on the relationship between cognitive fusion and health anxiety among older adults [33]. Studying cognitive fusion in this demographic may help develop tailored interventions to enhance coping mechanisms of older adults and improve their mental health and overall HRQOL [34].

The relationship between cognitive fusion and cyberchondria can be understood through the lens of cognitive processes and reinforcement. Cognitive fusion may contribute to negative perceptions of online health information [35]. In other words, the threatening thoughts about online health information, especially if this information is ambiguous or incongruent, are experienced as real and not a product of one's own interpretation or perception. This increases anxiety and makes a person search compulsively for health information in an effort to alleviate the sense of threat, thus leading to cyberchondria [29,36]. However, such behavior only reinforces the sense of threat, especially in the long run. For older adults whose health-related searches are often driven by anticipatory anxiety [12], seeking ambiguous or alarming information may deepen cognitive fusion ("I must be ill because I keep reading about symptoms"), creating a feedback loop. This aligns with studies showing that repetitive behaviors amplify cognitive rigidity in aging populations [33]. Thus, we hypothesized cyberchondria as a behavioral trigger that intensifies cognitive fusion, which in turn erodes HRQOL.

Research Questions and Hypotheses

Research Questions

Drawing from the theoretical and empirical considerations outlined earlier, this study proposed 2 research questions to guide the investigation. First, what are the levels of cyberchondria and cognitive fusion among older adults, and which sociodemographic factors correlate with these constructs? Second, how are cyberchondria, cognitive fusion, HRQOL, and mental well-being interrelated in older adults? To address the second question, 5 hypotheses were formulated. The conceptual framework is presented in Multimedia Appendix 1.

Hypothesis 1

Prior research has demonstrated that cyberchondria contributes to functional impairment and diminished quality of life [18]. In older adults, this effect may be amplified due to age-related vulnerabilities, such as reduced online health literacy and the presence of chronic illnesses, which heighten susceptibility to health anxiety and its consequences [37]. Therefore, we proposed, as hypothesis 1 (H1), that cyberchondria negatively impacts HRQOL in older adults.

Hypothesis 2

Studies have shown that excessive online health information seeking is linked to increased psychological distress, including heightened anxiety and reduced emotional well-being [38,39]. Older adults may be particularly vulnerable to these effects due to declining physical health, reduced resilience to stress, and limited digital literacy, which can exacerbate the psychological toll of cyberchondria. Thus, we hypothesized, as hypothesis 2 (H2), that cyberchondria negatively impacts mental well-being in older adults.

Hypothesis 3

Research has indicated that cognitive fusion, characterized by entanglement with thoughts and treating them as literal truths, is associated with anxiety-driven behaviors [40]. Cyberchondria, as a behavioral pattern driven by health anxiety, may similarly foster cognitive fusion by reinforcing rigid and catastrophic thought patterns about health. Accordingly, we proposed, as hypothesis 3 (H3), that cyberchondria positively impacts cognitive fusion in older adults.

Hypothesis 4

The theoretical framework of acceptance and commitment therapy, supported by studies, suggests that cognitive fusion amplifies the negative effects of maladaptive thoughts on well-being, including health-related outcomes [41]. In the context of cyberchondria, older adults who excessively seek online health information may develop rigid, catastrophic cognitions that impair HRQOL through cognitive fusion [42]. Therefore, we hypothesized, as hypothesis 4 (H4), that cognitive fusion mediates the negative impact of cyberchondria on HRQOL in older adults.

Hypothesis 5

Evidence from prior research indicates that cognitive fusion intensifies the emotional impact of anxiety-driven behaviors, mediating the association between repetitive thought patterns

XSL•FO
RenderX

and psychological distress [40]. For older adults, cyberchondria may similarly exacerbate emotional distress through cognitive fusion, undermining mental well-being [23]. Thus, we proposed, as hypothesis 5 (H5), that cognitive fusion mediates the negative impact of cyberchondria on mental well-being in older adults.

Methods

Data and Participants

This study used data from a web-based cross-sectional survey conducted between April 2024 and May 2024 to examine the health and social status of China's older population. The participants were recruited through Wenjuanxing, a Chinese survey company with an online panel of over 2.6 million members. The inclusion criteria were as follows: (1) age ≥60 years, (2) ability to read and speak Mandarin, (3) absence of cognitive impairments, and (4) ability to provide informed consent. Eligible participants were invited to complete a series of questionnaires starting with an informed consent form. Only those who consented to participate then completed the questionnaire. Several measures were implemented to ensure data quality. First, we used CAPTCHA (Completely Automated Public Turing test to tell Computers and Humans Apart) to prevent bot submissions, ensuring that only genuine human respondents participated. We also conducted a time analysis to exclude implausibly rapid responses, which could indicate a lack of thoroughness. Additionally, we limited submissions to one per IP address within a set time frame to prevent duplicate entries. To further enhance data integrity, we identified and filtered parallel response patterns, including both consistent and repetitive patterns, which could suggest inattentive or automated responses.

Measures

The standard and validated Chinese versions of all instruments were administered. The English versions are included in Multimedia Appendix 2 for reference only.

Cyberchondria

The severity of cyberchondria was measured using the Cyberchondria Severity Scale-12 (CSS-12). It possesses good psychometric properties, comparable to those of the original version, and has been validated in the Chinese population [43]. The CSS-12 items were rated on a Likert-type scale ranging from 1 (never) to 5 (always). The total score ranges from 12 to 60, with higher scores indicating higher levels of cyberchondria.

Cognitive Fusion

The Cognitive Fusion Questionnaire (CFQ) was designed to measure the extent to which individuals are entangled in their thoughts [23]. It consists of 7 items, each rated on a 7-point Likert scale ranging from 1 (never true) to 7 (always true). Total scores range from 7 to 49, with higher scores reflecting a higher level of cognitive fusion. The psychometric properties of the CFQ have been reported to be satisfactory in the Chinese population [44].

HRQOL

The EQ-5D-5L was used to measure HRQOL in this study. It comprises 5 health-related items (mobility, self-care, usual activities, pain or discomfort, and anxiety or depression), each rated on a 5-point Likert scale ranging from 1 (no problems) to 5 (extreme problems) [45]. To reflect HRQOL, all health states described by the descriptive system can be converted into a single utility score using a scoring algorithm based on public preferences. This study used the EQ-5D-5L China value set and scoring algorithm [46].

Mental Well-Being

The World Health Organization-5 Well-Being Index (WHO-5) is a widely recognized and validated tool for assessing subjective psychological well-being [47]. It consists of 5 questions that measure positive mood, vitality, and general interest over the past 2 weeks. Each item is rated on a 6-point Likert scale ranging from 0 (not present) to 5 (constantly present), allowing for a maximum score of 25. Higher scores indicate better well-being. The psychometric properties of the WHO-5 in the Chinese population have been reported to be satisfactory [48].

Statistical Analysis

Descriptive statistics were used to analyze participants' sociodemographic characteristics. Continuous variables (eg, age) were analyzed using means and SDs, whereas categorical variables (eg, sex) were analyzed using frequencies and percentages. Pearson correlation coefficients (r) were calculated to determine associations between variables, with r values ≥0.3 and ≥0.5 indicating moderate and large effects, respectively [49]. ANOVA was conducted to assess the differences in CSS-12 scores across different socioeconomic groups.

We used structural equation modeling (SEM) with full-information likelihood estimation to assess the hypothesized mediation model. Latent variables for cyberchondria (CSS-12), HRQOL (EQ-5D-5L), mental well-being (WHO-5), and cognitive fusion (CFQ) were created based on the sum score of the 4 instruments. Respondents' characteristics (ie, sex, age, education level, and presence of a chronic condition) were included in the model for adjustment. To assess the direct, indirect, and total effects, we used 5000 bootstrapped samples, derived effect estimates, and bias-corrected 95% CIs [50]. We assessed model fit using a Tucker-Lewis index>0.90, comparative fit index>0.90, root mean square error of approximation<0.05, and standardized root mean square residual<0.05 [51]. We set significance at P<.05 (2-tailed) and conducted all statistical analyses using R software [52].

Ethical Considerations

This study was performed in line with the principles of the Declaration of Helsinki. The study protocol and informed consent were approved by the Institutional Review Board of Hong Kong Polytechnic University (reference ID: HSEARS20230502006). Informed consent was obtained from all the participants. All data were anonymized to protect participants' privacy and ensure confidentiality.

Results

Participants' Sociodemographic Characteristics

Table 1 presents the sociodemographic characteristics of the 638 survey participants. The majority were men, comprising 64.1% (409/637) of the sample. In terms of educational background, 51.4% (328/637) had a high school education or less, 25.9% (165/637) had attended college, and 22.7% (145/637) held a university degree. Regarding their household registration, 37.5% (239/637) were from rural areas, while 62.5% (399/637) were from urban areas. When asked about their perceived socioeconomic status, 11% (70/637) considered themselves below the local average, 79.1% (505/637) felt they were equal to it, and 9.9% (63/637) viewed themselves as above it. Moreover, 60.7% (387/637) were long-term caregivers, and 55.3% (353/537) had chronic conditions.

Table 1. Participants' demographics and socioeconomic status (n=637).

Characteristics	Results, n (%)

Profiles of Cyberchondria, HRQOL, Mental Well-Being, and Cognitive Fusion and Associations Between Them

Table 2 presents the participants' scores on the 4 assessment instruments, while Table 3 shows the correlations among the instruments. The average CSS-12 (cyberchondria) score was 40 (SD 8.5) points. The mean WHO-5 (mental well-being) score was 20.4 (SD 5.0) points, the mean EQ-5D-5L (HRQOL) score was 0.8 (SD 0.19) points, and the mean CFQ (cognitive fusion) score was 36.8 (SD 12.3) points. The Cronbach α coefficients for all 4 instruments were above 0.8, indicating good internal consistency and reliability.

[a]CSS-12: Cyberchondria Severity Scale-12.

[b]WHO-5: World Health Organization-5 Well-Being Index.

[c]CFQ: Cognitive Fusion Questionnaire.

[d]Not applicable.

Mental well-being (WHO-5) was positively correlated with HRQOL (EQ-5D-5L; r= 0.36, P<.001), suggesting that greater well-being aligns with better HRQOL. Conversely, mental well-being was negatively correlated with cognitive fusion (CFQ; r=–0.42, P<.001), indicating that higher well-being corresponds with reduced cognitive fusion. Similarly, HRQOL was negatively correlated with cognitive fusion (r=–0.48, P<.001), demonstrating that better HRQOL is linked to lower cognitive fusion. Cyberchondria (CSS-12) had negative associations with mental well-being (r=–0.2, P<.001) and HRQOL (r=–0.3, P<.001) and a positive association with cognitive fusion (r=0.5, P<.001). These results suggest that elevated cyberchondria is associated with poorer mental well-being, diminished HRQOL, and heightened cognitive fusion (Table 3).

Differences in Cyberchondria Across Sociodemographic Groups

Table 4 illustrates the differences in cyberchondria (CSS-12) scores across various sociodemographic groups. Although no statistically significant differences were observed between the sexes, substantial variations were evident in all other group comparisons. Notably, individuals with higher educational levels, who resided in urban areas, who were younger, who had a higher socioeconomic status, who did not need caregivers, and who had no chronic conditions had lower cyberchondria scores.

XSL•FO
RenderX

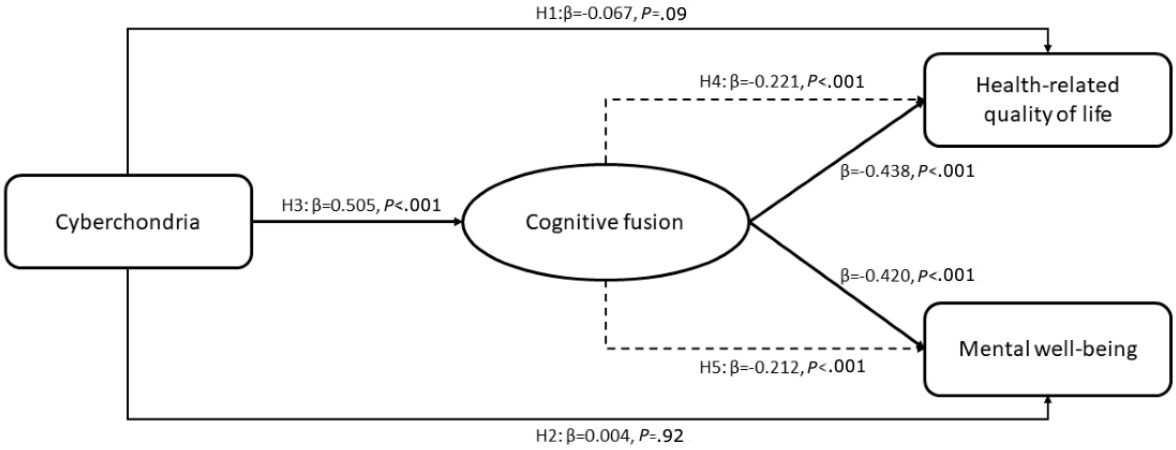
Differences in Cognitive Fusion Across Sociodemographic Groups



The differences in respondents' cognitive fusion across socioeconomic groups were similar to those found for levels of cyberchondria. Participants exhibited significantly higher cognitive fusion if they had lower educational levels, lived in rural areas, were older, had a lower socioeconomic status, and had caregivers or chronic conditions (Table 4).

Results of the Hypothesized Mediation Model

Figure 1 shows the results of the SEM analysis. The mediation model, adjusted for sex, age, and education level, demonstrated acceptable model indices (comparative fit index=0.997, Tucker-Lewis index=0.993, root mean square error of approximation=0.017), suggesting that unmeasured potential confounders were relatively unlikely to affect the results. Outcomes of the SEM analysis showed the lack of statistically significant direct effects between cyberchondria and HRQOL (β=–0.067, *P*=.09; H1 is not supported) and between cyberchondria and mental well-being (β=0.004, *P*=.92; H2 is not supported). The coefficients of the mediation paths were statistically significant. Cyberchondria was significantly positively associated with cognitive fusion (β=0.505, *P*<.001; H3 is supported) with significant negative indirect associations with HRQOL (β=–0.221, *P*<.001; H4 is supported) and mental well-being (β=–0.212, *P*<.001; H5 is supported).

XSL•FO
RenderX

Figure 1. Results of mediation analysis.

Discussion

Principal Findings

This study demonstrates that the levels of cyberchondria in the sample of older Chinese adults were rather high. Our participants had an average score of 40 (of the maximum score of 60) on the CSS-12, which surpassed the mean scores found in earlier research [53-56]. According to the CSS-12 cutoff value established by Xu [57], 60% of our participants exhibited significant features of cyberchondria. These results provide empirical evidence that internet-related mental health issues affect older adults, challenging the belief that such problems are mainly of relevance for younger individuals [58,59]. Additionally, the mediation analysis revealed that associations between cyberchondria and both HRQOL and mental well-being were complex, as no significant direct effects were observed in the model (H1 and H2 were not supported). However, cyberchondria appeared to have a negative and indirect effect on HRQOL and mental well-being by enhancing cognitive fusion among older adults (H3, H4, and H5 were supported). This highlights the importance of addressing cyberchondria not just as a mental health issue but also as a broader HRQOL concern. Interventions that aim to improve overall well-being, not just reduce anxiety, in this population should be encouraged. However, since the significant associations disappeared in the mediation models, the mechanisms relating cyberchondria to HRQOL and mental well-being might be complex and call for further research scrutiny.

The factors contributing to the high levels of cyberchondria are complex. Our study found that older adults with a lower socioeconomic status reported significantly higher cyberchondria levels than those with a higher socioeconomic status. This finding is consistent with results of previous studies conducted in other populations. For example, a Turkish study revealed a significant relationship between cyberchondria levels and family income among adolescents [60]. Several reasons may help explain this. Older individuals with a lower socioeconomic status often have limited access to health care resources, poor internet connectivity, and lower eHealth literacy [61,62]. These factors may compel them to rely heavily on potentially unreliable online health information. Moreover, older individuals with a lower socioeconomic status are more likely to experience social isolation and have smaller support networks [63,64], which may exacerbate their health anxiety and lead to higher levels of cyberchondria. Given these complexities, cyberchondria should be studied within the broader context of psychosocial determinants of health rather than as a simple health-related phenomenon.

A significant difference in CSS-12 scores emerged between urban and rural residents. Older urban residents exhibited lower levels of cyberchondria than their rural counterparts. Although a previous study found that health anxiety is more prevalent and severe in rural areas than in urban areas [65], the study empirically confirmed that the variation in cyberchondria levels was linked to household registration. The reasons for the striking difference in cyberchondria levels between urban and rural older adults largely overlap with the aforementioned reasons for the difference in cyberchondria levels between older individuals with higher and lower socioeconomic statuses. In addition, the urban migration of younger generations in China often leaves older family members in rural areas, which can hinder older people's access to direct support for using digital technologies [66]. Thus, a shift to digital health information, emphasized by the government, may become a challenge for rural residents [67,68].

The cognitive fusion scores in our sample of older adults were slightly higher than those reported in younger populations [32,69] but lower than those in populations with mental health problems, such as depression [70] and suicidal intention [71]. Gillanders et al [26] found that cognitive fusion is negatively associated with HRQOL, which is consistent with our findings. Additionally, we found a significant association between cognitive fusion and education; older respondents with higher educational levels had lower levels of cognitive fusion. Previous studies indicated that education often enhances cognitive flexibility [72], improves critical-thinking skills [73], and boosts problem-solving abilities [74]. These factors may help better-educated individuals avoid rigid thought patterns, thus reducing their proneness to cognitive fusion.

The mediation model revealed that cyberchondria may increase cognitive fusion, leading individuals to become overly entangled with their thoughts about online health information. Heightened

XSL•FO
RenderX

cognitive fusion can negatively impact HRQOL and mental well-being by making it challenging for older individuals to manage their distressing thoughts and emotions. This finding provides support to H2 of this study and partially aligns with the findings of previous studies showing that cognitive fusion significantly mediates the relationship between individual well-being and other health-related factors [75-78].

Building on previous research and clinical findings, our study extends the understanding of how cognitive fusion may serve as a potential mechanism by which cyberchondria causes negative health outcomes [79]. These findings provide valuable insights into how excessive online health information seeking may affect mental health and other functions. This study has clinical implications, as it suggests that interventions targeting cognitive fusion may be effective in mitigating the impact of cyberchondria on HRQOL and mental well-being.

As populations worldwide age, many countries are experiencing a surge in internet use among older adults, driven by increased access to smartphones and online platforms. The rising trend of cyberchondria among Chinese older adults found in this study is very relevant for other regions with aging populations, such as Japan, the United States, and much of Europe, where older adults increasingly turn to the web for health information [80]. The internet's role in amplifying anxiety through misinformation and compulsive online behavior is a universal concern [81]. Other countries can learn from China's experience to prepare for similar challenges, particularly where health care systems might struggle because of the increasing number of older patients with high levels of health anxiety and cyberchondria.

Strengths and Limitations

This is the first study conducted in China to specifically examine cyberchondria and its sociodemographic correlates in the older population. The novelty of this study lies in its examination of previously overlooked relationships between cyberchondria, cognitive fusion, HRQOL, and mental well-being in this population. The findings of this study enhance our understanding of cyberchondria by linking a specific cognitive construct (ie, cognitive fusion) with behavioral aspects (ie, excessive online health information seeking).

However, this study has several limitations that warrant consideration. First, our web-based sampling method, despite using various quality assurance techniques, may have introduced selection bias. Individuals unfamiliar with online surveys or those not part of the company's panel may have been excluded, potentially limiting the generalizability of our findings. Second, although national census data for the population aged 60 years and older was unavailable, our sample was representative only to some extent of the demographic characteristics of China's older population, as reported in previous studies. Specifically, our sample had higher proportions of educated individuals, men, and urban residents. These sampling differences may introduce bias in our findings. Third, our reliance on self-reported measures means that participants' subjective views may have influenced their responses. Fourth, the study did not assess some potentially important variables, such as digital literacy. This was due to the limited length of the study questionnaire and the need to reduce the cognitive burden on older respondents. Variables like digital literacy may affect cyberchondria, and their direct or moderating effects should be explored in future studies. Fifth, our decision to model HRQOL using the EQ-5D-5L single utility score as a manifest variable in the SEM analysis deviates from conventional SEM practices. An alternative approach, such as conceptualizing HRQOL as a latent construct with the five EQ-5D-5L dimensions as formative indicators, might better capture the multidimensional nature of HRQOL. Although this alternative does not align with the standard use of the EQ-5D-5L utility score, it might reflect the differential contributions of each dimension and adhere more closely to typical SEM frameworks. Our approach may have constrained the model's ability to account for the nuanced interplay of HRQOL dimensions, and future research should consider latent variable modeling to address this limitation. Last, our study used a cross-sectional design. Although SEM can offer some insights into potential causal relationships between variables, longitudinal data will be necessary in the future to establish definitive causal links.

Conclusion

This study shows that almost two-thirds of the older Chinese online population might exhibit features of cyberchondria. Higher levels of cyberchondria were observed among older adults living in rural areas and those with lower socioeconomic status. Targeted educational programs could be useful for empowering older adults to better navigate cyberspace and identify credible online health information. Cyberchondria can enhance cognitive fusion in older populations, resulting in poorer HRQOL and mental well-being. Interventions aimed at "defusing" cyberchondria-relevant thoughts and breaking the cycle of anxiety-fueled, excessive online health information seeking can help reduce cyberchondria and improve the overall well-being of older populations.

Abstract

Background: Technology-assisted physical activity interventions for older adults in their home-based environment have been used to promote physical activity. Previous research has reported that such interventions benefit body composition, aerobic fitness, cognitive abilities, and postural control, reducing the risk of falls and maintaining regular physical activity among the older population.

Objective: While previous reviews on technology-assisted physical activity interventions focused on health-related outcomes, this scoping review explores the characteristics of the technology in relation to the characteristics of populations, purpose of the activity, and usability in terms of adverse events, drop-outs, adherence, and user experience.

XSL•FO
RenderX

Methods: A full search was performed in Medline, Embase, CINAHL, SportDiscus, and Web of Science. Sources were considered for inclusion if the participants aged on average 60 years and older, if the physical activity intervention was assisted by technology, and if performed within home-based environments.

Results: We identified 8496 sources. After title and abstract screening, 455 full texts were assessed, and 148 were included, representing 12,717 participants aged 74 (SD 6) years. In total, 63% (93/148) of the sources reported on the population's health status. The main purpose of the interventions was balance (75/148, 51%), and strength and power (64/148, 43%) and the intervention purposes were not related to the embedded technology. In studies where the participant's health status was reported as healthy, 53% (78/148) implemented exergames compared to only 27% (40/148) in studies with participants with a clinical condition. Mobile apps (30/148, 20%) and trackers (16/148, 11%) were implemented likewise in both groups. The technology was embedded to provide continuous exercise information (40/148, 27%) and exercise feedback (40/148, 27%) or to record real-time movement data (38/148, 26%). Adverse events were reported in 46% (68/148) of the sources with three quarters (49/68) reporting no adverse events. Only two mild events were related to technology. Dropout rates were reported in 68% (100/148) of the sources, with no differences between intervention (16 SD 16%) and control (14 SD 12%) groups. Dropout reasons related to technology are only 3% (3/100). Adherence was reported in 53% (79/148) sources and was slightly higher in the intervention group (80 SD 18%) compared to the control group (71 SD 25%). A significantly higher adherence was found between interventions that were tailored (83 SD 15%) versus those that were not (75 SD 21%). General enjoyment of the technology was captured in 37% (55/148) of the sources. Within those sources, 91% rated positive (91/100), 7% neutral (7/100), and 2% negative (2/100). Occasionally reported wishes were related to goal setting, feedback, technical support, exercise variation, and social setting.

Conclusions: Various technologies were successfully used in healthy and clinical older populations, though evidence regarding their implementation in physical activity interventions in hospital settings remains limited. The embedded technology was not a reason for additional dropouts, led to slightly better adherence, and adverse events were rarely related to technology. When assessed, the technology was well accepted and positively enjoyed.

Introduction

The benefits of physical activity in advanced age are well-documented, yet paradoxically, sedentary behavior increases with age [1,2]. Even if individuals are motivated to engage in physical activity outside the home, environmental barriers such as weather conditions, infrastructure constraints, or specific constraints such as COVID-19 can pose challenges for older adults [3,4]. This paradox has prompted clinicians to seek technological solutions to encourage older adults to be more physically active within their home environment. It is important to distinguish between physical activity and exercise. Physical activity encompasses any bodily movement that expends energy, while exercise is a structured subset of physical activity specifically designed to improve fitness components [5].

Various electronic devices, software, or wearable technology such as smartphones [6], fitness trackers [7], mobile phone applications [8], tablets [9], virtual reality [10], exergames [11], E-coaching [12], and Robotics [13] have been reported to support beneficial changes in sedentary time and physical activity in the older adult population [14,15]. Such technological interventions benefit body composition, aerobic fitness, cognitive abilities, and postural control and reduce the risk of falls among the older population [9,16,17]. However, while there are indications that older adults tend to show high levels of adherence to technology-assisted physical activity interventions [15], quite a few barriers limiting the use of this technology have been reported, such as functional barriers related to the design of e-health programs and their interface with older end users, or lack of technological support [18].

With the continuously increasing number of technology-assisted healthcare tools, particularly those for home-based physical activity, and the difficulties older adults face in adapting to and operating these tools, it is not surprising that several reviews have been conducted in recent years to examine the usability of technology-assisted physical activity programs [15,19-25], more than half of them in recent years – 2021 - 2024 [19,20,22,23,25]. Most of these reviews focused on a specific population, egfor example, healthy, frail, or people with cardiovascular disease, focused on specific aspects of interventions, for example, balance or falls, or focused on a specific type of technology, for example, exergames [15,19-25]. Considering the boost of assistive-technology provision of physical activity in the recent five years, some are relatively dated [15,24]. A recent review by Costa-Brito et al elaborated on the usage of technology to improve physical function among older community-dwelling adults [23] and focused on the purpose and volume of an activity, types of technology, aspects of the usage of technology (adherence, acceptance, feasibility), and health outcomes. The review, however, did not go into the specific characteristics of the study participants, the technology's functionality, or its user interface. Furthermore, it did not explore or analyze key aspects of technology design, function, and interface in relation to specific populations or physical activity goals. Just as many other reviews [19-21,25],

XSL•FO
RenderX

Costa-Brito et al also neglected to examine safety concerns or adverse events associated with the use of technology.

Aligned with the recommendations of the PhysAgeNet, a European Cooperation in Science and Technology (COST) network devoted to evidence-based physical activity in old age [26] and with the proliferation of technology related to home-based physical activity, our aim in this study was to explore the characteristics of that technology in relation to the characteristics of older populations (eg, age group or health status) and the interventions. Furthermore, we aimed to examine the usability of that technology in terms of adverse events, drop-outs, adherence, and the user experience (acceptability and enjoyment). This may promote the optimal utilization of technology to provide efficient home-based physical activity programs for older adults. A scoping review was selected as the most suitable methodology due to its capacity to encompass a broad spectrum of study designs and methodologies. This approach facilitates the mapping of key concepts and the identification of research gaps, which is particularly critical in this emerging field characterized by diverse evidence sources, including randomized controlled trials, pre-post studies, feasibility studies, qualitative research, and mixed methods investigations.

Methods

Review Process

This scoping review was conducted in accordance with the Joanna Briggs Institute (JBI) methodology for scoping reviews [26] and the Preferred Reporting Items for Systematic Reviews and Meta-analyses extension for scoping reviews (PRISMA-ScR) checklist [27]. The protocol for the scoping review is available at the Open Science Framework Registries [28]. The review was conducted by an international interdisciplinary team of researchers with regular weekly meetings to discuss, distribute tasks, and ensure consistency during the different steps of the process.

Eligibility

Sources were considered for inclusion if they met the following criteria: (1) participants aged on average 60 years and older with and without health conditions; (2) studies that focused on technology-assisted physical activity interventions; and (3) the intervention was based within home-based environments. Table 1 gives a detailed definition of the participants, concept, and context.

Table . Details of the participants, concept, and context (PCC framework) which form the basis for source inclusion consideration.

PCC	Inclusion	Definitions and descriptions
Population	Older people	Older adults aged 60 years and older (the participant's group mean age should be ≥60 y), living independently or in residential facilities (aged care facilities), with or without health conditions.
Concept	Technology-assisted physical activity interventions	A physical intervention is a structured or unstructured measure taken to improve or maintain the user's physical activity and practiced individually. It can be tailored to specific health or fitness goals (structured) or it can be general and not specifically prescribed by a health professional (unstructured) [29]. The intervention includes any form of physical activity such as human daily activities, exercise, training, or physical fitness training. The technologies used to deliver the intervention are digital systems and include, among others, mobile applications, telemedicine, wearable electronic devices, exergaming, and virtual reality. The delivery of the intervention can take place supervised, facilitated (partly supervised), or unsupervised.
Context	Home-based environment	The home-based location and environment, ie, the immediate vicinity in the community environment, ie, a public open-access setting [29]. The participants may be living in a community setting on their own (community dwelling) or in an institution such as a care home or a hospital.
	Health status	People with or without mental or physical impairments.

Sources were excluded if (1) the study design was a review or study protocol, or if the publication type was an abstract or non-peer-reviewed conference proceedings, (2) participants were on average younger than 60 years of age, (3) no physical activity intervention was present or the intervention took place within clinical setting, (4) digital technology was not present or not an integral part of the intervention, (5) the intervention did not take place in home-based setting, or (6) the study language was other than English.

XSL•FO
RenderX

Search Strategy

According to JBI recommendation, an initial limited search of PubMed and Web of Science was conducted to identify potentially relevant key search terms for the PCC framework. In an iterative process, the keywords in the text of retrieved sources were analyzed. The search terms provided were consulted with experts within the team to capture all relevant keywords and then grouped into four main headings: population group, residence, technology, and intervention. The search string was further expanded by running searches with Medical Subject Heading (MeSH Terms) as well as with adequate non-MeSH terms for databases that do (eg, PubMed) or do not use a MeSH tree (eg, Web of Science), respectively and cross-checked by a subject librarian at Oxford Brookes University: ("aged" OR "elder*" OR "old" OR "older people" OR "geriatric" OR "senior#") AND ("home*" OR "resident*" OR "care facilit*" OR "nursing home*") AND ("digital technolog*" OR "mobile health" OR "telehealth" OR "eHealth" OR "mHealth" OR "exergam*" OR "video gam*" OR "serious gam*" OR "wearable technolog*" OR "wearable electronic device*" OR "application*" OR "mobile app*" OR "virtual reality") AND ("exercise#" OR "training" OR "intervention*" OR "physical activit*" OR "physical fitness") NOT ("review"[Title/Abstract] OR "rehabilitation" [Title/Abstract])

The created search strings were the basis for developing a full search strategy in Medline (PubMed), Embase (Ovid), CINAHL (Ebsco), SportDiscus (Ebsco), and Web of Science and converted as necessary (Multimedia Appendix 1). The search in the different databases was performed between September 26 and October 6, 2022, and all sources published in previous years were included. As a third step of the search strategy, an additional search was performed in the reference list of the identified sources selected from the full text search.

Source of Evidence Selection

Following the search, all identified sources were collated and uploaded into Rayyan [30], and duplicates were removed. Two reviewers performed a pre-screening pilot on 100 titles and abstracts to develop screening instructions (total agreement=95%, Cohen's Kappa=0.701). Any disagreements were resolved via consensus with the help of a third reviewer. After the whole team approved the final version of the screening instruction tool, the 2 reviewers screened the remaining titles and abstracts (total agreement=95.5%, Cohen's Kappa=0.515). Again, disagreements were resolved by a third reviewer.

Full texts of potentially eligible sources were uploaded into Rayyan. Ten different pairs of reviewers assessed these sources (total agreement =81%, Cohen's Kappa=0.696) within Rayyan [30]. Disagreements were resolved via consensus in a team of five other (independent) reviewers. The results of the search, the sources' inclusion process, and exclusion reasons have been reported in full and presented according to the PRISMA flow diagram [27]. All sources obtained after the search process were stored in Mendeley (Mendeley Ltd., Elsevier).

Data Extraction

A data extraction tool (Multimedia Appendix 2) was made in line with the JBI guidelines [26,31] and a template for intervention description and replication [32]. Five reviewers piloted the draft extraction tool, topic explanations were added to ensure the correct data was extracted into relevant columns and a final data extraction tool was prepared after which a group analysis and discussion was conducted, making sure that each extractor understood the tool. Finally, ten pairs of reviewers independently completed data extractions. When preparing the data for the analysis, a third reviewer cross-checked the extracted data and, where necessary, consulted the full text for details. Discrepancies and uncertainties were discussed within the team.

Data Analysis and Presentation

Four teams consisting of 3 - 5 reviewers analyzed the extracted data regarding the following topics: study design, participants, interventions and outcome measures, and technologies and key findings. An inductive thematic analysis was conducted. Codes or labels were defined to categorize the data and a coding framework with definitions of the categories and subcategories was developed. This coding framework allowed us to characterize the participants (age, health status, mobility, country of residence, etc), intervention (purpose, tailoring, temporal data, etc), the used technologies (design, function, interface), participation (feasibility, effectiveness, safety, etc), and health outcomes (physical and mental capacities, fall risk, quality of life, etc). A detailed description of the coding framework is presented in Multimedia Appendix 3. During the extracted data categorization process, the reviewers came together regularly in their small teams to discuss discrepancies until consensus was achieved and all data categorized. For this review, the focus lies with the participants, intervention, and especially the technology categories.

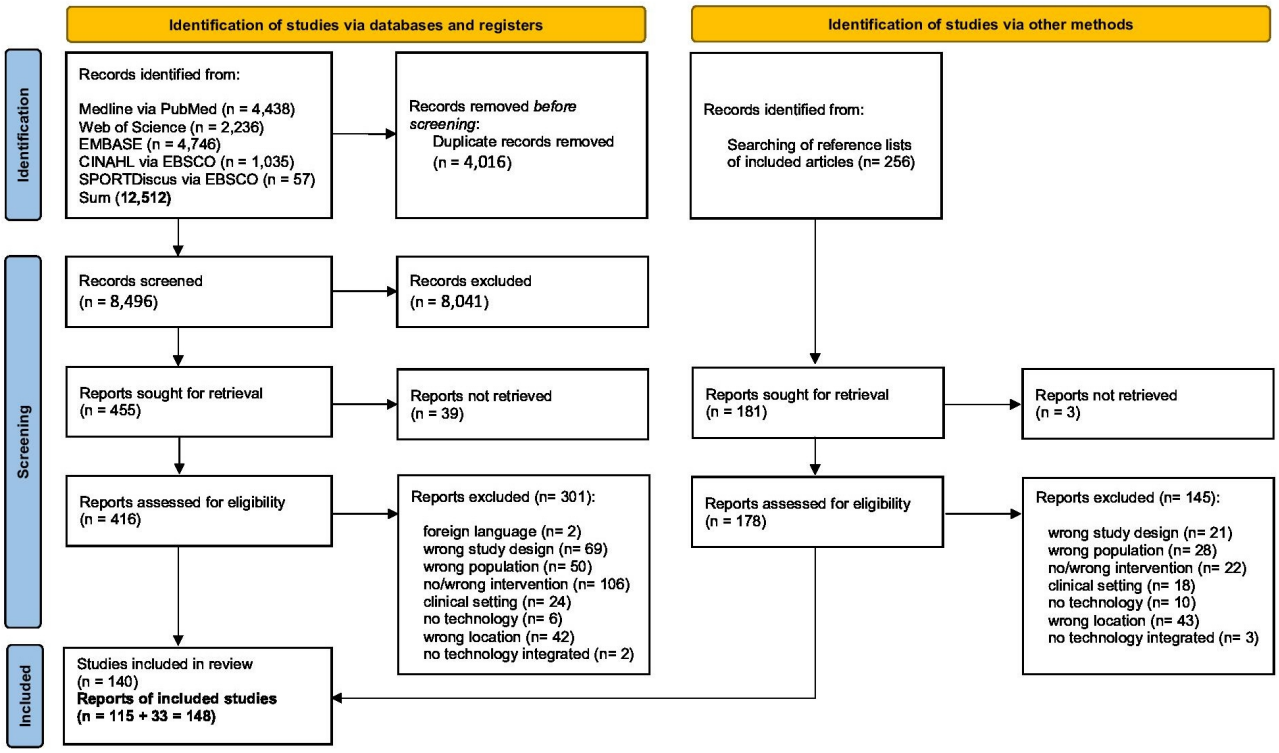
The quantitative and qualitative data were analyzed descriptively using absolute and relative frequency, percentage, average, and standard deviation. Pie charts and bar charts were made to visualize results.

Crosstabulation statistical analysis was used to get a better understanding of what kind of digital technologies were used to integrate specific physical activity intervention programs and for which populations. Observations between 2 or more nominal variables were explored, whereby the frequency of observations between variables was counted and reported accordingly and expressed as a percentage against all observations. Specifically, the cross-tabulation analysis was conducted between the following categorical variables: Technology (design, function, interface) versus Population (age group, health status, residency) and Intervention (aim of physical activity, tailoring).

Adherence (attendance and duration) and dropout rates were expressed as a percentage of the relevant study population and compared against population and intervention characteristics (2 or more categories) using differential tests. In the case of a binomial category, an independent *t* test was used. The following categories and linear outcomes were compared: Participation outcomes (dropouts, adherence) versus Population (age groups, health status) and Intervention (group, tailoring, supervision).

Relationships between linear parameters were regressed to extract the coefficient of determination (R^2) with associated *P*

XSL•FO
RenderX



value to indicate its significance. These were tested for the dropout and adherence outcomes, against the total number of intervention sessions and session durations.

Results

Source Selection

A total of 12,512 sources were identified during searching in Medline (PubMed), Embase (Ovid), CINAHL (EBSCO), SportDiscus (EBSCO), and Web of Science databases. After screening, 148 sources remained. Inclusion and exclusion details can be found in the PRISMA flowchart (Figure 1). An overview of all excluded sources with reasons and all included sources and corresponding extracted data can be found in the supplementary material. Detailed results from the data analysis and the references to the 148 included sources can be found in Multimedia Appendix 4 [33-175]. The full data extraction table and reasons for source exclusions from this review can be found in Multimedia Appendices 5 and 6, respectively.

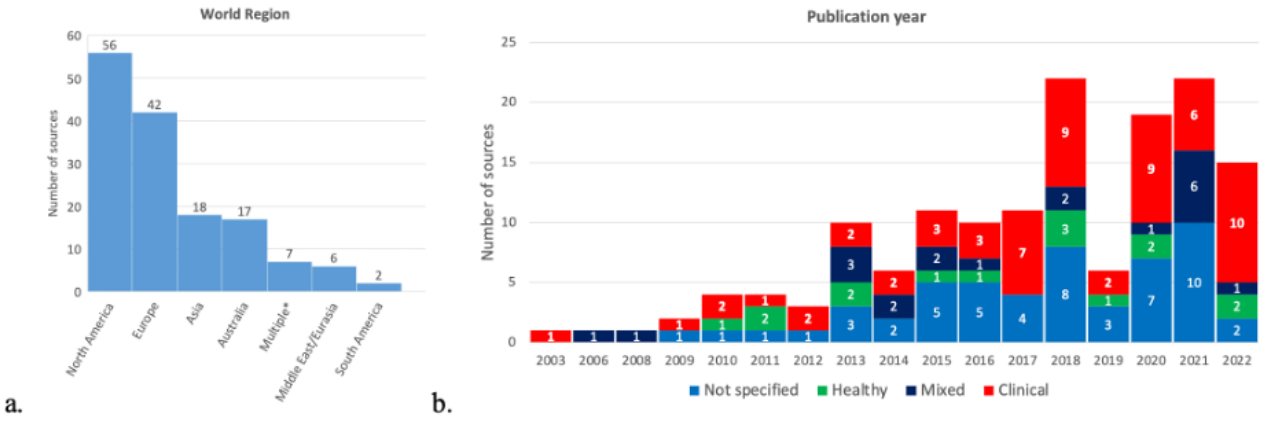


Figure 1. Flowchart search process.

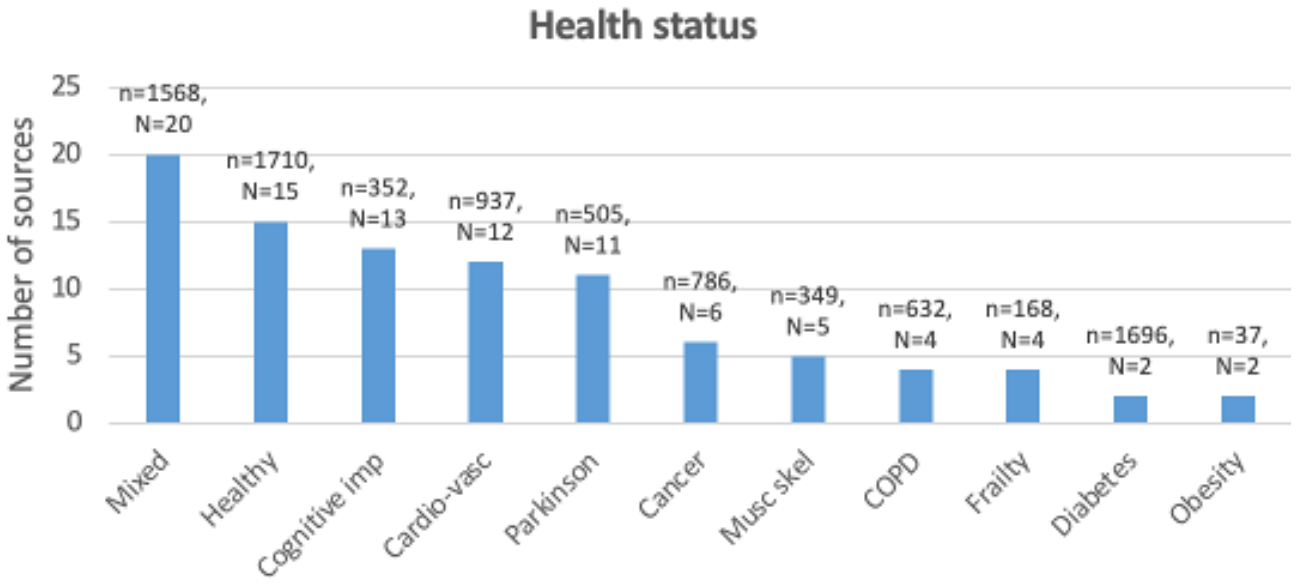
Study Characteristics

Publication years ranged from 2003 to 2022, with most of the included sources published in the last five years (84/148, 57%). An overview of the number of sources performed by region and publication year is presented in Figure 2.

Figure 2. (**A**) Number of included sources by world region. (**B**) and by publication year and health status.

The sources included 51% (75/148) randomized controlled trials, 24% (35/148) pre-post-test, and 12% (17/148) feasibility studies and to a lesser extent qualitative studies (6/148, 4%), non-randomized controlled trials (5/148, 3%), experimental studies (5/148, 3%), mixed methods (4/148, 3%), and one case study (1/148, 1%).



XSL•FO
RenderX

Participant Characteristics

The included sources contained a total sample of 12,717 participants, aged 74 (SD 6) years on average, with a range of 60 - 88 years. Most sources were devoted to the youngest-old group of 60 to 74 years (87/148, 59%), followed by the middle-old group of 75 to 84 years (51/148, 35%) and the oldest-old group of 85 years and older (6/148, 4%). A small sample of sources reported on mixed (2/148, 1%) age categories. In 2 studies, the age of the participants was not reported. With increasing age groups, the percentage of women increased from 53% (5160/9802) (youngest-old) to 70% (1750/2510) (middle-old) and 79% (119/150) (old-old).

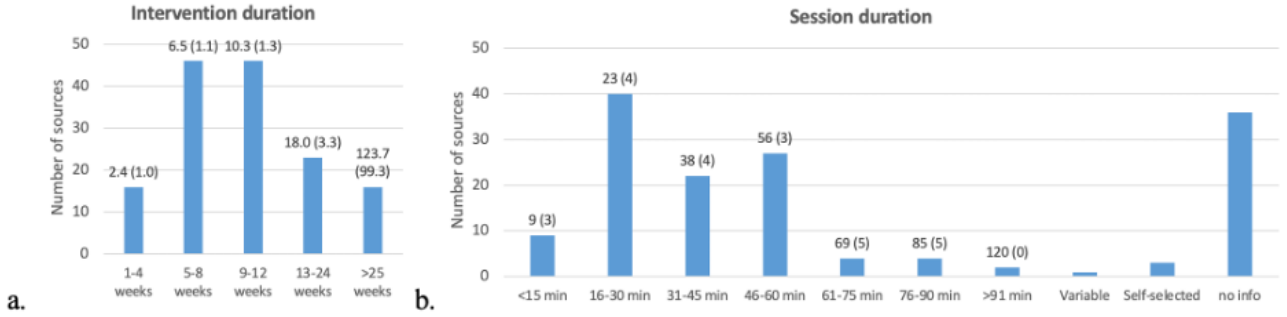
A larger focus on the clinical population is visible since 2017, although the health status is not always properly reported (Figure 2B). In total, 63% (93/148) of the sources reported on the population's health status (Figure 3). In 37% (55/148) of the sources, information on comorbid conditions was indicated, the average number of comorbidities was 4.2 (SD 2.6; range 1 - 10).

Figure 3. Number of included sources (N) by reported health status. With n being the total number of participants with cardiovascular disease (Cardio-vasc); cognitive impairments (Cognitive imp); chronic obstructive pulmonary disease (COPD) and musculoskeletal disease (Musc skel).

Most sources (101/148, 68%) included participants living in community-dwelling residences, 26% of the sources included participants from care homes, while 13% (19/148) of the sources were not specific on participant living arrangements (Figure 3). No source reported an intervention in a hospital setting.

Prior experience with technology was stated in 16% (24/148) of sources, and 15% (22/148) of sources stated that participants had access to technology at home before the implementation of the intervention. Five percent of the sources (7/148) highlight information about the prior frequency of use of these services or devices.

Intervention Design Characteristics



In 44% (65/148) of the sources, participants received supervised interventions (professional or non-professional) with a further 55% (82/148) of the sources including unsupervised interventions. Additionally, one source tested supervised versus unsupervised technology-based interventions.

In most of the sources (93/148, 63%), the intervention was tailored to individuals and/or groups of participants. The other 37% (55/148) applied a generic intervention approach to all participants. In the tailored interventions, the physical activity was adapted to the participant's specific needs, or the progression of the activity was personalized by adapting the difficulty, intensity, or frequency level of the activity. Furthermore, individual assessments and feedback systems allowed for continuous adjustment of activities based on performance.

Intervention durations varied from one week up to 288 weeks (Figure 4A). A total of 2 interventions (2/148, 1%) did not report intervention duration. Session duration varied by study from 5 minutes up to 120 minutes (Figure 4B). Session frequency was reported in 119 studies and ranged between one to 21 per week. In 2 studies, the weekly session frequency could be chosen independently. Most sources (87/148, 59%) ranged from one to three sessions per week.

XSL•FO
RenderX

Figure 4. Number of sources stratified by (A). intervention duration (average and SD) and (B) session duration (average and SD). For intervention duration in minutes (min), the average duration and corresponding standard deviation per group is also presented.

The activity intensity was described in only 14% (20/148) of the sources. Of these, 3% (5/148) used Rate of Perceived Exertion, 2% (3/148) the Borg scale, with a further 6% (9/148) of the sources reported intensity in a different manner, eg, the level of the game. Only one source (1/148, 1%) set the intensity at 60% of Heart Rate Reserve, with another 2 sources (2/148,1%) using self-pacing of intensity.

In total, 2 sources (2/148, 1%) did not report on the physical activity used as part of the intervention. The other 146 sources (146/148, 97%) reported 2 to 5 different purposes for the interventions resulting in a total of 296 different purposes. In these interventions, the top 5 purposes were balance (73/148, 49%), muscular strength and power (64/148, 43%), cardiorespiratory fitness (30/148, 20%), functional mobility (28/148, 19%) and general physical activity (25/148, 17%). In 40% (58/148) of the sources, the focus was on one purpose, whereas the majority (88/148, 59%) had on average 3 (min 2, max 5) purposes.

Technology Characteristics

An overview of the technology designs, functions, and interfaces used in the sources is given in Table 2. Below results of the cross-tabulation between technology and population or intervention characteristics are described. All detailed results can be found in Multimedia Appendix 4.

Cross-Tabulation Between Technology and Population

The results of the cross-tabulation between participant characteristics and technology design are presented in Table 3. The cross-tabulation results between participant characteristics and technology function and interface can be found in Multimedia Appendix 4. Exergames were implemented in half of the sources with oldest-old adult participants who are aged 85 years and older. In the sources with middle-old age groups (75 - 85 y), exergames (25/75, 33%) and mobile apps (16/75, 21%) were both frequently used, and alternative designs such as web/video phone call (10/75, 13%) were implemented as well. In sources with youngest-old age groups (60 - 74 y), trackers (18/125, 14%) were more often implemented than in the middle-old or oldest-old age groups (2/75, 3% and 1/18, 6% respectively). In sources where the participant's health status was reported as healthy, 53% (10/19) implemented exergames compared to only 27% (34/127) in sources with participants with a clinical condition. For both health status groups, mobile apps (20%, ie., 4/19 and 24/127) and trackers (11%, ie., 2/19 and 14/127) were likewise implemented. However, sources with participants with a clinical condition also made use of other

XSL•FO
RenderX

technological designs such as computer-based (14/127, 11%), web video/phone call (19/127, 15%) or wearable devices (10/127, 8%). Age and health status did not influence the technological functions or user interface.

Table . Cross-tabulation results for participant characteristic age, health status, and residency versus technology design.

Design	Sum[a]	Computer based	Sound/ video recording systems	Mobile apps	Web/ video phone call	Exer-games	Trackers	Virtual reality	Augmented reality	Wearable devices	Other
AGE											
Youngest old (60 - 74 y)	125	7%	2%	24%	15%	25%	14%	2%	-	6%	4%
Middle old (75 - 85 y)	75	11%	7%	21%	13%	33%	3%	4%	-	7%	1%
Oldest old (>85 + y)	18	11%	6%	11%	6%	50%	6%	-	-	6%	6%
Mixed	3	-	-	-	-	67%	-	-	33%	-	-
HEALTH STATUS											
Healthy	19	-	-	21%	5%	53%	11%	5%	-	-	5%
Clinical condition	127	11%	5%	19%	15%	27%	11%	2%	-	8%	3%
RESIDENCY											
Care Homes	42	10%	5%	7%	2%	50%	7%	10%	-	2%	7%
Community Dwelling	153	9%	3%	24%	18%	26%	10%	1%	1%	5%	3%
Hospital	1	-	-	-	-	-	100%	-	-	-	-
Other	33	6%	3%	24%	6%	21%	3%	18%	-	18%	-

[a]The horizontal rows add up to 100% of the sum in the second column. The other columns represent the percentages of the sum, and the total of each row equals 100%. With abbreviations: Apps, applications; cmnd, command; record., recording; y, years.

In community setting studies, exergames (40/154, 26%) and apps (37/154, 24%) were equally deployed. However, in care homes, half of the sources used exergames. Wearable technology was used frequently in settings where residency was unfortunately not specified, whereas the use of web video/phone call designs was highest (relatively) in community setting studies. Making use of specific functions and interfaces was similarly distributed for community dwelling and care home residents. Only the body movement interface was 34% (21/61) in care homes compared to 25% (59/236) in community settings, probably related to the implemented exergames.

Cross-Tabulation Between Technology and Intervention

The results of the cross-tabulation analyses for purpose of the physical activity and technology are presented in Multimedia Appendix 4. Exergame and mobile app designs were used to achieve improvements for a large range of physiological parameters such as balance, muscle strength, functional mobility, or cardiovascular health. Similar for web video/phone calls, but these technologies were incorporated into the sources to a much lesser amount. Exergames were predominantly used to improve cardiorespiratory fitness (17/41, 41%), neuromotor function (14/29, 48%), mental and cognitive function (16/32, 50%), and fall risk (8/14, 57%). Only enhancement of general physical activity was trained most using trackers (13/39, 33%, eg, for step counting). Regardless of the purpose, the technologies provided continuous information on the activity, feedback, and assessed real-time movement data. These technological functions were achieved through graphical (25% - 30%), body movement (20% - 36%), or auditory and visual (13% - 23%) interfaces with the users.

Tailoring of the intervention's physical activity was observed across all technologies. Hence, incorporating tailoring of the intervention's physical activity did not seem to be related to the type of technology design, function of user interface, and vice-versa.

XSL•FO
RenderX

Outcome Measurements

Adverse Events

In total, 64% (68/148) of the sources reported information on adverse events. Out of these, 72% (49/68) of the sources reported no adverse events, with the other 28% (19/68) reporting a total of 78 adverse events (n=78, 100%) categorized in grade 1 (mild, 40/78, 51%), grade 2 (moderate, 10/78, 13%), grade 3 (severe, 28/78, 36%) events, with none reported in grade 4 (life-threatening) or grade 5 (death).

Of these 78 adverse events, 47 events could be related to the intervention and included 37 mild events, e.g., primarily musculoskeletal pain in joints, 8 moderate events, e.g., rib fracture or COPD-related, and 2 severe events, eg, severe injury due to (bicycle) fall accident. Only 2 adverse events were related to technology and included mild impairments from a skin rash due to Fitbit wearing and nausea due to the Virtual Reality environment.

Dropout and Adherence

Information on dropout and adherence for the intervention groups was reported in 100 sources (68%) and 79 sources (53%), respectively. Information on dropout and adherence for the control groups was reported more sparely in 45 sources (47%) and 16 sources (17%), respectively. While the number of participants for all sources is variable, dropout rates of control groups (14 SD 12%) and intervention groups (16 SD 16%) were similar (t_{34} = −0.648, P=.521). Average adherence tended to be lower in the control groups (71 SD 25%) compared to the intervention groups (80 SD 18%), though this could not be tested statistically due to underreporting in the control group.

In total, the dropout reasons for 815 participants were quantitatively reported. Reasons for dropout were mostly health-related (28%), though these were unrelated to the intervention. Furthermore, dropout participants mentioned time-related issues (17%), such as lack of time or traveling and burden or motivation-related issues (15%) such as lost interest or feeling burdened. Often another reason (17%) was indicated for the dropout, or no reason was mentioned at all (15%). About 5% of the dropout participants were lost due to follow-up issues ascribed to e.g., loss of contact or moving. Only 3% of the dropouts were related to technology: for example, broken computer, internet malfunctioning, lack of device or space.

No differences (t_{98}=−1.209, P=.115, d=−0.252) were found in dropout when interventions were tailored (15 SD 16%) or not tailored (19 SD 14%). A significantly higher adherence (t_{77}=1.995, P=0.025, d=0.455) was found between interventions that were tailored (83 SD 15%) versus those that were not (75 SD 21%). On the contrary, no differences were observed when comparing supervised versus unsupervised interventions, when assessing dropout (t_{98}=-1.374, P=.086, d=−0.275) and adherence (t_{77}=0.606, P=.273, d=0.136).

Sources including participants with reported clinical conditions as health status (18 SD 11% dropout) reported a similar level of dropout rate compared to those who used healthy populations (17 SD 18% dropout), which was nonsignificant (t_{62}=0.063, P=.475, d=0.022). There were no differences between adherence rates when comparing the sources with reported healthy participants versus participants with a reported clinical condition (t_{48}=0.027, P=.489, d=0.010). Differential testing between age groups was not possible, due to the low reported dropout ratios across three age categories, although no trends were observed of dropout rate differences across age categories.

No further relationships were found between dropout or adherence, when regressing against the total number of intervention sessions (R^2=0.012, P=.924) or session duration (R^2=0.001, P=.850).

User Experience

A total of 55 sources (37%) explored the general enjoyment of the technology part of their intervention. An overwhelming 91% reported a positive experience, with a vast minority reporting a neutral or negative experience (7% and 2% respectively).

Only 21 sources (14%) investigated the system usability. The system usability was reported using the System Usability Scale (SUS, N=12, 8%) or other questionnaires, mostly using Likert scales or percentages (N=9, 6%). The reported SUS values ranged from 62 to 90 with an average of 77 (SD 9) indicating okay, good, and excellent overall user friendliness [176]. In several sources (N=2), it was reported that the SUS was assessed, but then the result was not presented.

Regardless of the study design, wishes and needs of the users were seldom (systematically) assessed. When reported, the wishes were related to goal setting, feedback (regarding own or other participants' performance, messages), support (technical, medical), the physical activity (variation, choice of level), the technology (access, comfort, malfunctioning, touch screen), and social setting (in groups, partnering up, avatar look, timing).

Discussion

Principal Findings

This scoping review explores the application of digital technologies in relation to the characteristics of populations (eg, health status), interventions and usability in home-based physical activity interventions for older adults. Analyzing 148 sources, the review finds that technologies like exergames and mobile apps are widely applicable and easy to use across diverse older adult populations, including healthy and those with clinical conditions. These technologies offer continuous features like information about the physical activity programs, feedback, and real-time movement tracking, addressing various goals such as balance, strength, functional mobility, and cardiovascular fitness. Interestingly, technology use did not lead to higher dropout rates, and adherence was significantly higher in tailored interventions. Adverse events directly related to the technology were rare. User evaluations indicated positive feedback regarding the usability and enjoyment of the technology, suggesting its potential to increase physical activity engagement among older adults.

XSL•FO
RenderX

Participants

Our research underscores the growing evidence of technology-based physical activity interventions in home-based environments (community dwelling and care homes) since 2010, with a notable increase over the past five years [177]. Our review revealed that technology-assisted physical activity interventions have been explored among older adults in various age groups and with various health conditions. Given the increasing prevalence of age-related diseases and chronic health conditions among older adults, technology holds promise in promoting physical activity engagement, particularly among those with health challenges [19,25].

The use of technology-assisted physical activity interventions for older adults in hospital settings is limited [178-180]. Initially, this review identified no such studies (N=0), likely due to excluding abstracts mentioning “rehabilitation” in our search. While physical activity interventions in hospitals generally show positive effects on functional decline or hospital-associated disability [3,181,182], Sheerman et al report inconsistent findings [183]. Similarly, technology-assisted interventions in hospitals report mixed results: adherence was high for supervised interactive gaming [180] and activity trackers [178] but low for self-regulated exergames [179]. Furthermore, Laver et al reported improved Time-Up-and-Go test results with no serious adverse events, while Oesch et al noted no balance improvements and 2 adverse events related to pain [179,180].

Studies failed to report participants’ education (only 40 %) and socio-economic status (only 9 %), which are critical factors as lower education and lower socioeconomic status often correlate with lower digital health literacy [184,185]. Lower education influences the level of health literacy in general as well [184], which may influence judgment on the relevance of engaging with health technology [186]. Furthermore, lower socio-economic status has been related to suboptimal access to internet and digital tools [184], e.g., due to costs [187]. Unfortunately, only limited information was reported by the included sources (15%) on access to technology. Also, technology familiarity or e-literacy was poorly reported (15%). Lower education and the lack of familiarization with technology may introduce barriers to the capacity of users to understand and attend a technology-supported intervention and may lead to increased anxiety and dropouts when attending [186-188]. Hence, the limited reporting on such participant characteristics raises concerns about sample bias and the generalizability of results.

Interventions

This scoping review reveals significant diversity in technology-assisted intervention designs, supervision levels, and tailoring. While many interventions are appropriately tailored to the specific needs of older adults and target populations, this tailoring naturally results in variability in intervention durations, session lengths, and frequencies. This does not necessarily indicate a lack of structure but reflects the necessary flexibility in designing interventions that meet individual or group needs. However, the lack of consistent reporting frameworks for these interventions poses a challenge for comparing results across studies. Our findings are consistent with other reviews in the field (eg, [177,189-191]), which also identified significant variability in intervention designs and reporting frameworks. Those reviews, like ours, emphasize the importance of individualization and tailoring as the key components in ensuring that interventions are effective, but the absence of standardized reporting makes it difficult to evaluate the relative success of these programs. Particularly, the underreporting of intervention intensity poses a significant challenge, with only 14% of sources detailing intervention intensity using varied methods. This is unexpected since technology can easily track and report intensity, providing both motivation and precise data for older adults. For instance, studies using Kinect systems and wearables like Fitbit have shown potential in accurately tracking activity intensity, enhancing engagement and usability [192-194].

Technologies

In the sources we reviewed, exergaming emerged as the most used approach, featuring 53% of interventions for healthy populations and 27% for clinical groups. Despite most exergaming applications targeting younger populations [195,196], our scoping review identifies a significant shift towards older users, with exergames implemented in half of the sources involving participants aged 85 and above. The findings support and build upon previous research suggesting the utility of exergames in promoting physical activity, cognitive enhancement, and overall well-being in the older population [11]. Furthermore, the diversity of exergame intervention contents highlights a comprehensive strategy for addressing age-related challenges such as cardiorespiratory fitness (41%), neuromotor functions (48%), mental and cognitive abilities (50%), and reducing falls (57%).

Our findings also indicate that while exergames and mobile applications are the primary technologies used in these physical activity interventions, web video and phone call technologies or wearable devices also play a role, albeit less prominently. Especially in the clinical population, more often other designs than exergames were used compared to the interventions performed with healthy older adults. These other forms of technology design, offering a more passive interaction than the dynamic engagement found in exergames, may not be as prevalent but are nonetheless vital. Older, or more prone older adults may prefer and benefit from their easy set-up and simple usage [197-199]. Their integration highlights their significance within a comprehensive technological intervention framework, which aligns with effective telehealth components like text messaging for education and reminders, web-based content for goal-setting, and interactive platforms for health data exchange [200].

In advocating for the integration of technology in physical activity interventions, our review highlights the pivotal role of technology functions and user interfaces, as supported by Bentlage et al. (2023), who stress their essential contribution to improve the activation factors skills, knowledge, and motivation, yielding effective behavioral change [20]. We pointed out the primary technological functions as the continuous provision of physical activity information (28%), performance feedback (28%), and the recording of real-time

XSL•FO
RenderX

movement data (26%). Such continuous and synchronous activity information offers users an immersive, enjoyable, and engaging experience [201], fosters regular habits [202], can facilitate the visualization of their movements, and significantly increase their motivation [203]. Enhancing user engagement and overcoming engagement barriers can be achieved by using advanced technology to incorporate different user interfaces, preferably multiple types [20,204]. While graphical or body movement interfaces were prevalent in many sources (each 63%), alternative user interfaces were limited (ie, 41% visual/auditory, 27% menu driven, and 16% command line).

Notably, the tailoring of intervention exercises or activities did not significantly influence the choice of technology design, function, or user interface. This might indicate that the deployed technological solutions are versatile and adaptable across various intervention needs without requiring significant modifications [205,206]. Moreover, our review emphasizes a shift towards personalized interventions tailored to individual or group needs, with 63% of interventions adopting this approach (versus 37% with a generic approach). This shift aligns with emerging evidence suggesting the effectiveness of personalized strategies in promoting adherence and achieving positive health outcomes among older adults [207].

Technology-Related Outcomes

Technology engagement and adherence to protocols are tightly linked to the usability, enjoyment, and effectiveness of physical activity-based interventions [208]. Yet only a slight majority of studies reported on dropout and adherence rates, whereas an even smaller number reported on reasons for dropout or (reduced) adherence. Despite the Consolidated Standard of Reporting Trials (CONSORT) [209] statement and TIDieR (Template for Intervention Description and Replication) [32] guidelines dating back to 2010 and 2014, and the relevant Standard Protocol Items: Recommendations for Interventional Trials (SPIRIT) 2022 extension [210], there is still a lack of consistency of reporting.

Sources that reported the reasons for dropout among participants primarily cited health-related issues, with only a few instances attributed to technology usage, underscoring the older participants' willingness and engagement with home-based technology. Such instances of technology-related dropout (3%) were predominantly due to technological failures, connectivity issues, or general disinterest. These findings are consistent with recent studies, which also identified a lack of motivation and low familiarity with technology as key barriers to its implementation in older adults [15,23,211]. Furthermore, tailored interventions resulted in significantly higher adherence than control interventions. This underscores that it is imperative to adapt the technology to the preferences and needs of the target aging population [22,23,197-199,212-214]. To achieve suitable technological approaches, a generative co-design framework, could be used to overcome technological barriers in an aging population, as suggested by Bird et al [215].

Strengths and Limitations of This Scoping Review

Adopting a common vocabulary and definition of terms is challenging in research on technology-assisted physical activity interventions, which can be the intersection of medicine, physiotherapy, engineering and informatics, sensor and gaming technology, and even psychology and social sciences. Though challenging, we discussed and agreed upon definitions and vocabulary usage at each phase of the review. Furthermore, multiple protocols and double-blind scoring were incorporated in most phases of the review process to ensure consistency [216]. The relatively large number of screeners and extractors involved may be considered a potential limitation. However, the screening, data extraction, and data analysis tools were carefully prepared and discussed within the group, and conflicts were solved with a third independent reviewer or group discussions.

Regarding the included sources, most of the reviewed studies were from highly developed and advanced countries. In addition, the sources included in this scoping review often failed to describe the used technology in sufficient detail to allow for replication of the design, function, and/or user interface. For example, exergames rely on an often bilateral interaction between the user and the system. However, the inputs (eg, handheld devices, sensors, video cameras) are poorly described on how these were adapted for use. Valenzuela et al 217 explored older adults' experiences using an interactive cognitive-motor step training program. Yet, there is no clear description of how the interface has been adapted for their specific user group. Other sources assumed prior or even in-depth knowledge of commercial exergaming setups used within the intervention, avoiding interpretation of the data or replicability due to unknown use of commercial games (Wii-Fit), body movement recognition through three-dimensional camera setups (Xbox Kinect), or not clearly described engagement elements of online video calling for physical activity class delivery (eg, Yoga via Zoom calls) [218,219].

This review has been carried out in a systematic and transparent manner [220]. However, we have not conducted a quality assessment or risk of bias of the included sources. Therefore, we cannot use the results of the included sources to draw significant conclusions on intervention effects on health outcomes.

Recommendations

There is no compelling reason to exclude specific older populations from home-based, technology-assisted physical activity interventions, as factors such as age, health status, and residency do not appear to negatively impact dropout rates, adherence, or result in technology-related adverse events. However, evidence regarding the use of such technologies in hospital settings remains limited. Vulnerable older adults, in particular, could benefit significantly from these interventions, as reduced physical activity during hospitalization often leads to functional decline and a loss of independence in daily activities at discharge. Regardless of the setting, the design of technology-assisted interventions must account for the physical and cognitive impairments commonly observed among older adults, which may result in a mismatch between their abilities and the demands of the intervention or technology [186]. Careful tailoring of both the intervention and the technology is therefore essential. For example, participatory design processes that

XSL•FO
RenderX

engage older adults directly can ensure better alignment with their needs and preferences [215]. Our review highlights that tailored approaches are associated with significantly higher adherence rates. Furthermore, feedback from older adults highlights their strong preference for tailored approaches, indicating that tailoring is not only beneficial but also actively desired by older adults. To improve the accessibility and impact of these interventions, training to enhance health literacy (knowledge of the intervention's relevance) and digital literacy (competence in using the technology) should be incorporated during both the recruitment and intervention phases. Developing clear recruitment guidelines may further promote inclusivity. Digital literacy barriers, often linked to low education levels and socioeconomic status, remain significant challenges to technology adoption and engagement [184,186-188]. To address this, technical support—either private or as part of the intervention—should be provided, aligning with preferences expressed by older adults in user feedback. Lastly, behavioral change techniques that enhance skills, knowledge, and motivation should be integrated into the design of technology-assisted physical activity interventions [20]. Feedback mechanisms, such as performance-based metrics, functional ability assessments, and real-time health data (eg, movement intensity), are currently underutilized, appearing in less than one-third of interventions. Implementing such features could encourage behavioral change and fulfill the desires for actionable feedback, as reported by older adults.

Furthermore, future research should prioritize transparent reporting. The participant's health status, including co-morbidities, mental and physical impairments, and activity level, as well as technology experience, should be recorded. The intervention design, including purpose, duration, intensity, supervision, and tailoring, should be well described. The technology design, functions (including consideration of behavioral change techniques), and user interface should be described in detail. Lastly, intervention and technology-related outcomes such as drop-out, adherence, adverse events, and feedback on user experience should be reported. Guidelines for the development of technology-assisted physical activity interventions in older adults with various health conditions may lead to conformity and could contribute to better designs engaging older adults. Such guidelines may improve the effectiveness of the interventions and make studies better comparable by adequate reporting. The latter results in a deeper understanding of user preferences and advances the development of tailored technology-assisted interventions.

Conclusions

The review suggests that using technology in physical activity interventions is feasible for all older adults in community dwellings and care homes, without additional risks of adverse events or dropouts. Furthermore, generally higher adherence was reported in technology-assisted interventions, which was significantly higher where interventions were tailored. Interventions were delivered to all older age groups, as well as those with and without clinical conditions and in a wide range of physical activity topics. The technology approaches for home-based physical activity interventions were found to be safe and enjoyable for older adults with acceptable usability. Despite the large number of sources that have been identified in this article, the lack of standardized reporting limited a more in-depth analysis of the main research question. Therefore, there is a need to update reporting guidelines for technology-specific interventions in this area.

Abstract

Background: People with dementia commonly display behavioral and psychological symptoms, which have multiple negative consequences. Artificial intelligence–based technologies (AITs) have the potential to support earlier detection of the behavioral and psychological symptoms of dementia (BPSD). The recent surge of interest in this topic underscores the need to comprehensively examine the existing evidence.

Objective: This scoping review aimed to identify and summarize the types and uses of AITs currently used for the early detection of BPSD among people diagnosed with the disease. We also examined which health care professionals were involved, nursing involvement and experience, the care settings in which these technologies are used, and the characteristics of the BPSD that were assessed.

Methods: Our scoping review was conducted in accordance with the Joanna Briggs Institute manual for scoping reviews. Searches were conducted in March 2025 in the following bibliographic databases: MEDLINE ALL Ovid, Embase, APA PsycINFO Ovid, CINAHL EBSCO, Web of Science Core Collection, the Cochrane Library Wiley, and ProQuest Dissertations and Theses A&I. Additional searches were performed using citation tracking strategies and by consulting the Association for Computing Machinery Digital Library. Eligible studies included primary research involving people with dementia and examining the use of AITs for the detection of BPSD in real-world care settings.

Results: After screening 3670 articles for eligibility, the review includes 12 studies. The studies retained were conducted between 2012 and 2025 in 5 countries and encompassed a range of care settings. The AITs used were predominantly based on classic machine learning approaches and used information from environmental sensors, wearable devices, and data recording systems. These studies primarily assessed behavioral and physiological parameters and focused specifically on symptoms, such as agitation and aggression. None of the retained studies explored nurses' roles or their specific skills in using these technologies.

Conclusions: The use of AITs for managing BPSD represents an emerging field of research offering novel opportunities to enhance their detection in various health care contexts. We recommended that nurses be actively engaged in developing and assessing these technologies. Future research should prioritize investigations into how effective AITs are across diverse populations, whether they can have a long-term impact on managing BPSD, and whether they can improve the quality of life of patients and caregivers.

Introduction

Background

The growing prevalence of dementia is a major global concern [1]. As the disease progresses, cognitive decline is often accompanied by the behavioral and psychological symptoms of dementia (BPSD) [2,3]. The International Psychogeriatric Association defines the BPSD as disturbances in perception, thought content, mood, or behavior [4]. These symptoms can be grouped into two subtypes: (1) behavioral symptoms, which are typically observed directly (agitation, verbal or physical aggression, wandering, sexual disinhibition, repetitive behavior, catastrophic reactions, sundowning, sleep problems, sleeplessness, and apathy), and (2) psychological symptoms, which are usually assessed through interviews with patients and relatives (psychosis, delusions, hallucinations, misidentifications, mood changes, anxiety, restlessness, and depression) [2,4]. BPSD has a deleterious impact on the quality of life of people with dementia, accelerating cognitive decline, reducing life expectancy, and precipitating hospitalizations and early placement in nursing homes [5,6]. Managing patients' BPSD often requires constant vigilance, leading to heightened stress and depressive symptoms among informal caregivers. Furthermore, indirect costs, including medical consultations, nonreimbursed medication, home adaptations, and reduced professional activity, can lead to substantial socioeconomic burdens [7-9]. For health care professionals, BPSD can increase workloads, stress, and the risk of professional burnout, which may reduce the quality of the care provided [10,11]. Regarding the health care system overall, BPSD leads to higher costs due to more consultations, hospitalizations, and prescriptions of psychotropic drugs [12].

The etiopathogeneses of BPSD are complex and multifactorial, influenced by biopsychosocial and environmental factors, and vary considerably in frequency and intensity between individuals [13,14]. Their early detection through the identification of subtle behavioral and psychological changes (eg, apathy, anxiety, sleep problems, irritability, and social withdrawal), before any formal clinical intervention, is of major clinical importance [15,16]. Early identification enables proactive management and personalized interventions, thereby helping to mitigate the symptoms' deleterious impact. However, early detection is challenging as early signs are often transient, underrecognized, and misinterpreted as normal aging or personality changes [15,16]. Furthermore, standard detection tools, such as the Neuropsychiatric Inventory, the Alzheimer's Disease Behavioral Pathology Assessment Scale, or the Cohen-Mansfield Agitation Inventory, can be time-consuming, and health care professionals do not always perceive them to be precise or practical [11,14,17]. These challenges are exacerbated by growing demands for care and persistent shortages of qualified health care staff [18,19]. New health care technologies offer promising solutions to these challenges [20,21].

Recent technological developments have focused on artificial intelligence–based technologies (AITs), which combine artificial intelligence (AI) with remote sensors, robotics, and decision support algorithms [21-24]. AI encompasses a wide range of techniques and methodologies designed to enable computer systems to mimic human cognitive functions, such as learning, problem-solving, and decision-making [24]. When combined with critical thinking and human judgment, AI can optimize clinical reasoning by accelerating and refining assessment, anticipation, the synthesis of multiple data sources, and knowledge generation [25]. In health care, AI is already applied in diagnosis and screening, treatment personalization, patient monitoring, robot-assisted surgery, and health system management [22]. In dementia care, current AITs include monitoring systems, social robots, and daily living assistance tools, primarily involving wearable and environmental sensors [26-28]. These technologies have shown positive impacts on depression, quality of life, social engagement, cognitive function, and patient monitoring [26-28]. They have also demonstrated good performance in health monitoring and dementia screening [26-28].

Management of BPSD requires a multidisciplinary team, with nurses playing a key role in the early detection of symptoms, thanks to their continuous proximity with patients [4]. However, due to the complexity of these symptoms and the diversity of beliefs and conceptualizations regarding BPSD, it is not uncommon for nurses' clinical judgments to be based on intuition and their standard practice rather than on a clear, standardized methodology [29,30]. This underscores the potential for introducing AITs to support clinical judgment and thus enhance the quality of nursing care for people with dementia. Registered and advanced practice nurses have been actively helping to develop and implement AITs in health care [31-33]. They engage in activities including problem-solving, defining contextual needs and formulating priorities, idea generation, finding concrete solutions, and determining end user satisfaction [31-33].

While previous reviews have examined the use of AITs in the care of patients with dementia and BPSD, their scope differed from this work [34-38]. Husebo et al [37] focused on treatment monitoring, and Jao et al [35] emphasized model performance without mapping contexts of use. AI has evolved rapidly since 2020, and it is likely that new solutions, not covered in these reviews, have now emerged. More recently, other authors have addressed the use of AITs in the general care of those with dementia and BPSD, combining prediction, assessment, and treatment, but without a specific focus on early detection [34,38]. Similarly, Shaik et al [36] reviewed remote sensing technologies and care frameworks without focusing on the application of AITs for the early detection of the BPSD. Our preliminary literature searches identified no completed or ongoing scoping reviews on the topic. Given the rapid evolution of AITs and their growing integration into dementia care, an updated and targeted synthesis of the literature is necessary.

Aim and Review Questions

This scoping review aimed to identify and summarize the different types of AITs currently available for the early detection of BPSD among older adults. It also sought to examine the functional uses of those technologies, the health care professionals involved, nursing involvement and experience with AITs, the care setting in which they are used, and the

XSL•FO
RenderX

characteristics of the BPSD they assess. Our research questions were developed following the population, concept, and context framework. First, what type of AITs are currently available for the early detection of BPSD among people with dementia? Second, what are the functional uses of the AITs involved in the early detection of BPSD? Third, which health care professionals are involved in the use and implementation of AITs for the early detection of BPSD? Fourth, in which care settings are AITs used for the early detection of BPSD? Which specific characteristics of BPSD do AITs assess? Finally, what are nurses' specific roles, responsibilities, and experiences regarding the use of AITs for the early detection of BPSD?

Methods

Protocol and Registration

This scoping review was conducted in accordance with the Joanna Briggs Institute manual for scoping reviews [39]. The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews; checklist provided in Checklist 1) standards were followed for reporting [40]. The scoping review's protocol was registered at the Open Science Framework [41].

Eligibility Criteria

The eligibility criteria for studies with the potential to be assessed in this review were defined based on their population, concepts, and types of sources. The inclusion and exclusion criteria are detailed in Table 1.

XSL•FO
RenderX

Table . Scoping review inclusion and exclusion criteria.

Criteria	Inclusion criteria	Exclusion criteria
Participants	• Studies involving people aged 65 y and older with any dementia (eg, Alzheimer disease, frontotemporal dementia, vascular dementia, and Parkinson dementia).	• Studies involving individuals with mental disorders other than dementia (eg, mild cognitive impairment, depression, delirium, schizophrenia, and bipolar disorder).
Concept		
Artificial intelligence: techniques and methodologies designed to enable computer systems to mimic human cognitive functions, such as learning, problem-solving, and decision-making [24]. Other terms: "computational intelligence," "computer reasoning," "machine learning," and "machine intelligence."	• Studies involving all types of devices and software based on AITs[a] to screen, detect, and assess clinical BPSD[b].	• Studies focusing on AITs intended for the prediction or management of symptoms or diseases (eg, type and stage of dementia, psychiatric disorders, chronic illnesses, and acute conditions).
BPSD: Disturbances in perception, thought content, mood, or behavior [4].	• Studies involving all types of clinical BPSD: agitation, aggression, verbal aggression, physical aggression, psychosis, delusions, hallucinations, misidentifications, repetitive behavior, wandering, sundowning, restlessness, catastrophic reactions, sexual disinhibition, mood changes, depression, apathy, anxiety, sleep problems, and sleeplessness [4].	• Studies that did not use scales rating BPSD to report psychological symptoms.
Context		
(1) Acute care: Immediate and intensive treatment services provided within the health care system to address severe, sudden and often unforeseen health episodes: emergency medicine, trauma services, prehospital emergency response, acute surgical care, critical care units, urgent care, and short-term stabilization of patients in an inpatient setting [42]. (2) Community care: social support services and programs designed to empower individuals with specific needs—including those with intellectual disabilities, mental health challenges, and older adults—to lead independent lives and actively engage in their communities [43]. (3) Long-term care: support services aimed at addressing the health and personal care needs of individuals who are unable to manage daily activities independently: home-based care, community care and residential care [44].	• Studies involving acute care, community care, or long-term care from any country.	• Studies involving virtual environments.
Types of sources	• Experimental and quasi-experimental studies; • Analytical and descriptive observational studies; • Qualitative and mixed methods studies.	• All types of reviews: narrative reviews, integrative reviews, scoping reviews, systematic reviews, umbrella reviews, and bibliometric analyses; • Opinion letters; • Commentaries; • Books and book chapters.

[a]AIT: artificial intelligence–based technology.

[b]BPSD: behavioral and psychological symptoms of dementia.

Information Sources and Search Strategy

In March 2025, we conducted a literature search of the following bibliographic databases in collaboration with a medical librarian (JRA): MEDLINE ALL Ovid, Embase, APA PsycInfo Ovid, CINAHL EBSCO, Web of Science Core Collection, the Cochrane Database of Systematic Reviews Wiley, the Cochrane Central Register of Controlled Trials Wiley, and ProQuest Dissertations and Theses A&I. No language or date restrictions were applied. The final search strategies were peer-reviewed by a second information specialist and are documented in Multimedia Appendix 1, detailing the search syntax, keywords, and index terms used. Using the studies that were retained, we performed a backward and forward citation search using

XSL•FO
RenderX

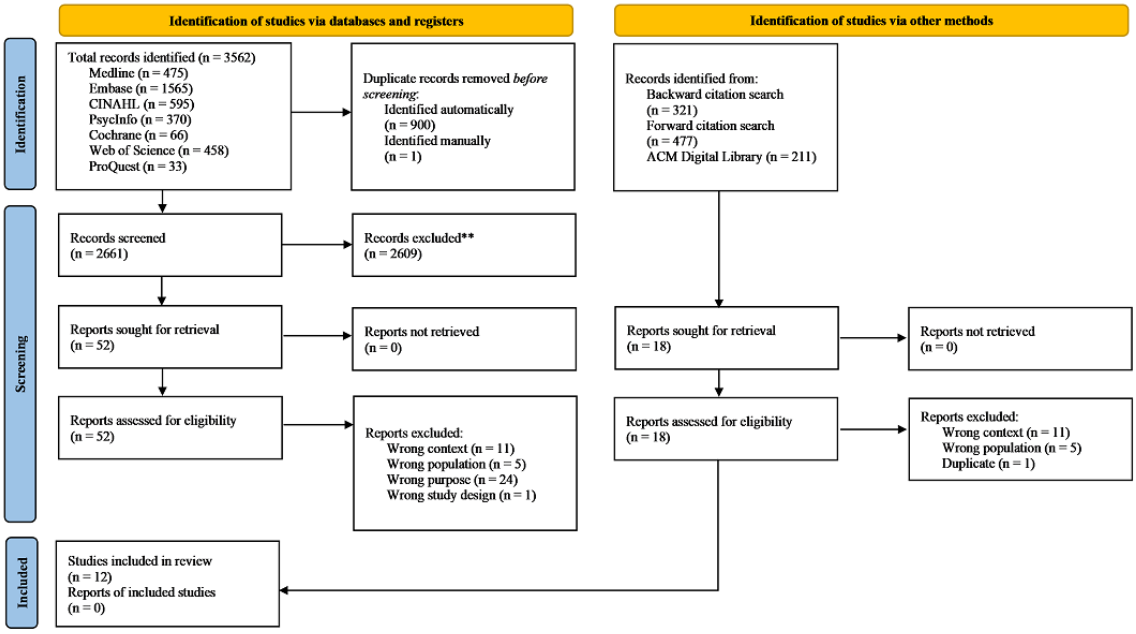
Citationchaser [45] (SF). Further research was carried out in the Association for Computing Machinery Digital Library (SF).

Study or Source of Evidence Selection

After the search, a medical librarian (JRA) imported all the references identified into EndNote 20 (Clarivate Analytics), and duplicate references from the databases were removed using Deduklick (Risklick AG) [46]. The references were then imported into the Rayyan interface, and 2 reviewers (SF and CGdR) independently screened the titles and abstracts according to the established inclusion criteria. All the potentially relevant sources were retrieved in full and imported into a database. Two reviewers (SF and EP) then independently assessed the full texts of the references retained to ensure they met the inclusion criteria. The rationales for excluding references at the full-text review stage were documented. Disagreements between the reviewers during this selection process were discussed and resolved with the assistance of a third reviewer (HV). Due to resource constraints, the selection of references identified through citation tracking was conducted by a single reviewer (SF). The results are presented in a PRISMA-ScR flow diagram [47].

Data Extraction

Data from the references retained for the scoping review were extracted by a single reviewer (SF), and a random 10% subset of the full-text articles included was verified by a second reviewer (HV) to ensure accuracy and completeness [48]. The second reviewer cross-checked the completed data extraction tool's results against the corresponding full-text articles. Data were extracted using a data extraction tool developed in accordance with the study's objectives and search questions. The data extracted included the year of publication, country of origin, study characteristics (design, objectives, sample size, health care setting, and health care professionals), participant characteristics (age, sex, and dementia type and severity), specific types of the AITs (sensors, social robots, and decision support systems), delivery methods for these AITs (remote monitoring platforms and mobile apps), the functional purposes of these AITs, the AI techniques applied, characteristics of the BPSD assessed, the traditional instruments used for detecting BPSD, nurses' involvement and experience, and key findings relevant to the review questions (eg, effectiveness, usability, feasibility, users' satisfaction with AITs, users' perspectives about AITs, and barriers and facilitators to adopting AITs). When necessary, study authors were contacted to request missing or additional data.



Data Analysis and Presentation

We use a narrative approach to present the extracted and analyzed evidence in the different sections below [39]. The sections include (1) the characteristics of the included studies, (2) the types and uses of AITs, (3) the characteristics of the BPSD detected, and (4) the involvement and experience of nurses. The types of AITs were analyzed and categorized according to the definitions proposed by Zhang and Lu [49], which distinguish the different drivers and technologies of AI. Tables, charts, and diagrams are used to summarize and make the evidence more readable.

Results

Our bibliographic database searches identified 3562 publications. After removing 901 duplicate records, 2661 publications underwent title and abstract screening. Of these, 2609 were excluded for not meeting our inclusion criteria, and 41 of the 52 full-text articles assessed for eligibility were excluded. Following the recommendation of an expert, 18 full-text articles were found using citation searching and a search of the Association for Computing Machinery Digital Library; however, after assessing them for eligibility, 17 were excluded. The scoping review finally retained 12 articles [50-61] (Figure 1).

RenderX

Study Characteristics

The 12 studies reviewed came from 5 countries and were published from 2012 - 25. Over half of the studies were published in the last 5 years (2020 - 2025) [50-56]. They included 3 single case studies [53,57,58], 2 studies using quasi-experimental approaches [52,59], 1 randomized controlled trial [60], 1 correlational study [61], 1 exploratory observational study [54], 3 retrospective longitudinal studies [50,55,56], and 1 qualitative study [51]. Furthermore, 3 publications examined acute care settings [52,57,61], 6 examined community care settings [50,54,55,58-60], and 3 examined long-term care settings [51,53,56].

The study participants included groups of older adults with mean ages ranging from 78.8 to 84 years old and presenting with mild to advanced dementia. Although 1 study [51] did not involve participants with a confirmed diagnosis of dementia, it was retained due to its focus on the implementation of a behavioral disturbance detection system in long-term care settings, which predominantly serve people with dementia. As such, it provided valuable contextual insights relevant to integrating such technologies into dementia care. Most of the health care professionals included in the studies were nurses [51-54,56,57], followed by physicians [53,56,57], care workers [51,56], a rehabilitation assistant [51,56], an occupational therapist [51,56], and a physiotherapist [51,56]. Table 2 describes the main characteristics of the studies retained.

XSL•FO
RenderX

Table . Characteristics of the studies retained (n=12).

Study, country	Design (aim)	Sample size (N)	Health care setting	Health care professionals involved	Participants (age, sex, dementia type, and severity)
Bafaloukou et al [50], United Kingdom	Retrospective longitudinal study (develop a machine learning framework able to identify episodes of agitation).	63	Community care (home)	—[a]	Age: N/P[b], sex: female (n=22), male (n=41), dementia: Alzheimer, vascular frontotemporal, Parkinson
Bourennane et al [57], France	Single case study (describe experiments to detect deviations in a patient's behavioral observations using a multi-sensor).	1	Acute care (Alzheimer's care unit)	Physicians and nurses	Age: mean 84 y, sex: female, dementia: Alzheimer
Choukou et al [51], Canada	Qualitative case study (explore the perceptions of healthcare professionals and family members about the potential for introducing a behavioral disturbances detector in long-term care homes).	8 health care professionals and 1 proxy	Long-term care (tertiary care facility)	Nurses, care workers, rehabilitation assistants, occupational therapists, and a physiotherapist	Age: N/P, sex: female (n=9), dementia: N/P
Enshaeifar et al [59], United Kingdom	Quasi-experimental, interrupted-time series (detect patterns directly correlated with agitation, irritation, and aggression in people with dementia).	12	Community care (home)	—	Age: N/P, sex: N/P, dementia: mild to moderate
Iaboni et al [52], Canada	Quasi-experimental, interrupted-time series (develop personalized machine learning models capable of detecting individual patterns in BPSD[c]).	17	Acute care (specialist dementia unit)	Nurses	Age: mean 78.9 (SD 8.9) y, sex: female (n=10), dementia: advanced
Kim et al [53], South Korea	Single case study (detect a dementia patient's abnormal behavior using sensors and developing a machine-learning-based system).	1	Long-term care (nursing homes)	Physicians and nurses	—
König et al [61], France	Correlational (investigate whether automatic speech analysis could be used to characterize and detect apathy).	60	Acute care (hospital memory clinic)	—	Age female with apathy: mean 79.50 (SD 5.86) y, age male with apathy: mean 79.58 (SD 5.45) y, dementia: N/P
Lee et al [54], South Korea	Exploratory observational study (investigate a predictive model for sleep efficiency and its associated features among older adults living with dementia in their own homes).	69	Community care (home)	Nurses	Age sleep efficiency >85%: mean 80.15 (6.11) y, Age sleep efficiency <85%: mean 80.64 (4.63) y, sex: N/P, dementia: N/P

XSL•FO

Study, country	Design (aim)	Sample size (N)	Health care setting	Health care professionals involved	Participants (age, sex, dementia type, and severity)
Lotfi et al [58], United Kingdom	Single case study (design unobtrusive activities in a daily living monitoring system for identifying and predicting abnormal behavior).	1	Community care (home)	—	Age: N/P, sex: female, dementia: N/P
Palermo et al [55], United Kingdom	Retrospective longitudinal study (identify episodes of agitation among people living with dementia using a deep recurrent model applied to continuous in-home monitoring data).	Total=46 (33 for training, 8 for validation, and 5 for testing)	Community care (home)	—	Age: mean 82.6 (SD 7.2) y, sex: N/P, dementia: Alzheimer, frontotemporal, vascular, Parkinson
Rostill et al [60], United Kingdom	Randomized control trial, parallel groups (test the technology integrated health management system in a real-world setting).	204 patients and 204 carers	Community care (home)	—	Age: N/P, sex: N/P, dementia: mild to moderate
Zhu et al [56], Australia	Retrospective longitudinal study (determine the prevalence of agitated behaviors among people with dementia using natural language processing).	3528	Long-term care (nursing homes)	Nurses, care workers, and other health care professionals (eg, physicians and therapists)	Age: N/P, sex: female (n=2267), male (n=1261), dementia: N/P

[a]Not applicable.

[b]N/P: not provided.

[c]BPSD: behavioral and psychological symptoms of dementia.

AITs and Their Use

Data Collection

Most of the studies adopted a multimodal input approach, combining 2 or more data types. In total, 6 studies reported on combinations of environmental sensors and wearable devices [50,53-55,57,59,60] and 1 study used wearable devices with video cameras [52]; 2 studies relied on signal data, referring to continuous, time-series measurements, captured through voice recorders or environmental sensors [58,61]. Voice recorders were not classified as wearable devices as they were set in fixed positions during structured interviews rather than being worn continuously for passive data collection. One study used structured data derived from an electronic health care records system [56]. The studies used a variety of environmental sensors, including passive infrared sensors or motion detectors, door and window entry point sensors, electricity power usage sensors, and bed and sofa pressure sensors. Wearable devices included wristbands, smartwatches, sweat patches, and GPS trackers integrated into textiles or attached to the body. These devices were equipped with sensors collecting motion data via accelerometers, monitored sleep patterns through actigraphy, and recorded other structured data, such as blood volume pulse, electrodermal activity, transpiration, and skin temperature. Smart thermometers and smart scales were used to collect physiological data, including body temperature, body composition, and heart rate. Furthermore, 4 studies reported using wireless technology systems to communicate between the various devices [53,57,58,60].

AI Learning Processes and Approaches

Supervised learning processes were used in 7 studies in which models were trained on labeled datasets to predict specific behavioral outcomes [50,52-55,58,61]; 2 studies used unsupervised learning approaches aiming to discover patterns or clusters within unlabeled data [56,59], while 1 study adopted a hybrid process combining both supervised and unsupervised methods [57]. Most of the studies relied on machine learning techniques, including algorithms such as random forest, logistic regression, k-nearest neighbors, decision trees, support vector machines, LightGBM, and CatBoost [50,52-54,56,57,59-61]. Only 2 studies applied deep learning methods, specifically recurrent neural networks and long short-term memory networks [55,58]. Table 3 provides an overview of the main data sources, AI techniques, learning processes, and AI approaches reported in the studies selected.

[a]AI: artificial intelligence.

[b]Machine learning is a set of algorithms that learn patterns from data using manually engineered features, often applied to structured datasets [24].

[c]Deep learning uses artificial neural networks to automatically learn hierarchical feature representations directly from raw data [24].

[d]Not applicable.

[e]N/P: not provided.

Data Availability and Visualization

Of the total, 2 studies included used cloud-based systems to retrieve data from devices and transmit them to AI-driven analytical platforms [53,60], while 1 study used the Zigbee communication protocol to transmit data [57]. Furthermore, 5 of the studies retained made their data derived from AI available and visualized it on secure web portals [55,57-60]. In comparison, 1 study used a mobile health app [53]. In addition, 6 studies described the use of AITs with alert systems triggered by the detection of abnormal behavior [50,53,55,57,59,60]; 4 studies reported using AITs to identify abnormal behavior without an alert system [52,56,58,61]. The studies retained in our analysis defined abnormal behavior heterogeneously, and 4 studies defined it as a deviation from the established norm in each participant's profile [53,57-59]. These deviations were characterized by different behavioral features, and their nature varied across studies, with 2 focusing on movement in specific rooms or living areas [57,58], 2 focusing on agitation [57,59], and 1 focusing on repetitive questions, behaviors, and sleep profiles [53]. None of these 4 studies provided any specifications regarding the variance defined by the norm. The principal elements of the interventional studies are outlined in Table 4.

XSL•FO
RenderX

Table . Principal elements of the interventional studies.

Study	Intervention duration	Device used	Intervention description
Bafaloukou et al [50]	27 mo	• Passive infrared sensors and door and kitchen appliance sensors • Bed mattresses	• Weekly behavioral monitoring questionnaire to report the presence or absence of participants' behavioral symptoms. • Traffic light system (interactive interface), grouping estimates of the probability of agitation produced by the model.
Bourennane et al [57]	30 d	• Wearable tag with an inbuilt GPS tracker • Infrared and pressure detectors in bed mattresses	• Wireless communication technology system to relay data to a central computer in the nursing staff area. • Abnormal behavior: hyperactivity, deviations from the standard means[a] for patient movements through common living areas by time of day and for agitation profiles from the past 30 d. • Alerts sent via SMS text messages to caregivers' mobile phones.
Enshaeifar et al [59]	6 mo	• Passive sensors: 2 passive infrared sensors, 4 motion sensors, 2 pressure sensors, 1 door sensor, and 1 central energy consumption monitoring device • Bluetooth-enabled medical devices	• Anomaly detection of outlying values[a] for agitation, irritation, and aggression during daily activities. • Alerts were generated on a secure web portal and verified by the clinical team by contacting the caregiver.
Iaboni et al [52]	8 wk	• Wristband (Empatica E4) • Video cameras installed in common living areas	• Customized machine learning models to classify the presence of behavioral symptoms by type (aggression and agitation).
Kim et al [53]	30 d	• Smartwatch • Lifelog sensors attached to assorted pieces of furniture	• Wireless communication technology system interacting between a smartwatch and lifelog sensors. • Abnormal behavior: repetitive questions or behaviors and sleep disturbances. • Multilayer perceptron machine learning model determined the presence or absence of abnormal behavior. • Alerts were transmitted to the smartphones of physicians and nurses via an app.
Lee et al [54]	14 d	• Wristband (Actiwatch2 [Respironics, Inc]) • Sweat patches (PharmChek [SCRAM Systems])	• Sleep efficacy analysis: actigraphy for sleep and physical activity, sweat patch for cytokines. • Machine learning analysis to select the sleep efficiency prediction model and exploration of its top 10 associated features. • Categorical boosting machine learning algorithm based on decision trees.

XSL•FO
RenderX

Study	Intervention duration	Device used	Intervention description
Lotfi et al [58]	18 mo	• JustChecking wireless motion sensor in the kitchen, bedroom, bathroom, and living room • Door entry point sensors in the front and back doors	• Abnormal behavior: deviations from the standard mean[a] for the length of time spent in a specific area of the house. • Recurrent neural networks to analyze data with results transmitted to caregivers via a secure web interface.
Palermo et al [55]	27 mo	• Motion and tracking sensors (multiple doors, hallway, kitchen, and other rooms) • Home appliance use, smart plugs (kitchen appliances, television, and other commonly used devices) • Wearable device • Smart temporal thermometer • Smart scale	• Digital platform to integrate and analyze data. • Data labeled as true (episode of agitation validated by a clinical monitoring team) or false (not an episode of agitation when the monitoring team contacted participants). • Recurrent neural networks are used to analyze the risk of episodes of agitation.
Rostill et al [60]	6 mo	• Sensors • Vital signs monitors • GPS tracker • Gateway device	• Machine learning algorithm to analyze data. • Alerts generated and prioritized on a digital dashboard and followed up by a centralized monitoring team overseen by clinicians. • Alert follow-up process: contact caregivers and, if necessary, liaise with other services (social care teams, Alzheimer's Society, and emergency services).

[a]Defined threshold not available.

AI Model Performance

Of the total, 8 studies reported that their AI model performed well in identifying and classifying distinct types of BPSD [50,52-56,59,61]. The performance metrics used included accuracy, precision, recall, F_1-score, and area under the curve, as they are commonly defined in the literature [62]: accuracy refers to the proportion of correctly classified instances among all instances; precision measures the proportion of true positives among all positive predictions, while recall reflects the proportion of true positives correctly identified among all actual positives; the F_1-score is the harmonic mean of precision and recall, balancing both metrics, the area under the curve indicates the model's ability to distinguish between classes across all thresholds. The parameters used and their corresponding scores are described in Table 5.

XSL•FO
RenderX

Table . Performance of the artificial intelligence models used in the retained studies.

Study	Model or algorithm	Performance metrics, mean (SD)				
		Accuracy	Precision	Recall	F_1-score	AUC[a]
Bafaloukou et al [50]	Gradient boosting algorithm	mean 71.3 (SD 7.21)	mean 71.81 (SD 7.94)	N/P[b]	mean 71.12 (SD 7.28)	mean 77.63 (SD 6.59)

The Adoption of AITs

In total, 2 studies reported that the participating health care professionals found AITs useful in helping them understand patients' health statuses [51,60]; 1 study reported that its participants perceived the use of AITs to be feasible [54]. Another study documented how the majority of its participants, both caregivers and patients, accepted and would have given a favorable recommendation on using the AIT under evaluation [60]. These positive perceptions were primarily linked to the devices' ease of use and the involvement of a clinical monitoring team to interpret the data generated by the system. Indeed, the few nonendorsements of that AIT were attributed to technical issues, user-perceived difficulties with device use, and the perceived inconvenience associated with the routine monitoring of vital signs. One study identified forgetfulness, refusal, and a lack of cooperation as the primary factors contributing to patients not adhering to their wearable device protocol [54]. Technical problems, such as battery discharge, software errors, device malfunction, and detection failures were also reported as contributing factors [54]. One study referenced future potential AIT users' perceived requirements for successfully incorporating AITs into clinical environments [51]. These included the necessity for training, the standardized use of technical devices and giving priority access to them to nursing and care staff. Furthermore, that study indicated that those potential AIT users had concerns about data confidentiality and the costs associated with AITs [51].

Characteristics of the BPSD Detected

The studies retained for analysis reported their assessments of specific behavioral and physiological parameters acting as surrogate markers of BPSD. Regarding behavioral parameters, 6 studies assessed motion [50,52,53,55,57,60], 4 assessed activities of daily living [53,55,56,58], 1 assessed sleep efficiency [54], and 1 assessed speech quality [61]. Regarding physiological signs, 5 studies assessed vital and biological signs (blood pressure, heart rate, body temperature, blood oxygenation, weight, and hydration) [50,52,55,59,60]. One study measured electrodermal activity [52], while another study examined patients' levels of cytokines, such as interleukin-6 and interleukin-10 [54]. One study examined environmental factors associated with BPSD, such as indoor light levels and ambient temperature [50].

Furthermore, 2 studies focused on detecting the 3 specific BPSD, that is, agitation, irritation, and aggression [59,60]; 3 studies examined agitation alone [50,55,56], while another concentrated on detecting agitation and aggression [52]. In addition, 1 study investigated apathy as a distinct form of BPSD [61], and another concentrated on sleep efficacy [54].

Regarding the use of specific scales for detecting and measuring BPSD, 4 studies used the Neuropsychiatric Inventory [50,52,54,61], and another combined the Neuropsychiatric Inventory with the Apathy Inventory [61].

One study indicated that biological parameters, including blood pressure, blood oxygen, heart rate, body temperature, and hydration, were the most significant markers for detecting agitation, irritability, and aggression [60]. Another study identified heart rate and body temperature as the principal markers for verbal aggression, while an accelerometer reading was the most significant marker for physical aggression [52]. One study identified respiratory rate, number of nocturnal awakenings, and the indoor light level as the most important

XSL•FO
RenderX

characteristics for identifying agitation [50]. Table 6 summarizes this information.

Table . Characteristics of the behavioral and psychological symptoms of dementia found in the studies retained for analysis.

Sign of BPSD[a]	Types of BPSD		
	Agitation or aggression	Apathy	Sleep problems
Behavioral	• Sleep • Daily activity pattern • Sequence of daily activities • Movement activity patterns	• Paralinguistic markers	• Physical activity • Percentage of time awake • Total sleep duration • Daytime sleep minutes • Nocturnal sleep minutes • Sleep regularity
Physiological	• Blood pressure • Heart rate • Blood volume pulses • Oxygen saturation • Electrodermal activity • Body temperature • Weight • Hydration	• None	• Interleukin-6 • Interleukin-10

[a]BPSD: behavioral and psychological symptoms of dementia.

Nurses' Involvement and Experience

Only 3 of the studies retained clearly described nurses' roles in identifying BPSD [51,52,54]. One documented their participation in data collection, specifically documenting episodes of BPSD [52]. Another study described their involvement as participants in a group of health care professionals and the exploration of their perceptions of the potential use of AITs in clinical practice [51]. In research contexts, nurses were part of the research team in 1 study [52] and led the design and implementation of another [54]. None of the retained studies reported on the extent of nurses' knowledge, skills, and experience in the use of AITs.

Discussion

Principal Results

This scoping review highlighted how AITs are emerging and being used for the early detection of BPSD, as evidenced by the limited but growing number of publications over the past 5 years (between 2019 and 2025). Despite this limited body of literature, the studies retained were diverse in terms of design, care environment, and health care professional involvement, as well as in terms of their study populations' characteristics, and this provided a more comprehensive understanding of the various approaches to using AITs in the care of people with dementia.

The studies included in this review encompassed the domains of acute, community, and long-term care and included several types of health professionals, such as physicians, nurses, home care workers, and therapists. Only one of the studies included explored the integration of AITs from an interprofessional perspective, highlighting potential benefits such as improved communication and more proactive care [51]. These findings aligned with previous reviews highlighting AITs' roles in enabling real-time clinical decision-making and interdisciplinary data sharing [36,38]. However, health care professionals also expressed concerns about how the challenges of implementing AITs might hinder their successful adoption in daily practice, such as workflow disruptions, overreliance on technology, threats to professional identity, costs, and data privacy [51]. These concerns, also reported in previous literature [36,63,64], involve organizational, technological, professional, and cost issues. Identifying these barriers early on is therefore essential to guiding implementation strategies and systems design, thereby enhancing the usability, acceptability, and integration of AITs, particularly in complex interprofessional settings such as dementia care.

Regarding data collection systems and devices, many of the retained studies reported on the combined use of environmental sensors and wearable devices [52,53,55,57,60]. It should be noted that the innovation in these studies does not lie in the use of particular devices or the application of AI, as both have been used before in dementia care settings, particularly to monitor and enhance cognitive function, as well as to track daily activities and physiological parameters [26,28,36,64-66]. Distinctive innovation lies in integrating data collected by these devices with an AI-based analysis specifically aimed at identifying and generating alerts for episodes of BPSD. While similar integrations have been explored in broader smart health monitoring contexts, their targeted use for the early detection of BPSD remains largely underexplored [26,37,38]. These findings are consistent with those reported in previous reviews, which also mentioned mobile apps, text analysis systems, and robots [27,36-38]. For instance, Shaik et al [36] reported on the use of robots capable of monitoring patient behavior. However, none of the studies included in our review used robots specifically for the detection of BPSD, reflecting a broader trend where AITs form parts of psychosocial interventions rather than acting as early detection tools [34].

The variety of connectable devices is particularly interesting, offering health care professionals the flexibility to tailor technologies to care objectives, patients' preferences, and

XSL•FO
RenderX

context-specific needs. Concerning communication systems and data visualization, most of the studies retained used wireless technologies and a secure web portal, reflecting the growing integration of the Internet of Medical Things in health care [53,57-60]. This type of infrastructure enables real-time data transmission and storage, supporting remote monitoring and system interoperability [67]. Using wireless systems facilitates technological integration by reducing the physical constraints that can be particularly relevant for people with dementia, as restrictive or obtrusive devices could cause distress or resistance [68]. However, device acceptability varied across the studies retained, reflecting the mixed findings reported in previous literature [27,36,67]. Acceptability was primarily judged according to ease of use [51,54,60], consistent with previous reviews that also emphasized the importance of simple, intuitive interfaces [27,36]. Regarding device design, 1 study on wearable devices reported their overall feasibility [54]. However, this contrasted with the conclusion by Loveys et al [27], who identified several barriers to acceptance, including discomfort when wearing devices, intrusiveness due to continuous monitoring, and sleep disturbances caused by bed sensors. Another study involving wearable devices similarly reported such inconveniences, particularly a feeling of being constantly monitored [60], in alignment with the barriers described by Loveys et al [27]. Additional concerns included technical issues and forgetting to wear the device [51,60]. These findings are consistent with previous literature [27,36,67] and further reinforce the importance of anticipating such barriers early on in the system design process to improve the user experience and support successful implementation in dementia care settings.

None of the studies included used advanced data storage and sharing systems (such as edge computing) that can improve security and enable the offline functionalities that are important in settings with limited or unreliable internet access, such as in home care or remote regions. While data security remains a major concern in the Internet of Medical Things, AI offers promising support. As Messinis et al [69] stated, machine and deep learning techniques can enhance cybersecurity. However, in the studies reviewed, AI was primarily used for data analysis in research contexts rather than being fully integrated into clinical practice.

Most of the studies retained used classic machine learning to classify or detect BPSD, training models on labeled data to identify predefined behaviors [50,52-55,58,61]. This reflects a broader trend in early-stage research, where annotated datasets are key for model development and validation [35,36].

While some of the studies retained defined abnormal behaviors as deviations from individual baselines, alerts for the occurrence of BPSD were not systematically triggered at fixed thresholds [53,57-59]. Instead, detection often relied on adaptive methods, such as multivariate pattern recognition or unsupervised learning algorithms that adjusted to individual variations over time. These approaches are particularly well-suited to the heterogeneity and fluctuation of BPSD [13,14] and have the added advantage of requiring few or no labeled data, making them suitable for real-time and continuous monitoring [24,70]. In parallel, some studies used expert validation to verify the accuracy or clinical relevance of alerts, either through retrospective review by clinicians [55,57,60] or the integration of rule-based insights during model development [52,53,59]. One study combined supervised and unsupervised techniques to enhance adaptability to individual patterns and clinical relevance, thus supporting a flexible, person-centered approach [57].

The studies retained for review assessed behavioral and physiological parameters as signs of the BPSD, with most being behavioral parameters, including movement and the activities of daily living [50,52-58,60,61]. Regarding specific BPSD, agitation, irritability, aggression, and apathy were the most frequently investigated [50,52,55,56,59-61], with biological parameters and accelerometer data being the most significant markers for detecting them [52,60]. This particular focus may be explained by the clinical urgency and disruptive nature of these symptoms, which place a significant burden on care staff and often require rapid intervention [5,71,72]. Furthermore, these behaviors tend to generate observable and measurable physiological signals, making them more technically accessible to current AITs. These findings were consistent with previous reviews, one of which also highlighted wandering as a distinct type of BPSD commonly targeted by AITs [35,36]. However, this trend underscores the need to assess how effectively AITs can capture the broader spectrum of BPSD, particularly those that are less externally visible, lack distinct physiological markers, and may manifest more gradually over time, such as anxiety, mood-related symptoms, or apathy.

Overall, the algorithms developed across the retained studies demonstrated a good ability to detect the BPSD targeted. This observation aligned with the findings of other reviews, which report the promising detection or classification accuracy of AITs in dementia care contexts [35,36]. However, some limitations must be considered, as they constrain the generalizability of our findings. These include the small sample sizes used in certain studies and the limited occurrence of behavioral events, which may have affected the robustness of algorithm training. Furthermore, although the diversity of study settings and populations represents a strength of the current body of evidence, the heterogeneity in study contexts and their definitions of abnormal behaviors may have limited their comparability and the broader applicability of our findings.

Although nurses represented the majority of the health care professionals included in the studies retained, their knowledge, skills, and experiences of using AITs to detect the BPSD remain undocumented. Given their central role in detecting and managing BPSD, the lack of insight into how nurses interpret algorithmic outputs, respond to alerts, and integrate AITs into their clinical reasoning raises concerns about the clinical relevance, acceptability, and long-term sustainability of such technologies. Only 2 studies included nurses in their research teams, and only one of those was clearly led by nurse researchers [52,54]. The absence of nursing-specific expertise in the development process may result in technologies that are misaligned with real-world care dynamics, increase the risk of misinterpreting AIT-generated alerts, or inadvertently add to workloads rather than reducing them. These findings appear to contradict the existing literature, which emphasizes nurses' active involvement in developing and implementing AITs in

XSL•FO
RenderX

diverse settings and domains of care, including geriatric care [31,33].

Implications for Practice and Research

Given the lack of studies examining the efficacy of AITs for detecting the BPSD, recommendations regarding their use remain limited and cannot be generalized to clinical practice. Furthermore, the heterogeneity of devices, data types, and analytical approaches hinders the establishment of standards and limits the development of evidence-based recommendations.

Nevertheless, the proliferation of AITs in clinical and care environments is an emergent phenomenon that cannot be overlooked. To ensure that these technologies are properly understood, safely integrated, and clinically meaningful, it is essential to develop core competencies and critical awareness of AITs at an early stage. In parallel, assessing health care professionals' readiness to provide feedback for training is equally important as it allows educational initiatives to be tailored to existing knowledge, expectations, and perceived needs. This effort should be grounded in an interprofessional perspective, as the implementation and interpretation of AIT outputs typically involve diverse professional disciplines, including nurses, physicians, and allied health staff. Frameworks, such as the conceptual framework for digitally supported communication, coordination, cooperation, and collaboration model, which emphasizes communication, coordination, cooperation, and collaboration, may provide a useful basis for aligning technological solutions with clinical goals, care contexts, and each profession's roles and responsibilities [73].

Building on this foundation, several actions are needed to support the effective and ethical integration of AITs into dementia care. Educational institutions should reinforce curricula in digital health literacy, algorithmic reasoning, and AI ethics across health care professions, including training on how to interpret algorithmic outputs and assess system reliability. In clinical settings, interprofessional training (through workshops, simulations, or case reviews) can foster shared understanding and critical reflection on AIT use [63]. Health care institutions should identify clinical champions to liaise with developers, support day-to-day integration, and promote peer learning [74]. Beyond health care and academic institutions, the development of these competencies should be supported by professional and regulatory bodies, including organizations issuing evidence-based practice guidelines, as well as geriatric and psychogeriatric associations, which can help contextualize AIT within ethical and clinical standards. Experts in long-term care can also contribute to preparing position statements and evaluation frameworks. From a research perspective, promoting nurse-led, co-designed research is essential to ensure that technological solutions are aligned with the day-to-day realities of care and person-centered values. Evidence shows that nurse-led research, especially by advanced practice nurses, improves care quality, successful implementation, and health system efficiency [75,76]. These efforts are particularly needed in settings where AITs are already being piloted, such as in long-term care and psychiatric units, to ensure safe, supported, and meaningful deployment from the outset.

Most of the studies retained used classic machine learning techniques, with only 2 exploring advanced methods like deep learning, which offers a greater capacity to model complex, temporal, and heterogeneous data [24,77]. Although some studies combined behavioral and physiological data, only 1 [55] applied deep learning to such multimodal inputs, suggesting that this is an underexplored area of research. The use of deep learning to explore the interactions between internal physiological states and external behavioral manifestations of the BPSD holds promise for enhancing the sensitivity, robustness, and contextual adaptability of detection systems. This is particularly relevant given the fluctuating and multifactorial nature of the BPSD. For instance, a review by Wu et al [78] showed that deep learning–based multimodal emotion recognition models outperformed conventional models by integrating behavioral, vocal, and physiological inputs, enabling a more robust and accurate interpretation of emotional and behavioral states.

However, the application of deep learning in health care raises well-known challenges, including a lack of transparency about analysis and prediction process, the limited interpretability of outputs, and a loss of clinical trust [24,74,79]. One promising strategy to address these concerns is the adoption of explainable AI approaches. These rely on techniques such as local interpretable model-agnostic explanations, which help clarify prediction accuracy, and Deep Learning Important FeaTures, which enable traceability by comparing neuron activations to reference states [24]. Promoting such approaches is essential to ensure that AI-driven decisions are not only technically reliable but also aligned with human values and ethical standards.

Furthermore, the practical value of advanced models depends not only on technical performance but also on feasibility and user acceptance. However, limited attention has been given to clinical and contextual factors, such as comorbidities, medication use, functional status, care environments, or staff ratios, which can all affect the expression and detection of the BPSD [2,79-82]. This reflects the exploratory nature of early-stage studies, which prioritized technical development, algorithmic performance, and system functionality. As previously highlighted, several studies also reported barriers to device acceptability, further underscoring the need for future research to consider issues involving clinical complexity and contextual variability.

In this regard, it is important to explore whether and how advanced methods, such as deep learning, can adapt to such variability and enhance the detection of BPSD. Multisite experimental studies should be conducted to assess the robustness and generalizability of algorithms across diverse care settings. Furthermore, the diversity of technological approaches used to detect BPSD highlights the need for experimental or quasi-experimental comparative studies to determine which AITs offer the most effective and reliable outcomes. Such evidence is critical for guiding clinical decision-making and future technological development based on proven efficacy.

In addition, mixed methods studies incorporating user-centered evaluations (such as perceived usefulness, usability, workflow

XSL•FO
RenderX

integration, perceived technical performance, and interprofessional communication) and guided by implementation frameworks may offer valuable insights into how contextual factors shape technical outcomes and clinical integration while helping to anticipate potential barriers to adoption. Finally, longitudinal studies will be essential to assess AITs' long-term impact on the detection and management of the BPSD, on the quality of life of people with dementia and their informal caregivers, on health care professionals' workloads, and on overall cost efficiency.

Limitations

This review had some limitations. The number of relevant publications was relatively limited compared with other reviews on the use of AITs in dementia care [34,36-38], which is probably attributable to AI's relatively recent integration into the management of the BPSD. During our study screening process, a substantial number of publications referenced the use of AITs to detect dementia and evaluate functional status. However, some studies may have involved the BPSD without using this explicit terminology, which could have resulted in their exclusion during the selection of references. Also, no formal quality appraisal of the studies included was performed, as per standard scoping review methodology. However, eligibility criteria and dual screening helped ensure relevance. Despite addressing several dimensions of this topic, the overall lack of available data limited our exploration of other important contextual factors, such as costs, the availability of AITs, and health care infrastructure. This, too, restricted the scope of our recommendations.

Conclusion

The use of AITs for the early detection of BPSD represents a rapidly emerging field of research with the potential to significantly enhance the quality of dementia care. This scoping review highlighted the diversity of AITs explored across various care settings, reflecting promising new avenues for improving the detection of BPSD. However, their clinical efficacy remains to be demonstrated. Future research should evaluate whether AITs support earlier and more accurate detection of BPSD, reduce symptom severity or duration, and improve the quality of life of people with dementia and their informal caregivers. Studies should also examine AITs' impacts on clinical decision-making, care coordination, and workload management—across diverse populations and care contexts—to ensure relevance and generalizability.

To support their meaningful integration, nurses must be more actively involved in developing and evaluating these technologies. Their clinical expertise and proximity to patients make them key stakeholders in assessing the applicability of these tools in clinical settings. Their contribution should be strengthened through participatory design approaches, inclusion in pilot implementation studies, and interprofessional collaboration throughout the development cycles of new AITs.

The successful integration of AITs into dementia care will depend not only on technical innovation but also on inclusive, clinical, context-sensitive research strategies that can provide robust evidence of their impact in everyday practice.

Abstract

Background: Global aging presents significant socioeconomic and health challenges, particularly for older adults who face an increased risk of chronic diseases and reduced physical activity levels. Although physical activity is crucial for maintaining health, most older adults do not meet the recommended guidelines. Gamification and mobile health (mHealth) technologies offer innovative solutions to motivate physical activity; however, research focusing on older adults is limited, especially regarding the effectiveness and sustainability of such interventions.

Objective: This study aims to synthesize evidence on the effectiveness of mHealth-based gamified interventions for improving physical activity in older adults.

Methods: This systematic review followed Preferred Reporting Items for Systematic Reviews and Meta-Analyses and Meta-Analysis of Observational Studies in Epidemiology guidelines and analyzed studies from PubMed, Embase, Web of Science, CINAHL, Scopus, and Wiley Online Library, covering relevant literature from their inception up to May 2025. The inclusion criteria focused on gamified mHealth interventions for adults aged 60+ years, excluding serious games. Quality assessment was conducted according to the Joanna Briggs Institute standards, with data extracted on study design, gamification elements, and outcomes such as step counts and moderate-to-vigorous physical activity.

Results: Of 2944 studies identified from the database search, 1454 individuals from 8 trials were included. Gamified interventions significantly increased daily step counts and time spent in moderate-to-vigorous physical activity among older adults. Goal setting and rewards were the most frequently used components, and the combined use of mobile and wearable devices offered greater flexibility and accessibility. A classification framework indicated that interventions integrating multiple gamification elements with hybrid technology systems were most effective, particularly when guided by a theoretical basis. However, the heterogeneity in study designs, small sample sizes, and lack of long-term follow-up studies limited the generalizability of the findings.

Conclusions: mHealth-based gamification interventions demonstrate potential for increasing physical activity in older adults. Future interventions should consider employing multifaceted designs combining advanced gamification with hybrid technology systems, while also prioritizing theoretical integration, long-term sustainability, and caregiver involvement to improve sustainability and inclusivity. This review highlights the need for theory-driven, technology-mediated strategies that address the unique health needs of older adults.

Introduction

The issue of global aging is becoming increasingly pronounced. According to United Nations statistics, by 2050, the global population aged 60 years and older is projected to reach 2.1 billion, accounting for 22% of the total global population [1]. The aging of the population not only has a profound impact on the socioeconomic landscape but also presents substantial challenges in the health management of older adults. As

XSL•FO
RenderX

individuals age, they commonly experience rising rates of chronic diseases, declines in physical function, and reductions in cognitive abilities—factors that collectively affect their quality of life and capacity for self-care [2].

Research indicates that daily physical activity plays a crucial role in maintaining the physical and mental health of older adults. Moderate exercise can significantly reduce the risk of chronic diseases such as cardiovascular disease, diabetes, and osteoporosis, while also promoting cognitive function and mental well-being [3]. However, the reality is that the daily activity levels of most older adults fall far below the recommended health guidelines. A sedentary lifestyle has become a prevalent issue, and insufficient physical activity accelerates functional decline, significantly increasing the risk of falls, disability, and social isolation [4]. Thus, identifying effective strategies to enhance the physical activity levels of older adults is a critical issue that requires urgent attention in public health.

Gamification, as an innovative behavioral intervention strategy, has garnered increasing attention in health promotion in recent years. Gamification involves incorporating game design elements—such as points, leaderboards, progress bars, and badges—into nongame contexts to motivate and enhance positive user behavior [5]. Existing studies have shown that gamification-based interventions are highly effective in promoting health behaviors, rehabilitation training, and chronic disease management, significantly improving participants' motivation and adherence [6-8].

Mobile health (mHealth) refers to a comprehensive technological system that employs mobile devices, sensors, and digital media technologies for health monitoring, disease management, and health promotion [9]. Compared to traditional gamified interventions, mHealth gamified interventions provide remote health management and real-time feedback and integrate personalized, adaptable health content. This enables older adults to engage in health activities more flexibly within their daily routines. Moreover, the widespread use of mobile devices allows this intervention model to reach a broader population of older adults, particularly in home care and telemedicine settings, where its advantages are particularly pronounced [10].

Although gamified interventions combined with mHealth technology show considerable potential in enhancing the activity levels of older adults, challenges such as cognitive decline, lower education levels, and limited digital proficiency among older adults have hindered their broader adoption [11,12]. As a rapidly growing group of technology users, older adults have unique needs and face significant challenges, but they are expected to undergo a phase of rapid development in the near future. However, there is currently a lack of systematic quantitative research that comprehensively evaluates the actual effects of gamified interventions on the physical functioning and activity levels of older adults. Therefore, synthesizing existing empirical studies into a systematic review to clarify their effectiveness and applicability holds significant academic and practical value.

Specifically, this study focuses on the following core issues:

1. Does gamification based on mHealth offer advantages over traditional interventions in promoting physical activity in older adults?
2. What are the most frequently used gamification elements and mHealth types in the existing studies?
3. Is the process of gamification design integrated with behavioral or other related theories or principles?
4. What factors may affect the feasibility and effectiveness of gamified interventions for older adults?

Methods

Overview

The reviewed protocol was developed and approved by all authors prior to initiation. It complies with all recommendations from the systematic review, strictly adhering to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist and Meta-Analysis of Observational Studies in Epidemiology guidelines [13]. Literature searches were performed across the following databases: PubMed, Web of Science, Embase, CINAHL, Scopus, and Wiley Online Library. The search period spanned from each database's inception until May 20, 2025. This study was registered with the International Prospective Register of Systematic Reviews (PROSPERO; registration number CRD420251056689).

Search Strategy

In most studies on gamification, younger individuals are typically the primary target group for game-based interventions due to their generally higher sense of self-efficacy and greater experience with digital gaming. In this context, the study initially focused on the research subjects and intervention measures but overlooked other retrieval elements when designing the retrieval strategy. However, during the subsequent literature screening, these overlooked elements will be reassessed and evaluated. To maximize the breadth of the search, the study selected the keywords "gamification," "game elements," and "elderly" and refined the retrieval strategy by incorporating a combination of controlled vocabulary, natural language terms, and synonyms, in accordance with the requirements of different databases. An additional file shows the search strategy in more detail (Multimedia Appendix 1).

Literature Inclusion Criteria

To ensure that the analyzed literature aligns with the objectives and to mitigate the impact of conceptual confusion on the validity of the research results, this review clarifies the distinction between serious games and gamification, incorporating this differentiation throughout the literature selection process. Gamification refers to the integration of game elements, such as points, leaderboards, and progress bars, into nongame environments to enhance user engagement and motivation through game-like experiences, without altering the nature of the tasks. For example, in rehabilitation training for older adults, adding a reward system or virtual progress bar can extend training time [14].

Serious games, on the other hand, represent a comprehensive design approach that provides an immersive gaming experience, with the primary goal of education, training, or therapy, rather

XSL•FO
RenderX

than entertainment. They are sometimes referred to as purpose-driven games (eg, virtual reality rehabilitation training games for older adults) [15,16]. However, the distinction between these 2 concepts may be ambiguous and subjective. When these concepts cannot be clearly differentiated, the research team engages in discussion and makes a final decision.

The studies included in this systematic review must meet the following criteria: (1) studies targeting older adults with a mean age ≥60 years and minimum age threshold aligned with World Health Organization functional aging criteria (typically ≥55 y). When the exact minimum age was unreported, statistical estimation (mean − 2SD) confirmed ≥90% of the participants met age criteria. (2) The use of gamification or at least 1 game element is clearly specified. Serious games (eg, video games, immersive virtual reality games, and augmented reality games) or studies that merely mention gamification without analysis are excluded. (3) Gamification is implemented through digital devices such as tablets, smartphones, or wearables. (4) At least 1 change related to physical or social activities is described, which may be presented as subjective self-reports or objective measurement indicators. (5) The study is original empirical research (must be experimental in nature). Review articles, research proposals, guidelines, policy documents, and research programs are excluded. (6) Only peer-reviewed, published papers in English are included, including doctoral dissertations and conference papers.

Quality Assessment

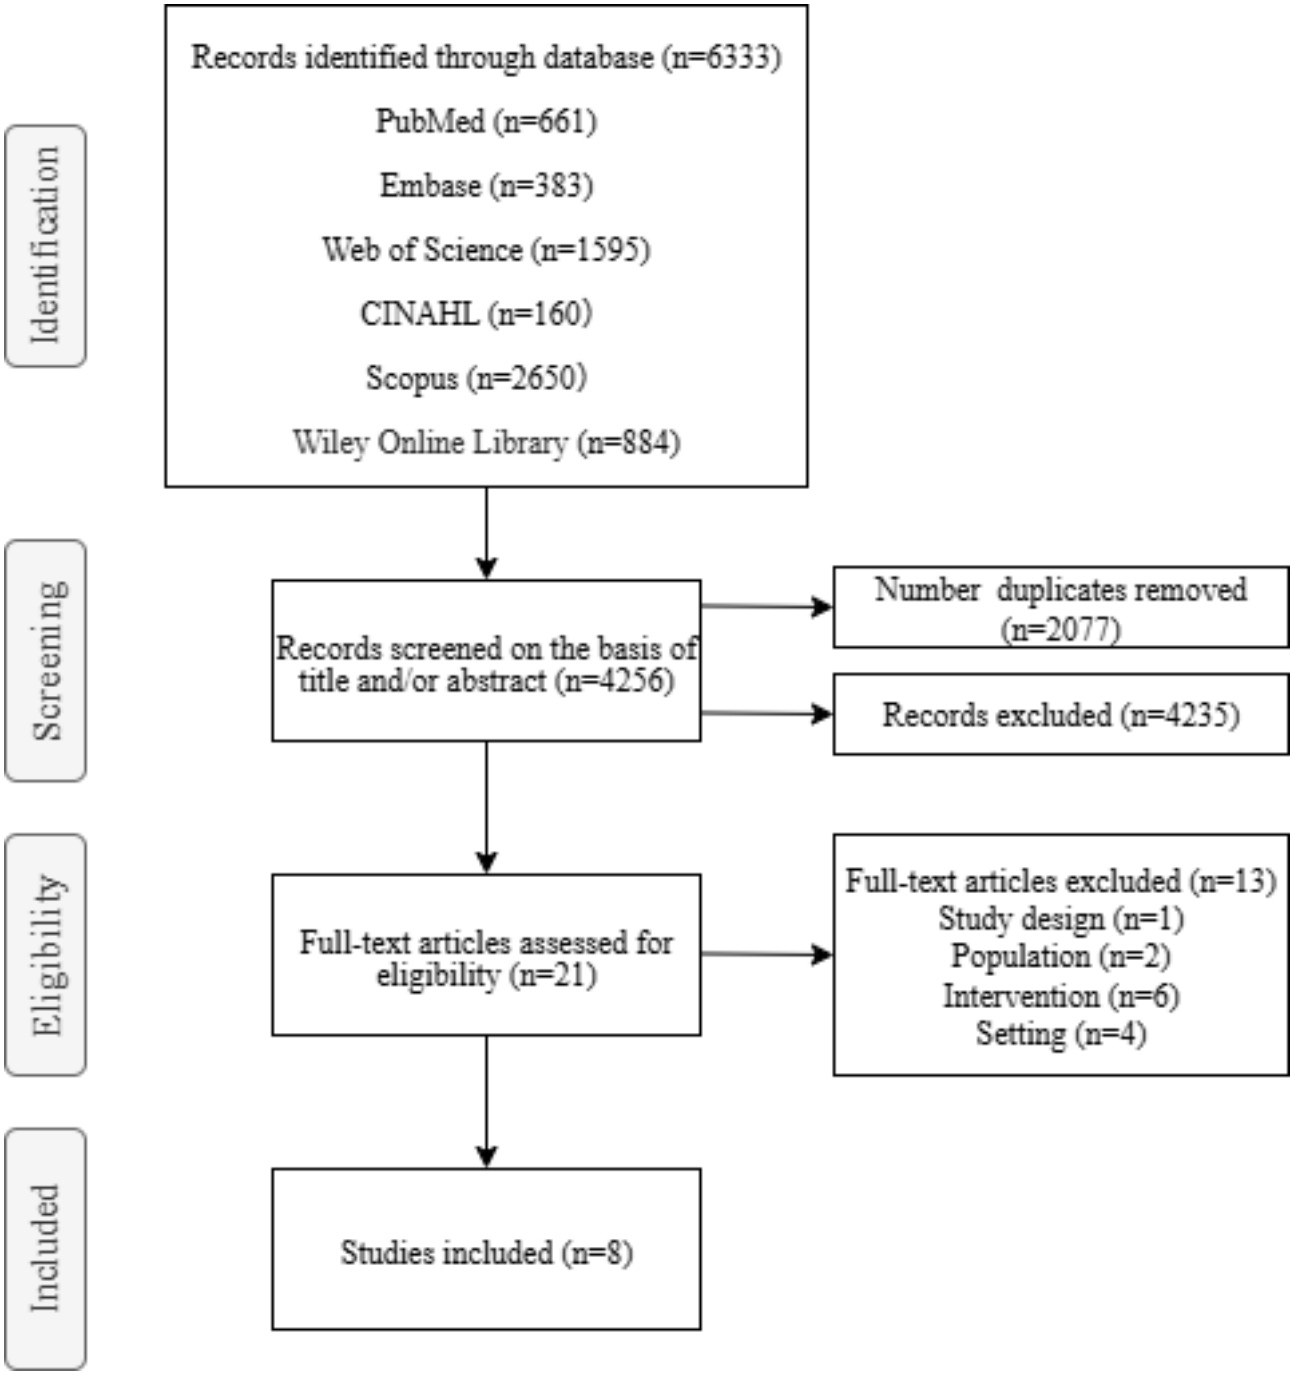
The research team conducted quality assessments of the studies that met the inclusion criteria, following the quality assessment standards established by the Joanna Briggs Institute [17,18]. There are 13 criteria for evaluating randomized controlled trials (RCTs) and 9 criteria for evaluating quasi-experimental studies. Studies that meet at least 50% of the assessment criteria are accepted for review. For RCTs, the research team decided to exclude the blinding of researchers and participants from the quality assessment, as blinding is considered impractical in the context of gamified interventions. Any disputes are resolved through discussions with a third-party investigator to reach a final consensus.

Data Extraction and Analysis

Two researchers independently extracted data from the selected studies using standardized forms based on the content of the literature. The extracted data included the first author's name, publication year, country, study design, subject characteristics (sample size, mean age, and gender distribution), intervention characteristics (study setting, type of equipment, and duration), gamification characteristics (game name, game elements, and theories used), primary and secondary outcomes related to physical activity, and a summary of the research conclusions. Any disputes were resolved through discussions with a third-party investigator to reach a final consensus.

Due to substantial methodological and reporting differences that prevented quantitative data synthesis, we conducted a narrative synthesis organized by the PICO framework to systematically summarize the findings of the studies.

To systematically address heterogeneity in gamification elements and technological platforms, we developed a dual-axis classification framework. The first dimension categorizes interventions by gamification complexity, distinguishing basic designs employing 1 or 2 core game elements from intermediate configurations integrating 3 or 4 elements, and advanced systems incorporating 5 or more interactive components. The second dimension classifies technological integration into standalone mobile apps, hybrid systems combining mobile apps with wearable devices, and wearable-centric approaches relying primarily on sensor technology. This framework enables structured cross-study comparisons while acknowledging inherent methodological variations.



Results

Search Outcomes

A total of 6333 records were identified. After removing 2077 duplicate entries using EndNote, the remaining 4256 records were screened by title and abstract. Following rigorous assessment, a substantial number of records were excluded, primarily due to ineligible age, nonphysical activity focus, or the others (Multimedia Appendix 2). Subsequently, 21 articles were initially included. Reviews, clinical record comparisons, case reports, and other literature that did not meet the inclusion criteria were excluded based on their titles and abstracts. Following a more detailed examination of the full text, 13 articles were further excluded for not meeting the inclusion criteria. An additional file shows this in more detail (Multimedia Appendix 3). Ultimately, 8 studies [14,19-25] were included in this review. The search results are presented in Figure 1.

Study Characteristics

The studies selected for this review were conducted between 2018 and 2024 in Sweden [14], Portugal [19], Japan [20,21,24], Brazil [21], and the United States [23,25]. At least 5 studies [14,22-25] were randomized controlled trials, while 3 studies [19-21] were quasi-experimental studies. Sample sizes ranged from 12 to 1062 participants, with a total of 1454 participants. The average age of participants ranged from 62 to 81.5 years, with a higher percentage of women. At least 4 studies [20-22,24] included community-dwelling older adults, 1 study [14] included participants with musculoskeletal conditions, 1 study [23] included participants at risk of cardiovascular disease, 1 study [25] included participants at risk of Alzheimer disease, and 1 study [19] did not specify participant characteristics or the gender ratio. A summary of the participants, measures, interventions, controls, and outcomes is presented in Table 1.

[a]RCT: randomized controlled trial.

[b]IG: intervention group.

[c]CG: control group.

Risk of Bias

The quality assessment scores for the RCT studies ranged from 7 to 10 points (Table 2). All 5 studies employed randomization; however, the concealment of treatment group allocation was unclear in 3 studies. Due to the nature of the intervention, blinding of participants or personnel was not possible. In 3 studies [23-25], outcome assessors were blinded to the treatment allocation. Control of confounding factors was unclear in 1 study [14]. The average score was 9/11, indicating that all the RCT studies demonstrated high methodological quality.

The 3 quasi-experimental studies each received a score of 6 points (Table 3) for methodological quality. In 1 study [21], the age of participants in the 2 groups was not similar, and the characteristics of health status and technical proficiency were not clearly presented. The criteria for this assessment were not explicit. None of the studies reported in detail whether participants in the intervention group received any other care or treatments besides the intervention. At least 2 studies [19,20] employed before-and-after designs without an independent control group. Another 2 studies [20,21] had incomplete follow-ups, and although the reasons for dropout were stated, the impact of dropout on the results was not analyzed. At least 1 study [20] only reported descriptive statistics (means, standard deviations) and did not perform significance testing or calculate effect sizes. The statistical methods used were relatively simple.

[a]Rating scale: Yes (Y), No (N), Unclear (?), Not applicable (NA); items for critical appraisal: (1) Are the study's "cause" and "effect" (ie, the order of the variables) evident? (2) Are the individuals being compared similar? (3) Aside from the intervention, do the individuals in the comparison group receive the same care or treatment? (4) Is a control group present? (5) Are the results measured more than once before and after the intervention? (6) Has the follow-up been completed? If not, are the differences sufficiently explained and analyzed? (7) Do the individuals being compared have the same outcome measured in the same way? (8) Is the outcome measurement accurate? (9) Is the correct statistical analysis applied?

Characteristics of the Described Interventions

Table 1 and Multimedia Appendix 4 display the gamification features of the studies included in our systematic review. The number of game elements used in the gamification interventions for older adults' physical activity ranged from 2 to 6, with the majority incorporating 5 game elements. The most commonly used game elements were goals and rewards, followed by challenges and collaboration, while virtual identity and points were the least used.

Half of the 8 studies [19,23-25] employed theories or principles to design the gamification interventions. At least 2 studies [23,25] conducted in the United States used prospect theory from behavioral economics, while the other 2 studies employed the theory of behavioral change [24] and the emotional

XSL•FO
RenderX

circumplex model [19]. All of these studies used a single theory without combining them.

In 1 study, family members or friends were incorporated into the gamified intervention as support partners to provide encouragement and assist participants in achieving their activity goals.

There are 3 digital approaches to gamification for older adults. Most studies [19-22] use mobile apps only (4/8), while some studies [14,24,25] combine mobile apps with activity monitors (3/8), and only 1 study [23] uses activity monitors alone (eg, Stepwatch or Fitbit). The shortest intervention time was 1 week [19], and the longest was 12 months [23]. Only 3 studies [18,23,25] included a follow-up period, highlighting the need for further evaluation of gamification interventions to assess their long-term sustainability. Another 5 studies [14,21,22,24,25] compared a gamification intervention to usual care, while 2 studies [19,20] did not include a control group. The study by Fanaroff et al [23] assigned participants to 4 groups and compared the effects of gamification to financial incentives, a combined intervention of both, and explored the impact of gamification on physical activity in older adults.

Effectiveness of Interventions

The included studies all assessed the effect of gamification interventions on the number of steps taken by older adults in their daily lives, as measured by activity monitors or smartphone sensors such as Google Fit. The findings from both controlled and single-arm studies were largely consistent in confirming the positive impact of gamification interventions on step count, including results observed during the follow-up period. The only exception was the study by Kawaguchi et al [24], which reported a nonsignificant increase in the number of steps following the gamification intervention. However, this study did report that intervention participants had a higher frequency of participation in specific types of activities, particularly hobbies and culture-related activities, compared to the control group.

At least 2 RCTs [23,25] reported changes in the time spent in moderate-to-vigorous physical activity (MVPA) per day, as measured by activity monitors. After adjusting for factors such as baseline activity levels, proficiency with the devices, and genetic risk, between-group differences indicated that gamification can significantly increase the duration of MVPA in older adults, with these effects being sustainable.

Patterns From Intervention Classification

Application of the classification framework revealed consistent patterns across the 8 included studies. Advanced gamification designs consistently demonstrated superior outcomes [23,25], particularly when integrated with hybrid technology systems, showing statistically significant improvements in both step counts and MVPA duration [23,25]. Basic gamification approaches proved effective for step count enhancement [20,21] but exhibited limited capacity for tracking complex activity metrics [19]. Standalone mobile apps demonstrated strengths in facilitating social interaction mechanisms [20,22], while wearable-centric implementations may suffer from scalability limitations [14]. Crucially, all advanced interventions incorporated theoretical frameworks [19,23-25], whereas basic and intermediate designs operated predominantly without explicit theoretical foundations [20-22] (Table 4).

Effect strength was evaluated through standardized criteria: strong, >15% improvement from baseline OR Cohen d >0.8 OR η^2>0.25 with P<.05; moderate, 5% - 15% improvement OR Cohen d 0.5 - 0.8 OR η^2 0.10 - 0.25 with P<.05; weak, <5% improvement OR Cohen d <0.5 OR η^2 <0.10 with P<.05, NS, nonsignificant.

Discussion

Principal Findings

The present review included only 8 full-text articles that met stringent inclusion criteria, reflecting both methodological rigor and domain-specific constraints. Strict adherence to gamification standards, mandatory mHealth components, and a focused eligibility criterion of adults aged 60 years and above resulted in the exclusion of a considerable proportion of initially identified records. This selectivity contrasts sharply with the broad application of gamification in general healthcare, which has largely targeted younger populations [11]. Nonetheless, this condensed evidence base captures a developing nexus among gerontechnology, behavioral engagement, and mHealth—an area that remains understudied yet highly relevant for physical activity promotion in older adults. Despite these constraints, the main findings indicate that mHealth-based gamified interventions offer meaningful benefits in improving physical activity levels within this demographic.

A larger sample size and longer intervention duration would enhance the generalizability of the data and provide more opportunities to determine usage patterns and preferences. However, most of the reviewed studies employed shorter intervention durations and did not include follow-up assessments, involving only a small number of participants. This phenomenon is also observed in other areas of gamified interventions for older adults. For example, Savulich et al [29] used a sample size of 21 participants in their intervention group for cognitive training using iPads for older adults diagnosed with amnestic mild cognitive impairment, with an intervention duration of 4 weeks. Costa et al [30] used a sample size of 20 participants in their intervention group for mental health interventions for community-dwelling older adults through a gamified learning platform, with an intervention duration of 6 weeks. Despite the increased opportunities to access new technologies in recent years, the application of these tools among the older adult population still faces significant challenges.

Choosing game elements that cater to the needs of older adults or developing corresponding gamified applications can significantly enhance the effectiveness, practicality, and sustainability of interventions, thereby increasing user participation and reducing sample attrition rates during follow-up processes [31]. The studies included in this review generally adopt goal-setting (eg, daily step counts) and instant rewards (eg, points and badges) as core elements. These elements are widely used due to their strong alignment with the core mechanisms of behavior change [32], while also addressing the research need for quick verification of the immediate effects of gamification through short-term interventions. This approach aligns with the conclusions of 2 previous systematic reviews, which did not specify the research subjects [33,34].

However, the adoption of complex gamification elements, such as virtual identities and social collaboration, requires older adults to construct abstract self-representations or coordinate rules for multilateral interactions. This may lead to cognitive load or operational obstacles for some older adults [29], resulting in fewer studies designed with such elements. Additionally, we note that the included studies all employed interventions with 2 or more combined elements, suggesting that combinations of multiple game elements may be more effective than single

XSL•FO
RenderX

elements. However, due to the lack of detailed information in the initial studies, no definitive conclusions can yet be drawn about the optimal number or composition of game elements in these interventions.

One point that needs clarification is that the most frequently used gamification elements do not necessarily indicate the optimal effectiveness of those elements on older adults or physical activity. As Dugas et al [35] pointed out, personality differences can significantly affect how certain gamification characteristics influence older adults' use of mobile health technologies. When gamification mechanisms are unsuitable, older adults often fail to understand and recognize the relevant benefits of these services. Therefore, we must approach the results of this systematic review with caution, as it could lead to cognitive biases. In the study by Kostopoulos et al [36], the authors established goal-setting and achievement features that allow users to receive different rewards after completing various goals and tasks. The purpose was to further explain how these goals and tasks are generated for each user, which may help in understanding the different motivations and preferences that drive users to perform various tasks. This is an innovative approach, as it provides feedback on user performance while validating the effects of gamification interventions.

We have also found that Greysen et al [25] systematically included primary caregivers (support partners) as a core component of the intervention. And although other studies did not independently analyze or evaluate the involvement of nursing staff, most of them indirectly addressed similar concepts through social functions or external support mechanisms. This suggests that incorporating nursing staff into the network could be a valuable development. Including family members, health care professionals, and social workers in mobile health gamification interventions may enhance older adults' perceptions of social and emotional support, thereby increasing their acceptance of these interventions [37]. Additionally, from a technical perspective, this model can improve older adults' understanding of the intervention content and their sense of security in using the interventions [38]. This approach is particularly beneficial for older adults who are interested in gamification but lack independent operational skills, as well as for those who prefer direct care from health care professionals, providing an effective pathway for the broader application of gamification.

Technological platforms that accompany gamification are another important factor attracting the interest of older adults. Currently, validated technological features used among the older adult population include self-management systems [9], physical robots [10], consoles [11], portable devices, and wearable technology [12]. Although studies by Kitakoshi et al [38] and Mocanu et al [39] have confirmed that older adults enjoy using systems and interacting with robots, mobile health offers more diverse gamification opportunities in real-world applications. This aligns with the viewpoint of Steinert et al [40], who pointed out that older adults are more motivated by tangible information provided by activity monitors, sensors, and smartphones, rather than more abstract game feedback. This is also the primary reason why our review is limited to gamification intervention research supported by mobile technology.

In this systematic review, the mHealth technologies used to provide physical activity gamification interventions include 1 activity monitor (1/8), 4 mobile apps (4/8), and 3 combinations of both (3/8). This distribution of technological application patterns reflects a shift in the current research field, from single-device use to multimodal and collaborative intervention plans. Tablet devices offer significant advantages in screen size and clarity, and previous research [30] has confirmed their ability to improve specific cognitive functions in older adults. However, the physical characteristics of the devices, such as weight, button design, and keyboard operation, may affect the user experience of older adults participating in activities. As a result, only 1 study in this review mentioned tablet devices [23].

The theoretical framework also warrants discussion, as it enables a deeper analysis of the behavioral mechanisms behind older adults' participation in physical activities, accurately addressing their physiological, psychological, and social needs. However, among the reviewed studies, only 4 [19,23-25] explicitly adopted a single theoretical framework or model to design gamified interventions for physical activities targeting older adults. The classification framework revealed that these theory-oriented designs demonstrated more effective outcomes while accommodating greater gamification complexity, suggesting that theoretically integrated gamification may play a positive role in reducing engagement burden among older adults.

At least 2 of these studies [23,25] utilized behavioral economics, incorporating design principles such as loss aversion, precommitment, and the fresh start effect. The significance of this theoretical application lies in viewing participation in physical activities as an investment in future health, guiding older adults' behavioral choices through subtle environmental adjustments rather than rigid directives. In another study [19], the circumplex model of affect was translated into operational gamification solutions, offering new insights for the design of digital therapeutics in geriatric health.

Self-Determination Theory, a comprehensive motivation theory, has become a key framework for health behavior interventions, but only 1 study [24] claims to have used it, differing from the 2 systematic reviews mentioned earlier [33,34]. Other commonly considered behavior change theories include the Health Belief Model [41], Theory of Planned Behavior [42], Transtheoretical Model [43], and Habit Formation Theory [44], but these theories appear to be rarely applied in gamified interventions for older adults, even in nonphysical activity areas. The reasons for this may partly stem from the relatively novel concept of introducing gamified design to the older adult population, where traditional theories may not align well. Alternatively, it could be that the behavior patterns of older adults are complex and diverse, making the application of theory more challenging. Therefore, a more systematic and appropriate gamification theory system for the older adult population could be developed in the future through qualitative exploration, theoretical integration, and other methods.

Finally, a study published by Bellotti et al [45] in the field of human-computer interaction suggested that game-based interventions could serve as a strategy for patient self-assessment, enriching the typical content of assessments

XSL•FO
RenderX

for older adults. Although no authors in the reviewed studies directly made such a claim, this idea may also apply to gamification for older adults. By continuously tracking the activity performance of older adults, research can gather multidimensional data, such as task completion rates, execution times, and failure counts. This information, when combined with commonly used assessment tools for older adults, such as the Activity of Daily Living scale [46] and the Morse fall risk assessment scale [47], could provide a more comprehensive reflection of functionality and psychological state, thereby guiding clinical decision-making and personalized intervention strategies. While this is a reasonable inference, further investigation is needed. Additionally, it is important to consider data privacy and the risk of false positives to avoid excessive monitoring, which could lead to psychological stress or self-report biases due to the Hawthorne effect.

Limitations

Although this study systematically reviews the effectiveness of mHealth gamification interventions on physical activity in older adults, several limitations should be noted. First, the included studies are relatively few (n=8), with generally small sample sizes, potentially limiting the generalizability and reliability of the findings. Second, intervention durations varied significantly (1 wk to 12 mo), and most studies lacked follow-up periods, complicating the assessment of long-term sustainability. Additionally, considerable heterogeneity existed across studies, including variations in gamification elements, technological platforms, theoretical frameworks, and outcome measurement methods, precluding meta-analysis and unified conclusions. Another limitation is the incomplete reporting of baseline participant characteristics (eg, digital literacy, health status), potentially biasing intervention effect interpretations. Finally, as most studies focused on high-income countries (eg, the United States, Japan, Switzerland), the findings may lack generalizability to older adults in other regions or cultural contexts. Furthermore, due to incomplete reporting of minimum participant ages, this review inferred population homogeneity using a functionally oriented aging definition and statistical estimation, which may overestimate or misrepresent intervention effectiveness.

Conclusions

This systematic review suggests that mHealth-based gamified interventions have potential benefits in increasing the physical activity levels of older adults, particularly by enhancing daily step counts and the duration of MVPA. Common gamification elements, such as goal-setting and immediate rewards, effectively stimulate the participation motivation of older adults, while the combination of mobile apps and wearable devices further enhances the flexibility and accessibility of these interventions. However, existing evidence still has limitations, including a limited number of studies, small sample sizes, and a lack of long-term follow-up data. Future studies should aim to expand sample sizes, extend intervention durations, and include more diverse older adult populations to validate the universality and sustainability of the intervention effects. Additionally, there is a need to further explore the optimal combination of gamification elements, the integration of theoretical frameworks, and the potential impact of caregiver network participation on the effectiveness of these interventions. Overall, mHealth gamified interventions offer an innovative and feasible strategy for promoting physical activity among older adults, but their design and implementation must carefully consider the specific needs and varying abilities of older adults to ensure the practicality and acceptance of these interventions.

Abstract

Background: Mild cognitive impairment (MCI) affects up to 20% of people older than the age of 65 years. The global incidence of MCI is increasing, and technology is being explored for early intervention. Theories of technology adoption predict that useful and easy-to-use solutions will have higher rates of adoption; however, these models do not specifically consider older adults with cognitive impairments or the unique human-computer interaction challenges posed by MCI. There are gaps in understanding the combined impacts of aging and cognitive impairment on factors affecting technology adoption for older adults with MCI, and it is not clear how MCI impacts human-computer interaction and device and interaction modality preferences in this population.

Objective: This study aimed to collate perspectives from older adults with MCI about technology solutions proposed for them, to understand whether solutions are perceived as useful, easy to use, and what changes are suggested. It also identifies which devices and interaction modalities are preferred, and other factors that may affect usage and adoption.

Methods: This scoping review was completed according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines. A consistent search was performed across 9 electronic databases (ACM Digital Library, EBSCOhost CINAHL Plus with Full Text, EBSCOhost Computers and Applied Sciences Complete, Google Scholar, JMIR Publications, IEEE Xplore, EBSCOhost MEDLINE, Scopus, and Web of Science Core Collection) for studies published between January 1, 2014, and May 1, 2024. Extracted data were analyzed using inductive thematic analysis.

Results: We identified 4271 studies, and after the removal of duplicates and screening, 83 studies were included for data extraction. Inductive thematic analysis of feedback from older adults with MCI about technology solutions proposed for them identified five themes: (1) purpose and need, (2) solution design and ease of use, (3) self-impression, (4) lifestyle, and (5) interaction modality. Solutions were perceived as useful, even though gaps in functional support exist; however, they were not perceived as entirely easy to use due to issues related to usability and user experience. Devices that are lightweight, portable, familiar, and have large screens are preferred, as is multimodal interaction—particularly speech, visual or text, and touch.

Conclusions: Using technology can create feelings that positively or negatively affect a user's comfort, confidence, and overall well-being. Older adults with MCI value independence and autonomy, and solution designs should support these. Usefulness, ease of use, security, privacy, cost, physical comfort, and convenience are important considerations for technology use. Reliable technology creates trust, confidence, and feelings of empowerment. This review recommends future work to (1) improve usability and user experience, (2) enhance personalization, (3) better understand interaction preferences and effectiveness, (4) enable options for multimodal interaction, and (5) more seamlessly integrate solutions into users' lifestyles.

Introduction

Background

Mild cognitive impairment (MCI) affects a person's memory or how they think, feel, or behave. It is not a normal part of aging, but up to 20% of adults older than the age of 65 years may be affected, and up to 15% of those may progress to dementia [1,2]. Historically, MCI was considered a decline in a person's memory, but the criteria and definition of MCI have expanded with more research to include other cognitive domain deficits and affective attributes such as language, executive functioning, or visuospatial ability [3-5]. A memory decline is only labeled single-domain amnestic MCI. A decline in 1 nonmemory cognitive domain is labeled single-domain nonamnestic MCI, and a decline in memory and one or more other cognitive domains is labeled multiple-domain amnestic MCI. People with MCI may forget things more frequently, lose items more often, struggle to remember words or have problems with language, have trouble making decisions or following instructions, lose their train of thought, have new difficulties regulating emotions, behave more impulsively, have trouble with visual perception, have trouble sleeping, experience motor coordination issues, or be less able to follow daily routines [2]. Given that visual, perceptual, cognitive, and behavioral functions are needed for human-computer interaction (HCI), the limitations associated with MCI create challenges for HCI, such as difficulties remembering process steps or commands, understanding instructions, interpreting feedback, correcting errors, or maintaining focus and attention. Changes to emotions, feelings, or mood may also make MCI more difficult and thereby create frustration, increase fear of making mistakes, and reduce self-confidence, all of which have been shown to contribute to factors influencing technology adoption (TA). These challenges can be managed through a considered design of technology solutions.

The global prevalence of MCI is increasing and placing additional stress on both health and aged care services [6]. The number of older Australians with MCI is estimated to grow from 884,000 in 2022 to 2.03 million in 2070 [7,8]. The Australian Royal Commission into Aged Care Quality and Safety [9] noted that aged care services are already under pressure and recommended exploring technology options to address the growing needs of older Australians. Australia's National Dementia Action Plan 2024 - 2034 [10] recommended that action be taken to (1) implement evidence-based early interventions to reduce cognitive decline, and (2) provide support and resources for people with MCI.

Research has shown that technology provides opportunities to increase health care service productivity [11], but only if solutions are adopted by the target users. Aging may result in slower cognitive speed, poorer memory, reduced concentration, and negatively impact vision, hearing, speech, dexterity, mobility, and learning abilities. These limitations have been found to discourage the use of technology [12], and studies have shown that the use of digital health solutions is lower among older adults than younger adults [13]. In addition, as people experience MCI uniquely and with different symptoms, older adults with MCI will have different and diverse needs for technology support.

Literature Review

TA has been studied from several perspectives. Early models, such as the technology acceptance model (TAM) [14], TAM2 [15], and TAM3 [16], take a behavioral perspective and consider TA in an organizational context. They describe TA as being dependent on a user's perception of the technology's usefulness, ease of use, and the determinants of these. The unified theory of acceptance and use of technology (UTAUT) [17] considers TA from a combined behavioral, psychological, and information management perspective, and UTAUT2 [18] extends UTAUT to consider TA outside of business settings, such as at home, and shows that the context of use has an impact on the relevance and contribution of determinants. However, these models were not developed based on data about older adults with cognitive impairment or the assessment of health care technologies. More recent models, such as the senior technology acceptance model (STAM) [19] and the model for the adoption of technology by older adults (MATOA) [20], focus on older users and the effects of physical and cognitive aging on TA. They note that ease of use becomes more important as users age, and MATOA identifies self-management (the extent to which a person can remain independent and maintain control of their life, emotions, and role) as a determinant for intention to use. The lifespan theory of control [21] describes the importance of control and states that people will attempt to retain control of how they behave and interact with their external environment for as long as possible because control contributes to a sense of well-being. It is therefore relevant to consider user empowerment as a valuable design feature in technology solutions designed for older adults, and this is supported by a literature review of older adults' intention to use technologies [22]. STAM and MATOA do not specifically consider TA by older adults with cognitive impairments or technology designed for health care or assistance with activities of daily living. The health care technology acceptance model (H-TAM) [23] describes acceptance of health care technologies by older adults with hypertension. It includes many factors that appear in TAM-based TA models and proposes compatibility (how well the technology integrates into a person's everyday life) as a determinant of facilitating conditions.

A study of people's intention to use service robots [24] suggests that TA models may need to be revisited to incorporate the influence of technology innovations such as smart technologies and robots, which may be adaptive and exhibit human-like features. These advances have enabled new uses and new modes of interaction, and users can now choose their device and interaction mode, which is empowering. However, it is not clear how this impacts TA for older users with cognitive impairments, in particular, perceptions of usefulness and ease of use, which are shown to be determinants of TA. Researchers have investigated the effectiveness of unimodal and multimodal interaction for older users and found that modality affects use [12,25-29]; however, these studies did not include older adults with cognitive impairments. Subtle speech differences can be observed in people with MCI [30], and literature reviews have reported on the use of voice-activated technology solutions by

XSL•FO
RenderX

older adults [27,31,32]. However, these did not always include older adults with cognitive impairment as participants.

There are gaps in understanding the combined impacts of aging and cognitive impairment on factors affecting TA for older adults with MCI. It is also unclear how MCI impacts HCI and device and interaction mode preferences. This scoping literature review examines published studies about technology solutions developed for older adults with MCI (amnestic or nonamnestic, and single- or multi-domain) to answer the following research questions:

- Research question 1 (RQ1): What are the opinions of older people with MCI about the technology solutions that have been proposed for them? (A) Are they useful? (B) Are they easy to use, or are changes and improvements suggested?
- RQ2: What feedback do older people with MCI provide about usage? (A) Preferred devices? (B) Interaction modality and ways of use?

To our knowledge, this is the first study that collates opinions and feedback from older adults with MCI about technology solutions proposed for them.

Methods

Overview

This scoping review design was guided by previous literature [33,34] and is reported according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines [35]. It was preregistered on the Open Science Framework Storage (United States) [36].

Eligibility Criteria

An electronic database search was performed to identify studies published in English between January 1, 2014, and May 1, 2024. A 10-year period is considered sufficient given the fast evolution of technology and the potential for change in people's opinions.

Information Sources

The search was performed consistently across nine electronic databases (ACM Digital Library, EBSCOhost CINAHL Plus with Full Text, EBSCOhost Computers and Applied Sciences Complete, Google Scholar, JMIR Publications, IEEE Xplore, EBSCOhost MEDLINE, Scopus, and Web of Science Core Collection).

Search Strategy

The search strategy was developed with the assistance of a qualified librarian. The following search query was used in all databases:

> *((MCI OR "mild cognitive impairment" OR "mild cognitive disability" OR "mild neurocognitive")AND(technolog* OR ICT OR smart OR wearable* OR computer OR PC OR laptop OR tablet OR "touch screen" OR "touch-screen" OR "mobile phone" OR "mobile device" OR "personal device" OR robot OR reality OR VR OR "assistive technolog*" OR "embodied conversational agent" OR ECA OR multimedia OR "multi-media")AND(modalit* OR mode OR channel OR interact* OR engage* OR touch OR type OR voice OR gesture OR use OR usage)AND(preference* OR experience* OR perception* OR attitude* OR feeling OR practices OR "technology acceptance" OR qualitative OR "design science" OR "innovation resistance theory"))*

Selection Criteria

Studies that satisfied the search criteria were imported into the referencing software program EndNote (Clarivate Analytics) and then uploaded to Covidence (Veritas Health Innovation) to remove duplicates and for screening [37].

Three reviewers and the primary author screened the titles and abstracts of each study and excluded any that did not meet the following inclusion criteria:

- Participants have MCI and were living independently in the community (not in residential aged care)
- Participants used or evaluated the technology solutions or devices
- Participants provided feedback about a technology idea, paper prototype, or abstract concept
- The study assessed one or more of the participants' experiences, feelings, or attitudes regarding the technology, and preferences for use

Papers were excluded if:

- Participants lived in residential care or a nursing home
- The paper did not report on participant feedback.
- The paper reported only on the efficacy of the solution
- If the study included multiple participant cohorts, the feedback was not identifiable or reported by cohort

Where it was unclear if a study met the inclusion criteria, or there was a disagreement among reviewers, the study was carried forward into the full-text review.

The primary author independently reviewed all full-text studies extracted from the previous stage. The remaining authors shared the role of second reviewer. Full-text papers were included if they reported the following:

- Research about participants' use of technology and their experiences, feelings, attitudes, opinions, or preferences
- If multiple participant cohorts were included, the data were identifiable and reported by cohort
- Participants were assessed for MCI
- Participants had no comorbidities that cause neurological issues or affect cognition

Any disagreements were resolved by discussion among the authors.

Data Analysis Process

Data were extracted into a structured Microsoft Excel spreadsheet by the first author and evaluated by 2 other authors. Data were extracted about (1) study details (such as author, location of study, year published, journal name, study aim, study type, technology being evaluated, and participant details) and

XSL•FO
RenderX

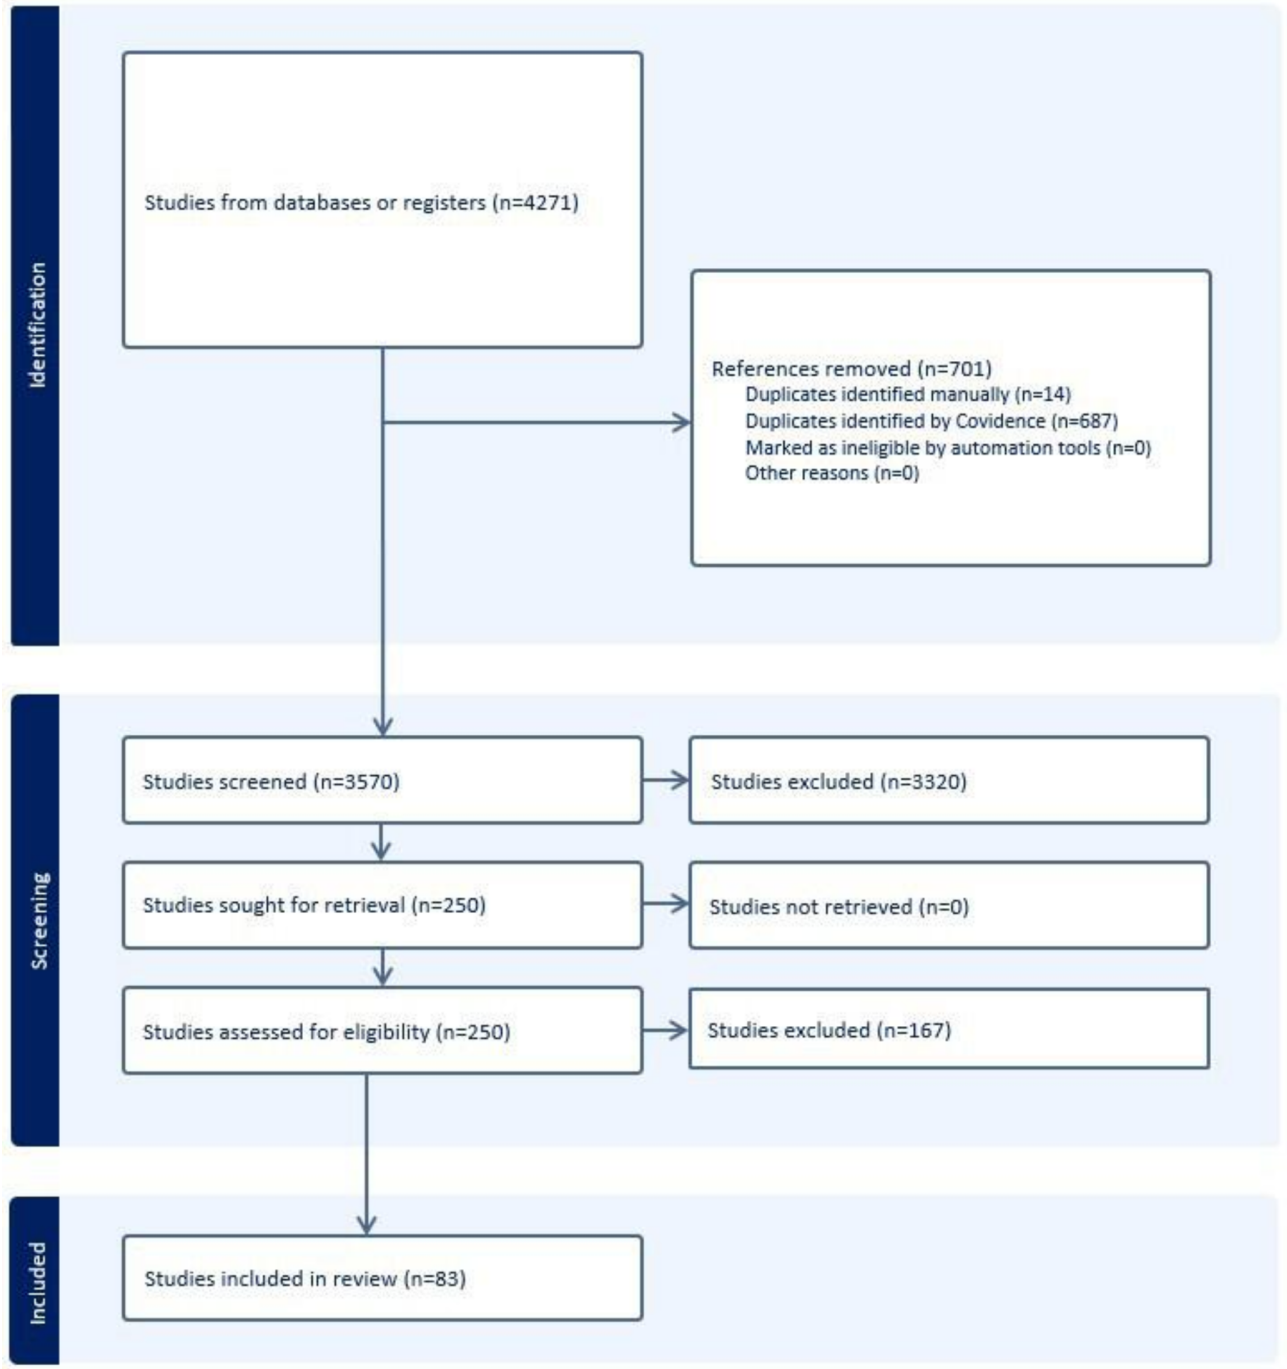
(2) participant feedback. Participant feedback was recorded as any reference to (1) a participant's opinion about the technology (usefulness, ease of use, usage, and context of use), (2) how the solution made them feel, (3) preferences for device or interaction, (4) issues or challenges with use, and (5) recommendations for changes. Statements were captured as written, relating to the type of technology and solution.

All extracted data were reviewed for familiarization and to start the process of identifying similarities, relationships, and trends. Participant feedback was organized and analyzed using inductive, thematic analysis as described by Thomas and Harden [38], to ensure transparency and traceability from the data to the outcomes. This process has been used effectively to complete other thematic analyses of qualitative data that describe people's experiences, opinions, and feelings.

Inductive thematic analysis of participant feedback was guided by the 2 research questions and completed in 4 steps:

1. Keyword allocation: each feedback item was assigned one or more keyword phrases that succinctly described its meaning. The first author used existing keywords or created new ones as needed.
2. Consistency check: review of all feedback items with the same keyword to ensure consistent allocation.
3. Category grouping: related keyword phrases were grouped into higher-level categories, which were then named.
4. Theme creation: the categories were reviewed, and 5 abstract themes were created to provide meaning to the feedback and answer the research questions.

During the above 4-step process, there was a continuous feedback cycle with coauthors.



Results

Overview

A total of 4271 studies were imported for screening, 687 duplicates were identified and removed by Covidence, and 14 duplicates were identified and removed manually. A total of 3570 studies were screened by title and abstract, and 3320 studies were subsequently excluded. The full text of 250 studies was assessed for eligibility, and 167 studies were excluded, leaving 83 studies for data extraction. Figure 1 presents the flow of studies through the PRISMA-ScR process, and Table 1 provides a summary of the studies and extracted data, sorted alphabetically by the author.

Table . Summary of studies, sorted alphabetically by author.

Study details	Study type	Type of technology	Purpose of the solution	Participant details
Afifi et al [39]	Quantitative	VR[a] headset	Social interaction, messaging, chat, or information provision	Female: 18; male: 3; location: community center; 9 participants had MCI[b]
Bartels et al [40]	Mixed methods	Mobile phone	Lifestyle (ADL[c]) support, social interaction, or companionship	Female: 5; male: 16; location: home
Beentjes et al [41]	Mixed methods	Touch-screen laptop or tablet	Lifestyle (ADL) support, social interaction, or companionship helps people find apps for self-management and meaningful activities	Female: 8 (3 in experimental group and 5 in control group); male: 12 (7 in experimental group and 5 in control group); location: home
Bernini et al [42]	Mixed methods	Touch-screen laptop or tablet	CBT[d]	Female: 5; male: 5; location: home
Bernini et al [43]	Quantitative	PC	CBT	Female: 17 telehealth and 13 in-person; male: 14 telehealth and 12 in-person; location: clinic (PC) or home (laptop)
Bogza et al [44]	Mixed methods	Web solution	Decision aid	Female: 6; male: 6; location: clinic, research center, or participant home
Bouzida et al [45]	Mixed methods	Robot with integrated touch screen	CBT	Female: 1; male: 2; location: home
Chang et al [46]	Quantitative	Screen and gesture sensitive device	Physical and cognitive training	Female: 8; male: 7; location: clinic
Chen et al [47]	Mixed methods	Touch-screen laptop or tablet	CBT	Female: 44 in evaluation group and 4 in focus group (same people); male: 13 in evaluation and 0 in focus group; location: clinic
Christiansen et al [48]	Qualitative	No device	Data collection (eg, UI[e] design feedback, technology use or acceptance, icon design preferences, changes to cognition, cognitive training or games design, and needs for robotic assistants)	Female: 6 (2 were 70 - 75 years and 4 were older than 81 years); male: 12 (4 were 70 - 75 years, 6 were 76 - 80 years, and 2 were older than 81 years); location: 15 at home and 3 in lab
Collette et al [49]	Qualitative	Integrated computer-based assistant	Health or medication management eg, BP[f], reminders to drink water	Female: 7; male: 3; location: clinic
Contreras-Somoza et al [50]	Qualitative	Touch-screen laptop or tablet	Lifestyle (ADL) support, social interaction, or companionship	Female: 11; male: 2; location: clinic
Contreras-Somoza et al [51]	Qualitative	Touch-screen laptop or tablet	Lifestyle (ADL) support, social interaction, or companionship	Female: 21; male: 14; survey: 35 participants (15 Spain, 4 Netherlands, 2 Italy, 2 France, 4 Israel, 5 Serbia, and 3 Slovenia)
Cunnah et al [52]	Qualitative	Web solution	Social interaction, messaging, chat, or information provision	Total: 100; location: home-100 dyads (49 control, 51 intervention); intervention group got 1:1 training followed by group training; 25% drop-out; 75 dyads completed the study (39 control and 36 intervention).

Study details	Study type	Type of technology	Purpose of the solution	Participant details
Demiris et al [53]	Mixed methods	Smart conversational assistant with touch screen (eg, Google Home and Alexa)	Companionship and reminders (computer-based pet)	Female: 10; male: 0; location: home
Dixon et al [54]	Qualitative	No device	Data collection (eg, UI design feedback, about technology use or acceptance, icon design preferences, changes to cognition, cognitive training or games design, and needs for robotic assistants)	Female: 1; male: 1; location: home
Franco-Martín et al [55]	Qualitative	PC	CBT	Not stated
Gasteiger et al [56]	Mixed methods	Robot with integrated touch screen with pen and magnetic blocks (tactile sensors) Used 3 robots (Bomy 1, Bomy, and Silbot) in the project	CBT	Not stated; location: location most convenient to participants, including the university, workplaces, clinic, home, or via Skype (for experts; developed by Janus Friis, Niklas Zennström, Ahti Heinla, Priit Kasesalu, and Jaan Tallinn)
Gelonch et al [57]	Mixed methods	Wearable camera	Memory aid-digital camera records daily activities	Female: 4; male: 5; location: adult day center
Givon Schaham et al [58]	Mixed methods	Touch-screen laptop or tablet	CBT	Female: 13; male: 15; location: clinic and home
Guzman-Parra et al [59]	Quantitative	No device	Data collection (eg, UI design feedback, about technology use or acceptance, icon design preferences, changes to cognition, cognitive training, games design, and needs for robotic assistants)	Female: 576; male: 510; location: used secondary data; 1086 dyads: 299 with dementia, 787 with MCI; data not split for the MCI and dementia groups
Haesner et al [60]	Qualitative	No device	Data collection (eg, UI design feedback, about technology use or acceptance, icon design preferences, changes to cognition, cognitive training, games design, and needs for robotic assistants)	Female: 3; male: 3; location: clinic
Hassandra et al [61]	Mixed methods	VR headset and controller, hand motion trackers, or wireless mouse	Physical and cognitive training	Female: 19; male: 8; location: clinic
Heatwole and Kendra [62]	Qualitative	No device	Data collection (eg, UI design feedback, about technology use or acceptance, icon design preferences, changes to cognition, cognitive training, games design, needs for robotic assistants)	Female: 6; male: 4; location: outing location
Hedman et al [63]	Qualitative	No device	Data collection (eg, UI design feedback, about technology use or acceptance, icon design preferences, changes to cognition, cognitive training, games design, and needs for robotic assistants)	Female: 2; male: 4; location: home

Study details	Study type	Type of technology	Purpose of the solution	Participant details
Hedman et al [64]	Mixed methods	No device	Data collection (eg, UI design feedback, about technology use or acceptance, icon design preferences, changes to cognition, cognitive training, games design, and needs for robotic assistants)	Female: 18; male: 19; location: home; only 21 participants left at year 5
Horn et al [65]	Qualitative	Mobile phone and smartwatch	Memory aid-facial recognition aid to identify people	Female: 6; male: 14; location: home
Hu et al [66]	Mixed methods	No device	Data collection (eg, UI design feedback, about technology use or acceptance, icon design preferences, changes to cognition, cognitive training, games design, and needs for robotic assistants)	Female: 18; male: 13; location: clinic
Infarinato et al [67]	Mixed methods	A robot and a separate touch screen	Physical and cognitive training	Female: 8; male: 7; location: home
Irazoki et al [68]	Qualitative	Touch screen laptop or tablet	Cognitive training or cognition assessment	Female: 11; male: 2; location: clinic
Korchut et al [69]	Mixed methods	No device	Data collection (eg, UI design feedback, about technology use or acceptance, icon design preferences, changes to cognition, cognitive training, games design, and needs for robotic assistants)	Female: 36; male: 21; survey
Kubota et al [70]	Qualitative	Robot with integrated touch screen	CBT	Female: 0; male: 3; location: online session
LaMonica et al [71]	Quantitative	No device	Data collection (eg, UI design feedback, about technology use or acceptance, icon design preferences, changes to cognition, cognitive training, games design, and needs for robotic assistants)	Female: 127; male: 94; survey: 137 had MCI, 61 had SCI[g], and 23 had dementia
Law et al [72]	Mixed methods	Robot with integrated touch screen	CBT	Female: 6; male: 4; location: lab
Lazarou et al [73]	Mixed methods	No device	Data collection (eg, UI design feedback, about technology use or acceptance, icon design preferences, changes to cognition, cognitive training, games design, and needs for robotic assistants)	Female: 9; male: 6; survey
Leese et al [74]	Mixed methods	Fitness tracker smartwatch	Collect daily movement and exercise data	Female: 1; male: 14; location: home
Lindqvist et al [75]	Qualitative	No device	Data collection (eg, UI design feedback, about technology use or acceptance, icon design preferences, changes to cognition, cognitive training, games design, and needs for robotic assistants)	Total: 5; location: clinic

Park et al [92]	Quantitative	VR headset and controller or hand motion trackers or wireless mouse	CBT	Female: 7 control group and 7 VR group; male: 3 control group and 4 VR group; location: clinic
Piasek et al [93]	Mixed methods	Robot with integrated touch screen	Physical and cognitive training	Female: 3; male: 1; location: home
Pino et al [94]	Mixed methods	Robot with integrated touch screen	Lifestyle (ADL) support, social interaction or companionship	Female: 6; male: 4; location: clinic
Quintana et al [95]	Mixed methods	Touch screen laptop or tablet with tablet pen	Memory aid for daily activities, cognitive support, rehabilitation, or share health information	Female: 3 (Sweden) and 5 (Spain); male: Sweden-6 (Sweden) and Spain-5; location: clinic and home
Rossi et al [96]	Mixed methods	Robot with integrated touch screen	Lifestyle (ADL) support	Female: 2 (phase 1) and phase 3; male: 2 (phase 1) and phase 4; location: lab (phase 1) and home (phase 2)-
Saini et al [97]	Mixed methods	Videoconferencing (Zoom) and webcam	CBT	Total: 12; survey: 6 in each randomized group (face-to-face CBT or CBT via videoconferencing)
Scase et al [98]	Qualitative	Touch screen laptop or tablet	CBT	Female: development: 3 focus groups (group 1: 4; group 2: 4; group 3: 3), evaluation: 22; male: development: 3 focus groups (group 1: 5; group 2: 1; group 3: 1), evaluation: 3; location: clinic and home
Scheibe et al [99]	Qualitative	TV with remote control or tablet; sphygmomanometer (to measure blood pressure)	Telemonitoring medical app to communicate with multidisciplined health professionals	Female: 8; male: 4; location: home
Shamir et al [100]	Mixed methods	Touch screen laptop or tablet	CBT	Female: 6; male: 8; location: home
Shellington et al [101]	Mixed methods	Mobile phone	CBT	Female: 14; male: 5; location: home
Shin et al [102]	Qualitative	Remote controlled robot (robot is not with user, but controlled via app on PC, tablet, or mobile phone)	Lifestyle (ADL) support	Female: 0; male: 6; location: clinic or home
Stogl et al [103]	Quantitative	Robotic walker (user holds handles and pushes the device for exercise)	Physical and cognitive training	Female: 2; male: 8; location: clinic
Stramba-Badiale et al [104]	Mixed methods	VR (or TV), joystick, and foot pad or rudder	Assist with navigation and training of spatial memory	Female: 4; male: 3; location: lab
Tuena et al [105]	Mixed methods	VR (or TV), joystick, foot pad or rudder, and 3D glasses	Assist with navigation and training of spatial memory	Female: 2; male: 6; location: lab
Van Assche et al [106]	Qualitative	Robot with integrated touch screen	Data collection and design guidance for robot use cases	Female: 16; male: 14; location: home
Votis et al [107]	Qualitative	Touch screen laptop or tablet	CBT	Total: 17; location: lab
Wargnier et al [108]	Mixed methods	Smart conversational assistant with touch screen (eg, Google Home and Alexa)	Health or medication management (eg, BP and reminders to drink water)	Female: 11; male: 3; location: clinic (5 had Alzheimer disease)

Study details	Study type	Type of technology	Purpose of the solution	Participant details
Weering et al [109]	Qualitative	Web solution	Physical and cognitive training	Female: 43; male: 14; location: clinic
Wolf et al [110]	Mixed methods	VR headset	Lifestyle (ADL) support	Female: 6; male: 0; location: clinic kitchen
Wu et al [111]	Qualitative	No device	Data collection (eg, UI design feedback, about technology use or acceptance, icon design preferences, changes to cognition, cognitive training, games design, and needs for robotic assistants)	Female: focus group 4, interview 12; Male: focus group 1, interview 3; location: lab
Wu et al [112]	Mixed methods	Robot with integrated touch screen	Lifestyle (ADL) support	Total: 6; location: clinic
Yamazaki et al [113]	Qualitative	Robot (sitting on table, programmed to interact with user, sing, talk, and respond to spoken words)	Companionship	Female: 2; male: 0; location: home
Yun et al [114]	Quantitative	VR headset and controller or hand motion trackers or wireless mouse	CBT	Female: 6; male: 5; location: clinic
Yurkewich et al [115]	Mixed methods	Touch screen laptop or tablet	Social interaction, messaging, video chat, or information provision	Female: 6; male: 2; location: home
Zafeiridi et al [116]	Mixed methods	Web solution	Lifestyle (ADL) support, social interaction, or companionship	Female: 14; male: 10; location: home
Zedda et al [117]	Mixed methods	Robot with integrated touch screen	CBT	Female: 6; male: 10; location: clinic
Zhang and Gao [118]	Mixed methods	No device	Data collection (eg, UI design feedback, about technology use or acceptance, icon design preferences, changes to cognition, cognitive training, games design, and needs for robotic assistants)	Total: 5; location: clinic
Zhang and Liu [119]	Mixed methods	Touch screen laptop or tablet with foot stand with pressure sensors	Physical and cognitive training	Female: 79; male: 58; location: survey and usability evaluation in lab: 137 responses for phase 1 (requirements gathering) but only 30 responses were from people with MCI; 107 responses were from family of people with MCI
Zhu et al [120]	Mixed methods	Mobile phone	Memory aid-digital storytelling	Female: 9; male: 3; location: clinic
Zubatiy et al [121]	Mixed methods	Smart conversational assistant with touch screen (eg, Google Home and Alexa)	Lifestyle (ADL) support	Female: 4; male: 6; location: home (MCI and caregiver dyads included in study)

[a]VR: virtual reality.

[b]MCI: mild cognitive impairment.

[c]ADL: activity of daily living.

[d]CBT: cognitive behavioral therapy.

[e]UI: user interface.

[f]BP: blood pressure.

[g]SCI: subjective cognitive impairment.

XSL•FO
RenderX

Below, we first list 4 broad categorizations of the examined studies in terms of (1) study details and nature of participants, (2) purpose of technological solutions, (3) types of interaction devices, and (4) interaction modalities, and provide a short description of how studies evaluated usability. This is followed by the resulting themes derived from analysis of participant feedback.

Categorization of Examined Study Details

Characteristics of Included Studies and Study Participants

Over half of the included studies (n=45) were conducted in Europe, with almost a quarter (n=10) of these in Italy. Some of the European studies included participants from multiple countries [51,59,67,69,90,95,116]. Table 1 shows that 61 studies included fewer than 20 participants, 49 studies included fewer than 15 participants, 25 studies included fewer than 10 participants, and 8 studies included fewer than 5 participants. Many studies commented on the lack of cultural diversity among their participants.

Studies used a mixed methods (n=47), qualitative (n=26), or quantitative (n=10) approach. Studies that did not explicitly declare their design type are classified in this paper based on the type of data collected. Qualitative studies used semistructured interviews, focus groups, workshops, and observations to collect data. Quantitative studies used surveys or questionnaires with closed questions to gather data. Most studies, regardless of type, collected quantitative data about participant demographics. Quantitative data about usability, acceptability, and user experience (UX) were typically gathered using questionnaires with responses on a Likert-type scale.

Purpose of Technology Solutions in Studies

Over a third (n=32) of solutions provide cognitive training in the form of cognitive behavior therapy (CBT; n=21), a combination of CBT and physical training (n=9), or CBT and cognitive assessment (n=2). Other functions mentioned as needs by participants and supported by solutions were lifestyle or activities of daily living support (n=13), memory training or management (n=6), health and medication management (n=4), staying in touch with family and friends, social engagement, entertainment (n=4), companionship (n=2), spatial navigation or orientation (n=2), insomnia intervention (n=1), and daily exercise monitoring (n=1). Solutions also provided support for decision support (n=1) and mood regulation (n=1), but these were not identified as needs by participants. Further needs identified by participants but not supported by solutions were the management of finances and help to locate lost items. Sixteen studies were designed to collect data to (1) guide the design of future solutions, (2) inform amendments for existing solutions, or (3) collect information about the needs of people with MCI.

Interaction Devices

Studies included various technology platforms and devices as presented in Table 2 in the Multimedia Appendix 1. Almost half (n=37) of the proposed solutions include a touch screen as a component of a laptop or tablet (n=17), a robot (n=14), or a mobile phone (n=6). This reflects research by [25,122], which showed that touch screen devices are effective and easy to use by older adults. Some (n=4) robot solutions did not include sound, but the majority (n=12) included voice or sound. Eleven solutions involved the use of virtual reality (VR). Eight solutions included wearables (other than VR headsets or 3D glasses) in the form of a smartwatch (n=5), a wearable motion sensor (n=1), a sphygmomanometer to measure blood pressure (n=1), and a wearable camera (n=1). Six studies included a mobile phone, among which 3 paired the phone with a smartwatch. Five studies used a conversational agent such as Google Home (n=3), an integrated conversational agent on a laptop (n=1), and a computer-based pet avatar on a laptop or tablet (n=1).

Interaction Modalities

The variety of technology and devices made different options available for users to interact with the solutions and vice versa. Over half the studies (n=48) involved touch interaction either as unimodal (n=24) or multimodal (n=24). Seven of these touch solutions could also be used with a keyboard and mouse. This reflects research by [25,122], which demonstrates that touch screen interaction is an effective interaction mode for both old and young users, even with some usability issues. Nine studies combined a touch screen device with speech output, while 13 studies combined a touch screen device with speech input and output. Combining visual and speech modalities is supported by research findings that multimodal interaction is more effective and usable for older adults [123], as compared to unimodal touch or speech [124]. Voice or sound was associated with 29 solutions; 13 studies involved solutions that provided speech or sound outputs, and 16 studies involved solutions that afforded speech or sound input and output. Voice or sound outputs were associated with VR solutions (n=4), robots (n=6), tablet device solutions (n=2), and a web solution (n=1). Voice or sound input-plus-output was associated with VR solutions (n=2), robots (n=6), tablet device solutions (n=3), embodied conversational agent solutions (n=3), a web solution (n=1), and a mobile phone app (n=1). Only 2 studies used gesture as an interaction modality; 1 used a robot that gestured to the user as a demonstration of extraversion [117], and the other was a cognitive game based on Tetris, which included a user gesture capture device [46]. Four studies used haptic (vibration) interaction via a smartwatch and a touch screen device (n=2), a vibrating keyboard with a touch screen device (n=1), or a vibrating handset as part of a VR solution (n=1). Additional interaction modalities provided by VR solutions included joysticks and pedals or rudders (n=4), and robot solutions with lights, facial expressions, and movement (n=7). Table 2 in the Multimedia Appendix 1 lists the device and interaction modality combinations for each study.

How Studies Evaluated Usability or Acceptability

Studies used different methods to evaluate usability. Some studies used the System Usability Scale [42,44-46,61,80,81,88,95,104,105,109], which is a simple, 10-item Likert scale used to assess usability [125]. Research [126] has shown that the System Usability Scale is suitable for evaluating digital health applications. Some studies of robotic solutions used the Almere questionnaire [127], which is based

XSL•FO
RenderX

on UTAUT and developed to evaluate acceptance of assistive social agents by older adults [86,93,94,96,108,112]. Several studies designed their own questionnaires based on TAM, TAM3, STAM, MATOA, or UTAUT.

Themes Derived From Thematic Analysis of Participant Feedback

Inductive thematic analysis of extracted data identified five themes: (1) purpose and need, (2) solution design and ease of use, (3) self-impression (how the solution makes the user feel), (4) lifestyle (how well the solution fits with the user's life and routines), and (5) interaction modality.

Purpose and Need

Participants identified that improving or maintaining their existing cognition level is the primary need, and over a third of solutions focused on this function. The remaining studies reveal other needs identified by participants, and only 2 studies provided solutions for activities that were not identified as needs. Assistance with managing personal finances was identified as a need [75,76]; however, none of the studies provided a solution to this end. Being able to manage one's own finances decreases vulnerability and is an important enabler for independence. Further investigation is needed to determine how to support older adults with MCI to have control of and manage their finances in a safe and secure manner. Participants also identified help to find lost items as a need [93], which was again not supported by any studies. The answer to RQ1A is that proposed solutions for older adults with MCI are perceived as useful, but there are also gaps where functional support is missing. Given the demonstrated importance of perceived usefulness for TA, this is an area where further work is needed.

Solution Design and Ease of Use

Study participants reported a variety of usability and usage issues and noted that an ability to configure and personalize a solution provides flexibility and increases usability.

> *There's all grades of dementia as well isn't there. And some would need more help than others.* [56]

Participants said it would be useful if they could adjust (1) solution tasks to match user skills [42,49,52,60], (2) task complexity [45,55,56,81], (3) task workflow [115], (4) timing of reminders [65], (5) user interface design (colors of background, text, and widgets [56,98], size of text and widgets [47,66], and color contrast [56]), (6) speed, volume, and accent of speech [56,95], (7) language (formal or casual) [108], (8) robotic facial features and height [69,86,94,112], and (9) avatar image [50].

Consistent design, labeling, and widget placement were mentioned as important enablers of usability [88,120], and this is especially critical for users with cognitive impairments or memory concerns. Participants added that they may use multiple toolsets and that seamless integration and consistency across these toolsets would increase usefulness and ease of use.

Participants provided ideas about how to increase usability of solutions, such as (1) reduce or eliminate the need to remember passwords or specific trigger words because this increases complexity [121], (2) make messages specific and include sufficient detail so the message is actionable [80], (3) provide sufficient time to read text messages [42,68,105], (4) use language appropriate for older users [98], (5) use simple, familiar, and common words [88,95], (6) use sound as well as visual indicators to make it obvious that an action was performed successfully [95], (7) avoid loud noises and too many animations because these create a distraction [60], and (8) make task steps simple [119]. Participants prefer solutions that provide immediate feedback about task progress and task completion because they are engaging and provide motivation and incentives for use [60,63,74,80,90,64]. This illustrates how UX can influence TA.

Specific feedback points about user interfaces were (1) layout should be simple and not too busy or overwhelming so that controls are obvious and the interface does not overstimulate or place a burden on the user's cognition [44,68,88,120], (2) use visual aids [70], (3) use simple images so the item is easily recognizable [66,110], (4) use intuitive and simple navigation [41,107], (5) use bright and contrasting colors [89,98,107], (6) use large text, buttons, and widgets [40,88,107], (7) ensure all options are visible so information is transparent [44], and (8) list options in order of user priorities because users often select the first option listed [44]. These comments are consistent with design principles proposed by Nielsen [128-130].

Reliable technology creates trust, confidence, and feelings of empowerment [94,95]. Studies where participants experienced technical issues [56,67,72,108], or if the device had a low battery life or charged slowly [99], resulted in frustration and negative feedback.

Participants commented that age-related physical limitations may affect how they use technology, so accessibility is an important design feature of technology solutions for older adults with MCI [40,95,98,121]. Context of use and location were also raised as considerations in this regard (eg, rural vs metropolitan and speed of internet connection [55]).

Studies showed that older adults with MCI prioritize security and privacy [48,94]. Some participants said they prefer robots to have mechanical features and to be shorter than a person [94,112] because they felt less under surveillance. This preference has also been reported by other research [131]. Safety was identified as a priority, related to both (1) personal safety when using technology (especially robots or VR solutions) and (2) when using the internet or social media [48]. Participants said that even though privacy is a need, they are willing to compromise privacy and share personal data or their location with medical professionals or carers in an emergency [73]. Some participants said that it would be useful to receive regular reminders of what data is being shared [116].

Given the breadth of usability issues reported and the number of changes suggested, the answer to RQ1B is that proposed solutions for older adults with MCI are not perceived as completely easy to use, and this is an area where future technologies need to focus.

Self-Impression

Participants commented that the feelings they experience while using a solution can positively or negatively affect their comfort,

XSL•FO
RenderX

confidence, and overall well-being. The wearable camera solution made participants feel uncomfortable because it drew attention to them, and they felt conspicuous.

> *If people don't know you, they look at you as if they are thinking. Well, what is he doing?* [57]

Participants also felt vulnerable because the camera may capture private moments, such as when they are going to the bathroom.

> *The camera is black and people look at it a lot. I think that if it were a more natural color, people would look at it less.* [57]

Some participants said that technology would be useful for other people, but not themselves. Technology is often associated with negative aspects of aging, such as loneliness or ill health [111] because it advertises the user's limitations and lack of independence.

> *The telecare system would be useful for me if I had more deficits. But so far, I can manage by myself at home* [84]

Participants said they want solutions to reflect their identity and present a positive self-image. They suggested that solutions should (1) use affirming language that does not remind them about their cognitive limitations [40,68,72,76], (2) include nondirective task workflows (eg, participants prefer a system to check in rather than remind [80]), and (3) not draw attention to the user or the solution; this is especially true for robotic solutions [94,111,112] and the wearable camera [57]. Self-concept and social presence have been shown to be determinants of TA in the MATOA model, and a literature review [132] describes similar feedback.

Participant personality traits did not appear to affect acceptance of robots in the long term [96]; however, differences were observed over the study duration. Some participants felt comfortable engaging with a robot and interacted with it in a human-like manner [86,106]. They said a robot is novel and suggested that it should be human-like with autonomy, be able to perform simple tasks, and interact via 2-way communication [45,69]. This is consistent with existing research [133], which demonstrated that robots that take initiative, exhibit more activity, and are extraverted are better accepted by users.

> *I don't see much difference between [my doctors] and the robot except one is ran by electricity and the other one is a human being.* [45]

Other participants said they want to engage with real people rather than anthropomorphic technology. They value human connection [88,106,111], and there is a concern that the use of technology will reduce their existing human contact. These participants preferred more machine-like robots that did not imitate human traits.

> *A robot doesn't have a heart, It must be for people who are very handicapped. It's not for me. It makes me think that my life is terminated. I'd rather die than live with a robot.* [112]

Other concerns identified by participants relating to the use of robot solutions were that the robot would (1) be hard to use or experience technical problems, (2) not do what they needed or wanted it to do, (3) be expensive, (4) increase isolation, or (5) make them too dependent on the robot [94,111,112]. Nevertheless, many participants felt optimistic about anthropomorphic solutions and recognized their potential.

> *The human aspect, the "feeling," is hard to create with a robot. But there is an enormous progress in that world, and I do believe in it. Of course, still in combination with us, humans.* [106]

Participants who said they prefer more machine-like robots were less willing to create an emotional connection with the robot [111,112]. However, some participants got very attached to their robot solutions, treated the robot like a friend, and became sad when the study ended [53,69,78,113]. This raises important issues for designers about how to support users if technology solutions fail or become unavailable.

Lifestyle

Participants said that independence and autonomy are important, and some said they felt a responsibility to their relatives and carers to maintain their self-sufficiency [45]. Participants want to feel in control of their lives [45,51,60,75,76,80,88,103,111], and technology solutions that create a sense of user empowerment are preferred rather than solutions that impose mandatory interventions or training [60]. While participants appreciate the increased independence technology can provide [76], they are also concerned about receiving too much assistance (from technology or people) in case they become reliant on this and lose their autonomy [111] or independence [69,76]. The studies reinforced that IT literacy, training, and availability of support from carers and family are enablers for acceptance and continuing use of technology [47,48,63], which is consistent with TAMs. However, it is important that technology solutions do not create a dependence on support services, which in turn would erode independence.

Cost was identified by study participants as an important factor when considering adoption of a technology solution [63,84,94,106,112]. This is consistent with UTAUT2 and H-TAM, which include cost, price, and value or perceived benefit as determinants of adoption.

Physical comfort and convenience are important considerations for the use of technology. Most participants enjoyed the novelty of VR solutions; however, some experienced visual discomfort or nausea, found the headsets uncomfortable, or said the VR solutions were not practical [79,81,110, 39].

> *Well, I liked it, but it was too heavy and big for me. I had difficulty breathing because it wasn't staying in place and fell into my face blocking my nose.* [81]

The answer to RQ2A is that participants prefer devices that are light and portable (mobile phone or tablet), commonly owned (mobile phone), readily available, and have a reasonably large screen [74,84,119,120]. This review also identified that older adults with MCI do not like small wearable technology, such as watches, because the screens are too small, and many participants said that watches are not convenient because they are no longer part of their everyday toolset [74]. In addition, the physical size of the technology solution and its placement in the home affect ease of access and contribute to convenience

XSL•FO
RenderX

(eg, smaller robots take up less room and are less intrusive in a home setting [45,106]).

Studies where solutions were integrated into participants' existing lifestyles and routines made participants feel comfortable, confident, and more in control. This is consistent with the STAM, MATOA, and H-TAM models, which show that compatibility, ease of use, and maintaining a sense of control are important for older users of technology.

> *I like that Google kind of feels like a part of the house, and not something that I have to keep answering to all the time like my morning alarm.* [80]

Interaction Modality

Study participants provided positive feedback for voice interaction and said it was intuitive and easier than writing [45]. They also mentioned challenges such as (1) the solution's accent was hard to understand or the solution did not understand the user's accent or speech pattern [56,72], (2) the speech was too fast or the volume was too loud or too soft [68,78], (3) the solution spoke for too long [108], (4) the solution only recognized a limited vocabulary and participants had to remember specific "trigger" words to activate the solution or give it commands [53,110,121].

> *If it was more New Zealand English spoken it would be easier for me I think.* [56]

Similar feedback has been documented by other researchers studying voice interaction with older users [27,32]. Research has demonstrated that subtle differences in speech can be observed in older adults with MCI [30], and people with cognitive decline speak slower, in smaller chunks, pause more often, have longer silences, respond slower to questions, and provide shorter answers [134]. This highlights the importance of including older adults with cognitive impairments when designing and evaluating voice interaction solutions. Mozilla [135] is leading the world's largest open-source voice data project called "Common Voice." The project is building and refining a voice dataset that is being used to teach machines to speak, and so far, it includes 131 languages and 32,584 hours of recorded voice data. However, analysis [136] shows that people older than the age of 90 years are represented only in the Mongolian and Polish languages, and people in their 80s are only represented in the Esperanto, Turkish, Abkhazian, Toki Pona, and Hebrew languages. Of the English-contributing voices, there are 0.01% in their 70s, 0.04% in their 60s, 0.05% in their 50s, 0.09% in their 40s, 0.14% in their 30s, 0.25% in their 20s, 0.06% in their teens, and 0.36% of unspecified age. It is not known if any of the recorded voices are from older adults with MCI. Technology solutions using speech interaction increase their risk of error if they cannot recognize the speech of older users or the speech of people who are cognitively impaired. Users' current optimism creates an opportunity to invest in voice interaction to improve its usability and effectiveness.

Participants said that touch interaction is effective and easy, especially for less IT literate people [55,107], but they experience difficulties such as (1) trouble dragging items across the screen, (2) knowing how much pressure to use [100], (3) small screen or widget size making it hard to select the target accurately, and (4) using the touch screen if the user has dexterity problems [41,72,95,100]. Some participants chose to use an instrument to avoid these challenges [41,95].

> *I have a problem only with, first, with the gentleness of the finger. My finger isn't the gentlest thing.* [100]

These findings are consistent with outcomes from a literature review investigating the use of touch screens by older users [122], and an investigation of touch interaction, which identified usability issues associated with clicking, dragging, zooming, and rotating on a touch device for both older and younger users [25]. Based on feedback from study participants in this review, it appears that these challenges have not been fully resolved.

Participants said robotic assistants should be able to engage in both a verbal and nonverbal manner, and they preferred robots that can speak, listen, and answer questions rather than those with 1-way interaction via a touch screen [45,69]. If the solution is embodied, they want to be able to touch it physically and interact with it rather than simply view it on a screen [53]. Active robots that performed tasks were deemed more pleasant [96]. This is consistent with findings that robots with unimodal auditory 2-way feedback are highly usable and acceptable for older adults [27].

Participants were agnostic to haptic interaction, except for conveying that a smartwatch was not a preferred device, and suggested that it is useful to be able to control technology remotely [108,119], which supports the need for comfort and convenience.

The answer to RQ2B is that participants prefer multimodal interaction, in particular speech, visual or text, and touch [60,80,88,115,118,121] because it is flexible, provides options for use if people have physical or cognitive limitations, and makes solutions accessible to people with poor hearing or vision or speech limitations. This supports existing research about the effectiveness of different interaction modalities for older users, which showed that multimodal interaction is most effective [28,29,137] and that the effectiveness of interaction modalities and multimodalities is task- and user-dependent [26,29,138]. However, no studies included older adults with cognitive impairment, which creates a gap in understanding the effectiveness of different interaction modality combinations for this population.

Discussion

Principal Findings

Participants across studies reported similar needs but often in a different priority order, and this scoping review cannot (1) provide a definitive priority order for needs; (2) identify if needs are relatable to technologies or devices; or (3) attribute differences to the context of use, cultural differences, participant demographics, or the way MCI is affecting participants' lives. Mondellini et al [85] found that user needs appear to be location-specific, but further research is required to understand which needs are location-specific versus those that are generalized.

XSL•FO
RenderX

Fadzil et al [139] completed a review of existing technology solutions for older adults with cognitive impairments and found that current solutions are focused on (1) caregiver support, (2) strengthening cognition, (3) cognitive rehabilitation, and (4) using technology for disease prevention or self-management. Fadzil et al [139] do not comment on reported needs, technology preferences, or opinions about existing solutions for older adults with cognitive impairments. Neither does it describe how well existing technology supports user needs, nor how well technology is aligned with users' preferred ways of doing things. This gap contributes to the lack of understanding of TA by older adults with MCI.

Our review identified that security and privacy are important for older adults with MCI; nonetheless, they are prepared to compromise these to feel safe. However, they do not want to be continuously watched or feel like they are under surveillance. Nastjuk et al [140] used the term "techno-invasion" to describe the stress caused by constant observation and monitoring. Solutions must balance the need for users' privacy and security with their need for safety and well-being.

A positive UX is a significant enabler for technology acceptance, and ease of use contributes greatly to UX, which suggests that designers must give both priority. User attitude has been identified in TAMs as a determinant of use, and several studies commented that MCI has an impact on a person's attitude toward technology use [48,74]. This observation has also been made by other researchers [43], who noted that we need a greater understanding of how sociodemographic factors and cognition affect attitude.

Some older adults with MCI are not willing to connect with a robot because they prefer to interact with a human, while others are comfortable engaging with anthropomorphic solutions. Our review identified that participants who created an emotional connection with an anthropomorphic solution were vulnerable to becoming depressed once the solution was no longer available. This raises important issues for designers about how to support users if technology solutions fail, and ethical issues about how to manage emotional connection and attachment to more anthropomorphic solutions. It illustrates that technology represents part of the solution but not the entire solution [75], and that service providers must balance the need for human connection with the need to increase efficiency and reduce demand on health services.

Our review found that participants experience a variety of usability and usage issues, and that the flexibility of use and the ability to configure a solution increase ease of use. Older adults with MCI feel more comfortable, confident, and in control when solutions are consistent, predictable, and integrate into their existing lifestyles and routines. People often use multiple toolsets, and technology providers should prioritize consistency and seamless integration of their products. Overall, our analysis reveals that technology solutions should support how people behave and live, not require them to change and adapt to how the technology operates.

Some studies recommend that technology solutions for older adults with MCI should be designed together with this population [48,73,74,95,102,107,116] to ensure that all needs are identified and appropriately prioritized. This recommendation is supported by our findings, which show that while there is consistency in the top-priority need, there are differences in how participants in different locations prioritize the order of needs. Existing research shows that there is cultural and contextual influence on TA, and differences in the needs and priorities for independent living of older adults in Sweden and Poland, and the technologies they would consider using [141]. Given the evidence for the importance of perceived usefulness and ease of use as factors for TA, it is critical to understand the needs and characteristics of the target user base so we can design to maximize TA. User-centered design (UCD), first proposed by Kling [142], is a design methodology that focuses on usability and UX. UCD promotes the inclusion of end users in every stage of solution creation, starting with initial data gathering to understand users' characteristics, environment of use, and requirements. UCD is iterative and incorporates regular artifact evaluation and refinement based on user feedback. UCD processes and techniques have been applied successfully to design assistive technologies for people with dementia and shown to be an effective way to accurately capture requirements and ensure solution usability and acceptance [143].

Scope of Future Work

This review revealed that older adults with MCI have opinions about how and when they want to use technology, and it is imperative that future solutions are designed collaboratively with this population. Research is needed to accurately identify the needs of older adults with MCI so we understand what would be considered useful and how best to position technology in their lives. It would also be beneficial to identify needs that are common and which needs vary depending on demographics, location, or other factors.

Solutions designed for older adults with MCI must generate a positive experience because this affects a user's comfort, confidence, and overall well-being. This review collated suggestions from participants, but more research is required to fully understand the factors to be considered.

Participant feedback suggests that personalization and control, and enablement are important for older adults with MCI, but it is not clear how choice with respect to technology, device, and interaction modality affects TA. This review identified that older adults with MCI do have preferred devices and interaction modalities; however, further work is needed to fully understand the effectiveness of different combinations of interaction modalities and how these are influenced by the effects of MCI, context of use, device being used, and task being performed.

Based on the findings, older adults with MCI want to have autonomy, independence, and feel safe. They are accepting of technology if it positively contributes to their lifestyle and provides a sense of well-being. Future research should aim to provide clarity about how to effectively meet safety, privacy, and security needs and establish technology as an enabler for independence and autonomy in older age.

Finally, the collection of longitudinal data about technology use by older adults with MCI would capture changes to usage patterns, preferences, and adoption factors as MCI advances

XSL•FO
RenderX

and enable us to understand how solution designs should allow for adaptation to support MCI progression.

Study Strengths and Limitations

This review comprehensively searched 9 databases for studies over a 10-year period. It considered research about a broad set of technology solutions proposed for older adults with MCI in the pre– and post–COVID-19 environments.

However, the study is not without limitations. This scoping review only included studies in English, so it is possible that untranslated relevant studies were overlooked. Most studies published their outcomes promptly after data collection; however, [56] began data gathering in 2016 but did not publish the results until 2022. This is a long time in terms of technology evolution and potential for change in people's opinions and attitudes. Some studies did not analyze nonverbal feedback, so it is possible that important information was missed [50,68].

Most studies established an MCI diagnosis using the Montreal Cognitive Assessment [144], the Mini-Mental State Examination [145], or Petersen's criteria [146]. However, the cutoff criteria for each assessment tool were not applied consistently across studies.

The definition of "older adult" is not consistent across the 83 studies. Most studies considered older than 65 years as "older;" however, some studies included participants aged between 48 - 59 years. Some studies did not have an equal representation of genders.

Many studies listed small participant numbers or a lack of cultural diversity as limitations, and most studies included participants from only one location, meaning it may not be possible to generalize outcomes. Less than half of the studies were completed in a real-life setting, so outcomes may not be fully representative of real-life results.

Studies did not collect a consistent set of participant data (such as IT literacy, existing devices and technology being used, education level, or profession), so it is not possible to comment on how these may have impacted participants' opinions, although age, sex, education level, or experience are listed as moderators in existing TAMs such as TAM, UTAUT, and MATOA.

Some studies did not have people with MCI represented in all phases or excluded people with physical limitations, so the opinions of these people have not been considered. In addition, the perspectives of other important stakeholders, such as medical and allied health professionals who treat older adults with MCI, are not considered in this paper. A study exploring the perspectives of 20 medical and allied health professionals from France, Italy, Japan, and Germany, who treat older adults with cognitive impairments [147], identified that physical, social, and cognitive interventions are considered important, and technology is an effective way to deliver and support these. This scoping literature review is the first part of a multistage research project, and future studies will include other stakeholders, such as medical and health professionals, family, and caregivers.

Conclusions

This scoping review identified that improving or maintaining their current level of cognition is the top-priority need for older adults with MCI. Proposed technology solutions are perceived as useful by this population, even though gaps exist where functional support is missing. However, they are not perceived as completely easy to use, due to a variety of usability issues. In addition, technology solutions may have a positive or negative effect on the user's comfort, confidence, self-esteem, self-image, and overall well-being, depending on the feelings and emotions triggered by the solution design. Older adults with MCI have preferences for how they use and interact with technology, and which devices they use. They prefer multimodal interaction—especially speech, visual or text, and touch—because it is effective and provides options for use, and devices that are comfortable, convenient, lightweight, readily available, cost-effective, and have large screens. Future work should focus on (1) gathering information about the needs of older adults with MCI and clarifying how these are dependent on location, demographics, or other factors; (2) improving ease of use and UX; (3) enabling customization and personalization; (4) further exploring interaction preferences and the effectiveness of different interaction modes; (5) providing options for multimodal interaction; and (6) integrating technology solutions more seamlessly into people's existing lifestyle and routines.

Abstract

Background: Assistive technologies (ATs) are used increasingly in community settings to assist in the care of older adults. Despite a rapid increase in the capabilities and uptake of these technologies, gaps remain in understanding the main barriers to their usage.

Objective: This systematic review investigated the barriers and facilitators to the use of AT in the care of older adults.

Methods: Six electronic databases were searched from January 2011 to March 2024. Primary studies were included if they used qualitative methods reporting findings related to barriers or facilitators to the implementation of AT (eg, ambient and wearable sensors, alarms, telehealth or mobile health [mHealth]) for older adults (from the perspective of either carers or older adults) in community settings. All data were screened independently by two reviewers. Study quality was assessed using the Critical Appraisal Skills Program (CASP). Data from each included study were synthesized using thematic synthesis, before barriers were mapped against the domains of the Technology Acceptance Model (TAM).

Results: Ninety-five studies were included in the review. The number of studies published in the field of barriers to AT use has increased 3-fold post-COVID-19 in comparison to the previous decade. Ten barriers—privacy, cost, insufficient knowledge, fear of misuse, usability, poor functionality, perceived lack of need, stigma, and lack of human interaction—were identified, as well as three facilitators—awareness of health benefits, targeted training, and user-centered design. Persistent barriers relating to all domains of the TAM were identified, with the majority of these relating to the "behavioral intention to use" domain (cost, privacy, stigma, and fear of misuse). The majority of studies had a moderate/high risk of bias.

Conclusions: There remain distinct barriers to sustained usage of AT for the care of older adults, particularly concerning adoption as defined by the TAM. Further studies investigating the acceptability of ATs are needed to increase the understanding of optimization strategies.

KEYWORDS

older adult; assistive technology; care; aging in place; barriers; facilitators

Introduction

Increased life expectancy in many regions around the world has not been matched by improvements in health span (average length of disease-free healthy life) [1]. This has in turn increased the need for health and social care in older populations [2]. Assistive technologies (ATs) could potentially help enable older adults to live independently for longer, which is most people's

XSL•FO
RenderX

preference, and potentially reserve other kinds of more expensive care for those with higher needs. The term ATs covers a range of devices or products designed to support older people to perform activities of daily living such as sensors, wearables, robotics, and information communication technologies (ICT) such as telemedicine [3]. The challenges to in-person delivery of health care experienced during the COVID-19 pandemic led to rapid development and deployment of technology to remotely address gaps in care provision [4].

There are potential benefits of AT for older adults and their caregivers, such as reduced caregiver burden and increased perceived independence [5,6]. However, there is frequently a mismatch between the design, functionality, and usability of AT, on the one hand, and the needs and preferences of end users, on the other hand [7], leading to significant rates of abandonment [8] and barriers to optimal use [7,9-11].

The Technology Acceptance Model (TAM) offers a framework to assess how barriers to AT use may influence sustained adoption [12]. The TAM essentially proposes that an individual's motivation to adopt new technology can be explained by three factors: perceived ease of use, perceived usefulness, and attitude toward using or behavioral intention to use. Although other comprehensive technology frameworks exist (eg, Unified Theory of Acceptance and Use of Technology 2 [UTAUT2]), the advantage of TAM in relation to others is its relative simplicity, which is often preferred by practitioners and patients over complexity [13].

Systematic reviews of technology adoption in the care of older adults have shown that barriers such as cost, unfamiliarity with technology, perceived lack of need, and poor functionality can all impede the sustained adoption of AT [7,13-17]. However, these reviews either investigated just one technology type [15], only included specific populations with chronic conditions [7,13], or were older than 4 years [16,17]. Given the broad range of available AT, its adoption across diverse older adult care groups, and the pace at which it is developing, this review [18] aimed to synthesize the latest published qualitative literature, informed by the TAM. This then allowed for the identification of barriers and facilitators to implementing a wide range of AT to support paid and unpaid care for older adults.

Methods

Protocol Registration

The protocol for this systematic review was prospectively registered on PROSPERO systematic review registry (CRD42021266656) in July 2021 and was reported in accordance with the Preferred Reporting Items for Systematic Review and Meta-Analyses (PRISMA) statement checklist [19] and the Transparency in Reporting the Synthesis of Qualitative Research guidelines [20].

Search Strategy and Selection Criteria

A comprehensive search strategy was developed in collaboration with a medical librarian prior to execution in 6 electronic databases (Medline, CINAHL, Embase, PsychINFO, Web of Science, and Cochrane Library) from January 2011 to March 5, 2024. Searches were limited by year to capture the most recent evidence and technological advances. Searches included appropriate keywords and medical subject headings. Database searches were supplemented with searches for gray literature in Google Scholar, OpenGray, and MedRXiv preprint server and forward and backward citation searching (to October 2024), including the reference lists of similar systematic reviews found from Google Scholar. The full search strategy used in Medline can be viewed in Table S9 in Multimedia Appendix 1.

Inclusion and Exclusion Criteria

Primary studies using qualitative methods to understand contextualized personal perspectives of the barriers and facilitators of ATs to support paid and unpaid care for older adults in the community setting were eligible for inclusion. We restricted the search to more recent studies, given rapid changes in AT [21-23]. Barriers and facilitators could be from the perspectives of either older adults or their carers. Studies exclusively containing participants with a single condition were excluded (such as heart failure or diabetes), as a review that only included participants with chronic conditions was published in 2024, which removed the need to synthesize studies in this area [13]. Therefore, this present review only included studies of the general population of older adults receiving care. Given the large volume of studies published in the field of AT for care, this also allowed the review to remain manageable in terms of the number of potentially relevant studies. Similarly, studies exclusively reporting on the use of technology to replace normal care practices during COVID-19 social distancing were also excluded, as these were often temporary and were not planned as a long-term care solution. A detailed description of further inclusion criteria used to select relevant studies is outlined in Textbox 1, while Table 1 describes the definitions applied throughout this review.

XSL•FO

Textbox 1. Inclusion and exclusion criteria

Inclusion criteria

- Participants were older adults (defined as aged 60 years or older).
- Participants were receiving some form of paid or unpaid care in the community setting (at home receiving domiciliary care or family care, assisted living, care homes, short-term care in the community, eg, rapid response teams to prevent emergency admission, long-term stays in community hospitals).
- The study explores some aspects of either barriers or facilitators of assistive technology usage, or both.
- Technologies explored must be in the context of assisting in the care or independence of older adults (eg, via remote monitoring).

Exclusion criteria

- Studies where participants' mean age was <60 years.
- Participants are in short-term or acute hospitals.
- A study population made up exclusively of older adults with a specific condition (with the exception of dementia).
- Studies using technology explicitly to replace usual care during social isolation periods of the COVID-19 pandemic.
- Quantitative research.
- Secondary research.
- Study focuses on the general use and acceptability of technologies without exploring barriers or facilitators to actual usage.

Table . Definitions used for inclusion or exclusion criteria application.

Criteria name	Descriptor
Paid and unpaid care	Any care provided to older adults by health care professionals, third sector organizations (paid/formal care), and friends and family (unpaid, informal care).
Assistive technologies (AT)	Any devices, products, systems, and services that were installed or utilized within a participant's living environment, community-based care environment, or on their person, with the primary aim to assist in activities of daily living or with the process of care provision through remote monitoring or data generation for care provision.
Facilitators	Factors that increase, improve, promote, facilitate, or enable the use of AT.
Barriers	Factors that prevent, obstruct, or decrease the use of AT.

Screening and Data Extraction

Consistent with the Joanna Briggs Institute Manual for Qualitative Evidence Synthesis [24], title and abstract and full-text screening were undertaken by two independent reviewers using Covidence® systematic review software, with conflicts discussed and resolved by consensus (SM screened all studies, with second screening by either BG, AOD, HF, SDS, SWM, BB, AE, KM, or CP). Data extraction was undertaken using a predeveloped data extraction template covering study identifiers, methods, population, technology, and facilitators and barriers. One reviewer extracted all studies, with a second reviewer checking extraction for accuracy, with any discrepancies discussed and resolved by consensus.

Quality Appraisal

Studies were assessed for quality using the Critical Appraisal Skills Program (CASP) tool for qualitative studies [25], extracting methodological issues that could be sources of bias, rather than assigning scores of quality.

Thematic Synthesis

We adopted the principles of framework analysis to conduct a deductive thematic synthesis [26]. Two researchers with qualitative experience (SM and AOD) independently coded facilitators and barriers from two primary studies to develop a working analytical framework, which was then tested on a further study. After modifications, the remaining studies were coded by the lead author. During the final stage of data interpretation, facilitator and barrier themes were developed by the lead author by looking at the data set as a whole and through discussions with the wider team, in addition to categorizing studies by participant type (ie, carer, older adult, or both). Illustrative quotes relating to each theme are presented in Table S6 in Multimedia Appendix 1 to provide context. Following thematic synthesis, barriers were mapped onto the domains of the TAM (by SM) to help identify aspects of technology adoption which may present greater need for support, or where particular interventions can facilitate usage. Specifically, identified barriers were aligned with the stage of the TAM at which they were determined to present themselves within the literature. For example, cost is a barrier that mainly prevented

XSL•FO
RenderX

participants from uptaking AT in the first place; therefore, this barrier would be mapped to the "behavioral intent to use" TAM domain. While a multitude of technology acceptance frameworks have been developed [27], the TAM was selected as the most appropriate framework for this review for two reasons. First, the TAM was developed using two behavioral theories which directly influence adoption behaviors; namely, theory of reasoned action [28] and theory of planned behavior [29]. Second, the TAM is a simple model consisting of five easily interpreted domains, rendering it a useful framework for a wider audience to comprehend or apply to their own work, thus potentially increasing transferability of the review findings.

Additionally, the proportion of barriers within each TAM domain for papers classified as pre-COVID (ie, primary studies indicate data collection was conducted prior to January 2020) or post-COVID (ie, primary studies indicate in methods that data collection was conducted post January 2020) was calculated. Results were summarized to observe both the volume of papers published in these two periods and any proportional change in TAM domains (represented by different colors) covered by identified barriers.

Results

Summary of Included Studies

Ninety-five studies met inclusion criteria (Figure 1). There was considerable study-to-study variation in both the type of technologies reviewed and the level of detail reported regarding the technologies. Studies related to AT facilitated remote monitoring. The most commonly investigated technologies were telehealth or mHealth systems, generic information communication technologies such as smartphones, and other communication devices such as tablets (n=44). Smart home technologies such as ambient sensors were the second most common technologies (n=23), followed by wearables such as sensors and alarms (n=13). The remaining studies investigated workforce support tools such as electronic health records or decision support tools (n=8) and robots (n=10); four studies reported on findings for more than one AT type. Further details on each included study can be viewed in Tables S1-S5 in Multimedia Appendix 1.

Study Quality

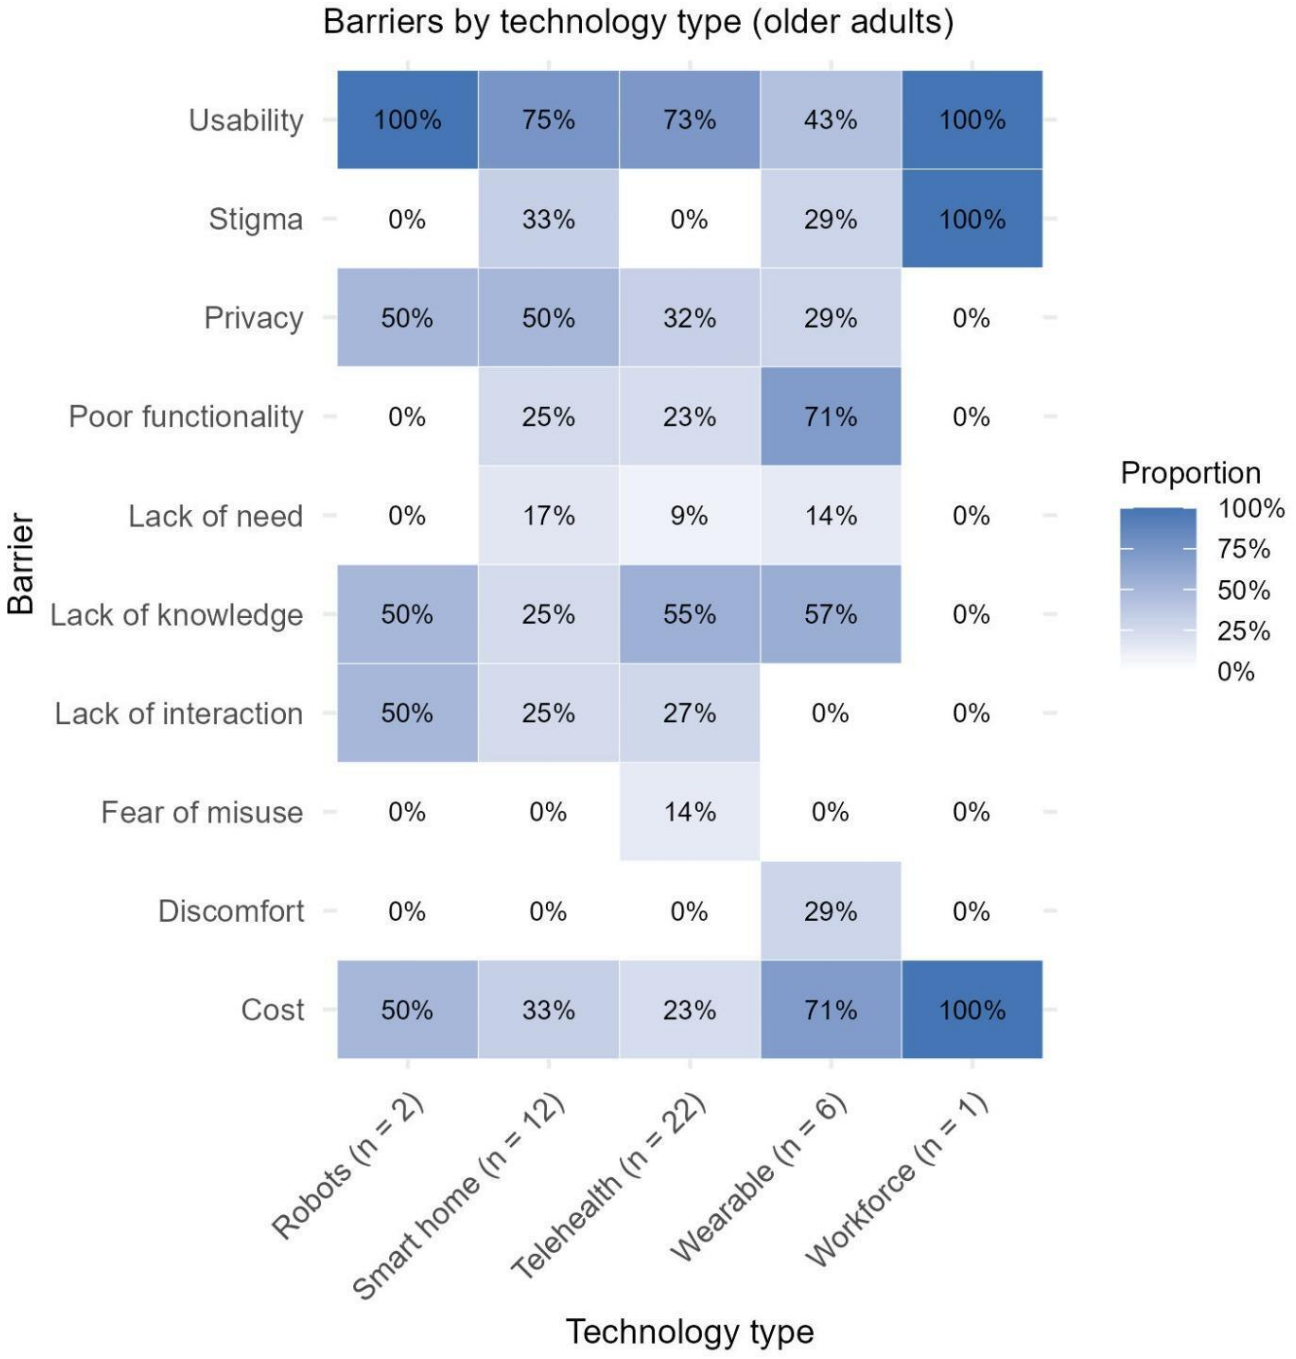
Overall, studies included in this review effectively specified their research question—target population group—and described their findings adequately in relation to the aims of the study. Recruitment strategies were often not reported in sufficient detail. Additionally, in general, studies did not adequately report steps taken to ensure rigor of findings, with only five studies adequately considering any potential influences the researcher(s) may have had over participants (eg, whether the researcher is known to the participants, is an external evaluator, or a member of the intervention implementation team), in turn meeting all criteria of CASP [30-34]. Some studies provided limited descriptions of the types of technologies tested in the studies, which in turn made defining specific barriers between technologies challenging. The majority of studies were small scale and of a moderate to high risk of bias overall. Table S7 in Multimedia Appendix 1 provides full CASP scores for all included studies.

Barriers to AT Use

Three of the 10 themes were related to technology design (intrusive/discomfort, poor functionality, and usability; see Table 2). The most common barrier across all technology types was usability, and lack of knowledge was also consistently identified (eg, lack of experience with technology, unfamiliarity with digital interfaces, etc). Stigma showed considerable variation, with no barriers related to stigma identified for telehealth or mHealth but 30% (n=4) of studies assessing wearables reporting stigma as a barrier. In particular, stigma was more common in wearable technologies and alarm systems, which were perceived to draw attention to users. Indeed, certain barriers appear to be unique to a specific AT. For example, discomfort was cited as a barrier to use in 36% (n=5) of wearable studies but not across any of the other AT groups. Similarly, lack of human interaction was more common in smart home technology, robots, and telehealth or mHealth but not cited for wearables or workforce support. A narrative summary of each identified barrier and facilitator is provided below, with supporting quotes available in Table S6 in Multimedia Appendix 1.

Table . Overarching barrier themes with descriptions.

Barrier and facilitator theme names	Descriptor
Barriers	
Privacy	Any reference to perceptions of the AT[a] invading personal privacy, such as data breaches, being watched, or having access to personal information
Cost	Any reference to the financial implication of using AT, such as the cost of the equipment, its upkeep, or subscription cost.
Usability	Any reference to how easy the AT is to use. For example, if buttons are hard to press or screens are small, making legibility difficult
Poor functionality	Distinct from usability. Any perception that the AT does not work as it is intended to, reducing confidence in its effectiveness, for example, false alarms, poor battery life
Stigma	Any perception that using AT draws negative attention to the user such as pity or perceptions of frailty
Intrusive/discomfort	Distinct from privacy, AT that is uncomfortable to wear or creates obstacles in home
Lack of need	Perception that the AT is not required for care or that the participants do not feel they require such devices for their health
Lack of knowledge	Perception that the participant does not know enough about the correct way to use the AT to use it effectively
Fear of misuse	Reluctant to use AT for fear of breaking it due to incorrect use or compromising safety/privacy through incorrect use
Lack of human interaction	Perceptions that AT is replacing human carers to the detriment of older adults, for example, reduced carer visits due to smart home monitoring, reducing social interactions
Facilitators	
Tailored training	Any form of structured training/education in the use of AT
Viewed positively by trusted relations	Carers, medical professionals, or family members encourage the use of the AT and advocate for it
Support	Any informal help from carers, friends, or family members to be more proficient at using AT



[a]AT: assistive technology.

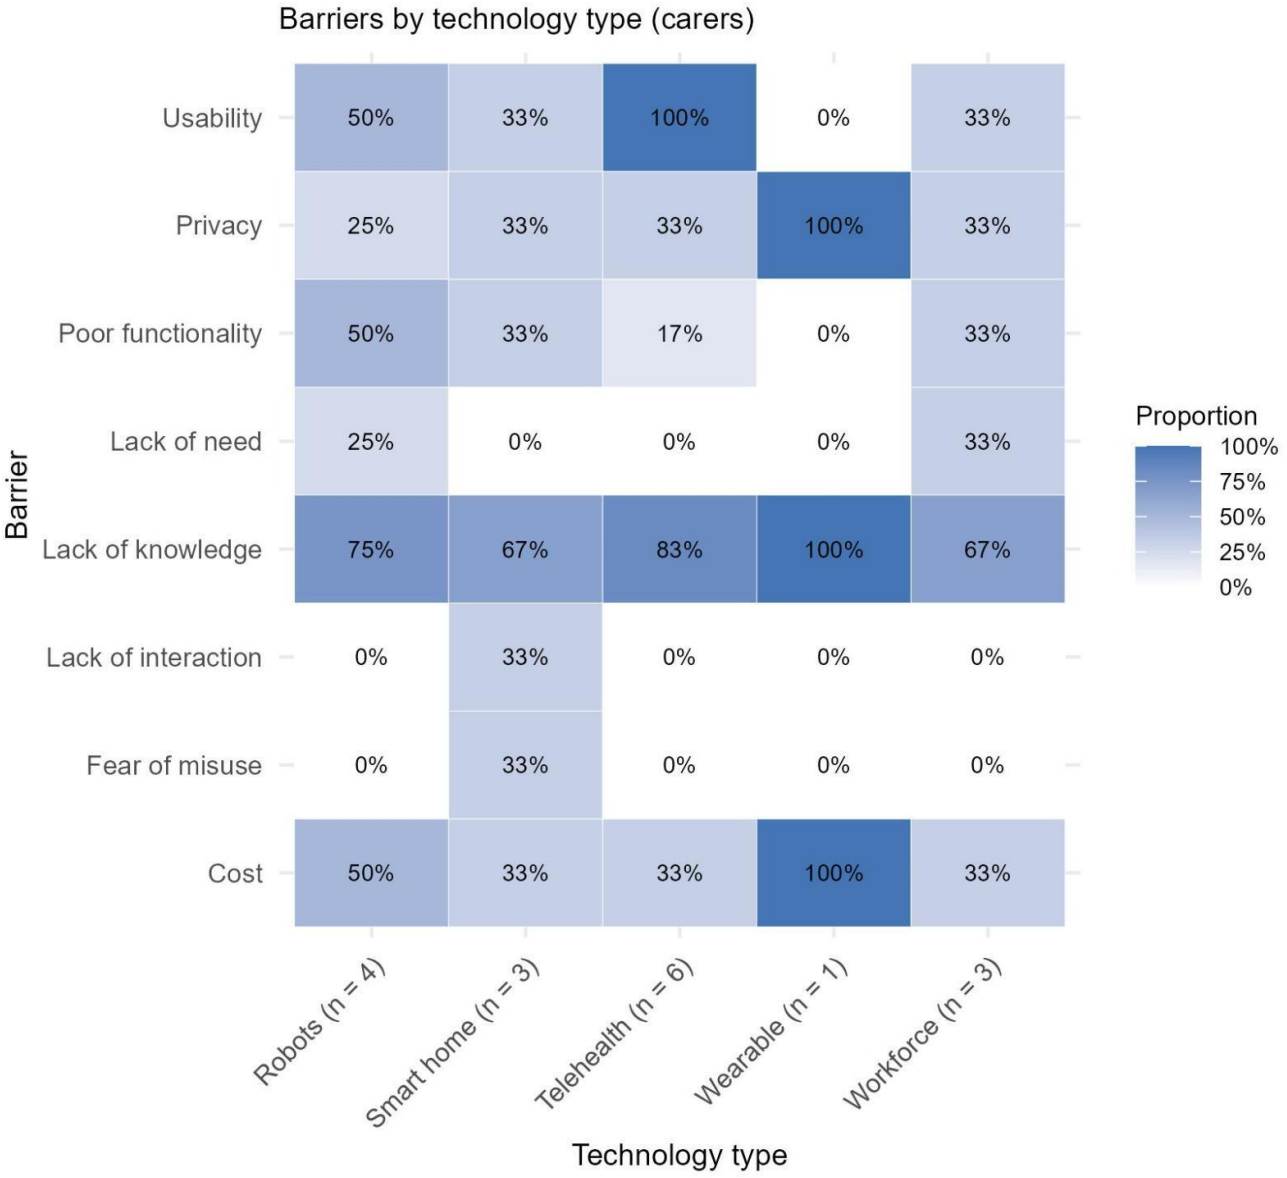
Identified Barriers by Study Participant Group



The majority of studies exclusively included older adults as the research participants, with no carer perspectives included (n=43). Conversely, a minority of studies exclusively recruited carers (n=17), with the remaining studies (n=36) including both older adults and carers in the study sample. Of these combined studies, presentation of distinct findings by each group was limited, making separation of barriers or facilitators experienced by older adults versus carers challenging. Figure 2 present the proportion of barriers for each technology type across studies of older adults, carers, and combined samples separately. When identified barriers between the carer group and older adult group are considered, there are clear differences in the proportional distribution of some barriers. For example, no barriers related to stigma were identified for any technology among carers, while this was a significant barrier for older adults, particularly regarding wearables and smart home technologies. Lack of human interaction also appeared to be more of an issue across technology types for older adults than for carers. Conversely, carers generally identified lack of knowledge as a barrier across all technologies to a greater extent than older adults.

Technology Design

Usability

Usability was the most persistent barrier across all AT types (Figures 2-4) [5,30,31,34-87]. Complex interfaces, intricate buttons/controls, and small text/letters coupled with physical and cognitive limitations were all cited as barriers to effective use of these technologies.

Poor functionality

Poor functionality was a persistent barrier across all AT types [33,35,37-39,41,46,55,60,70,71,80,81,85,88-102]; this pertained to the perception that AT did not actually address the issue it was designed to assist with. This was particularly true where the technology failed or did not work as intended (eg, battery life of sensors was not fit for purpose, inaccurate alarms sounding when no adverse event had taken place, or software that crashed).

Discomfort

Some wearable devices (but not other AT types) were also viewed as uncomfortable to wear, which discouraged usage. Four studies [61,81,97] highlighted that participants did not like wearing the device as it felt uncomfortable and "in the way."

Other Barriers Related to Particular Technologies

Cost

Cost was a major barrier identified across AT types, with 28 studies citing concerns with the financial implications of installing or using AT [5,32-34,38,43,45,47,49,50,53,58,59,70,75,77,82,83,94,96,99,100,103-107]. There was a perception that there would be ongoing costs associated with owning these technologies.

One study of falls prevention technology highlighted that financial cost was only identified as a barrier for participants in their sample that were considered low income but not for

XSL•FO
RenderX

more affluent participants [92], highlighting the potential for AT to widen health inequalities if the barriers imposed by cost are not considered from the outset.

Out of all the barriers identified in this review, cost was one for which there could be potential contextual implications relating to geographical location. Specifically, as the United States is the only high-income country without universal health care, it could be theorized that cost would be a more pronounced barrier among US-based studies. However, of the 27 US-based studies included in this review, only 9 (33%) identified cost as a barrier, which does not considerably differ from the 24 out of 69 (34%) non US–based studies that found cost to be a barrier.

Lack of knowledge and fear of misuse

A lack of knowledge or general fear and anxiety about using technology incorrectly or breaking devices was common. This barrier was particularly evident in studies focused on technology that required participants to interact with software, such as smartphones, wearable devices, or computers [51,66,74,85,97,98,108,109]. In contrast, lack of knowledge was distinctly lower proportionally for smart home technologies, which tend to be more passive in their function (Figures 2-4).

This lack of knowledge and fear of incorrect use often led to feelings of anxiety among older adults that they were unknowingly using the technology wrong, which could lead to negative consequences (eg, inaccurate information being communicated to their providers regarding their health) [98].

Perceived lack of need

Perceived lack of need was a persistent barrier to AT usage, particularly for technologies designed to assist older adults to live independently (such as robots or fall prevention systems). This relates to individual self-perception that they were not yet of the age or physical condition to require such assistance, even when it was recommended by health care professionals or family members [44,48,57,62,66,78,92,94,98,104,106,110-112]. One study of older adults' usage of technology to assess frailty in the home demonstrated that although participants acknowledged that such technology could be useful in older age, they did not think that they personally needed such AT to live independently at this point in time, a sentiment shared by participants in other studies [88]. Similarly, some of the technologies reported in this review were perceived by participants (both older adults and caregivers) as simply not useful [88,109].

Concern About Adverse Consequences

Lack of interaction

Lack of interaction was a commonly identified barrier in studies relating to smart home tech, telehealth or mHealth, and robots, in the sense of ATs leading to a decrease in human interaction and opportunities to have informal discussions with health care providers [5,31,35,45,47,52,56,62,84,103,104,113-115]. For some individuals, this represented one of their only opportunities to get out of their home and meet another person (eg, a health care provider), or for someone to visit them (eg, a carer).

Privacy

Thirty-eight studies identified privacy concerns as a barrier to AT usage [5,30-32,34,36,44,45,47,50,56,58,63,67-70,72,75,77,85,89,96,99,100,105,111,112,115-117], either due to perceived intrusion on personal data or potential invasion of personal privacy by smart home technologies. Both older adults and carers in a number of studies perceived the installation of technologies such as ambient sensors or cameras as an invasion of personal space and privacy, which could make them feel uneasy in their own home.

Older adults also expressed concern that health professionals, insurance companies, or members of their family would be receiving private or delicate information regarding their health status, movements, or activities, which was perceived as an invasion of privacy.

Stigmatization

Stigmatization or general awareness of what others would think of them as a result of AT use was also a persistent barrier among older adults identified in ten studies [53,59,70,79,89,92,103] . This was evident in a study of ATs for older adults with age-related vision loss.

Stigma was most prevalent as a barrier to use of wearable technologies, while no studies relating to telehealth or mHealth cited stigma as a barrier. This is likely due to the attention some wearables can draw to the individual due to audible alarms or the visual design of the AT [118].

Facilitators to AT Use

Overview

As is common in research on barriers and facilitators in health care, many of the facilitators identified in this review directly reflect the removal of the barriers described above. For example, affordability, privacy measures, and ease of use were all identified as facilitators to AT use. Below we explicitly describe three identified facilitators that are distinct from simple removal of barriers.

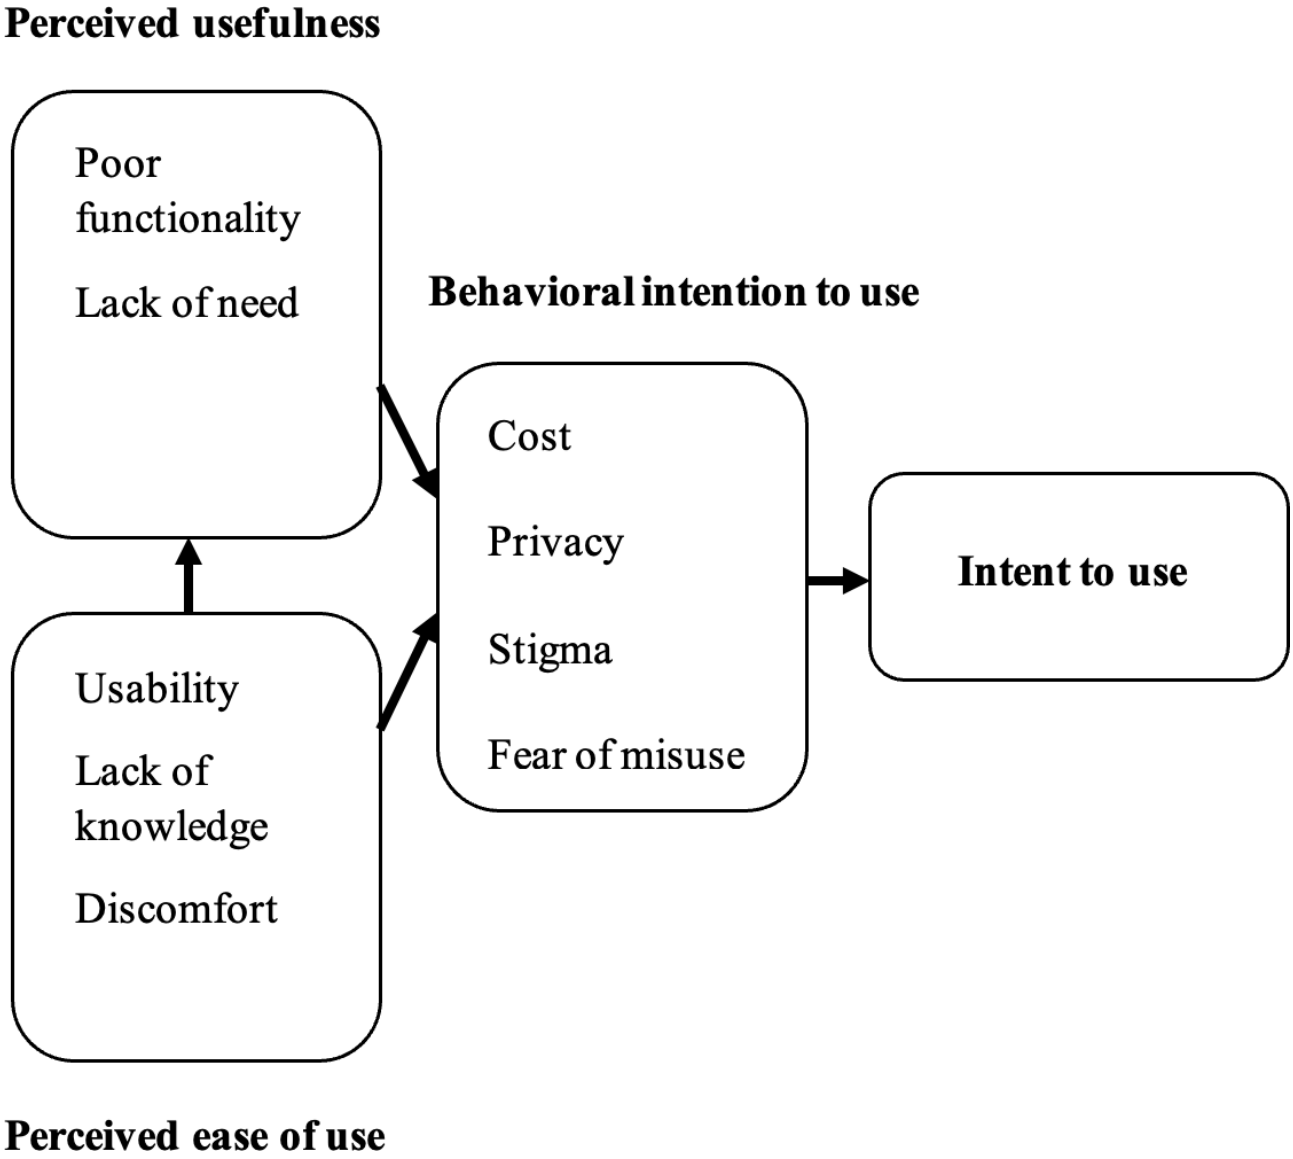
Awareness of Benefits

Certain ATs were highlighted as allowing older adults to learn more about their own health behaviors and daily activities, which was viewed as a facilitator (particularly for wearables) [119,120]. If technology was perceived to increase safety and independence, participants were more likely to state that they would be willing to use it in a number of studies [40,119,120]. For example, across multiple studies of ambient sensors, participants highlighted that the AT offered real benefits by increasing safety and reducing caregiver burden.

Targeted Training

One of the most consistent facilitators to AT usage cited in the included studies was the use of training for older adults on how to properly use the technologies they were to be given [54]. This included strategies such as preimplementation of training materials on AT use to familiarize older adults with the technology [39], and one-to-one or group assistance with usage during initial implementation [53].

XSL•FO
RenderX



User-centered design

A user-centered design was viewed as a facilitator of more user-friendly technology development in 23 studies. Participants in a number of studies cited efforts to involve users in the design process as a benefit to usability. For example, Young and colleagues [87] employed an iterative design process (involving formal interviews and journey mapping) to develop a digital home cognitive screening tool. They found this person-centered design approach to be an asset in developing an AT that was acceptable across different user groups.

Barriers and Facilitators in Relation to the TAM

Figure 5 illustrates how all 10 of the identified barriers from the primary studies map onto the TAM, highlighting the points at which specific barriers present problems in sustained use of AT for care. While the majority of these aligned with the "behavioral intention to use" domain of TAM (cost, privacy, stigma, fear of misuse, and lack of human interaction), barriers such as poor functionality and lack of need impacted on "perceived usefulness," and three barriers (discomfort, usability, and lack of knowledge) mapped onto the "perceived ease of use" domain. Likewise, ATs that were found not to work as intended, or where no explicit care need was perceived to have been addressed, corresponded with perceived usefulness domain. All identified barriers were able to be mapped against a domain of the TAM (Figure 5).

Figure 5. Identified barriers to assistive technology use mapped against the technology acceptance model.

Barriers to AT by TAM Domain Pre- Versus Post-COVID

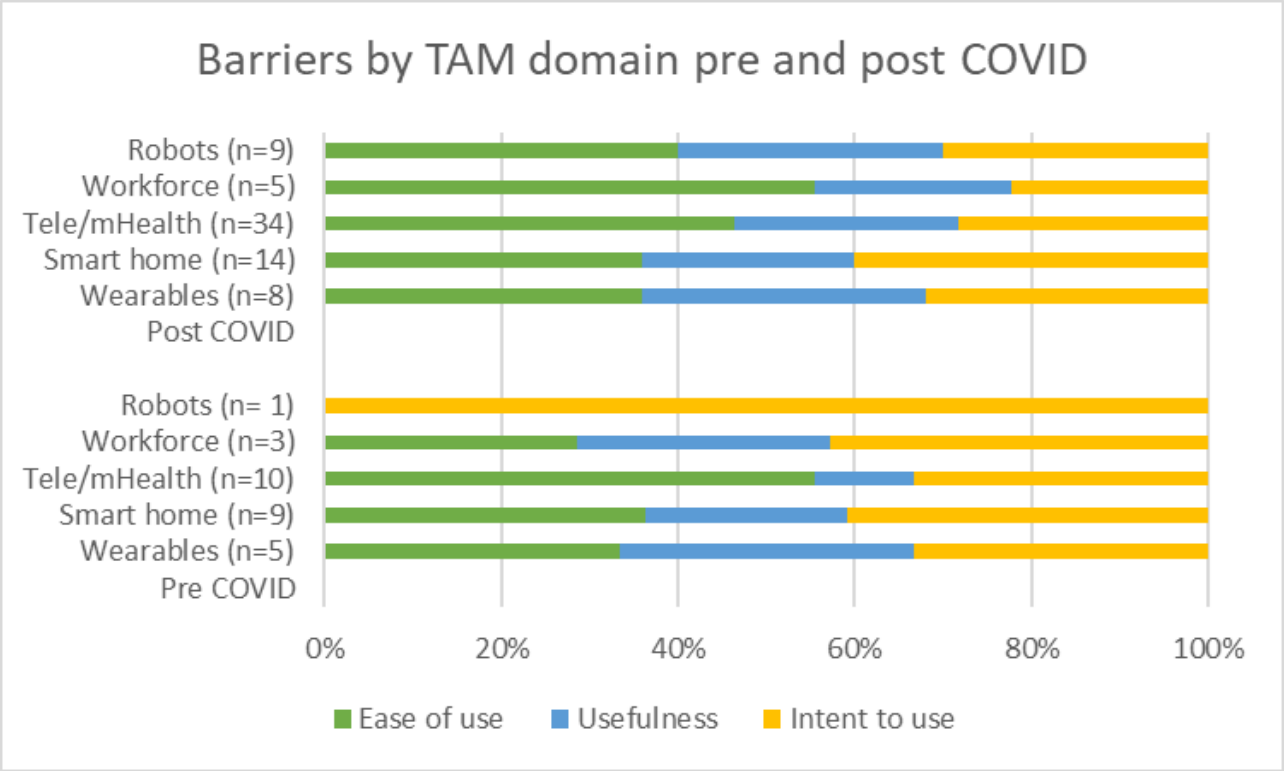


Figure 6 illustrates the potential influence that the COVID-19 pandemic may have had on both the quantity of studies assessing AT for care and their acceptance by users in relation to the domains of the TAM.

The type of barriers and their proportions in relation to the TAM is generally similar between pre- and post-COVID. However, for robots, studies identified further barriers in ease of use, usefulness, and intent to use. In telehealth or mHealth, there was a proportional increase in usefulness barriers, and for workforce support tools, there was a proportional increase in

XSL•FO
RenderX

usability barriers. There was no marked change in barriers relating to intention to use AT in any technology type.

Figure 6. Proportions of identified barriers by TAM domain for studies published pre (2011 - 2020) and post COVID (2021 - 2024). TAM: Technology Acceptance Model.

Discussion

Principal Findings

This systematic review identified 10 barriers related to the use of AT for the care of older adults in community settings. These mapped onto various domains across the TAM, highlighting the point at which such barriers may negatively influence adoption. The findings of this review are reinforced by previous reviews on this topic [13,15,16]. For example, privacy of AT was a consistent barrier, reflecting the findings of previous reviews [15,17]. Specifically, Yusif et al [17] identified privacy to be the most prevalent barrier identified in their review, being cited within 34% (n=15) of the 44 included studies. Similar findings were observed for usability, both for our review and existing reviews [14,17]. Also, in line with the findings of our review, Kruse et al's [14] review of 57 telehealth and mHealth acceptability studies found both technical illiteracy and a lack of desire to be two of the most prevalent barriers identified. This reflects findings in our review whereby perceived lack of need and lack of knowledge were persistent barriers identified across all AT, including studies of telehealth and mHealth. Stigma was also cited as another barrier to AT adoption across several reviews [14,15,17]. This appears to be more prevalent in ATs that are perceived to draw attention to the user, such as body-worn sensors or alarm systems [118]. Wang et al's [16] mixed methods review of long-distance care technologies including 41 studies highlighted the importance of considering personal factors which may mediate adoption of AT among older adults. Specifically, their review highlighted that factors such as individual personality and cohabiting circumstances can influence AT adoption, just as frequently as technology factors such as poor functionality and usability. These personal factors are often more challenging to capture in primary studies, highlighting the need for more robust study designs such as controlled studies with representative participant groups. Additionally, Vassli and Farshchian's [15] systematic review of qualitative studies investigating ICT adoption in older adults mapped identified themes to the UTAUT2. Barriers identified largely mirrored those identified in our review (cost, functionality, lack of knowledge, lack of human interaction, discomfort, and stigma). Mapping the UTAUT2 provided further nuance to these findings, highlighting where specific barriers may influence adoption in relation to each domain. For example, obtrusiveness or discomfort was theorized to negatively impact effort expectancy, thus in turn reducing behavioral intention to adopt intrusive ICT, while stigma could be classified as a barrier to adoption within the social influence domain of the UTAUT2 [15].

To our knowledge, this is the first review to also assess the barriers of a comprehensive range of AT types in conjunction with stages of the TAM. This exercise allowed for the identification of the barriers to AT use in relation to TAM domains. In conducting this exercise, it was important to acknowledge that the COVID-19 pandemic increased the volume of research output in this field exponentially and is likely to have expedited the pace at which a number of technologies have progressed from state of the art to well established and commonly used in the care of older adults [18]. What is less clear, however, is whether these advances in widespread use of ATs have also coincided with progress in addressing the

XSL•FO
RenderX

persistent barriers, which prevent older adults from optimally engaging with care technologies. This review has demonstrated an almost 3-fold increase in the volume of studies in this area, within a third of the timeframe post-COVID-19. It is important to note, however, that it was not possible to identify the mechanisms and drivers behind the increase in research output post-COVID-19. While the pandemic and the necessity to adhere to social distancing played a role, the natural increase in pace and progression of technological advances was also a factor.

Using the TAM domains to map identified barriers, our analysis demonstrates persistent challenges in addressing barriers, which affect older adults' behavioral intention to use technologies. Barriers relating to ease of use and perceived usefulness are largely similar in proportion for both pre and post COVID-19, with the exception of robots, for which a large increase is observed mainly due to more studies now being published versus the one study that existed pre-COVID. This indicates that despite the increased rate of publication in the field, barriers remain the same as those which impeded AT use before the pandemic.

This is unsurprising given the known complexities involved in influencing behavior change in clinical interventions [121]. In older studies of AT adoption, barriers relating to ease of use and perceived usefulness tended to be easier to rectify with alterations to AT hardware or software (albeit with unique challenges related to use by older adults, who often have additional needs such as frailty or vision loss that can require products to need further optimization) [122]. Conversely, addressing barriers such as perceived stigma, fear of misuse, or a lack of human interaction requires more than adaptations to the AT itself and will likely require multicomponent strategies to address the cultural and behavioral issues around the adoption of such technologies [16]. While both primary research and systematic reviews such as the present study can help identify barriers to AT use, adopting strategies to overcome such barriers will require careful planning from all stakeholders. Implementation science frameworks offer researchers and practitioners a viable avenue to achieve this [123]. One such framework that has been successfully applied to technological interventions is the Consolidated Framework for Implementation Research (CFIR) [124,125]. Briefly, CFIR consists of five domains (intervention characteristics, outer setting, inner setting, individual characteristics, and implementation processes). These domains contain further constructs upon which identified barriers of an intervention or ICT can be mapped in order to determine relevant implementation strategies [126]. If used in conjunction with the TAM, these implementation strategies can be further optimized to suit the stages at which barriers occur in the adoption process, as recent studies have achieved. For example, Gallant et al [127] conducted a mixed methods preimplementation study whereby the CFIR was used in conjunction with UTAUT to inform the implementation of automated pain behavior monitoring technology in a health care setting, leading to increased understanding of behavioral intentions to use technology and refinements to the UTAUT, which may help in making the framework more widely applicable to practice. Therefore, the results of this review, which has mapped commonly identified barriers in AT adoption to the TAM, can help researchers to expedite this process when adopting frameworks such as CFIR.

Strengths of this review include the comprehensive search strategy and the consideration of the potential influence of the COVID-19 pandemic to understand how this has influenced technology acceptance. There are a number of limitations that should be considered when interpreting the findings. For example, following the risk of bias assessment using CASP, a large portion of the included studies was deemed to be of moderate to high risk of bias, limiting the trustworthiness of the findings reported. Specifically, studies generally did not adequately address the relationship between the interviewer and the participants. This observation is not limited to this current review. A review of qualitative study methodologies found that none of the 19 included articles adequately described reflexive practice in data collection/analysis [128]. It was noted that most of the included studies appeared to be stand-alone, small-scale feasibility studies. While such studies are an important step in the refinement of ATs, their formative status can limit their generalizability when attempting to use such findings to inform practice at scale [129]. Additionally, previous reviews of the literature have highlighted that participants in studies of technology acceptance tend to be higher than average socioeconomic or educational status and at the younger end of older age [130]. Similar issues likely apply to the studies included in this review (Tables S1-S5 in Multimedia Appendix 1), which could limit generalizability. Finally, we applied a pragmatic approach to data synthesis, using double coding of a proportion of studies to develop a coding framework, before single coding was applied to the remaining studies as is common practice in reviews of a similar nature [131]. Consequently, there is an increased risk of misclassification bias of identified themes due to this. However, given the barriers typically identified in AT use among older adults are fairly distinct and straightforward to define, the true impact of this methodological limitation is likely minimal.

Conclusions

The scope and scale of ATs offering support to older adults and their carers continues to expand. However, ATs commonly are not optimized for use in this context, which could be addressed by better codesign or user-centered design (TAM domains of usefulness and ease of use). Other important barriers relate to the TAM domain of behavioral intent to use ATs, which requires a different set of interventions. Future research should take an implementation science approach by identifying solutions to the barriers to AT use, while conducting more rigorous evaluations of optimized ATs accompanied by robust process evaluations to help identify the impact of any persistent barriers on adoption and other outcomes of interest.

Abstract

Background: More than half of people with HIV are now older than 50 years, and they face an approximately 60% higher risk of developing dementia compared with the general population. In recent years, the application of artificial intelligence, particularly machine learning, combined with the growing availability of large datasets, has opened new avenues for developing prediction models that improve dementia detection, monitoring, and management.

Objective: This systematic review aimed to synthesize the existing literature on the application of machine learning in dementia research among older people with HIV and identify directions for future research.

Methods: A comprehensive search was conducted in PubMed, CINAHL, and Embase in September 2024, limited to studies published within the past 10 years. Eligible articles included original research involving people with HIV applying at least 1 machine learning technique and reporting dementia-related outcomes.

Results: The search yielded 721 articles, of which 26 (3.6%) met the inclusion criteria. Most studies were retrospective and conducted in the United States (n=14, 53.8%), primarily focusing on neurocognitive impairment and HIV-associated neurocognitive disorders. Supervised machine learning techniques were most frequently used and demonstrated strong predictive performance. Common methodological challenges included small sample sizes, lack of external validation, limited participant diversity, and concerns about biological interpretability and generalizability.

Conclusions: Machine learning research on dementia among older people with HIV primarily targets HIV-associated neurocognitive disorders, with limited exploration of age-related neurodegenerative diseases such as Alzheimer disease and related dementias. The absence of longitudinal studies and external validation remains a key limitation. Future research should broaden the focus to all-cause dementia beyond HIV-specific conditions; apply advanced machine learning methods; and leverage large-scale longitudinal, multimodal datasets. Strengthening methodological rigor and enhancing real-world applications will be critical to improving early detection and effective management of cognitive health in this unique aging population.

KEYWORDS

aging; HIV; dementia; cognitive impairment; machine learning; artificial intelligence; PRISMA; Preferred Reporting Items for Systematic Reviews and Meta-Analyses

Introduction

Globally, there were approximately 39.9 million individuals living with HIV at the end of 2023 [1]. With advances in antiretroviral therapy, people with HIV are living longer, and more than 53% of them in the United States are now older than 50 years [2]. Although “older adults” commonly refers to individuals aged 65 years and above, research in the context of HIV often considers aging-related health concerns to emerge earlier due to accelerated and accentuated aging processes. There is a high frequency of neurocognitive decline reported in people with HIV, with approximately a 60% higher risk of developing dementia as they age compared with the general population [2]. Given that there is no cure for dementia, early detection and effective management are critical [3].

However, developing early diagnostic and effective management tools for dementia in this population presents unique challenges. People with HIV exhibit distinct neurological changes, which

XSL•FO
RenderX

include not only Alzheimer disease (AD) and AD-related dementias (ADRD; such as vascular dementia, Lewy body dementia, frontotemporal dementia, and mixed dementia) but also HIV-associated neurocognitive disorders and HIV-associated dementia. The complexity of HIV-related pathologies and comorbidities, along with inconsistent reporting, has posed significant challenges in HIV and aging research [4-6].

Despite this elevated risk, existing dementia detection and management strategies often fail to address the unique needs of people with HIV. In recent years, the application of artificial intelligence, particularly machine learning, combined with the increasing availability of large datasets, has opened new avenues for developing prediction models to improve dementia detection, progress monitoring, and management [3,7-11], offering promising alternatives for unraveling these complex relationships. Although the number of studies leveraging machine learning in predictive modeling of dementia outcomes in people with HIV has been growing, the scientific literature still lacks a synthesized review focused on this population. To address this gap, we conducted a rapid systematic review that followed the core principles of systematic review methodology but omitted a formal study quality appraisal to expedite evidence synthesis [12-14]. The objective of this review was to synthesize the existing literature that has applied machine learning in dementia research for people with HIV and to highlight directions for future research.

Methods

This systematic literature review followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement [15].

Data Sources and Search Strategy

A comprehensive search strategy was developed by the authors (Hwayoung Cho, LL, and RL) through a literature review, with assistance from a health sciences librarian at the academic institution where the study was conducted. Using 3 databases (ie, PubMed, CINAHL, and Embase), we searched the literature on September 24, 2024, with a 10-year publication limit to ensure inclusion of the most current advancements in artificial intelligence and machine learning applications in this area of research. To capture all relevant studies, additional hand searches were also conducted using reference lists obtained from the literature relevant to this review. The search terms used in the title, abstract, or keywords included the following themes: HIV infections; all-cause dementia including AD and ADRD, HIV-associated dementia, and HIV-associated neurocognitive disorders; machine learning approaches including artificial intelligence, machine learning, and deep learning. Medical Subject Headings (MeSH) terms for PubMed, CINAHL Headings for CINAHL, Emtree terms for Embase, and free-text terms were used with the Boolean searching technique. Details on the search strategies are presented in Multimedia Appendix 1.

Overview of Machine Learning Techniques

To provide context, we briefly summarize the most common machine learning techniques [11,16,17]. Supervised learning approaches, such as support vector machines (SVMs) [18,19], random forests, and logistic regression, use labeled data to classify or predict outcomes. Unsupervised methods, such as clustering, identify hidden patterns in unlabeled data. Semisupervised methods combine these two approaches, while deep learning techniques [20], including convolutional neural networks [21] and deep neural networks [22], use multilayered neural architectures to capture complex nonlinear patterns. These approaches are increasingly applied in health care research to improve diagnostic accuracy and risk prediction [11,16,17].

Study Selection and Eligibility Criteria

A web-based collaboration software platform that streamlines the production of systematic reviews, Covidence (Veritas Health Innovation), was used to facilitate the title and abstract screening, full-text review, data extraction, conflict resolution, and data verification. During each screening and review stage, titles and abstracts (LL, RL, RM, JS, and Hannah Cho) and full texts (JS and Hannah Cho) were independently assessed by two reviewers to determine study eligibility. To assess interrater reliability during the screening and review phases, the Cohen κ was calculated. Differences were resolved by consensus and, if necessary, by a sixth reviewer (Hwayoung Cho).

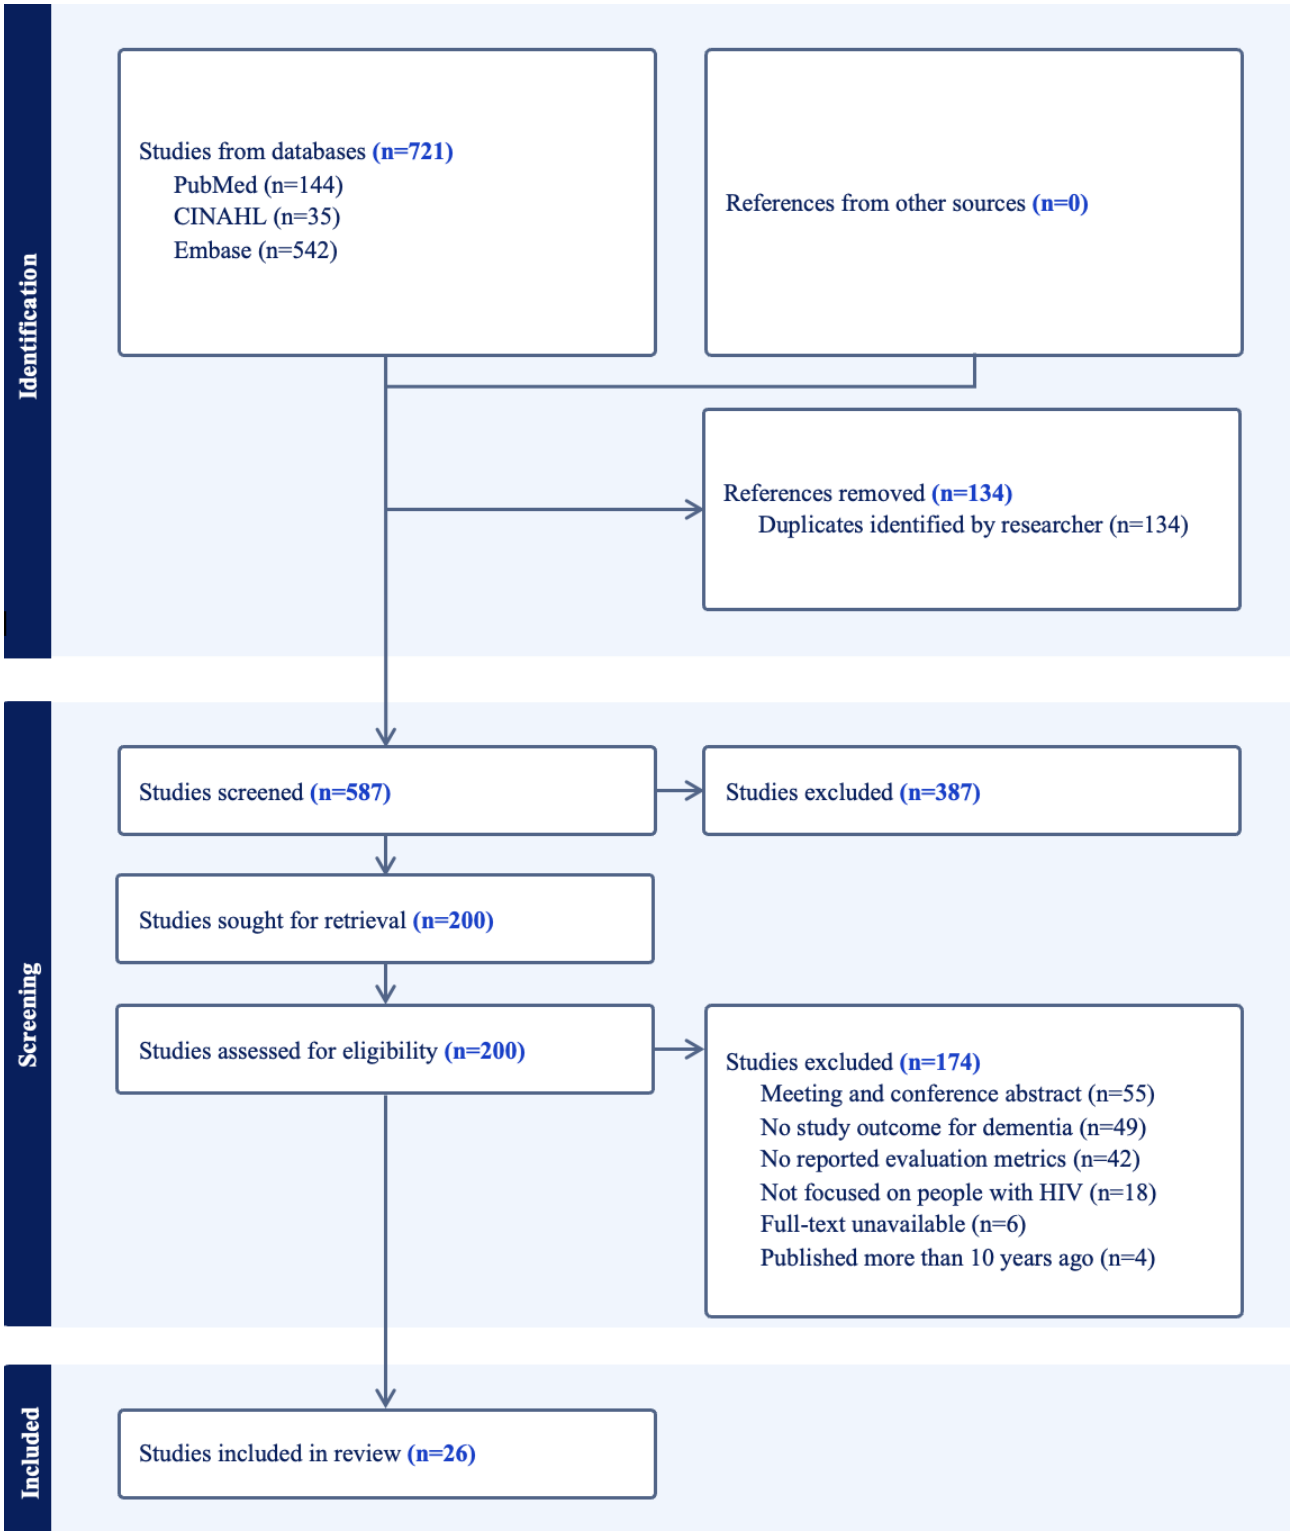
The inclusion criteria included an original research article that (1) focused on people with HIV as the target study population, (2) examined at least one dementia-related outcome, and (3) applied at least one machine learning technique and reported evaluation metrics (eg, area under the curve [AUC] of the receiver operating characteristic, sensitivity, specificity, precision, and F_1 -score). We excluded studies that examined only mild cognitive impairment without including any form of dementia, as our focus was on research specifically involving dementia-related conditions. We also excluded studies that were not available in the English language or full text, or gray literature (eg, clinical trials registries, conference abstracts, dissertations or theses, government reports, issues papers, letters, comments, editorials, correspondences, blogs, or newsletters).

Data Extraction and Synthesis

The following information was extracted from the studies included in the final review using a Microsoft Excel spreadsheet: last name of the first author, year of publication, location of the study conducted, study objective, study design, study sample (eg, demographics and sample size), data source, data period, and subtype of dementia focused. We also synthesized the following information: main aim of using machine learning, type of machine learning techniques, evaluation metrics used for machine learning models, key outcomes from machine learning models, and machine learning–related limitations reported in the article. Adopting machine learning breakdown frameworks [11,17], we subcategorized machine learning techniques by how they infer patterns from data into the following five types: (1) supervised, (2) unsupervised, (3) semisupervised (ie, a combination of supervised and unsupervised), (4) reinforcement learning, and (5) deep learning.

XSL•FO
RenderX

Consistent with rapid review methodology, we did not perform a formal study quality appraisal. Instead, we summarized the methodological challenges reported in the included studies. This approach aligns with the goal of rapid reviews to provide timely, systematic evidence synthesis using streamlined methods [12-14].



Results

Search Results

The initial searches resulted in 721 articles, including 144 (20%) from PubMed, 35 (4.9%) from CINAHL, and 542 (75.1%) from Embase. After removing duplicates, 587 (81.4%) articles were screened for titles and abstracts, and 200 (34.1%) articles were reviewed with full texts based on our eligibility criteria. We had high agreement between raters when making review decisions (Cohen $\kappa \geq 0.80$). A total of 26 (13%) studies that met the criteria were included in the review. The PRISMA flow diagram illustrating the review process is depicted in Figure 1.

XSL•FO
RenderX

Figure 1. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flow diagram of the study selection process.

Study Characteristics

An overview of study characteristics for a total of 26 studies is presented in Multimedia Appendix 2. Most studies were conducted in the United States (n=14, 53.9%) [23-36], followed by China (n=5, 19.2%) [37-41]; Canada (n=3, 11.5%) [42-44]; and other countries (n=4, 15.4%) including Colombia [45], Brazil [46], Ethiopia [47], and Japan [48].

The majority of studies used retrospective observational designs, including 3 (11.5%) cohort studies [25,27,42] and 2 (7.7%) cross-sectional [45,47] studies, while 21 (80.8%) did not specify their design. Data sources included neuroimaging (magnetic resonance imaging [MRI] and functional MRI [fMRI]) [26,28,29,31,32,34,39-41,44], neuropsychological tests, clinical and demographic variables from electronic health records and research cohorts [27,38,40,43,44,47], and other specialized data such as substance use questionnaires [25], the Center for Epidemiological Studies Depression Scale [25,46], and

XSL•FO
RenderX

biological samples from research programs [25,30,31]. Cognitive measures varied across studies and included the Mini-Mental State Examination [26,45], the International HIV Dementia Scale [47], self-reported memory assessments [25,31], and comprehensive neuropsychological test batteries [36,41,43].

The studies examined multiple forms of cognitive impairment among people with HIV, including neurocognitive impairment [26-28,38,42,46,47] and HIV-associated neurocognitive disorders [23-25,29,30,34,39,44,45,48], with particular attention to asymptomatic neurocognitive impairment as a subset of HIV-associated neurocognitive disorder [37,40,41]. Control groups included healthy individuals [26,28,35,38-40,48], HIV-negative cognitively normal participants [24,31,37,39], preclinical HIV-asymptomatic neurocognitive impairment cases [41], and neuropsychologically normal controls [23,30,33,43].

Sample sizes ranged from 9 to 8490 participants, with ages spanning 21 to 81 years. Almost half of the 26 studies (n=12, 46.2%) focused on middle-aged adults (40‐50 years) [24-27,32,33,36,42-46]. Most participants were male (>70%) [23,24,26,28,31-33,36,37,42,44,46]. Several studies (n=4, 15.4%) reported that participants were predominantly White, followed by African American or Black individuals [30-32,42]. Two (7.7%) US studies included primarily African American samples (82.6 % and 69.1%‐89.8%) [27,33]. Hispanic participants were represented in some studies (n=4, 15.4%) [23,30-32], typically comprising 4.8% to 24% of samples [23,31]. A few studies (n=3, 11.5%) reported Asian or other racial groups, but these consistently accounted for less than 5% of participants [23,31,32].

Key Findings on Machine Learning

An overview of main findings from the 26 studies is presented in Multimedia Appendix 3, summarizing machine learning applications in dementia research for people with HIV, the techniques and model performance used, and the limitations of these applications reported across studies.

Applications for Machine Learning in Dementia Research Among People With HIV

In this review, machine learning was applied to improve the diagnosis, prevention, and management of dementia among older people with HIV across studies. Of the 26 studies, some (n=12, 46.2%) applied machine learning algorithms to enhance diagnostic accuracy by analyzing neuroimaging data, cognitive assessments, and biomarkers (including 1, 3.8% study focusing on genetic features [48]) to identify early signs of dementia in people with HIV [23,28-30,33,35,36,41,43,46-48], while other studies (n=2, 7.7%) used machine learning to monitor disease progression, identify symptom clusters, and optimize tailored treatment plans for people with HIV [38,45].

Machine Learning Techniques and Model Performance

Various machine learning techniques were identified across the 26 included studies and classified into supervised, unsupervised, semisupervised (a combination of supervised and unsupervised), reinforcement learning, and deep learning [11,17]. Supervised machine learning was the most prevalent approach, applied in 20 (77%) studies [23,24,26,28-33,35-37,39-43,45-47]. Only 1 (3.8%) study applied an unsupervised machine learning approach [38], while a combination of supervised and unsupervised methods was used in 5 (19.2%) studies [25,27,34,44,48]. Deep learning was used in 2 (7.7%) studies [35,36], whereas reinforcement learning was not reported in any of the included studies.

Supervised machine learning techniques included SVMs, random forests, logistic regression, ensemble models (eg, Adaptive Boosting and Extreme Gradient Boosting), and feature selection methods such as least absolute shrinkage and selection operator and classification and regression trees [23,24,26,28-33,35-37,39-43,45-47]. SVMs were the most frequently applied algorithm, used in 7 (26.9%) studies [24,30,32,33,39,41,48], with reported AUC values up to 0.85 and classification accuracy as high as 82% [24]. Logistic regression was also implemented in 7 (26.9%) studies [25,26,28,37,43,46,47], achieving classification accuracy between 68% and 90% [43]. Random forests were used in 5 (19.2%) studies [31,42,43,46,48], demonstrating strong predictive performance with AUC values up to 0.87 and accuracy levels exceeding 80% [46]. Ensemble models, such as Adaptive Boosting, showed robust performance, with precision and recall scores of 0.80 and 0.77, respectively [46].

Unsupervised learning techniques, including k-means clustering, hierarchical clustering, and mutual connectivity analysis, were primarily used to stratify patients into subgroups and identify distinct cognitive profiles. For example, k-means clustering was applied to classify HIV-associated neurocognitive disorder subtypes and demonstrated strong performance in identifying connectivity profiles, achieving AUC values up to 0.89 [34].

Deep learning techniques were applied in only a few (n=2, 7.7%) studies [35,36]. Convolutional neural networks demonstrated classification accuracies surpassing 90% across various domains [35], while deep neural networks achieved an accuracy of 82% for cognitive impairment and 75% for frailty classification [36].

Internal validation methods, such as k-fold cross-validation, were implemented in 18 studies (69.2%) [24,26,28-36,39-41,43,45,46,48]. In contrast, 6 (23.1%) studies did not explicitly report validation methods [23,25,37,42,44,47], and none included external validation.

Limitations of Machine Learning in Dementia Research Among People With HIV

The researchers in the included studies acknowledged several methodological challenges. A predominant limitation across studies was small sample size [26,30-32,35-37,39-43,48]. Additionally, study cohorts were largely male, limiting generalizability [23,26,40,43]. Some (4/26, 15.4%) studies highlighted unaddressed confounding variables, such as recreational drug use [37,47], antiretroviral therapy resistance [42], and comorbidities, including hepatitis C virus coinfection [42] and depression [23]. Overlapping variables between HIV-associated neurocognitive disorders and other conditions were also reported [43], along with potential overdiagnosis due to scoring methods such as the Global Deficit Score [33].

The “black box” nature of machine learning models raised concerns about clinical relevance and whether predictive

XSL•FO
RenderX

accuracy should outweigh biological plausibility [24,33]. For example, brain connectivity patterns in fMRI data [24] and least absolute shrinkage and selection operator-selected MRI features [33] lacked clear neuropathological explanations, undermining interpretability. Finally, some (3/26, 11.5%) studies did not explicitly acknowledge limitations [28,34,46], potentially omitting critical considerations.

Discussion

Principal Findings

This is the first systematic review to examine how machine learning has been applied to dementia-related outcomes in people with HIV, addressing a critical gap in the literature at the intersection of aging, HIV, cognitive decline, and artificial intelligence. Historically, research on cognitive decline in HIV has centered on HIV-associated neurocognitive disorders, including HIV-associated dementia—a form of neurocognitive impairment resulting from the direct effects of HIV on the brain [4,49-56]. This emphasis largely reflected the shorter life expectancy in the early antiretroviral era, when age-related dementias were less prevalent.

We identified 26 studies, most of which focused on neurocognitive impairment related to HIV-associated neurocognitive disorders, with few investigating age-related dementias such as AD and ADRD. This imbalance underscores a major gap in the current literature and highlights the need for future research exploring the full spectrum of cognitive decline among older people with HIV. Although “older adults” is a common term in aging research, many included studies focused on middle-aged populations, reflecting the earlier onset of aging-related concerns in the context of HIV. As people with HIV continue to age, our findings highlight the need for future research to explore the intersection of HIV, aging, and neurodegenerative conditions beyond HIV-associated neurocognitive disorders.

A rigorous study design is essential when applying machine learning techniques in health care research. Most included studies were retrospective or cross-sectional, limiting understanding of disease progression. Because most studies used cross-sectional designs, they were unable to model change over time or to distinguish transient from persistent cognitive impairments. Such designs cannot capture how small errors in measurement or prediction may accumulate and influence dementia trajectories. Future research should use longitudinal designs and temporal modeling approaches to track cognitive changes and evaluate progression risk among older people with HIV.

In addition, retrospective and cross-sectional study designs restrict the ability of current machine learning models to account for real-world contextual factors such as environmental influences, day-to-day variability in cognitive performance, social interactions, and cultural factors that may affect how dementia symptoms manifest or are reported in people with HIV [57,58]. Without longitudinal or ecologically valid data, current machine learning models cannot fully capture the dynamic and multidimensional nature of cognitive changes over time [59,60]. Moreover, most studies did not incorporate contextual or social determinants of health, such as social support, treatment adherence, living conditions, or daily activity patterns, even though these factors are known to influence cognitive trajectories and dementia risk among older people with HIV. Integrating such variables into future machine learning frameworks could enhance the ecological validity and predictive performance of dementia models [61,62]. Longitudinal datasets are also critical for developing models that predict dementia onset or progression [63], as they enable temporal analyses and improve generalizability. Leveraging multimodal data, such as MRI and fMRI, laboratory tests, and neuropsychological assessments across time, can provide a comprehensive view of brain health and facilitate early detection of dementia among older people with HIV.

Integrating biomarker and genetic data with clinical and neuroimaging features offers promise for enhancing prediction of dementia outcomes [64-67]. Of the studies included in this systematic review, only 1 used machine learning to identify key genetic features predictive of HIV-associated neurocognitive disorder status and proposed a framework for biomarker development [48]. Future research should integrate biomarker and genomic information to improve predictive performance and support clinical applications.

Supervised learning methods, including SVMs, logistic regression, and random forests, were the most frequently used and generally demonstrated strong predictive performance across studies. However, despite their high accuracy, supervised machine learning models often require large datasets and substantial computing resources that may limit their scalability and generalizability, particularly in resource-constrained settings or smaller research cohorts [68]. Unsupervised and semisupervised methods (eg, k-means clustering and mutual connectivity analysis) were less common but useful for identifying subgroups and latent cognitive profiles (eg, brain connectivity profiles) [34]. Deep learning methods, although applied in only a few studies, showed promising performance in classifying cognitive impairment and related outcomes. No studies used reinforcement learning, representing an opportunity for future work. As datasets grow in size and complexity, advanced approaches such as deep and reinforcement learning could enhance early detection and personalized risk assessment for dementia in people with HIV [69]. Lessons from these machine learning–based dementia studies may also inform broader efforts to develop scalable, multimodal prediction tools for older populations with complex comorbidities. These approaches can extend beyond HIV-specific contexts to other aging populations facing overlapping challenges in cognitive health and care delivery.

A key limitation identified in this review was the lack of external validation across studies. Although most studies used internal validation methods (eg, k-fold cross-validation), few tested models on external datasets, limiting generalizability and real-world applicability [70]. Future research should prioritize external validation to enhance reproducibility and clinical relevance of machine learning–based dementia prediction in people with HIV.

Limitations

Our systematic review has several limitations. First, although a comprehensive search strategy was used across multiple databases, it is possible that relevant studies were missed due to publication bias or indexing issues (eg, the limited timeframe, exclusion of non-English publications, or exclusion of gray literature). Second, despite the systematic screening and review process conducted independently by multiple reviewers, the subjective nature of eligibility assessment might introduce potential reviewer bias. To mitigate this, we assessed interrater reliability using the Cohen κ and achieved strong agreement. We also did not perform a formal study quality appraisal; rather, we reported the methodological limitations noted by individual studies. While this approach aligns with rapid review guidance [12-14], it limits formal assessment of study quality. Several included studies relied on self-reported measures, such as subjective memory complaints, which are inherently susceptible to recall bias and response error. These sources of measurement bias were not explicitly addressed or adjusted for in the reviewed studies, limiting the interpretability of self-reported cognitive outcomes. Finally, while our review aimed to categorize and evaluate machine learning techniques used for dementia-related outcomes in people with HIV, the rapid advancements in machine learning may mean that recently published or ongoing studies were not captured at the time of our search; thus, continuous updating is needed in future systematic reviews.

Conclusions

This review examined how machine learning methods have been applied in dementia research for people with HIV, summarizing the techniques used, their strengths and limitations, and practical implications for future research. Despite promising predictive performance, most studies used supervised machine learning methods and lacked external validation, which limits their generalizability. Future dementia research in HIV could benefit from the adoption of advanced machine learning methods. The dominance of studies focused on HIV-associated neurocognitive disorders, with little attention to age-related neurodegenerative diseases such as AD and ADRD, underscores a critical gap in literature. As the population of people with HIV ages, there is a need to expand longitudinal cohort studies using large-scale real-world data that integrate multimodal information from multiple sources, including clinical covariates, neuroimaging, cognitive assessments, and genetic data, to capture disease progression, identify early biomarkers, and enable personalized risk assessment.

Future machine learning research in this area should ensure methodological rigor, the inclusion of diverse data sources, and external validation to enhance clinical applicability and ultimately improve dementia-related outcomes in older people with HIV. By highlighting current trends and research gaps, this review provides a foundation for advancing machine learning–driven cognitive health research to improve early detection and management of all-cause dementia in older people with HIV. These insights may also inform broader efforts to enhance neurodegenerative outcomes in aging populations through informatics and digital health tools.

Funding

This study was supported by the National Institute on Aging under grant K01AG090118 to the principal investigator Hwayoung Cho; the National Institute of Mental Health under grant R34MH135768 to multiple principal investigators Hwayoung Cho and Yiyang Liu, PhD; the National Heart, Lung, and Blood Institute under grant 1K99HL169940 to principal investigator JS; and the National Institute of General Medical Sciences under grant R35GM151089 to principal investigator QS of the National Institutes of Health. The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health.

Data Availability

All data generated or analyzed during this study are included in this published paper and its multimedia appendices.

Authors' Contributions

Hwayoung Cho, LL, and RL were involved in the study concept and design. Hwayoung Cho, LL, RL, RM, JS, and Hannah Cho performed data acquisition and analysis through the systematic review process. All authors contributed equally to later manuscript drafts and agreed to the final submitted version of the manuscript.

Abstract

Background: Health data are growing rapidly, and the processing of such data is evolving. Research on data governance in older persons' health care is unexplored, providing little guidance for practice and future studies.

Objective: This scoping review aimed to synthesize available information on data governance in the context of older persons' health based on evidence from literature.

Methods: The study followed the methodological framework of Arksey and O'Malley and PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews). Online databases, namely, PubMed, Cochrane, Ovid, ACM, IEEE Xplore, and Google Scholar were searched by 2 independent reviewers (AG and AMB) for studies on older persons' health data governance published from January 2000 to April 2024. The independent reviewers performed the search, screening, data extraction, and review of full-text papers. A third reviewer (YP) made the final decision for unresolved discrepancies between the first 2 reviewers. The framework by the World Health Organization Pan American Health Organization, a high-level framework for planning and implementing data governance in public health, was used in the data extraction and analysis. Descriptive statistics were used, and a descriptive approach was used to summarize the results of the scoping review.

Results: A total of 9840 titles were identified and 57 papers were included. Of these, 35 (61.4%) focused on technology, 19 (33.3%) on processes, and 3 (5.3%) on people. Data controller, processor, researchers, data subject or patient (including family or relatives), and relevant organizations were involved in older persons' data governance. Data governance frameworks were designed and implemented by reviewing the current evidence, involving the stakeholders throughout the process, implementing specific procedures (eg, collection and aggregating health data), and monitoring and evaluating them.

Conclusions: The review underscores the importance of the involvement of relevant stakeholders and the use of various innovative tools and approaches in governing data related to the health of older persons. Meanwhile, research specifically addressing data governance for older persons' health conditions is limited. To enhance health outcomes for older persons, effective data governance is essential, alongside further research on relevant policies and practices.

KEYWORDS

older persons; health; data governance; scoping review; medical records

Introduction

Data governance is a management discipline and an emerging data management approach in health care. It is defined within the context of information technology as specifying the framework for decision rights and accountabilities to vitalize desirable behavior in the use of data [1]. Data governance highlights the responsibilities of those with authority in the organization [2], internal and external stakeholders [3], such as data stewards [4], civic society, public bodies [5], professional bodies [6], and the individuals who contributed their data [4], in managing data through its life cycle to generate quality information that can inform decision-making. Data life cycle begins with the capture or collection to the processing, use, storage, and disposal of data [7].

Data governance is also important in health systems as it is considered by many organizations as a promising method of maintaining health data [8]. Health data are considered an important asset to improve health through their use in public health, epidemiology, and health informatics [9]. Governance of such data allows health organizations to successfully manage, protect, maintain, and use data to generate information that

XSL•FO
RenderX

improves health care quality, health outcomes, and health system performance [10].

Real-time generation and efficiency in obtaining knowledge are possible when data governance principles are applied in health care [3]. In contrast, the absence of data governance could lead to failure in decision-making and addressing the individual needs of the public sector [11]. Literature underscores the impact of data governance on a nation's health care system, and the need to collect the right data, effectively process it to generate quality information for evaluating the health system, and identify where and when it is not functioning well [12]. Available evidence calls for the need to establish, streamline, and institutionalize a strong and comprehensive data governance process [5,13-19].

Data governance is essential in digital transformation initiatives of organizations as it improves data quality and accuracy and facilitates real-time data exchange [20]. One of the principles of the global health sector's digital transformation is accelerating progress toward inclusive digital health with emphasis on the most vulnerable populations [15]. These vulnerable populations include the older persons. The potential of data governance in the field of older persons' care has been highlighted by the World Economic Forum by presenting a new approach to data governance [21]. It emphasized that the combination of caregiver skills, for example, with the older persons' data such as their specific care needs, can result in better and more precisely tailored care for older persons.

The state of research on data governance in the health care of older persons is unexplored locally and internationally. This leaves little guidance for its application in practice and for future research on the topic. Thus, this scoping review aimed to map out the available literature on data governance in the context of older persons' health. Specifically, this review sought to answer the following questions: Who is involved in the planning and implementation of data governance ("people")? How are data governance frameworks designed and implemented? What are the governance processes that lead to the improvement of older persons' health ("process")? What tools and technologies are used to effectively govern data ("technology")?

Methods

Study Design and Framework

This scoping review followed the methodological framework of Arksey and O'Malley [22] and PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) [23]. The review questions were informed by the data governance framework in public health by Pan American Health Organization (PAHO), a high-level framework for planning, implementing, and continuously improving data governance [10]. The framework highlights the involvement of 3 components: people, processes, and technology. The people component includes establishing decision-making structures (eg, both the executive decision-making and the technical bodies); defining roles and responsibilities of those involved in the management of data throughout its life cycle; communicating these roles and responsibilities, data-related decisions, policies, and processes; and ensuring transparency on adherence to standards. Processes include managing data assets, enabling processes and standard operating procedures, and establishing processes for policy management and ensuring standards. The technology component pertains to identifying and implementing tools and technology required to manage data such as hardware and software; ensuring quality, availability, and security of information systems; and ensuring performance of the tools [10].

Aside from the framework for planning and implementing data governance, the data governance functions throughout the data life cycle also guided this scoping review. Data governance should address and include defining accountabilities, prioritizing investment requirements, establishing policies, implementing processes, setting standards, managing risks, and monitoring performance related to data throughout its life cycle. The data life cycle is as follows: data collection; data aggregation; data quality assurance and monitoring; data storage; data protection; data access, use, and disclosure; and data retention and destruction [10].

Sources of Information

Six databases, namely, PubMed, Cochrane, Ovid, IEEE Xplore, Association for Computing Machinery (ACM), and Google Scholar were searched. PubMed, Ovid, and Cochrane contained a vast collection of health literature. IEEE Xplore and ACM digital libraries contained resource materials from the fields of electrical engineering, information technology, computer science, and electronics, which capture the technology-related aspect of this review. Google Scholar indexes the full text or metadata of scholarly literature and contains a wide variety of disciplines and sources.

Search Strategy

The strategy was developed in consultation with an academic librarian and the search terms used were "data governance," "health data governance," "older person," "older people," "older adult," "elderly," "senior citizen," and "aged." Boolean operators were used to filter search results (Table S1 in Multimedia Appendix 1).

This review also included evidence from nonresearch sources [24] such as reports, projects, and economy papers from Google Scholar. Moreover, experts in data governance, eHealth, and geriatrics were consulted to explore additional literature sources. The experts were identified through the existing networks of the investigators and organizations relevant to digital health. Searching the reference list of the identified data governance literature was also conducted.

All the literature searched through the online databases, digital libraries, consultation with experts, and reference listing was uploaded in a shared Google Drive folder accessible only to the reviewers using their official university email addresses. The titles were encoded using Google Sheets to identify and remove duplicates.

Selection Process

Considering that data governance was introduced in 2000 and literature on the topic started to be published around the same

XSL•FO
RenderX

time [1,2,25], the search was filtered by publication dates between January 1, 2000, and April 22, 2024. The papers that meet the following criteria were included: (1) topic related to data governance including people, processes, or technology, (2) topic relevant to older persons' health care, (3) peer-reviewed publications, reports, policies, programs, and policy briefs, and (4) in the English language. Resources that were not related to data governance and older persons' health, conference abstracts, and published in languages other than English were excluded.

Following the eligibility criteria, 2 reviewers (AG and AMB) independently searched databases, screened papers for eligibility, reviewed the full texts, and extracted data from the included studies. If the reviewers are unable to screen papers based on the title alone, abstract screening was done to check whether the papers are related to health, data governance, and older persons. Initial data extraction from the abstracts was done to document the topic they covered using a data extraction form.

The reviewers independently documented the search yields and listed the titles obtained per online database using Google Sheets. The search yields of each reviewer per online database were compared as a form of initial validation. To ensure consistency among the reviewers, the procedures from searching to data extraction were pilot tested using 10 randomly selected samples. Reviewers proceeded with the next phases only upon reaching 75% agreement [24].

For each phase, the reviewers documented the reasons for exclusion and settled discrepancies by discussing them throughout the selection process. The reviewers met online and conferred about the discrepancies, which led to an amendment of the eligibility criteria. Based on the initial assessment of the abstracts and available full texts, there were various papers with mixed populations as their study samples (eg, 18 years and above). Considering the focus of this review, the reviewers decided to only include papers with older persons explicitly stated in their titles or abstracts or representing more than 50% of the study sample. Meetings between the reviewers were conducted to discuss which of the papers would be included in the review.

Data Extraction

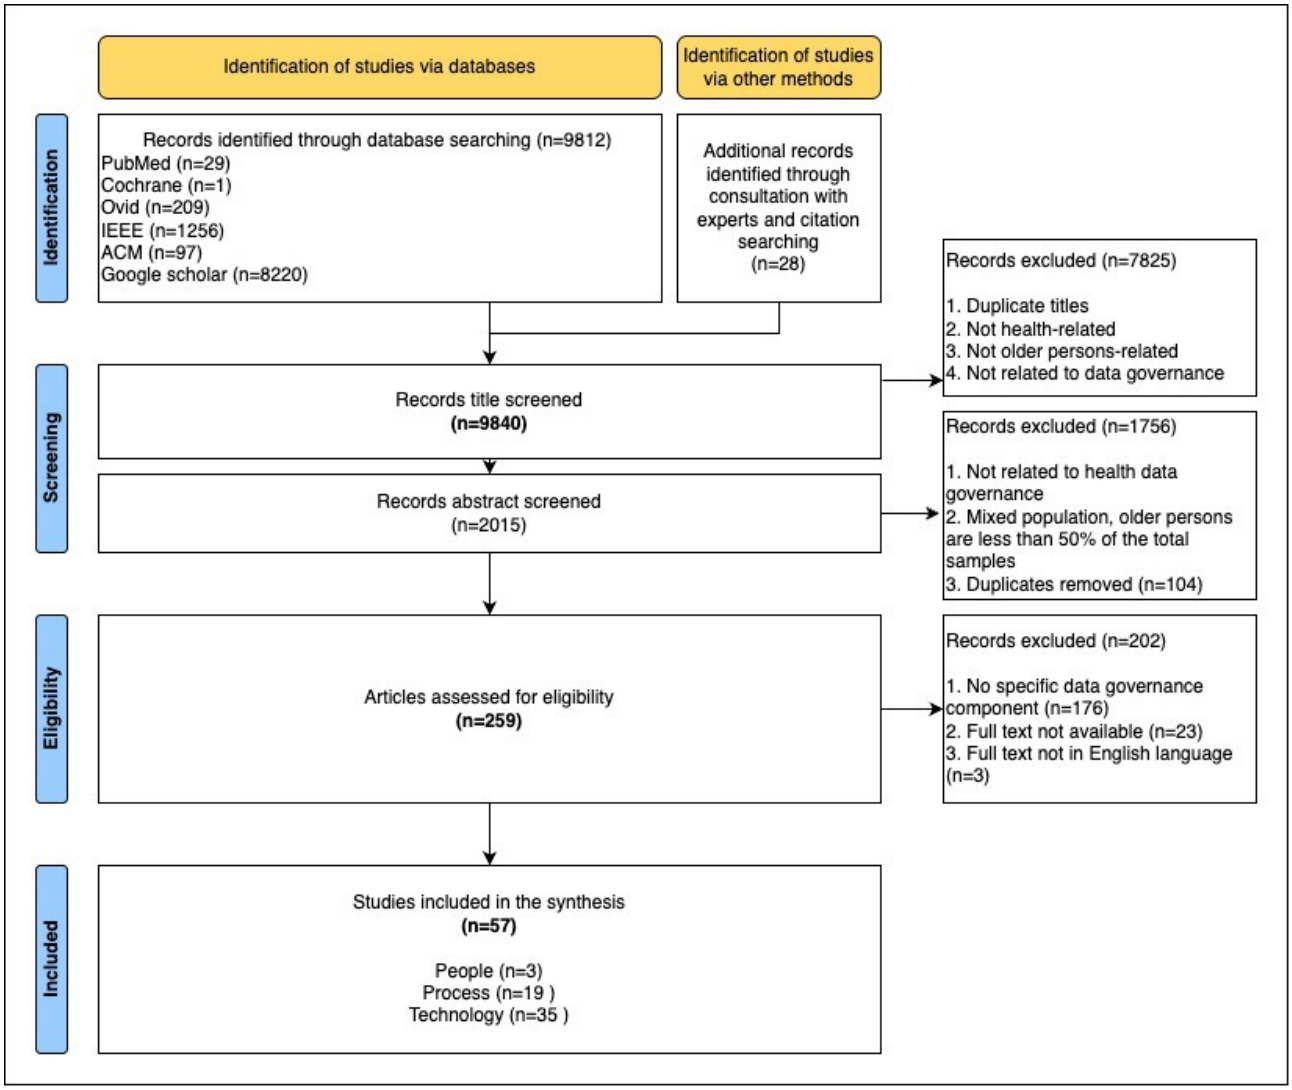
Once the list of included studies was finalized, the 2 reviewers (AG and AMB) independently extracted the relevant information using an extraction tool in Google Sheets. Information such as authors, citation, publication year, type of publication, research design, setting of care, population, data governance function and component, and outcomes of the study and the technological intervention, among others, were extracted for further analysis. The reviewers conducted regular meetings to discuss and reconcile differences in the extracted data. Any disagreements that remained unresolved were discussed with a third reviewer (YP) to arrive at a consensus. The third reviewer made the final decision for the unresolved disagreements between the first 2 reviewers.

Data Management and Analysis

The search results and study selection process are documented in this scoping review report and presented using a PRISMA-ScR flow diagram. All data were documented in a Google Sheets document and exported into an Excel file after the entire process ended. For the unstructured texts in the data extraction form, a qualitative content analysis was conducted to describe how data governance is planned and implemented in the care of older persons. The data were coded according to the framework components involved, namely, person, processes, and technology, and data governance functions. A descriptive approach was used to summarize the result of the scoping review. Numerical or categorical data were presented using counts and proportions. Tables and a figure were used to present the extracted data for each extraction category.

Ethical Considerations

The study was monitored and classified as exempt from ethics review (UPMREB 2023 - 0864-EX) by the University of the Philippines Manila Research Ethics Board.



Results

Overview

A total of 9840 titles were identified from 6 databases, consultation with 3 experts, and reference listing (Figure 1). Duplicates and all papers not related to older persons, health, and data governance, and those with mixed populations were removed during the screening phase, leaving a total of 259 papers assessed for eligibility. Of these papers, 202 were removed due to the unavailability of full texts, non-English language, and lack of specific data governance components. A total of 57 (22%) papers met the criteria for inclusion in the synthesis.

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) diagram.

Description of Included Studies

The included studies were published between 2003 and 2024; 56.1% (32/57) of these were published in the year 2020 onwards. The majority (32/57, 56.1%) of the included studies were from the IEEE digital library. Most (47/57, 82.5%) were journal papers, followed by conference proceedings (7/57, 12.3%). These conference proceedings were peer-reviewed full papers from IEEE and ACM (Table 1).

In terms of study design, 36.8% (21/57) were observational, followed by 29.8% (17/57) classified as experimental studies. These experimental studies are subdivided into 2 groups, namely, technology development and randomized controlled trials. About 30% (16/57) of the studies did not specify their design.

The studies were conducted mostly in home settings (11/57, 15.8%), followed by those conducted in multiple settings of care such as home and hospital, community and hospital, and hospital and long-term care facilities. More than 30% of the included studies did not specify their study setting. In terms of geographic coverage, most were conducted in Europe, followed by Asia and those with multicountry sites. There were no included studies that covered the following continents: Africa, Middle East, and South America (Table 1).

Sixty-seven percent of the included studies provided information about the study population, particularly, the age group, mean age, or age range they covered. Although 33.3% (19/57) did not indicate the specific age of their study population, the technology or the data governance component being relevant to older persons was explicitly stated in the title, abstract, and full text. Due to the variation of available information on age and unavailability of other information, the overall mean age cannot be computed.

About 70% of the included studies specified the sample size. A study had 1 older person sample, which was about a novel cloud-based framework for the older adult health care services [26]. The largest sample size among the included studies was 591,726 electronic health records of primary care patients aged 65 years and older [27].

Data Governance Components and Functions

A majority (35/57, 61.4%) of the included studies were largely related to technology, tools and technology, in particular (Table 2). This is followed by processes (19/57, 33.3%), which are mostly centered on enabling processes and standard operating procedures. Only 3 papers were focused on people, particularly, roles and responsibilities and decision-making structure.

Interestingly, there were no included studies on communication and transparency under the people component, standards and policy management in the process component, availability and security, and performance alone in the technology component (Table 2).

Table 2 also shows that the data governance function of the included studies mostly focused on implementing processes, while only a few covered monitoring performances [27-30], defining accountability [31-33], setting standards [34,35], and managing risks [36].

Designing and Implementing Data Governance

The identified actors involved in designing and implementing data governance related to the health of older persons include data controllers, processors, and subjects. Specific data controllers identified in this review include a hospital [32], researchers [33], and a steering committee [37]. The data subjects were patients [32], persons with dementia [33], nursing home residents [37], friends or relatives [32], legally authorized representatives [33], and hospital staff [32]. The data processors were a platform service provider [32], research team members [33], and privacy, scientific expert, and data access committees [37].

All included studies on the people component of data governance highlighted the crucial roles of relevant stakeholders (eg, controllers, processors, and subjects) in planning, designing, and implementing data governance [27,32,33]. Moreover, the composition, roles, and accountabilities of these stakeholders vary depending on the settings (eg, hospital, research, and nursing home).

An example specifying the roles and responsibilities of people involved in data governance was highlighted by Bernsmed [32] in the context of medical data collected from sensors that are exchanged between the older persons, their families and friends, and health personnel. The roles of data controller, processor, and subject were defined, and the accountability obligations were outlined. A data controller, which can be a person, public authority, agency, or other actors, determines the purposes and means of personal data processing. The data processor processes the personal data on behalf of the controller. Meanwhile, a data subject is a person who can be identified directly or indirectly through a reference identification number. In the study, the patients and relatives or friends, as well as the hospital staff, were the data subjects, while the hospital is the controller of its patients' and personnel's data. The data controller (hospital) is accountable to patients, relatives or friends, and hospital staff (data subjects) in informing and obtaining consent for the collection, processing, and management of their data [32].

A total of 10 papers provided information on how frameworks related to data governance of older persons' health data are

XSL•FO
RenderX

designed and implemented [26,32,33,35,37-42]. Specific examples of the use of data governance frameworks were related to addressing a particular issue such as fall detection [41], dementia care mapping [42], depression risk prediction [35], cardiac image processing [40], and digital twin health care for real-time supervision and crisis warning [43].

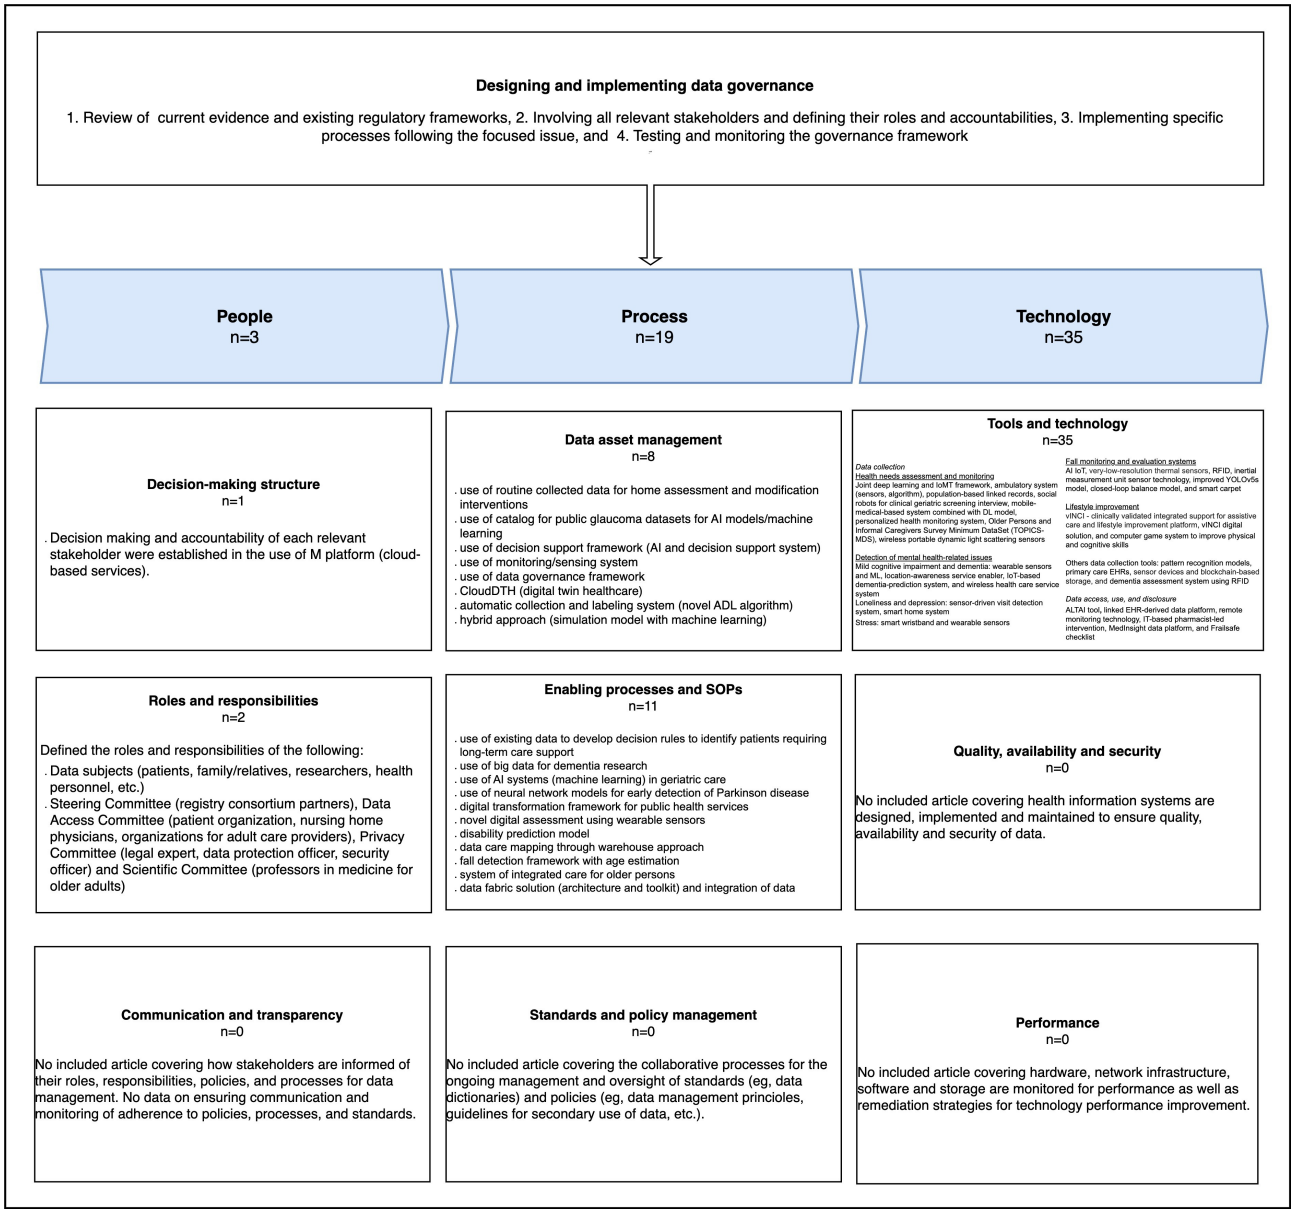
Conceptual content analysis of the methods using the PAHO framework emphasized the involvement of relevant stakeholders, implementation of specific processes, and conduct of literature review, demonstrating the feasibility or testing of the developed framework and defining the roles and accountabilities of the actors or stakeholders (Table S2 in Multimedia Appendix 1).

Data Governance Processes, Tools, and Outcomes

A total of 19 papers provided information on the specific processes or interventions relevant to older persons' health [26,30,34,35,38,39,41-53]. Majority focused on implementing processes pertaining to data collection, aggregation, and access, use, and disclosure. One study covered 6 data life cycles from data collection up to disclosure [44]. There were no papers that covered the process of defining accountability, managing risks, prioritizing investment, and establishing policy (Table 2).

Several tools and technologies were identified and used for data governance throughout the data life cycle. A total of 35 papers provided information on the specific technologies relevant to older persons' health [27-29,36,40,54-82]. Most of the identified technologies focused on implementing processes while only a few were related to use of technology in monitoring performance, defining accountability, and managing risks. Furthermore, these technologies are mostly involved in data collection.

In implementing data governance processes, various tools and technologies are used in collecting data for the assessment and monitoring of health needs; assessment of fall risk and detection of fall; identification of mental health–related issues such as mild cognitive impairment, dementia, stress, loneliness, and depression; and improvement of lifestyle and health (Table S2 in Multimedia Appendix 1).



In terms of specific outcomes of the technology component of data governance, a total of 34 papers provided information on these. Most of the outcomes were process-related, such as efficient data access; quality control; communication and care support; recognition, detection, and prediction of various conditions; monitoring; and others. Only 2 included papers provided information on health outcomes among the older person samples, namely, improvement of quality of life [62] and cognitive skills and function [68] (Table S2 in Multimedia Appendix 1).

Older Persons' Health Care Data Governance

Figure 2 summarizes the results of this scoping review following the data governance framework in public health by PAHO [10].

Discussion

Principal Results

This scoping review aimed to synthesize available information on how data governance is planned and implemented in the context of older persons' health based on evidence from literature. Specifically, it aimed to answer the following questions: Who are involved in the planning and implementation of data governance (people)? How are data governance frameworks designed and implemented? What are the governance processes that lead to the improvement of older persons' health (process)? What tools and technologies are used to effectively govern data (technology)?

Findings show that available studies related to the health of older persons covered mostly data governance components related to technology and process. Moreover, data governance is designed and implemented by initially examining the current evidence and existing regulatory frameworks, involving all relevant stakeholders and defining their roles and accountabilities, implementing specific processes following the focused issue, and testing and monitoring the governance framework. Various data governance processes, tools, and technologies are used and contribute to the improvement of older persons' health. The use of these mostly leads to process outcomes.

This review emphasizes the involvement of stakeholders, particularly in technology development and testing process [40,41], sharing perspectives on digital transformation of public health services [39], and mapping of service users [42]. Moreover, the accountability of data controllers, processors, and subjects was outlined [32,33,37]. This underscores the data governance responsibilities of those with the authority in the organization [2] (data controller), the internal and external stakeholders (data processors and subjects) [3-6], and, ultimately, the data subjects who contributed their data [4] in

XSL•FO
RenderX

managing data through their life cycle to inform decision-making.

Limitations

This review included literature only on data governance relevant to older persons published from the past 2 decades and those peer-reviewed publications, reports, policies, programs, or policy briefs written in English language. Identified studies eligible for review but without full texts were excluded from the synthesis. Despite the efforts of the reviewers and consultant librarian in accessing the papers, 23 full texts were not retrieved. These papers were mostly from ACM and Google Scholar, published 2021 and beyond, included conference proceedings, and focused on the technology component of data governance. These exclusions might have affected the comprehensiveness of the reported findings on technology.

Many included studies did not specify the study design, setting, geographic coverage, age of the study population, and sample size. It would be helpful if this information were available to provide a complete description of the state of data governance literature for older persons. Moreover, the assessment or appraisal of the included studies for methodological rigor and quality was not performed as this review aimed to describe information only on data governance in the context of older persons' health.

Various processes and technologies aimed to contribute to the improvement of older persons' health based on their objectives and purpose were identified. However, since most of the included studies are related to technology, at their preclinical stage of technological development, and focused only on data collection, limited information on the actual health outcomes of data governance specific to older persons was collected.

Comparison With Prior Work

Studies related to health information systems included in this review [27,60,79] also support data governance as an important player in the health system, a promising method of maintaining health data [8], and recognize its potential in the field of older persons' care [83,84]. Various processes, tools, and innovative approaches in governing health data of older persons were explored in this review. Available evidence suggests that the use of these tools and technologies supports data governance, leading to positive health outcomes and better processes [27,31,61-63,68,75-77]. Although positive health outcomes were noted, further interventional studies with utilization of a data governance framework are essential to determine its direct effects on actual health outcomes among the older population.

In terms of processes, findings in this review are consistent with Cave [85] where strategies for implementing data governance were explored through a qualitative case study. These strategies include structured oversight with committees and boards, obtaining stakeholder buy-in, and benchmarking and standardization. Benchmarking and standardization through review of current evidence and existing regulatory frameworks were identified to be important steps in planning and implementing data governance [32,33,35,38,39,42]. These preliminary steps are crucial in ensuring a well-designed and effective governance framework.

Strategies for effective and strategic communications and compliance with regulations were not adequately covered in this review due to the lack of studies on this topic. Communication and transparency, as well as compliance with standards and policies, should be considered in implementing data governance. This is to ensure the protection of people, promotion of health value, and prioritization of equity, which are the key health data governance principles [86]. Moreover, although there were no papers that covered the processes of defining accountability and managing risks, these were discussed in the literature in terms of the role of persons involved in data governance and as integral components of designing and implementing data governance.

Various geriatric syndromes, such as falls and fall risk [54,55,65,69,71,73,74], mild cognitive impairment and dementia [33,42,53,64,66,75,82], frailty [29,80], loneliness, social isolation, and depression [56,57], were the focus of the studies included in this review. However, there were no included studies related to other geriatric syndromes such as functional decline, incontinence, delirium, pressure ulcers, polypharmacy, malnutrition, sleep problems, and others. These geriatric syndromes are common health conditions among older persons [87-90], often having multifactorial causes, and may have a major impact on their quality of life and disability [90]. Data governance covering these conditions can also generate information on strategies to address the needs of older persons and provide quality care to improve their health and quality of life.

Only 1 paper explicitly proposed a data governance framework specific for older persons, which was published a decade ago [38]. The proposed framework was drawn from the Data Management Body of Knowledge of the DAMA International, Inc [2,91] and the work of Cleven and Wortmann [92]. Dahlberg's [38] motive for proposing this specific governance framework was the fragmentation of older persons' data and the necessity to consolidate these data to make it more useful. The paper defined the types and sources of data that exist about older persons, and how these can be integrated into a comprehensive framework. It suggested defining the data categories, attributes, and sources of data first to improve data governance of older persons. There is no evidence that the framework has been validated. Hence, testing this framework is essential to determine its value in data governance for older persons.

It is notable that the included papers that provided information on designing and implementing data governance mostly came from high-income countries such as Australia, United States, Canada, United Kingdom, Japan, Singapore, Netherlands, and other countries in Europe. These countries are actively implementing digital health care solutions in the forms of telemedicine, electronic records, mobile health, and other digital tools for diagnosis and management, hence, the availability of data governance frameworks. On the other hand, no studies were included in the review from Africa, Middle East, and South America. This can be attributed to the challenges experienced in digital health, such as limited infrastructure, affordability issues, and data privacy concerns, especially in low-income and middle-income countries [93-95]. While others have established

XSL•FO
RenderX

and are implementing data governance, the rest are yet to address the challenges of digital health transformation.

The need for data governance in general [14] and in the care of older persons has been highlighted by the reviewed papers specifically on dementia research [42,53], health care applications for geriatric clinical care [49], and nursing homes for quality improvement [37]. New paradigms on the use of big data in dementia research and clinical care [42], as well as international dementia care mapping, require data governance [53]. Likewise, the standardization of machine learning approaches tailored to health care applications is required to evaluate whether these applications improve clinical care for older persons [49]. In nursing homes, literature suggests the need for enhancing transparency, specifically in presenting understandable information to the residents and their representatives on which data will be used, how they will be used, and for what purposes [37].

Findings agree with other papers not included in this review such as the call for institutionalizing a strong and comprehensive data governance process [5,10,12-19,96-98], a national health data governance framework to ensure availability and use of personal health data for public interest [99], and data governance for learning health systems to reduce concerns about privacy and trust in the system [100,101].The included studies were analyzed according to the data life cycle, data governance function, and components they covered to identify research gaps. The people data governance component covered only data access, use, and disclosure. Information on how people are involved, their roles and responsibilities, and communication and transparency during data collection, aggregation process, quality assurance, storage, data protection, retention, and destruction, is lacking. In terms of the process component, limited studies were related to data quality, storage, and protection, and none for defining accountability and managing risk. Meanwhile, no tools and technology were identified from the studies that covered data aggregation, data quality, data protection, and setting standards.

Studies on data governance in health care of older persons are largely focused on various forms of technology followed by process. The major research gap across all data governance components was the lack of included studies on data retention and destruction, prioritizing investments, and establishing policy (Table S3 in Multimedia Appendix 1). Findings and gaps that were identified from this review inform future research directions and practices of older persons' health data governance.

Conclusions

This review highlighted the importance of benchmarking, involvement of relevant stakeholders, and the use of various innovative tools and approaches in governing data related to the health of older persons. However, studies that are explicitly centered on data governance of older persons' health data, their common health conditions, or other geriatric syndromes, are limited. Likewise, identified research gaps include the lack of studies on data retention and destruction, establishment of policy, prioritizing investment, and communication and transparency.

Available studies on the health of older persons covered mostly technology and process data governance components. Only a few focused on people, which were identified to have crucial roles in designing governance frameworks, planning, and implementing data governance. To optimize the use of data in improving the health and quality of life of older persons, a well-designed process that considers the essential data governance components, functions, and principles should be developed and implemented.

Recommendations

Effective governance of older persons' health data requires a multisectoral approach. Benchmarking, utilization of innovative tools and approaches, and collaboration between relevant stakeholders, including policy makers, program planners, health facility administrators, health care providers, information and communication technology and digital health experts, data privacy and legal experts, and, ultimately, the older persons and their families, are essential in designing and implementing data governance.

In establishing health data governance policies or incorporating them into the national standards, legislations, and organizational policies, the key governance principles, components, functions, and data life cycle should be considered. In practice, health settings and personnel should ensure the involvement of the patients (including their families and relatives) in collecting and processing their data. The practical application of data governance frameworks and technologies in the care of older persons is essential to support favorable health outcomes. Further studies on the governance of data on common health conditions of older persons to inform clinical practice, health data retention schedules and destruction methods, and data governance policies and investments are recommended.

Acknowledgments

This scoping review was funded by the National Institutes of Health (NIH), University of the Philippines Manila through the NIH Commissioned Grants 2023 (project code: NIH 2023-027). The project team would like to thank and acknowledge the following: the NIH Executive Committee for funding this scoping review; Dr Shelley Ann de la Vega, director of the Institute on Aging, for her valuable support to the project especially during the funding application; Ms Vivian Biala for providing research grant administrative support; CAMP Research Committee for carefully reviewing and providing technical approval of the proposal; UP Manila Research Ethics Board for exempting the study from ethical review; experts consultants (Dr Alvin Marcelo, Dr Evelyn Hovenga, and Dr John Richard Hizon) for providing valuable insights based on their expertise; Mr Cristopher Naguit for helping the team process the salary and disbursement documents; and, finally, to the UP Manila channels for the processing of administrative,

XSL•FO
RenderX

legal, financial, and technical documents needed for this project. This project would not have been completed without the support of the above personalities and offices. All authors declared that they had insufficient or no funding to support open access publication of this manuscript, including from affiliated organizations or institutions, funding agencies, or other organizations. JMIR Publications provided APF support for the publication of this paper.

Data Availability

All study data are present in this paper and the supplementary materials.

Authors' Contributions

AG performed protocol development, data collection, analysis, manuscript writing, review, and approval of the paper; AMB performed data collection, analysis, manuscript writing, review, and approval of the paper; and YP performed protocol development, data analysis, manuscript writing, review, and approval of the paper.

Conflicts of Interest

None declared.

Abstract

Background: As the global population ages, the prevalence of dementia is expected to rise significantly. To alleviate the burden on health care systems and the economy, it is essential to develop effective strategies to enhance cognitive function in older adults. Previous studies have shown that combined nonpharmacological interventions can improve cognition across various domains in older individuals. However, there is no established gold standard for the exact combination and duration of these interventions, which makes it challenging to assess their overall effectiveness.

Objective: Given the diversity of nonpharmacological multimodal interventions aimed at preventing cognitive decline in older adults with mild cognitive impairment (MCI), this scoping review sought to identify and summarize the characteristics and outcomes of these interventions.

Methods: We adhered to the Arksey and O'Malley methodological framework and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) and searched 4 electronic databases (MEDLINE, PsycINFO, CINAHL, and Web of Science) systematically on July 6, 2023, and updated the search on April 17, 2024, using specific terms and keywords.

Results: This review included 45 studies from 18 countries with 4705 participants from 2014 to 2024 encompassing different combinations of physical training (PT), cognitive training (CT), nutrition intervention, psychosocial intervention, social activities, and electrical stimulation. There is a growing numbers of studies combining PT and CT for MCI treatment, with additional modalities often added to address various aspects of the condition. Compared to single-modal interventions and usual care, multimodal approaches demonstrated significantly better improvements in cognition domains such as attention, global cognition, executive function, memory, processing speed, and verbal fluency. Technology has been instrumental in delivering these interventions and enhancing the effects of PT and CT. Multimodal interventions also show promise in terms of acceptability and user experience, which can improve treatment adherence.

Conclusions: Research is limited regarding the cost-effectiveness and optimal dosage of these interventions, making it difficult to assess the additional benefits of incorporating more modalities. Future research should examine the long-term effects of incorporating multiple modalities, using standardized MCI criteria and outcome measures.

Introduction

Overview

Mild cognitive impairment (MCI) represents a transitional stage between normal aging and dementia, characterized by cognitive decline greater than expected for age, impacting one or more domains such as attention, memory, orientation, executive functioning, language, and visuospatial skills [1,2]. However, the decline does not significantly interfere with daily activities [3]. The lifetime prevalence of MCI in individuals aged above 60 years is estimated to be 15% to 20% [4], with this prevalence increasing with age. The annual transition rate from MCI to various subtypes of dementia ranges from 10% to 15% and can reach up to 25.2% for adults aged 80 to 84 years [5,6]. Older adults with MCI are 46% more likely to develop dementia within 3 years compared to just 3% in the normal-aging population [7].

The trajectory for individuals with MCI may vary, leading to dementia, stable cognition, or a return to normal cognition function [6]. Untreated MCI may progress to dementia, a neurodegenerative disease that significantly impacts daily functions and affects one's physical, psychological, social, and economic aspects. Dementia also directly affects one's caregivers, families, and society [8]. With the global population of individuals aged 60 years and above projected to double from 1 billion in 2020 to 2 billion by 2050 [9], there is mounting concern regarding the rising prevalence of dementia and the urgent need for preventive measures to address the associated social and economic burdens. Factors, such as modifiable risk factors, genetics, and interventions, can affect MCI progression [10]. Therefore, understanding various interventions and their effectiveness in preventing progression from MCI to dementia is crucial given the rising prevalence of dementia among older adults.

Currently, there is no gold standard for treatments or interventions to manage MCI. The American Academy of Neurology guidelines indicate insufficient empirical evidence to support pharmacological treatments for MCI in older adults [11]. Conversely, numerous studies have advocated nonpharmacological interventions, such as physical training (PT) or cognitive training (CT), as effective strategies for managing MCI [11-13].

Nonpharmacological Interventions

PT, including aerobic, strengthening, and balance exercises, has been shown to stimulate norepinephrine release in the brain, promote brain plasticity, increase brain volume, and enhance cerebral blood flow [14]. These effects are crucial for improving cognition, mood, and physiological abilities [15]. Combining aerobic and strengthening exercises has been identified as particularly effective for cognitive improvement [16].

On the contrary, CT primarily uses cognitive stimulation and repetitive tasks to enhance various cognitive domains, particularly memory, attention, and executive function [17]. The effectiveness of CT in improving cognition lies in its capacity to strengthen the functioning and plasticity of neural networks and cognitive reserves [17]. Research suggested that memory-focused CT increased activation and connectivity in the frontal, temporal, and occipital brain regions [18]. These areas are crucial for memory, motor function, processing, attention, language, mood, and problem-solving. Therefore, CT shows promise for improving overall cognition in older adults with MCI.

Given that both PT and CT can enhance brain plasticity and stimulate brain regions responsible for various cognitive functions, their combined application, whether delivered separately or through dual tasking, is the most common approach for managing cognitive impairment in MCI. This multifaceted approach effectively targets different aspects of cognitive decline, countering cognitive decay and neurodegeneration.

Growing evidence suggests that engaging in more social activities (SA) can lower the risk of cognitive decline in individuals with MCI [5], making SA a potential key modality for MCI management. SA involves participation in activities that allow interactions or engagements with others [5]. Karp et al [19] found that older adults with MCI who participated in a broader range of activities, including mental stimulation, physical activities, and social recreation, had a lower risk of developing dementia than those who participated in fewer or no such activities. On the other hand, beyond PT, CT, and SA, emerging evidence suggests that modifiable lifestyle factors, including diet and nutritional intervention (NI), electrical stimulation, or psychosocial intervention (PI) may also improve cognitive functions in this population [10,20].

Multimodal Interventions

A multimodal intervention, integrating various methods such as PT, CT, SA, NI, electrical stimulation, and PI, either sequentially or simultaneously, addresses cognitive decline across different domains of MCI. This approach has been proven effective in managing MCI in older adults, enhancing cognitive abilities, mood, sleep, activities of daily living, functional capacities, and physical abilities, with benefits lasting up to 2 years [14]. A systematic review and meta-analysis [21] showed that combining 2 or more interventions had small to medium effects on global cognition, memory, executive function, and verbal fluency, demonstrating a synergistic effect. Studies also showed that multimodal interventions outperformed single-modal interventions in managing MCI [15,16]. Another systematic review and meta-analysis [22] also supported that combined PT and CT had a small to medium effect on global cognition than various types of cognitive-only interventions in older adults with MCI. However, these reviews solely focused on the effects of combined PT and CT [22] or compared the

XSL•FO
RenderX

effectiveness of multimodal interventions only with single-modal interventions [21], thus lacking direct comparisons between various types of multimodal interventions to inform researchers or clinicians regarding which combinations of multimodal interventions would yield better results. In addition, previous reviews did not consider the user experience of multimodal interventions, which limits the clinical applicability of their findings and important factors to determine the feasibility of multimodal interventions. Thus, a comprehensive evaluation of multimodal interventions should include both feasibility and user experience to optimize benefits.

Optimizing Multimodal Interventions: Technology, Dosage, and Cost-Effectiveness

The increasing adoption of digital health care technology in managing MCI [23] could enhance the delivery and reduce the costs of interventions, especially benefiting those in remote areas [24]. Given the high prevalence and economic burden of MCI on communities and health care systems, technology such as the use of computerized CT (CCT) can help mitigate costs associated with nonpharmacological interventions, addressing the shortage of trained professionals. While previous systematic reviews and meta-analyses have acknowledged the role of technology in MCI management, they mainly focused on CCT [24-26] without considering the broader potential of technology beyond CCT.

Addressing the impact of different dosages of nonpharmacological interventions for MCI is crucial for developing effective and sustainable therapeutic strategies. This involves determining the optimal frequency, intensity, type, and duration of interventions to maximize cognitive benefits while balancing time and financial costs [27]. A study [27] highlighted that CT, PT, NI, and the majority of combined PT and CT significantly improved cognition in individuals with MCI, with particularly effective doses being 1 to 2 sessions per week with 60 to 120 minutes per session and interventions lasting over 12 weeks. However, as this study focused on only one type of multimodal intervention (combined PT and CT), the dosage effects of other nonpharmacological multimodal interventions remain uncertain. Therefore, this scoping review aimed to summarize dosage effects from the literature on multimodal interventions.

In addition, managing cognitive decline imposes a significant global economic burden. The cost-effectiveness of multimodal interventions varies by region because of the differences in health care resources. Although previous research supported the effectiveness of multimodal interventions for cognitive decline, their adoption of multiple modalities often increases cost. However, no prior review has summarized the cost-effectiveness of these interventions, so this scoping review aimed to address this important gap to inform clinical decision-making.

Rationale for a Scoping Review

Considering the variety of multimodal MCI interventions, both with and without technology, and the diverse methodologies and research focus of the existing literature, a scoping review is warranted to identify the current research gaps to inform future research and clinical practice. The complexity and heterogeneity of the interventions, coupled with the rapidly evolving nature of this field, make a systematic review less feasible for comprehensively mapping the use of different types of multimodal interventions and investigating the current research trends. As such, this scoping review aimed to map and describe the latest development in MCI interventions and provide researchers and clinicians with insights into current trends and limitations of the existing approaches and studies. Specifically, this review mapped the current landscape of nonpharmacological multimodal interventions for older adults with MCI, identified and summarized the components of these interventions, research trends, and the use of different outcome measures. It aimed to enhance the understanding of MCI management and provide future research directions on multimodal interventions.

Methods

Overview

This review adhered to the Arksey and O'Malley methodological framework [28] and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) [29]. The protocol was registered on the Open Science Framework platform [30]. The review process involved five key steps: (1) formulating the research questions; (2) devising the search strategy; (3) identifying and selecting relevant studies; (4) data charting; and (5) synthesizing and presenting findings.

Identified Research Questions

This review explored the following research questions:

1. What are the research trends in multimodal interventions for older adults with MCI?
2. What components were included in these multimodal interventions? What results have been reported?
3. How cost-effective were the identified multimodal interventions?
4. What role did technology play in these interventions for older adults with MCI?
5. What insights were available regarding the acceptability, user experiences, and dose responses of these interventions?

Identifying and Selecting Relevant Studies

We conducted a search across 4 databases—MEDLINE, PsycINFO, CINAHL, and Web of Science—on July 6, 2023, and updated the search on April 17, 2024, using specific Medical Subject Headings terms and keywords such as "combine," "multi," "dual," "mix interventions, and "mild cognitive impairment" (Multimedia Appendix 1). Although quality assessment is optional for scoping reviews [31], this review included only randomized controlled trials to enhance study quality. Two independent reviewers (JHSZ and RCFC) screened titles, abstracts, and full texts against the eligibility criteria (Textbox 1). Disagreements were resolved by consensus or by consulting a third reviewer (AYLW). The interrater reliability of the screening process as measured by the kappa coefficient was 0.87.

XSL•FO
RenderX

Textbox 1. Selection criteria for the scoping review.

Inclusion criteria

- Participants: diagnosed with mild cognitive impairment (MCI) by clinicians or psychologists using well-established criteria
- Intervention: at least one combination of a nonpharmacological multimodal intervention in managing older adults with MCI
- Control: received at least one or multiple forms of an intervention, a placebo or sham training, health education, or treatment as usual
- Outcome: must use at least one well-established measurement for testing cognitive outcomes
- Study design: must be an experimental study (randomized controlled trial or quasi-experimental study)
- Other: full-text and peer-reviewed study written in English

Exclusion criteria

- Participants: diagnosed with dementia or the cognitive impairment resulted from drug use or psychiatric or other neurological disorders (eg, bipolar disorder, schizophrenia, stroke, Parkinson disease, or epilepsy)
- Intervention: pharmacological interventions or nonpharmacological experimental studies with a single-modal intervention
- Study design: systematic reviews, scoping reviews, opinion letters, conference proceedings, dissertations, and research design protocols
- Other: gray literature

Definition of Types of Intervention and Control Groups

The included studies featured diverse intervention components and control groups. Detailed operational definitions for these interventions and control groups are provided in Textbox 2.

Textbox 2. Operational definition of the intervention and control groups in the included studies.

Interventions

- Physical training: activities, exercises, or training that required older adults to do physical activities with or without the guidance or supervision of a professional trainer or clinician
- Cognitive training: activities or training that used a standardized systematic cognitive stimulation, rehabilitation task, and training to improve cognitive function
- Nutrition intervention: the use of any type of dietary supplement, including herb extract, or any form of dietary counseling
- Psychosocial intervention: the use of activities, training, counseling, therapy, or education that aimed to improve psychological well-being, including music therapy and mindfulness
- Social activities: activities that encourage social engagement or facilitate social interaction between older adults
- Electric current stimulation: the use of current stimulation including transcranial alternating current stimulation and transcranial direct current stimulation

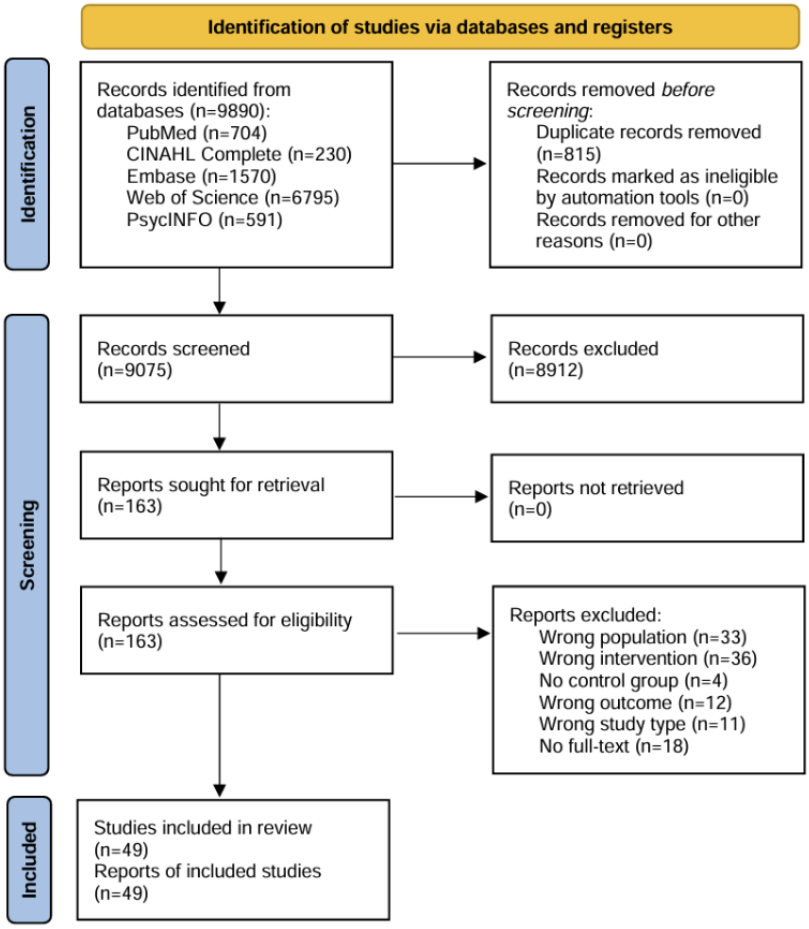
Control groups

- Active control: a group of participants who received at least one form of intervention
- Placebo control: a group of participants who received a placebo or sham training
- Health education control: a group of participants who received health education
- Inactive control: a group of participants who received no additional treatment, treatment as usual, or only health advice

Data Extraction

Relevant data, including authors, publication year, country, place of recruitment, diagnostic criteria, participants, intervention types, outcomes, treatment frequency and duration, follow-up time points, use of measurement tools, control group characteristics, results, and interpretations of findings, were extracted by 2 independent reviewers (JHSZ and RCFC). All extracted findings were compared. Discrepancies were reconciled by consensus or through consultation with a third reviewer (AYLW).

Results



Study Selection and Characteristics

The initial search identified 9890 articles. After removing 815 duplicates, 9075 titles and abstracts were screened; 163 out of 9075 titles and abstracts were selected for full-text screening. Studies based on the same cohort were counted as a single study, including 4 studies by Hagovská and Nagyova [32], Hagovská and Olekszyova [33,34], and Hagovská et al [35] and 2 studies by Liao et al [36,37]. Exclusions were made for reasons

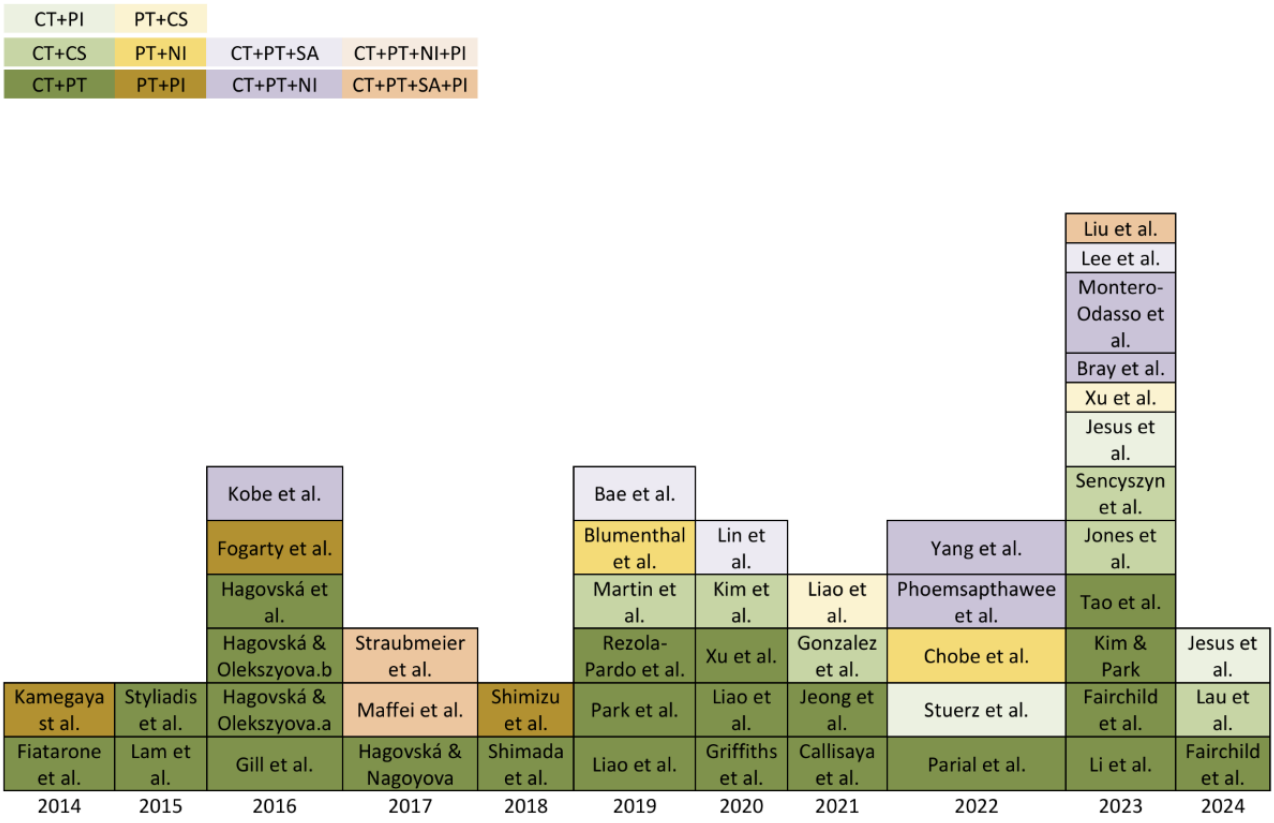
XSL•FO
RenderX

including incorrect target population (n=33), absence of multimodal intervention (n=36), lack of a control group (n=4), different study outcomes (n=12), absence of cognitive outcomes (n=11), and unavailability of full text (n=18). Ultimately, 45 studies from 49 articles published between 2014 and 2024, encompassing a total of 4705 participants, were included in this review. A detailed description of the study selection is presented in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram of literature search and screening.

The characteristics of the included studies, including participant characteristics, intervention tasks, treatment duration and frequency, and assessment time points, are presented in Multimedia Appendix 2. These studies used various criteria to diagnose MCI, such as the Peterson criteria (n=14) [15,16,38-49], the Albert criteria (n=5) [50-54], and cutoff scores from established screening tools like the Alzheimer Disease Assessment Scale–Cognitive subscale (cutoff score not provided) [38,40], Mini-Mental State Examination between 20 and 27 [55], Montreal Cognitive Assessment with scores up to 28 [15,23,36,37,52,56-65], Clinical Dementia Rating scores from 0.5 to less than 1 [45,60,66], or direct diagnoses from professional psychologists. Table 1 provides a detailed description of the diagnostic criteria used for a comprehensive reference.

Table 1. Diagnostic criteria used in the included studies.



Criteria	Definition
Peterson criteria [11]	• Self-report cognitive decline • Objective cognitive impairment compared with age • No impact on daily functioning • No dementia
Albert criteria [3]	• Cognitive change reported by the patient, informant, or clinician • Objective evidence of cognitive impairment in one or more domains (typically 1 to 1.5 SDs below the mean when compared with their peers with matched age and education level) • Independent in functional abilities • No dementia

Publication or Study Trend

There has been a noticeable increase in both the number of studies and the variety of multimodal intervention combinations from 2014 to 2024 (Figure 2 [15,16,32-78]). Specifically, studies incorporating NIs as part of multimodal MCI interventions grew from 1 in 2016 to 3 in both 2020 and 2023. In addition, the use of technology in delivering multimodal interventions has gradually increased from 1 study in 2015 to 5 in 2023.

Figure 2. The number of studies that incorporated multimodal interventions for mild cognitive impairment throughout the years. CS: current stimulation; CT: cognitive training; NI: nutritional intervention; PI: psychosocial intervention; PT: physical training; SA: social activities.

Types of Multimodal Interventions

The included studies used combinations of 2, 3, and 4 types of interventions. Although most included studies primarily focused on combining PT and CT, there is an increasing number of studies integrating additional interventions to address the multifaceted nature of MCI. The following section details these specific combinations, the types of control groups used, and the overall outcomes across cognitive domains, such as attention, executive function, global cognition, memory, processing speed, and verbal fluency. Comprehensive outcomes, measurement tools, and targeted cognitive domains of the included studies are summarized in the following sections.

Bimodal Interventions

Overview

Most studies that used combined PT and current stimulation [45,67], or PT and NI [56,58] reported significantly greater improvements in various cognition domains compared to active control groups, while the use of combined CT and PI [61,68,69] reported significantly greater improvements compared to inactive control groups. However, studies with combined PT and CT showed mixed results. Conversely, most studies comparing combined PT and PI [39,41,48], CT and electroacupuncture [42], or CT and current stimulation [44,47,53,60,62] with an active or inactive control intervention found little to no significant advantage in the intervention groups (Table 2).

The Combination of PT and CT

Among these 18 studies, 4 used a single-modal active control group [34,59,63,70], 3 compared against a health education group [15,40,71], and 5 used a passive control group [51,52,57,72,73]. Two studies used both a single-modal active control and a passive control group [65,66]. One study compared results with 2 single-modal active controls and a placebo group [38], while another used 3 single-modal active control groups [74]. In addition, 1 study contrasted results with 2 single-modal active controls, a health education group, and a passive control group [16]. Another study used a bimodal active control group [36].

Among these studies, 7 reported significantly greater improvements in all measured cognitive functions within the bimodal intervention groups [15,35,40,52,59,63,72]. Three studies revealed improvements in both bimodal intervention and control groups [16,37,61,70]. One study found greater improvements in executive function, global cognition, and verbal fluency within the PT-only control group, whereas attention and processing speed improved significantly across all groups [38]. Another study reported no changes in cognitive function across any group [57]. In addition, 1 study observed improvements in attention, episodic memory, and working memory across all groups but no changes in global cognition [74]. Finally, 1 study reported greater improvement in global cognition within the NI-only control group [65].

Three Studies Investigated the Combination of PT and PI

Among these 3 studies, 2 studies compared results with a single-modal active control group [39,48], and one compared with a passive control group [41]. One study found that both the bimodal intervention and control groups enhanced attention, memory, and processing speed, but only the intervention group significantly improved executive function [39]. Another study

XSL•FO
RenderX

revealed improvements in global cognition only within the bimodal intervention group, although both groups improved in executive function [41]. In addition, one study reported significantly greater improvements in global cognition exclusively in the bimodal intervention group [48].

Two Studies Investigated the Combination of PT and NI

One study compared the intervention group with 2 single-modal active control groups and a health education control group [56]. It found that both the bimodal intervention and PT-only groups showed greater improvements in executive function and global cognition, although no gains were observed in memory or verbal fluency across groups [56]. Conversely, another study contrasted the intervention group with 2 single-modal active control groups [58] and revealed improvements in global cognition in all groups [58].

One Study Investigated the Combination of CT and Electroacupuncture

This study compared the intervention group with a single-modal active control group. It found that all groups demonstrated significant improvements in global cognition [42].

Three Studies Investigated the Combination of CT and PI

One study compared a reverse sequential control group [68], whereas 2 studies compared results with a passive control group [61,69]. Results from the latter 2 studies revealed significantly greater improvements in attention, episodic memory, and global cognition in the bimodal intervention group [61,69]. Conversely, the study with a reverse sequential control group found enhanced global cognition in both groups. Notably, the group starting with the PI showed more significant attention improvements after the initial training, while the group beginning with CT exhibited greater improvements following the second, combined training phase [68].

Five Studies Investigated the Combination of CT and Current Stimulation

Two of these studies compared the intervention group with a bimodal active control group [53,62]. One study contrasted the intervention group with a single-modal and a bimodal active control group [60]. Another study used a combination of CT and sham current stimulation as a control group [44]. One study included a current stimulation–only group, a sham current stimulation–only group, and a sham current stimulation control group [47].

One study observed improvements in everyday memory and global cognition across all groups, with attention improvements unique to the bimodal intervention group [60]. However, the CT-only control group showed greater working memory improvements than the bimodal intervention group [60]. Notably, transcranial direct current stimulation (tDCS) appeared to enhance the efficacy of CT in processing speed [60], despite not being a direct target. Another study showed that the bimodal intervention group demonstrated more significant attention improvements than both the placebo and CT groups [62]. In addition, 1 study found improvements in attention; processing speed; subjective cognitive functioning; and verbal, visual, and working memory across all groups [53]. Another study revealed improvements in episodic memory, executive function, and visual memory in both bimodal and active control groups [44].

Two Studies Investigated the Combination of PT and Transcranial Brain Stimulation

One study compared the intervention group with a bimodal active control group (PT and sham brain stimulation) [45], while another study used 2 bimodal active controls (PT and sham stimulation and sham PT with brain stimulation) along with a passive control group [67].

Results showed improvements in episodic memory, executive function, global cognition, and visual working memory in both the bimodal intervention and control groups [45]. However, the bimodal intervention group displayed greater enhancements across all cognitive functions compared to the control groups [67].

Trimodal Interventions

Overview

Studies comparing combined PT, CT, and SA with health education controls reported significantly better cognitive improvements, especially in the memory domain [55,75,76]. Similarly, 3 out of 5 studies using combined PT, CT, and NI [46,49,54] showed significantly greater improvements in global cognition compared to control groups (Table 3).

Five Studies Investigated the Combination of PT, CT, and NI

One study compared the trimodal intervention group with an NI-only active control group [43], another compared it with both a PT-only active control and a placebo group [46], and a third study used an inactive control group [49]. One study contrasted outcomes with 4 control groups: combined PT and CT with placebo NI; combined PT and NI with sham CT; combined PT with sham CT and sham NI; and an inactive control group [54]. The fifth study compared the trimodal intervention with various combinations of PT, CT, and NI placebos [50].

In the first study, the trimodal intervention group study reported no substantial changes in cognitive functions across all groups [43]. Conversely, the second study found the intervention group showed significantly greater improvements in all cognitive functions compared with the placebo group, but not when compared to the PT-only control group [46] and the third study observed more significant enhancements in global cognition in the trimodal intervention group [49]. The fourth study also found greater improvements in global cognition in the trimodal intervention group, but no significant changes in other measures [54]. In the last study, the trimodal intervention group showed no significant difference compared to the controls [50].

Three Studies Investigated the Combination of PT, CT, and SA

All 3 studies contrasted the intervention group with a health education control group, revealing significant improvements in global cognition and memory for the trimodal intervention group [55,76]. In addition, 1 study found significant enhancements in memory compared to control groups [55], while another reported significant improvements in both attention and executive function during a 12-month follow-up in the intervention group [76].

Quadrimodal Interventions

Most studies incorporating quadrimodal interventions reported small to moderate effects across various cognition domains, especially in global cognition (Table 4).

XSL•FO
RenderX

[m]PALT: Paired Associative Learning Test.

Two Studies Investigated the Combination of PT, CT, PI, and SA

The 2 studies compared a quadrimodal intervention group with a passive control group [64,77]. One study found significantly greater improvements in global cognition in the quadrimodal intervention group [77]. In contrast, the other study reported no significant improvement in cognitive function within the intervention group, but the control group experienced deterioration [64].

One Study Investigated the Combination of PT, CT, PI, and NI

Compared to a passive control group, the quadrimodal intervention group showed significantly larger posttreatment improvements in global cognition and memory. However, these effects showed no difference between the two groups at the 12-month follow-up [78].

The Use of Technology in MCI Interventions

Between 2015 and 2024, a total of 16 studies incorporated technology to enhance intervention delivery. The Nintendo Wii (n=1) was first used as a hardware platform for delivering PT [16]. Subsequent studies used various technologies, including virtual reality (VR) technology (n=1) for combined PT and CT intervention [37]; Nintendo Switch (n=1) [44]; and iPad (n=2) [50,57] for sensorimotor, visuomotor [54], and CT [50], respectively.

In addition, 13 studies used a range of computerized programs for CT targeting functions such as attention, memory, and executive function. These included AKL-T01 (n=1) [62], Brain Fitness (n=1) [16], COGPACK (n=2) [53,68], CogniPlus (n=1) [32], NeuronUP (n=1) [60], Neuropeak (n=1) [54], and RehaCom (n=3) [42,47,63] and 2 studies with no specified programs [44,49]. In addition, 1 study used the FitForAll program [16] for PT. Studies that incorporated CCT alongside other modalities showed significantly better improvements, particularly in global cognition, than studies with either active and inactive control groups. Details on tasks, duration, and major findings of these programs are presented in Multimedia Appendix 3.

Five studies incorporated tDCS with CT [44,47,53,60,62], while 2 studies combined tDCS with PT [45,67]. Specifically, they applied 1.5mA to 2 mA of tDCS to the left dorsolateral prefrontal cortex (DLPFC) or 1.5 mA of transcranial alternating current stimulation (tACS) on the prefrontal cortex [62].

Acceptability and User Experience

User compliance is influenced by the acceptability and experience of treatments. Four studies indicated high acceptability and positive user experiences regarding multimodal interventions. Jesus et al [61] reported that 24 out of 27 participants demonstrated a 97% acceptability rate for the treatment effect and frequency of a combined CT and PI. Another study on a combined PT, CT, and PI intervention reported that 78% (39/50) of participants rated the program as “very good,” 20% (10/50) rated it as “good,” and 2% (1/50) rated it as “pleasurable” [68]. In addition, a study on a combined PT, CT, and SA program showed that 86% (35/41) of

XSL•FO
RenderX

participants were satisfied with the intervention duration and 81% (33/41 participants) expressed a desire to continue [55].

Similarly, a study on a combined PT and CT intervention reported that 39 out of 44 (89%) participants perceived subjective benefits. In terms of overall satisfaction, 14 out of 44 (32%) participants rated it as "very good," 24 out of 44 (54%) participants rated it as "good," and 6 out of 44 (13%) participants rated it as "neither good nor bad." In addition,12 out of 44 (27%) participants considered the user-friendliness of the intervention as "very good" [57].

Dosage Effect and Health Economics

While treatment dosage may affect clinical outcomes, only 1 study evaluated the dosage effects of a quadrimodal intervention (combined PT, CT, PI, and SA) [64]. It found that 1 to 2 sessions per week of the quadrimodal intervention in daycare centers yielded no significant difference in cognitive outcomes compared with 3 to 5 sessions per week [64]. As such, the study suggested that less-frequent sessions (1-2 wk) might be as effective as more frequent sessions, thus further studies are warranted to validate these findings and test with other multimodal interventions.

In addition, while the cost-effectiveness of multimodal cognitive interventions is important for clinical practice, none of the included studies examined the cost-effectiveness of the identified intervention.

Discussion

Overview

This scoping review examines the current research landscape on nonpharmacological multimodal interventions for MCI, highlighting publication trends, intervention types, technology use, user experience, and dosage effects. Over the past decade, the variety of multimodal intervention combinations has increased. The most common interventions combine PT and CT, with additional components, such as NI, electroacupuncture, PI, and current stimulation. Cognitive outcome measures are diverse, targeting various domains. Bimodal and trimodal interventions generally outperform single-modal ones in improving global cognition, attention, and executive function. Notably, PT with current stimulation and PT with NI often demonstrate better cognitive improvements compared to active controls, while CT with PI shows more improvements compared to inactive controls. However, most studies on combined PT and CT report mixed results. Quadrimodal interventions also show superior improvements, although their long-term effect remains uncertain. This review, following the Arksey and O'Malley framework, did not conduct a meta-analysis or risk of bias assessments. The included studies suggested that trimodal and quadrimodal interventions, especially those including SA, might offer better cognitive outcomes, but findings should be interpreted cautiously due to the limited number of studies. Technologies, such as VR, gaming, computerized programs, and transcranial stimulation, are increasingly adopted in MCI interventions. Although technology-assisted training showed significant improvements in various cognitive domains comparable to traditional trainings, results should be interpreted with care given the limited studies. Future research should investigate whether technology-assisted training, with or without additional modalities, offers significantly better cognitive improvements than traditional training. Although only 4 included studies assessed the acceptability of multimodal interventions, they were generally well-received by users. Only 1 included study evaluated the dosage effects of a quadrimodal intervention, suggesting that 3 or more sessions per week may not be beneficial, although this finding should be interpreted cautiously. As none of the included studies evaluated the cost-effectiveness of these interventions, future studies should address this gap.

Types of Modalities

Aside from traditional PT like aerobic and stretching exercises, recent research has been expanding to explore various PT types beyond traditional methods, including mind-body exercises such as tai chi [66], yoga [58], and dancing [15] as viable components in multimodal interventions for managing MCI.

Mind-body exercises, which engage the mind to influence bodily functions, are popular among older adults, partly due to cultural preferences in certain populations. The effectiveness of such exercises, such as tai chi, varies between Asian [74,79] and Western populations [39], highlighting cultural influences. tai chi, for instance, demands whole-body coordination, rhythmic movements, dynamic weight shifting, single-limb support, integrating movement recall (memorization and concentration), spatial orientation, and cognitive activities such as attention and executive control. This provides simultaneous PT and CT that could be beneficial for older adults with MCI [20,66]. In addition, these mind-body exercises offer relaxation and social support in group settings, potentially improving mood and motivation to participate in activities. Given their multifaceted benefits, mind-body physical activities may be incorporated into multimodal interventions for MCI.

With the growing interest in multimodal interventions, there is a noticeable increase in incorporating various interventions in addition to combined PT and CT. Modifiable lifestyle factors, including NI, are crucial for cognitive improvements among older adults with MCI. However, the effectiveness of NI as a standalone intervention has yielded mixed results for cognitive outcomes. Different dietary patterns and supplements have been suggested to promote cognitive health. For instance, the Mediterranean-Dietary Approaches to Stop Hypertension Intervention for Neurodegenerative Delay diet is popular. However, a large-scale study found that the Mediterranean-Dietary Approaches to Stop Hypertension Intervention for Neurodegenerative Delay diet was not significantly superior to a control diet with mild caloric restriction over 3 years [80]. In addition, systematic reviews suggest that certain single-nutrient supplements, such as folate, vitamin E, omega-3 fatty acids, and probiotics, show promising but preliminary results, often based on weak evidence or low-quality studies [81-83].

NI has drawn attention to its potential in multimodal interventions for MCI. All the included studies that incorporated NI demonstrated promising outcomes when combined with PT and CT compared to the control groups. However, some studies

XSL•FO
RenderX

lacked detailed descriptions of their use of dietary guidelines, limiting the understanding of whether the specific dietary changes could be contributed to cognitive improvement. The current findings suggest that while a single NI may offer limited results, a combination of different modalities can provide a synergistic protective effect, highlighting the effectiveness of a multimodal approach over a single intervention.

In addition, there is an increasing use of PI and SA as supplementary components. Previous studies suggested that engaging in SA could help delay the development of dementia and cognitive decline [84,85]. SA and leisure activities not only have therapeutic benefits but also allow participants to engage with peers, fostering long-term adherence to interventions. It is important to note that the number of studies that incorporated the use of PI and SA is still relatively small; more studies are warranted to strengthen whether the implementation of additional PI and SA might provide additional benefits in a multimodal intervention for MCI.

Collectively, all the aforementioned intervention components play a role in enhancing mental health and cognitive functions across various aspects of MCI, suggesting that a larger number of combined modalities could be beneficial. This aligns with a previous systematic review that suggested an increased number of modalities might yield greater improvement in cognition [21]. Indeed, most of the included studies incorporating 3 or 4 modalities reported notable improvements in various cognitive domains, especially when additional modalities (including SA, NI, and PI) were combined with PT and CT. However, there is no consensus regarding the optimal number or combinations of modalities for multimodal interventions. Furthermore, it is worth noting that adopting multiple lifestyle changes may pose challenges for older adults. As Schneider and Yvon [86] suggested, such changes are more feasible for older adults in better health and with higher education levels. In current MCI management, while health advice is important, it may not sufficiently inform or motivate individuals with MCI to adopt new management strategies. Therefore, health education emerges as a crucial component for the successful implementation of lifestyle changes because it provides vital information on lifestyle modifications and guides the execution of physical or cognitive exercises at home.

Nonetheless, it is noteworthy that most of the included studies only compared the effectiveness of 3 or more modal combinations with single-modal interventions, health education, or passive control groups. It remains unclear whether there are more modalities or specific combinations that would offer greater benefit to individuals with MCI.

The Current Use of Technology

Beyond traditional interventions, technology is increasingly embraced by researchers for its potential as a valuable asset in delivering multimodal interventions for clinicians and researchers from 2015 (n=1) [16] to 2023 (n=4) [47,54,62,63]. CCT comprises guided drill-and-practice on standardized tasks aimed at various cognitive domains that gradually progress with adjustable difficulty based on user performance. This approach is both cost-effective and safe for widespread use [87].

This review identified several computer programs that provide personalized CCT targeting various cognitive domains. Our findings concur with a previous systematic review, showing CCT and VR-CT as effective in enhancing attention, executive function, global cognition, memory, processing speed, verbal fluency, and visuospatial ability in older adults at risk of cognitive decline [25]. These outcomes are on par with traditional in-person PT and CT, suggesting CCT and VR-CT as promising ways for broad-scale cognitive intervention delivery.

Interactive video game–like programs offer training across multiple cognitive domains, including attention, executive function, processing speed, and visuomotor and visuospatial abilities, providing more engaging and motivating experiences for older adults with MCI than traditional face-to-face CT [26,88-90]. These programs also facilitate PT through diverse hardware. For instance, one included study used Nintendo Wii, Wii Remote, and Wii Balance Board for physical exercises (eg, aerobic exercises) [16]. Advanced technologies such as the latest Nintendo Switch, which tailored physical exercise games and hardware (eg, Ring Fit Adventure), adapt challenges to individual capacities, progressively improving cognitive function in older adults with MCI.

In addition to the computerized training program, the included studies that incorporated VR technology in delivering combined PT and CT demonstrated significant improvement in executive function and global cognition. These improvements were greater and consistent with the improvements from the combined PT and CT control group without the use of VR [36,37]. This positions VR as a promising tool for integrated therapy. As suggested by recent systematic reviews, VR could act as an assistive device to deliver training and help improve executive function and global cognition in individuals with MCI [25,88]. Compared to traditional PT and CT, VR-PT and VR-CT offer accessibility, cost-effectiveness, and immersive personalized experience to facilitate skill transfer to activities of daily living [36,37,90]. With advancements in technology, VR equipment has become more user-friendly, affordable, and suitable for home use and rehabilitation, benefiting older adults with mobility issues. However, potential side effects such as stimulator sickness, discomfort, tiredness, mood change induced by immersive experience, and some health-related issues from wearing the VR headgear [90] highlight the need for clinician oversight to adjust treatment as necessary.

Although the development of computerized training programs can be costly, the potential for widespread deployment can offset the expenses of hiring numerous qualified assessors or clinicians and the costs associated with traveling for face-to-face training. Future research should explore integrating these programs with multimodal interventions, such as NI, to enhance their effectiveness and improve the overall well-being of individuals with MCI.

MCI affects multiple cognitive functions. The DLPFC plays a crucial role in functional connectivity with other brain regions and controls various cognitive functions, including attention, decision-making, planning, and working memory. Research has found that individuals with MCI exhibit functional disconnection

XSL•FO
RenderX

in the left DLPFC, leading to attention and working memory deficits [60]. This review included studies that used noninvasive brain stimulation techniques (eg, tDCS [45,53,60] targeting the left DLPFC and tACS targeting the prefrontal cortex); results from these studies suggested that using tDCS or tACS alongside PT or CT could enhance the effectiveness of PT or CT by improving cognitive capacity and reducing the load needed to perform cognitive tasks, thereby increasing processing speed and potentially serving as a viable component in future studies.

Taken together, technology stands as a valuable adjunct in administrating PT and CT, offering standardized, cost-effective, and assessable personalized experiences. Such technological integration could help researchers develop comprehensive management strategies for the widespread treatment of MCI in older adults.

Acceptability and User Experience

Acceptability and user experience are pivotal for the success of interventions aimed at managing MCI, which directly influence its adherence rates. Adherence, in turn, significantly affects the effectiveness of multimodal interventions. Therefore, the interplay between user experience, acceptability, and adherence is vital in developing and implementing MCI interventions. However, most included studies have not investigated these factors, which may hinder clinicians or senior management in choosing or recommending treatment options. One included study suggested that the low adherence rate in older adults might be attributed to family responsibilities, health issues, and social commitments. Leveraging technology, particularly eHealth and mHealth tools, could improve adherence by alleviating barriers to adherence [65]. These tools could be used to facilitate easier implementation and monitoring of interventions, thereby reducing the time and cost required for broader deployment across various populations and regions [91]. Although none of the included studies have implemented such technological applications, future research should explore the potential of mobile technology in enhancing adherence in older adults with MCI.

Limitations and Future Directions

While this scoping review offers a comprehensive overview of current study directions in multimodal interventions for MCI management, it has several limitations. First, by focusing solely on experimental studies with control groups, it may have overlooked relevant insights from qualitative research and gray literature. Second, this scoping review only included English articles, which may introduce cultural bias. Third, this review concentrated exclusively on the cognitive outcomes, omitting physical and psychological outcomes that might be crucial considerations for policy or clinical decisions. Fourth, several included studies had relatively small sample sizes, ranging from 19 to 27 participants [16,43,45,62,65]. Therefore, results should be interpreted with caution. Fifth, adhering to the Arksey and O'Malley framework and PRISMA-ScR guidelines meant no risk of bias assessments or evidence syntheses were conducted. Future systematic reviews or network meta-analyses should aim to summarize evidence regarding the relative effectiveness of different combinations of various multimodal interventions for MCI management.

While the current American Academy of Neurology guidelines for MCI management only recommend PT or CT, recent studies highlight the potential benefits of NI, PI, and SI for MCI management. With the annual conversion rate of MCI to dementia ranging from 10% to 15% per year [7], further research should explore various multimodal intervention combinations, focusing on follow-up, treatment duration, and frequency to potentially reduce or delay conversion rates. Although some included studies used brain imaging, most relied on self-reported or assessment scores, which might not accurately reflect real-world improvements. Future research should incorporate brain imaging technologies to validate results more robustly and elucidate the mechanisms underlying clinical improvements in cognitive function.

Considering the limited research on the cost-effectiveness of multimodal interventions for older adults with MCI and the growing aging population, future studies should investigate the economic viability of these interventions. In addition, the unclear dosage effects of different multimodal intervention combinations warrant investigation. Only one included study revealed that attending 1 or 2 sessions per week of a quadrimodal intervention was not significantly different from 3 to 5 sessions per week, suggesting that fewer sessions of quadrimodal intervention (PT, CT, PI, and SA) might still significantly improve global cognition [64]. However, this finding from a single study is not conclusive, further research is needed to determine the optimal dosage and combination of modalities to optimize the effectiveness of multimodal interventions for MCI.

Previous studies highlight the potential of lifestyle modifications such as dietary patterns in managing cognitive decline in older adults [92-94]. However, these studies used diverse nutrition supplements or dietary patterns. Similarly, while social engagement could help manage MCI [5], there is a dearth of studies on its effectiveness in enhancing physical and emotional well-being in older adults with MCI.

Finally, the included studies used diverse diagnostic criteria and cognitive measurements with different cutoff scores, potentially resulting in heterogeneous participant cohorts that could affect the results. An international consortium should be formed to develop standardized outcome measures for consistent outcome comparisons.

Conclusions

This scoping review provides a comprehensive update on the use of multimodal interventions for improving cognitive functions in older adults with MCI. It presents study directions, multimodal intervention types, respective findings in the included studies, the role of technology in these interventions, and potential research directions. The most common multimodal intervention combines PT and CT. However, various types of interventions such as NI, PI, SI, and brain stimulation have also been incorporated into multimodal interventions more recently. Given the capacity of these interventions to stimulate multiple cognitive domains, the effectiveness of various combinations of modalities should be explored. The research gaps highlighted in this review pave the path for future large-scale clinical trials to help develop more effective management strategies for cognitive decline in older adults with MCI.

Abstract

Background: Using remote monitoring technology in the context of Alzheimer disease (AD) care presents exciting new opportunities to lessen caregiver stress and improve patient care quality. The application of wearables, environmental sensors, and smart home systems designed specifically for patients with AD represents a promising interdisciplinary approach that integrates advanced technology with health care to enhance patient safety, monitor health parameters in real time, and provide comprehensive support to caregivers.

Objective: The objectives of this study included evaluating the effectiveness of various remote sensing technologies in enhancing patient outcomes and identifying strategies to alleviate the burden on health care professionals and caregivers. Critical elements such as regulatory compliance, user-centered design, privacy and security considerations, and the overall efficacy of relevant technologies were comprehensively examined. Ultimately, this study aimed to propose a comprehensive remote monitoring framework tailored to the needs of patients with AD and related dementias.

Methods: Guided by the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) framework, we conducted a systematic review on remote monitoring for patients with AD and related dementias. Our search spanned 4 major electronic databases—Google Scholar, PubMed, IEEE Xplore, and DBLP on February 20, 2024, with an updated search on May 18, 2024.

Results: A total of 31 publications met the inclusion criteria, highlighting 4 key research areas: existing remote monitoring technologies, balancing practicality and empathy, security and privacy in monitoring, and technology design for AD care. The studies revealed a strong focus on various remote monitoring methods for capturing behavioral, physiological, and environmental data yet showed a gap in evaluating these methods for patient and caregiver needs, privacy, and usability. The findings also indicated that many studies lacked robust reference standards and did not consistently apply critical appraisal criteria, underlining the need for comprehensive frameworks that better integrate these essential considerations.

Conclusions: This comprehensive literature review of remote monitoring technologies for patients with AD provides an understanding of remote monitoring technologies, trends, and gaps in the current research and the significance of novel strategies for remote monitoring to enhance patient outcomes and reduce the burden among health professionals and caregivers. The proposed remote monitoring framework aims to inspire the development of new interdisciplinary research models that advance care for patients with AD.

Introduction

Background

Alzheimer disease (AD) is the most generic form of dementia, and significantly affects the brain cells, declines cognitive abilities, and makes it difficult to perform daily tasks [1]. The main effects of the disease are loss of memory, inability to use problem-solving and logical thinking skills, anxiety, depression, and confusion [2]. AD has remained the leading cause of death among people aged >60 years. The main cause of AD is the accumulation of abnormal proteins such as β-amyloid and microtubule-associated tau protein in the brain; the aggregation of these proteins causes synaptic disintegration and neural loss, which characterize AD [3,4]. Disturbingly, it is estimated that the number of AD cases could grow to 13.8 million by 2060. The pervasive nature of this disease underscores the pressing need for continued research, intervention strategies, and support systems to address the growing challenges posed by AD in an aging population [5,6].

Caring for individuals with AD is an enduring and demanding journey, often placing a significant burden on family members who become primary caregivers or on those who opt to hire professional caregivers [7]. The responsibilities encompass a spectrum of care, requiring a deep commitment to providing the essential support needed for patients with AD to navigate their daily lives. Caregivers play a crucial role in assisting individuals with AD in tasks integral to their routine while also implementing lifestyle adjustments aimed at alleviating stress, confusion, anxiety, and agitation. The caregiving journey involves fostering an environment that promotes mental, physical, and social well-being. This includes implementing tailored strategies to keep patients with AD mentally engaged, encouraging physical activities that align with their abilities, and facilitating social interactions to prevent isolation. However, continuous monitoring and provision of care for patients with AD causes a substantial burden on both the family members and caregivers [8,9]. This responsibility often causes a lot of stress and depression among those providing care. Family members and caregivers find themselves dealing with the progressive loss of individuals with AD. In addition to that, they must navigate between caregiver responsibilities and sustaining a work-life balance. Disputes between family members, financial burdens, and escalating medical expenses extend the challenges that those undertaking caregiver roles face [10]. While existing research has identified various scales to measure the burden on family members, there is a notable gap in the literature concerning effective strategies to alleviate this burden. Manzini and do Vale [11] and Liao et al [12] address this critical gap by exploring remote monitoring methods facilitated by ITs. By leveraging innovative approaches, the research seeks to enhance the quality of care provided to patients with AD and substantially reduce the burden experienced by family members and caregivers. Through the implementation of such technological solutions, the aforementioned studies [11,12] aspired to contribute valuable insights into improving the overall well-being of both patients with AD and those entrusted with their care.

Despite the growing body of research on remote monitoring for AD and related dementias (ADRD), significant gaps remain in the literature, particularly regarding interdisciplinary integration. Previous reviews have primarily focused on individual aspects of remote monitoring, such as wearable devices [13-16], smart home sensors [17-19], or privacy and security considerations [20,21], often in isolation. However, the effectiveness of these technologies depends on a holistic approach that integrates expertise from health care, computer science, cybersecurity, and user-centered design. The lack of interdisciplinary research has led to fragmented solutions that may not fully address the practical needs of patients and caregivers. This review sought to bridge these gaps by offering a comprehensive assessment of remote monitoring technologies while emphasizing their usability, security, and ethical implications. Therefore, we formulated four research questions (RQs) to explore existing remote monitoring technologies and their applications, assess their needs and advantages, examine privacy concerns related to remote monitoring, and investigate technology adoption among older adults:

- RQ 1: What are the primary remote monitoring technologies to capture different behavioral, physiological, and environmental data?
- RQ 2: To what extent do these existing remote monitoring technologies achieve an optimal balance of efficiency, practicality, and empathy in addressing the needs of both patients and caregivers?
- RQ 3: What are the critical security and privacy considerations and concerns involved in these remote monitoring technologies?
- RQ 4: What are the critical design considerations and technology components for a comprehensive remote monitoring framework specifically tailored to patients with AD?

While this review focused on remote monitoring for individuals with AD, it is important to acknowledge that many of the challenges, technologies, and solutions discussed are also relevant to other dementia subtypes. Conditions such as vascular dementia [22,23], Lewy body dementia [24], and frontotemporal dementia [25] share overlapping symptoms [26,27], including cognitive decline, behavior changes, and mobility issues, which can similarly benefit from remote monitoring interventions. However, our decision to center this review on AD was guided by its high prevalence and the significant body of research available on remote monitoring solutions tailored specifically to ADRD. The insights presented in this paper may be broadly applicable to dementia care, although future research should further explore technology adaptations for different dementia subtypes.

The remainder of this paper is divided into 3 key sections. Section 2 outlines the methodology, comprising 3 subsections that detail the scoping criteria, literature search strategy, and

XSL•FO
RenderX

data analysis procedures. Section 3 addresses the RQs in depth. Finally, section 4 concludes the literature review, summarizing the key findings and their implications.

Objectives

Our objective with this paper was to critically assess the effectiveness of various remote sensing technologies in enhancing patient outcomes, particularly for individuals with ADRD, while also identifying strategies to reduce the burden on health care professionals (HCPs) and caregivers. To perform this assessment, the research comprehensively examined key factors essential for the successful implementation and adoption of these technologies. These factors include patient and caregiver compliance, ensuring that the technologies are used consistently and effectively; user-centered design, which focuses on creating accessible and intuitive systems tailored to the specific needs of end users; privacy and security concerns, addressing the safeguarding of sensitive patient data and ensuring adherence to ethical and regulatory standards; and the overall efficacy of these technologies, evaluating their accuracy, reliability, and impact on patient care.

Methods

Overview

In the landscape of AD care, this review undertook a comprehensive examination of the complex dynamics introduced by remote monitoring technologies. We focused on different remote monitoring technologies, types of algorithms used to process the data, issues and concerns related to security and privacy, caregiver burdens, and specific monitoring frameworks for patients with AD. We conducted an extensive search to identify relevant research papers across multiple disciplines from 2011 to 2024. Our search encompassed a diverse array of digital libraries, including Google Scholar, IEEE Xplore, PubMed, and DBLP on February 20, 2024, with an updated search on May 18, 2024, to ensure coverage across multidisciplinary domains, including health care, engineering, and computer science. These databases were selected based on their relevance to remote monitoring technologies, security and privacy considerations, and AD care. While Scopus, Embase, and Cochrane are widely recognized for systematic reviews in clinical and biomedical research, our focus on technological, interdisciplinary, and engineering aspects made IEEE Xplore and DBLP particularly valuable sources. In addition, PubMed was included to ensure coverage of relevant medical and health care studies. Google Scholar was used to capture a broader range of studies, including conference proceedings and gray literature, which are crucial for emerging technologies. On Google Scholar, the search string used was *"Remote monitoring technologies" AND "Wearable sensors" AND Alzheimer AND "Privacy concerns,"* ensuring a broad examination of related literature. PubMed and IEEE Xplore were queried using the search string *(Remote monitoring technologies) AND Alzheimer AND ("Privacy concerns")* to capture articles with a focus on technical and medical perspectives. In addition, DBLP was queried using the search string *Alzheimer AND "Remote monitoring"* to include publications emphasizing computer science and engineering insights. In addition, we cross-referenced the citations of each article to uncover additional relevant articles or government reports aligning with our inclusion criteria. Notably, we imposed some constraints on the period during which the papers were published, and only English-language papers were considered. In total, we identified 31 articles that fulfilled our inclusion criteria.

Our search strategy included keywords such as "Remote monitoring technologies" AND "Wearable sensors" AND "Alzheimer" AND "Privacy concerns" to ensure the inclusion of studies addressing security and data protection—critical challenges in adopting remote monitoring solutions. However, we acknowledge that this keyword choice may have limited the retrieval of studies focusing on broader aspects, such as clinical effectiveness, usability, and caregiver perspectives. While our selection process incorporated additional screening to identify studies covering a wider range of topics, future research could benefit from refining the search terms to ensure a more balanced representation of different remote monitoring challenges.

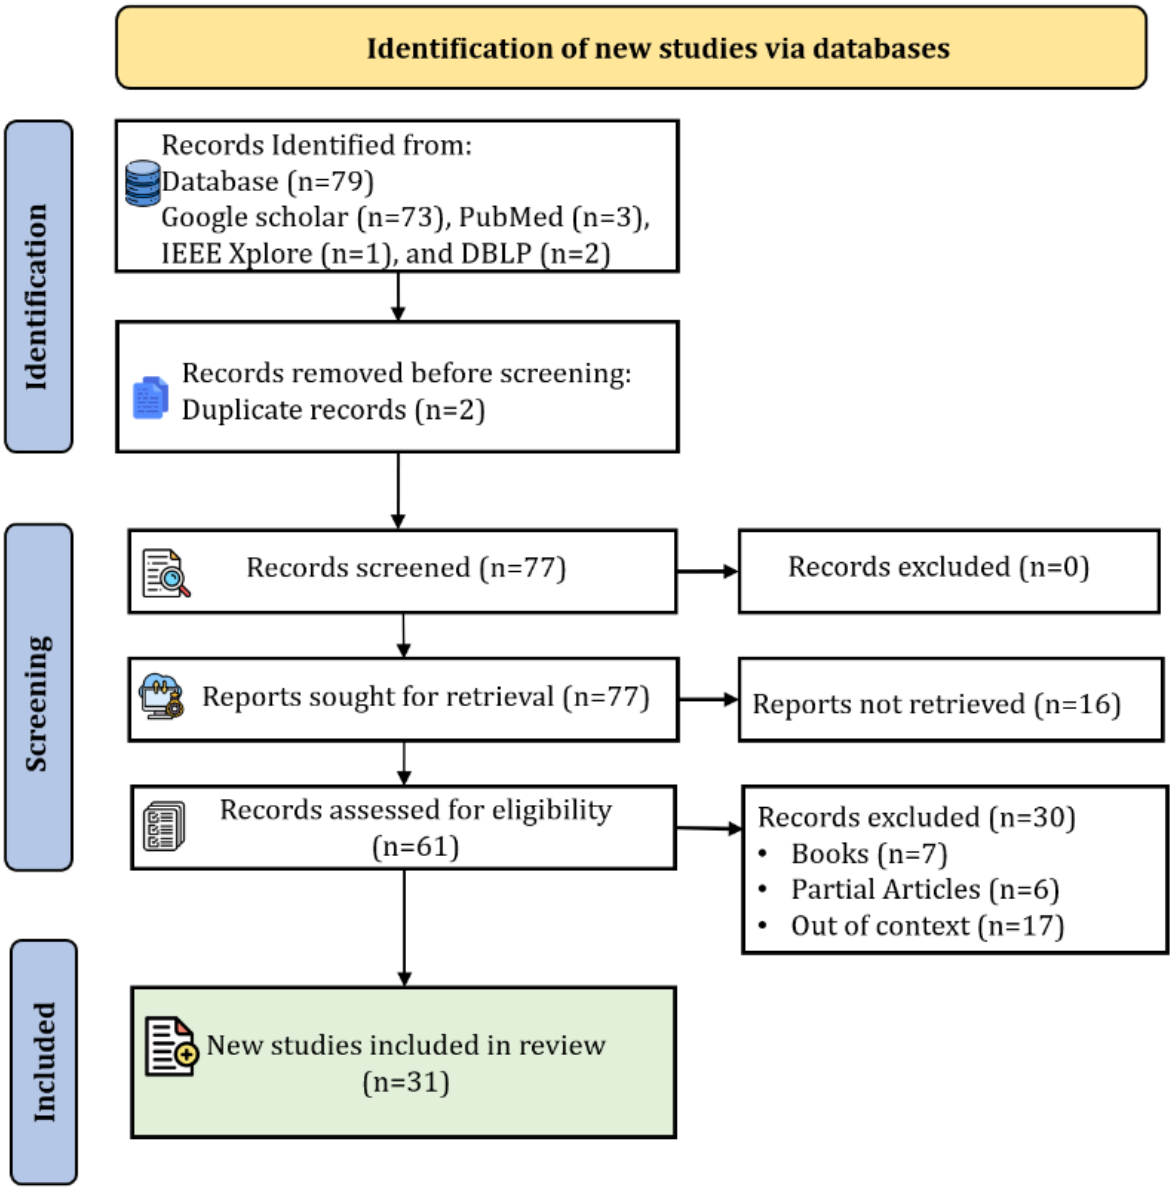
Study Identification and Selection

A total of 79 papers were initially identified based on their titles and abstracts that were deemed to be potentially relevant to the research topic. Of the 61 records assessed for eligibility, 30 (49%) were excluded for various reasons: 7 (23%) were books, 6 (20%) were partial articles, and 17 (57%) were out-of-context studies. Finally, 31 papers were identified to extract information and insights related to the RQs. These papers were thoroughly analyzed to identify common themes, methodologies, findings, and gaps in the existing literature. This analysis provided a deeper understanding of the current research and valuable insights to guide this review. This systematic approach to literature review and analysis enhanced the validity and reliability of the research, contributing to its overall credibility.

In the following sections, the findings from the papers are presented and discussed. The results are organized based on the information identified in the literature review with respect to the RQs.

Results and Discussion

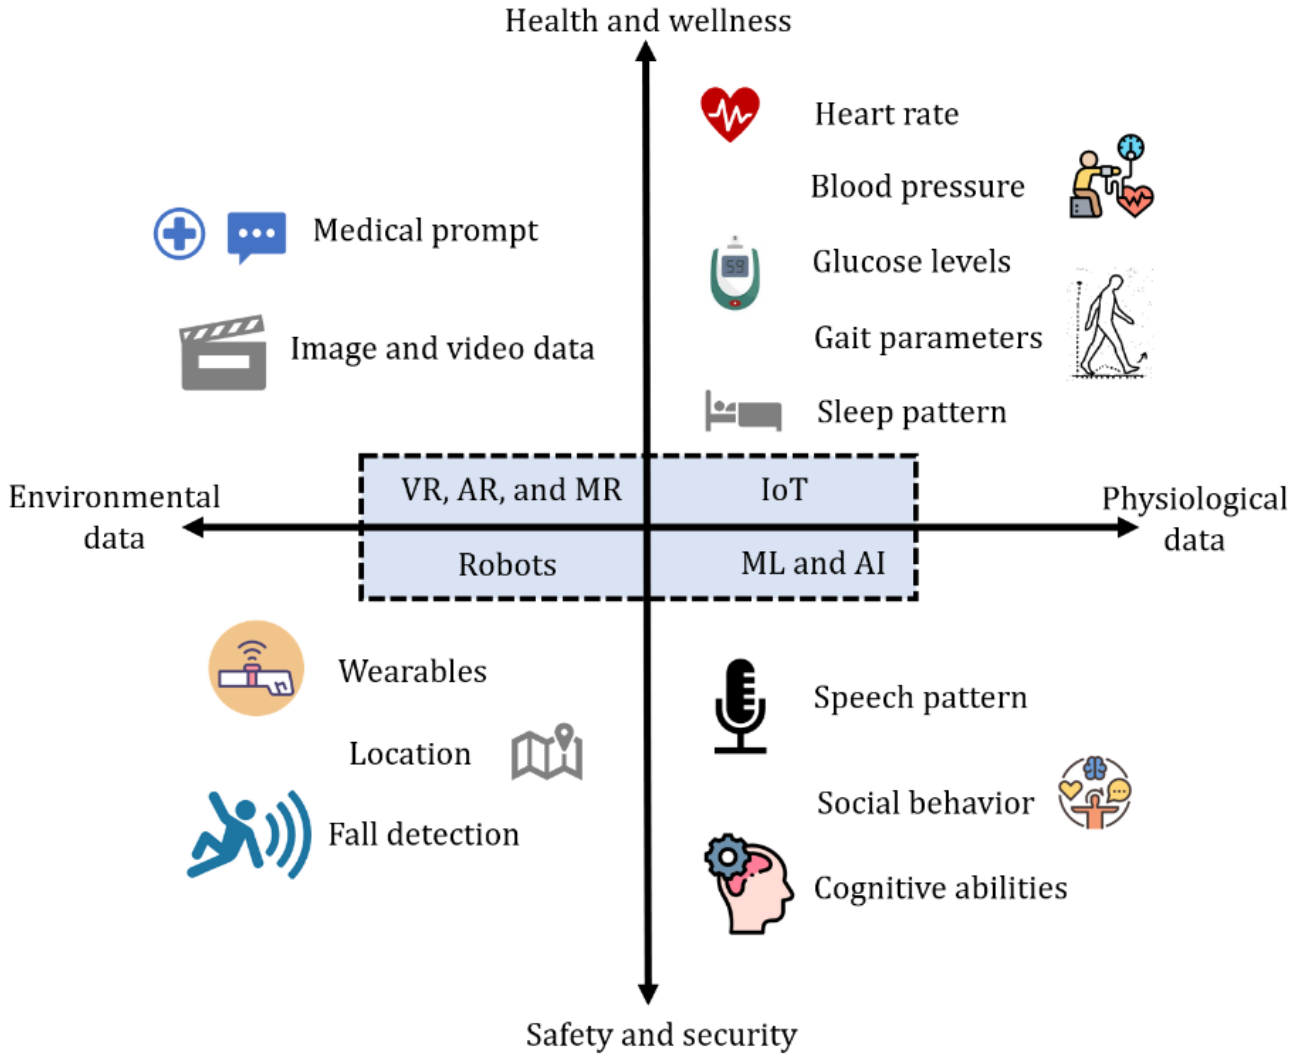
Primary Remote Monitoring Technologies (RQ 1)



Overview

Remote monitoring technologies using wearable and portable device–based sensors have revolutionized health care by enabling continuous and real-time tracking of various physiological and environmental parameters. These sensors, embedded in devices such as smartwatches, fitness bands, and portable health monitors, can measure heart rate, blood pressure, glucose levels, temperature, and physical activity [28,29]. They offer significant advantages in managing chronic conditions, detecting early signs of health deterioration, and providing personalized care. Wearable sensors are particularly beneficial in monitoring older patients and individuals with chronic diseases, allowing for prompt interventions and reducing hospital visits. Furthermore, the integration of these devices with mobile health (mHealth) apps and cloud-based platforms facilitates seamless data collection, analysis, and sharing with

XSL•FO
RenderX



health care providers, enhancing patient engagement and improving health outcomes. The subsequent subsections provide a detailed description of the various aspects of remote monitoring technologies. To ensure a systematic approach, a thorough review of the literature was conducted following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) framework [30,31] (Multimedia Appendix 1), as shown in Figure 1. Figure 2 illustrates the integration and synergy of different remote monitoring technologies based on relevant parameters. These are further elaborated on in the following subsections and in Multimedia Appendices 2-5 [14,32-52].

Wearables

Wearable technologies refer to devices worn on the body either as an accessory or as clothing. Devices embedded with an accelerometer and gyroscope, such as wrist or ankle devices, are used for analyzing gait parameters such as speed, variability, and stride length [32]. There are also wearable devices that capture physical activity data, including steps taken, intensity, and duration, aiding in tracking physical activity, which helps the patient with AD be physically active and slow down the progression of the disease [32]. In addition, wrist devices and smart clothes are equipped with sensors, whereas various wearables, including wristbands, smartwatches, and chest straps, collect different data such as physiological signs, posture, gait, movement, and sleep data, and enable the continuous monitoring of blood pressure. Devices such as the Basis Health Tracker, Misfit Shine, Fitbit Flex, Withings Pulse O2, and Actiwatch Spectrum actigraph are used for sleep detection and monitoring daily activities [53-57]. These devices enable continuous monitoring of vulnerable patients, offering medical specialists a comprehensive view of the patients' health for more accurate diagnosis and treatment [33,34]. Moreover, dream headbands are used to record and store physiological data in real time during sleep, facilitating the monitoring of daily sleep patterns and enabling patients and caregivers to access their reports freely [35]. Further details are provided in Multimedia Appendix 2 [32-35,37-45] and Multimedia Appendix 3 [32-34,36-38,42,45-47].

Environment and Home Sensors

Remote monitoring through advanced environment and sensor technology provides a promising approach to enhancing care, monitoring daily activities, and detecting early signs of cognitive decline. In the context of home-based remote monitoring, various sensors are used to capture and analyze vital health and activity data. Infrared sensors strategically placed throughout the home facilitate gait analysis by detecting individual movements and providing insights into gait characteristics such as walking speed, rhythm, and variability [32]. Wireless mattress sensors and ambient sensors are used to monitor sleep time, movements, and patterns, aiding in the early detection of mild cognitive impairment (MCI) and AD. In addition, night monitoring systems equipped with motion detectors are used to monitor sleep patterns and alert caregivers to unusual nighttime behavior [32]. In the case of continuous physical activity monitoring, infrared sensors are used to collect internal

XSL•FO
RenderX

movement data, which allows for the assessment of activity level without the need for active participation of the individual [32,36]. A multisensory approach, including sound sensors, video cameras, radio-frequency identification readers, pressure sensors, light sensors, proximity sensors, temperature sensors, humidity sensors, and location trackers, has been applied to many activities and environmental conditions in the home [33]. This rich dataset facilitates the assessment of disease progression and provides valuable information about changes in daily activities and environmental factors. Behavior patterns are tracked using sensors installed in various areas of the home, including the kitchen, bedroom, and bathroom, along with fall detection sensors. These sensors help monitor mobility, stability, frequency, and time spent in different areas, contributing to a deeper understanding of daily routines and potential risks [32]. Microsoft Kinect cameras are specifically used for gait monitoring to detect and assess falls among older individuals, with the collected video data aiding in fall prevention efforts [37].

Finally, motion sensor–activated light paths and bed pressure sensors are used for fall prevention and sleep problem detection, respectively. These sensors provide an additional layer of safety and monitoring, enhancing the overall effectiveness of the remote monitoring system [34].

Personal Devices

Personal devices, specifically, smartphones equipped with advanced sensors such as accelerometers, gyroscopes, and magnetometers, play a pivotal role in gait analysis and physical activity monitoring. Apps installed on these smartphones analyze the sensor data to determine various gait characteristics, including stride length, walking speed, and rhythm, providing valuable insights into mobility patterns [32]. Moreover, waist-worn accelerometers facilitate continuous monitoring of physical activity parameters such as movements and acceleration, aiding individuals in maintaining optimal levels of physical activity and energy use [32]. In addition to physical activity monitoring, smartphones serve as effective tools for assessing social behavior. By monitoring calls, SMS text messages, and internet-browsing activities, these devices offer insights into an individual's social activity levels and patterns. This information is crucial for health care providers and caregivers to understand the social interactions of individuals, identify potential signs of isolation, and implement interventions to promote social engagement and well-being [37].

Machine Learning and Artificial Intelligence

Machine learning and artificial intelligence (AI) play a pivotal role in health care by leveraging diverse data sources to enhance diagnostic capabilities, predict disease progression, and support clinical decision-making. Driving patterns collected through GPSs are analyzed to detect early signs of preclinical AD. These patterns are compared with disease progression to identify behavior changes linked to AD [32]. Activity data from sensor-embedded devices such as wearables are used for data mining and predictive modeling, aiding in identifying potential health issues and informing health care decisions [46]. Sleep patterns collected from these devices offer valuable insights into an individual's health status, providing clinicians with early warnings of health deteriorations or relapses and enabling timely interventions to improve patient outcomes [47].

Speech pattern analysis using data from health records, including calls and SMS text messages, offers diagnostic capabilities for neurodegenerative diseases such as Parkinson disease and AD, enabling early detection and intervention [38]. In addition, AI-powered image and video processing techniques assist in diagnosing various conditions, such as cancer from x-ray and computed tomography scans and degenerative diseases from fundus photography, enhancing diagnostic accuracy and treatment planning [38]. Furthermore, data collected from wrist-worn actigraphy devices such as the ActiGraph wGT3X are analyzed using a variety of machine learning algorithms, including logistic regression, random forest, gradient-boosting machine, and support vector machine. These algorithms help predict the risks and progression of disease, providing valuable insights for personalized health care management and intervention strategies [45].

Robots

Robots such as Nao, Pepper, Paro, Stevie, Zoro, Mini, and Tangy are emerging as valuable tools in health care settings, particularly for supporting the needs of older adults. These robotic companions engage older individuals through interactive activities such as conversations, quizzes, tongue twisters, and arithmetic calculations, demonstrating promising results in enhancing social engagement and alleviating feelings of isolation [46]. AI-powered robots equipped with advanced sensors and algorithms can access environmental data and user-specific characteristics to deliver personalized medical prompts and emotional support. These robots play a crucial role in physical rehabilitation, reducing feelings of isolation and promoting overall well-being by providing companionship and interactive engagement [38,42]. Furthermore, specialized robots such as Nao, Pepper, and Paro are designed to cater to the unique needs of patients with dementia with cognitive impairment. These robots offer a comprehensive range of services, including behavioral monitoring, physical exercise tutoring, recreational activities, stress management, and medication reminders. By providing multifaceted support, these robotic companions significantly enhance the quality of life of older adults and contribute to improved health care outcomes [34]. Robots named Stevie and Zoro are specially tailored to support caregivers and older adults with memory loss. These robots offer care support, entertainment options, cognitive engagement activities, and social connectivity features. Their interactive nature stimulates older adults through engaging exercise and interaction, fostering a sense of community and connection [32]. Robots such as Mini and Tangy enhance cognitive abilities in older adults using educational games and imitation learning, aiming to improve memory, cognitive function, and mental agility through innovative stimulation and support [37].

Internet of Things

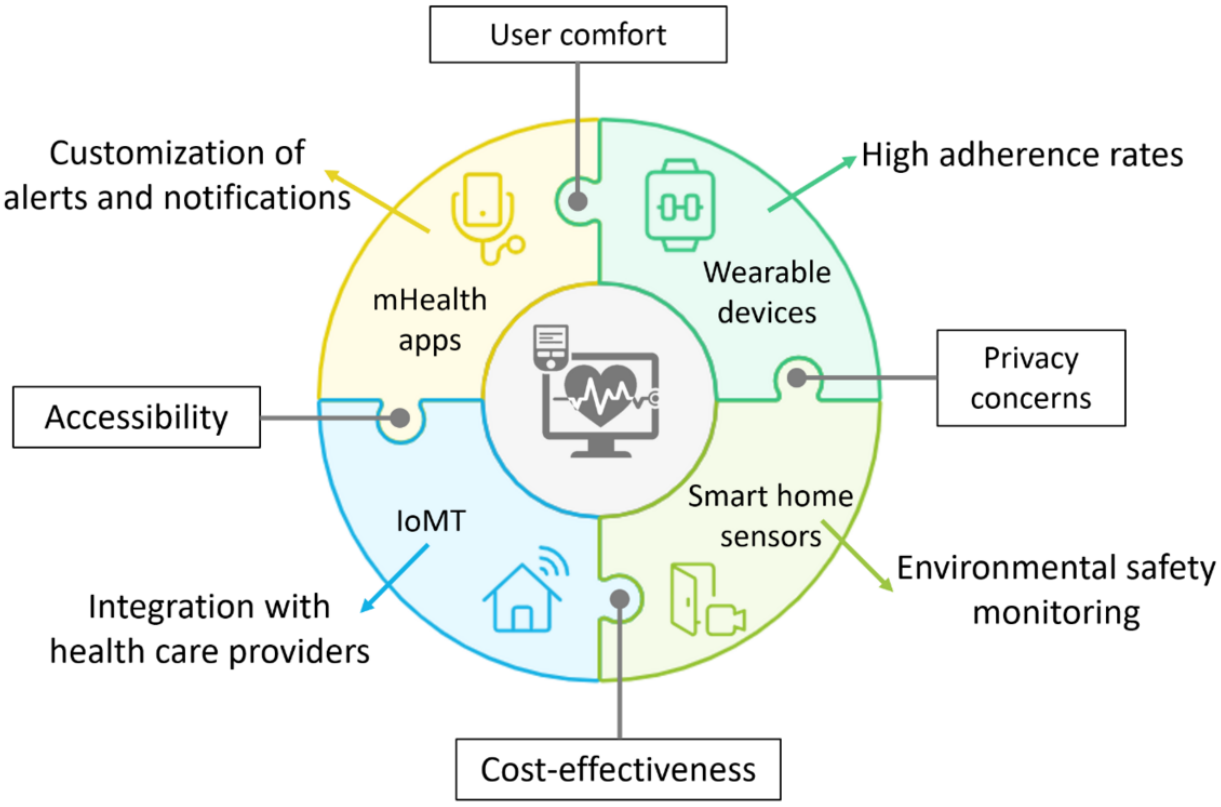
The Internet of Things (IoT) has revolutionized health care monitoring by using novel sensors and wireless communication methods such as Bluetooth, Wi-Fi, near-field communication, and Zigbee to access and securely store real-time data on vital signs, including temperature, blood pressure, heart rate, and

XSL•FO
RenderX

glucose levels, in the cloud. This advancement facilitates effective device management and real-time data monitoring and offers a secure storage solution, enhancing patient care and treatment outcomes [47]. Furthermore, the integration of multiple sensors into wearable devices, environment monitoring systems, and in-home setups provides pervasive and unobtrusive intelligence to support individuals proactively in their daily lives. These sensors enable continuous monitoring of various parameters, including temperature, humidity, and blood pressure, offering valuable insights for personalized health care interventions [39,42].

IoT-based tools such as smart pillboxes assist individuals in medication management by sending reminders according to prescribed medication plans, ensuring adherence to treatment regimens, and improving medication compliance [39]. Moreover, the implementation of semantic frameworks and advanced data processing techniques enables the collection and analysis of multi-sensor data to determine disease progression and provide timely alerts through real-time monitoring. This approach aids in the early detection of health deterioration, facilitating timely interventions and improved patient outcomes [40]. In addition, the DCARE model used a computational approach to process data from monitoring devices, incorporating content prediction, behavior recognition, and content recognition. This model serves as a comprehensive solution for general monitoring, data processing, and sending alerts to caregivers in case of potential risks or emergencies, enhancing patient safety and care coordination [41].

Virtual, Augmented, and Mixed Reality



Virtual reality, augmented reality, and mixed reality technologies, facilitated by devices such as headsets, smart glasses, and next-generation smartphones, offer an immersive experience that extends beyond entertainment to include web-based home shopping, leisure activities, and communication, enriching both social interaction and physiological well-being [42]. Smart spectacles equipped with machine learning algorithms for face and object recognition enable personalized video and image playback, assisting patients with dementia and memory loss by stimulating memory recall and cognitive engagement [43]. In addition, GPS and device tracking functionalities, combined with medication reminders via Bluetooth connectivity, empower caregivers to monitor patient locations and medication adherence, ensuring timely interventions and enhancing patient safety [44].

Effectiveness of Remote Monitoring Technologies (RQ 2)

Overview

In addressing RQ 2, which investigated the effectiveness of remote monitoring technologies for individuals with ADRD, a thorough review of previous research papers was conducted. The findings are synthesized and summarized in Multimedia Appendix 4 [14,32,33,36-38,42,45,46,48-52] and Figure 3, providing a detailed comparison of various monitoring methods, their advantages, and their limitations. This comprehensive assessment helps achieve an optimal balance in addressing the needs of both patients and caregivers. The following subsections delineate different aspects pertaining to RQ 2.

Figure 3. Key features and considerations of different remote monitoring technologies. IoMT: Internet of Medical Things; mHealth: mobile health.

XSL•FO
RenderX

Wearable Devices

Wearable devices have emerged as valuable tools for remote monitoring of various health conditions, including cerebrovascular diseases, neurodegenerative diseases, and MCI. Godkin et al [48] investigated the adherence value of wearable devices focusing on 3 key aspects—adherence based on sensor location, time of day, and wear location—and participant and study partner acceptance of continuous multi-sensor wear for a week-long period. The outcomes of this study demonstrated the feasibility of a continuous multi-sensor approach to remote monitoring for individuals living with cerebrovascular diseases and neurodegenerative diseases, showing high adherence rates during both day- and nighttime wear throughout the study period. The aforementioned study also addressed concerns related to device discomfort, including itchiness, catching on clothing during dressing or on bed sheets during sleep, device size, and appearance.

Similarly, a comprehensive investigation conducted by Stavropoulos et al [14] focused on public involvement activities to capture the preferences, priorities, and concerns of people with AD and their caregivers regarding the use of monitoring wearables. Face-to-face discussions with the patient advisory board revealed varying levels of acceptance toward new technologies among older individuals, highlighting concerns regarding the cost of devices, adaption to modern technologies, and potential difficulties in operating technology. Furthermore, Stavropoulos et al [14] used a questionnaire to understand the specific requirements, preferences, barriers, and daily obstacles faced by individuals with MCI, their caregivers, and HCPs in using wearables. The Human Factors and Technology Requirements Questionnaire collected survey responses to various types of questions, such as open-ended, multiple-choice, and closed-ended questions, and the importance of user-centered design for assistive technologies using wearables and highlighted the implications for future research. The aforementioned study provided valuable insights into the perspective of individuals with MCI, caregivers, and HCPs regarding the use of assistive technologies with wearable trackers, emphasizing the need to consider privacy and ethical issues in the technology design and the disadvantages of traditional record-keeping methods.

Smart Homes (Multiple Sensors)

Smart home technologies equipped with multiple sensors have shown promising benefits in remote monitoring, particularly through video monitoring methods. However, there is a growing interest in exploring novel remote monitoring technologies beyond traditional video monitoring, emphasizing the need to diversify research in this area [36]. Despite the potential advantages, there is limited evidence to conclusively determine the acceptance of these remote sensing technologies, indicating a gap in understanding alternative methods [36]. In a comprehensive systematic review, it was highlighted that smart home remote monitoring has the potential to support older persons and caregivers by addressing individual family needs [49]. Nevertheless, critical barriers need to be addressed for successful adoption and implementation, including concerns about the time, training, and technical challenges associated with smart home technologies [49]. These challenges include issues with battery life, unstable wireless connectivity, and incompatibility, which have raised concerns about potential feelings of loneliness and isolation among older people with cognitive impairments [49]. Furthermore, there is a need for more research on alternative remote sensing technologies, such as vibration and acoustics technologies, to better understand their potential applications and effectiveness [36].

Addressing stigma and negative associations with disability through appropriate design and customization of sensing technologies, such as the use of smart fabric sensors, could help mitigate privacy concerns and enhance acceptability [36]. Future research should focus on understanding end-user conditions for acceptability and addressing various barriers, including usability, technical issues, cost concerns, and social implications, to facilitate the broader adoption of smart home technologies in health care settings [36,49].

Multimode Sensor (Machine Learning Approach)

In addressing the challenges of predicting and managing the behavioral and psychological symptoms of dementia (BPSD), multimode sensor technologies coupled with machine learning approaches have emerged as promising tools [45]. These approaches leverage diverse data sources to offer valuable insights into the relative contributions of various factors, such as caregiver-perceived triggers, cognitive and functional status, personality traits, and actigraphy-derived parameters, in predicting BPSD. However, the efficacy of these technologies can be compromised by challenges related to the improper wear of devices, leading to limited data availability for accurate prediction [45]. Despite these obstacles, machine learning models have demonstrated their capability to effectively predict different subsyndromes of BPSD. Such predictive capabilities hold significant potential to inform personalized interventions tailored to individual symptom profiles, thus facilitating timely and targeted care.

Nevertheless, it is essential to acknowledge the existing limitations and gaps in current research [45]. Cho et al [45] emphasize the need for future studies to address these challenges. This includes validating findings in larger and more diverse populations, integrating objective monitoring technologies, and developing more precise prediction algorithms to enhance the accuracy and reliability of these predictive models. Such advancements could significantly contribute to improving the quality of care and support provided to individuals living with dementia and their caregivers.

Patient and Public Involvement Survey

Patient and public involvement surveys emphasize the importance of prioritizing user-friendly design and personalized approaches when developing mHealth apps tailored for individuals with cognitive impairment [50]. Survey findings in the study by Lazarou et al [50] highlighted participants' keen interest in brain games aimed at memory enhancement, showcasing a strong demand for cognitive support tools. In addition, the participants expressed a desire for medication reminders and GPS tracking functionalities within mHealth apps, demonstrating the potential utility of such features in enhancing daily living and emergency response for individuals

XSL•FO
RenderX

with cognitive impairment [50]. Despite these valuable insights, it is important to acknowledge the survey's limitations. The research was conducted among a limited population, potentially introducing self-bias and not capturing the full spectrum of needs and preferences across diverse groups [50]. To address these challenges, future research should aim to explore more diverse populations and incorporate a broader range of user perspectives. This will help in developing more inclusive and effective mHealth interventions that cater to the diverse needs of individuals with cognitive impairment, caregivers, and HCPs.

Internet of Medical Things and Robots

The Internet of Medical Things (IoMT) is revolutionizing the health care landscape by integrating advanced technologies into smart health care systems. In the study by Mathkor et al [52], the authors provided a comprehensive overview of IoMT, highlighting its role in current and future biomedical systems. The study emphasized the integration of technologies such as deep learning, machine learning, blockchain, AI, radio-frequency identification, and Industry 5.0. These technologies hold immense potential in enhancing patient care, improving diagnostic accuracy, and streamlining health care operations. However, the implementation of IoMT systems presents several challenges that need to be addressed for successful adoption. High costs associated with device development, infrastructure setup, and connectivity solutions can pose financial barriers. In addition, many IoMT devices operate on battery power, leading to concerns about battery life and continuous operation. Data quality issues, including noise, biases, and inaccuracies, can also arise due to device limitations or environmental factors. To fully realize the benefits of IoMT, it is crucial to address these challenges and develop robust, scalable, and secure solutions. Companion robots have emerged as potential tools to address the social and emotional needs of older adults, particularly those with dementia.

In the study by Pou-Prom et al [51], the authors conducted an experiment involving 19 participants diagnosed with AD to explore the feasibility of using conversational companion robots. The study revealed that, while some participants enjoyed interacting with the robots, others expressed doubtfulness and reluctance. Technical limitations such as speech recognition challenges, lack of dialogue context, and keyword matching were identified as barriers to seamless communication. Furthermore, the absence of features such as miscommunication and acoustic features hindered the assessment of dementia-related symptoms through robot interactions. The mixed reactions from participants highlighted the importance of ongoing research to refine companion robot technologies. Future work should focus on addressing the identified limitations, exploring the trade-off between autonomous and semiautonomous approaches, and optimizing the design and functionality of these robots to better support the well-being of older adults. Collaborative efforts involving HCPs, engineers, and end users are essential to develop more effective and user-friendly companion robot solutions that can have a meaningful impact on the lives of older adults with dementia.

Cognitive Monitoring for Dementia Care

Advancements in remote monitoring have enabled the integration of cognitive assessment tools to track disease progression and evaluate treatment effectiveness in dementia care. Digital cognitive assessments such as smartphone-based memory and attention tests offer frequent, scalable evaluations that provide real-time insights into cognitive changes. In addition, AI-driven speech and typing analysis can detect subtle linguistic and motor impairments associated with cognitive decline, enabling early intervention and treatment adjustments. Gaze tracking and eye movement analysis further enhance cognitive monitoring by assessing reading patterns, recognition abilities, and attention shifts, which may indicate neurological changes over time. Meanwhile, wearable electroencephalography devices and neurofeedback tools provide continuous, objective measurements of brain activity, allowing researchers and clinicians to assess how therapeutic interventions impact cognitive function. These emerging technologies hold great promise for improving personalized treatment strategies, monitoring drug efficacy, and facilitating early diagnosis, ultimately enhancing the quality of care for individuals with dementia.

Privacy and Security in Remote Monitoring (RQ 3)

Overview

When examining the critical security and privacy considerations involved in remote monitoring technologies, particularly for patients with AD, it is essential to delve into several layers of complexity that encompass data security, privacy regulations, ethical issues, and the unique vulnerabilities of the patient population. Remote monitoring technologies, including smartphones, wearables, and environmental sensors, offer significant benefits for managing AD by enabling continuous health monitoring and early detection of anomalies and providing valuable data for research. However, these benefits come with substantial security and privacy challenges. Different aspects of privacy and security concerns are summarized in Multimedia Appendix 5.

Data Types and Associated Risks

First, the nature of the data collected by these devices—ranging from personal details to medical records, geolocation, and behavioral patterns—makes them highly sensitive. Ensuring data security is paramount as it requires robust encryption methods to protect data both in transit and at rest. Encryption safeguards the data from unauthorized access during transmission and storage. Equally important is implementing strong access control measures, ensuring that only authorized individuals such as health care providers and approved caregivers can access the patient data. Regular security audits and vulnerability assessments are crucial to identifying and addressing potential security gaps, thereby maintaining the integrity of the monitoring systems.

Privacy concerns are equally critical, particularly given the stringent requirements set forth by regulations such as the General Data Protection Regulation (GDPR) in Europe and HIPPA (Health Insurance Portability and Accountability Act) in the United States [58-60]. These regulations mandate that

XSL•FO
RenderX

patients' personal health information be protected and that individuals have control over their data. Adherence to these regulations involves ensuring that patients (or their legal guardians) provide informed consent for data collection and use. This consent process must be clear and comprehensive, detailing what data will be collected, how they will be used, who will have access, and how long the data will be retained. Data minimization principles should be applied, collecting only the necessary data required for the intended purpose, thus reducing the risk of unnecessary exposure. Patients with AD may not fully understand the implications of data collection and their rights regarding data privacy. Therefore, it is imperative to involve caregivers or legal guardians in the consent process to ensure that the patients' rights and preferences are respected. Furthermore, patients with AD are particularly vulnerable to exploitation and abuse. Continuous monitoring can inadvertently infringe on their privacy and autonomy, raising ethical concerns. Balancing the need for constant monitoring to ensure safety with the patients' rights to privacy and dignity is a delicate task. Ethical considerations must guide the implementation of these technologies, ensuring that monitoring practices do not become overly intrusive.

Device and IoT Security

From a technical perspective, the integration of various monitoring devices such as smartphones, wearables, and environmental sensors introduces additional security challenges. Each device and sensor can be a potential entry point for cyberattacks. IoT devices are often targeted due to their typically lower security standards. To counteract these risks, it is crucial to ensure that all devices are secured against tampering and hacking. This involves regular firmware updates to patch vulnerabilities, the use of strong authentication mechanisms to prevent unauthorized device access, and the use of data anonymization techniques to protect patient identity in the event of a data breach [41,61].

Furthermore, the use of advanced technologies such as AI and machine learning in processing and analyzing the collected data presents its own set of risks. While these technologies can enhance the accuracy and efficiency of health monitoring, they also require access to large datasets, which can exacerbate privacy concerns if not handled properly. Ensuring that AI and machine learning models are trained on anonymized data and that they adhere to strict privacy standards is essential to mitigate these risks. Potential attackers pose significant threats to the security of remote monitoring systems. These attackers might attempt to intercept data transmission, gain unauthorized access to monitoring devices, or exploit vulnerabilities to extract sensitive information. Addressing these threats requires a multilayered security approach, including end-to-end encryption, secure communication protocols, and robust incident mechanisms to quickly address and mitigate breaches when they occur [47].

Balancing Safety and Patient Autonomy

While remote monitoring offers substantial benefits for managing AD, it also presents critical security and privacy challenges that must be carefully addressed. Ensuring robust data security through encryption, access controls, and regular audits; complying with privacy regulations; obtaining informed consent; and addressing the unique vulnerabilities of patients with AD are essential components of a secure and ethical monitoring system [62,63].

Balancing safety and patient autonomy in remote monitoring for AD care presents a complex challenge that requires a nuanced approach. While the technology offers substantial benefits, such as continuous health monitoring, early anomaly detection, and timely interventions, it must be implemented thoughtfully to prevent undue intrusion. The need for constant observation can infringe on the patients' sense of independence, raising ethical questions about dignity and consent. To address these concerns, remote monitoring systems should integrate customizable privacy settings that allow caregivers to modify the monitoring level based on the patients' current health status and preferences. Noncritical data anonymization and local data processing using edge computing can significantly reduce the sense of surveillance, ensuring that only essential information is transmitted to central servers [64].

Obtaining informed consent from patients with AD is another critical aspect due to cognitive impairments that often affect their decision-making capabilities. In such cases, involving caregivers or legal guardians becomes essential to uphold the patients' rights while ensuring that their best interests are protected [65,66]. Technologically secure consent management systems can be used to store and track consent records digitally. Leveraging blockchain technology for tamper-proof consent logs can enhance transparency and accountability, making it clear who has agreed to data collection and how the data will be used. This approach ensures compliance with regulations such as the GDPR [60] and HIPAA [58,67], reinforcing trust among patients, caregivers, and health care providers.

Adaptive monitoring systems that support variable levels of oversight can help maintain patient autonomy by shifting from comprehensive tracking to minimal oversight as needed. This adaptability allows caregivers to balance the safety needs with the patients' right to privacy. Moreover, implementing user-controlled privacy features empowers patients and their caregivers to configure data sharing preferences, such as choosing which types of data are collected and how frequently they are transmitted. This flexibility can significantly improve user satisfaction and trust in the monitoring system.

AI integration into monitoring systems should prioritize ethical standards, ensuring that data handling is minimal and transparent. For instance, using federated learning allows algorithms to be trained directly on local devices, avoiding the need to transfer raw data to external servers [68]. This method safeguards privacy while maintaining the system's ability to deliver valuable insights. In addition, explainable AI frameworks can provide justifications for alerts and decisions, ensuring that caregivers understand the reasoning behind the system's actions [69]. Such transparency bolsters confidence in the technology and facilitates informed decision-making.

To enhance safety protocols without compromising privacy, remote monitoring systems should use multilayered privacy protocols that combine encryption, robust user authentication, and differential privacy [70]. By injecting noise into datasets,

XSL•FO
RenderX

differential privacy makes it difficult to trace data back to individual patients while allowing for meaningful analysis. Regular security audits and ethical reviews should also be conducted to ensure that monitoring practices do not become overly invasive. Independent ethics committees can provide oversight, ensuring that the technology aligns with patient-centric values and preserves autonomy.

Maintaining patient dignity is paramount, especially when using advanced monitoring technology. Nonvisual sensors such as microradar [71] systems can detect falls and wandering without capturing images or videos, offering a less invasive alternative to camera-based surveillance. Moreover, patients and caregivers should have the option to customize notification settings, choosing to receive only high-priority alerts to minimize stress. This selective alert system can enhance quality of life by allowing patients to maintain a degree of normalcy and autonomy in their daily lives.

Potential Remote Monitoring Framework for Patients With AD (RQ 4)

Overview

Critical design considerations for a potential remote monitoring framework for patients with AD include ensuring privacy and data security to comply with HIPAA regulations, using nonintrusive monitoring technologies such as microradar sensors to maintain patient dignity, and incorporating AI-driven analytics for accurate detection of falls and wandering. The system should offer real-time alerts to caregivers, be user-friendly for both patients and caregivers, and integrate with existing health care platforms for seamless data sharing. In addition, providing customizable and scalable features can accommodate diverse patient needs and facilitate broader adoption.

The development of our proposed remote monitoring framework was directly informed by the insights gained from our literature review. Our findings revealed that existing monitoring solutions such as wearable sensors and camera-based systems present significant limitations in terms of user compliance, privacy concerns, and real-time responsiveness. Wearable devices require active patient participation, which may not always be feasible for individuals with ADRD, whereas camera-based systems raise ethical and privacy concerns. In response, our framework integrates microradar technology, which allows for the nonintrusive monitoring of falls and wandering behaviors without compromising user privacy. In addition, AI-powered analytics enhance the accuracy of detection by processing microradar data to identify anomalies in movement patterns. To support real-time caregiver intervention, our system uses Web Real-Time Communication (WebRTC) and peer-to-peer (P2P) communication for seamless alerts. By addressing these limitations and leveraging interdisciplinary advancements, our framework offers a comprehensive, privacy-conscious, and scalable solution for the monitoring of patients with ADRD. Different aspects pertaining to RQ 4 are discussed in the following subsections.

Ensuring Patient Safety

Patient safety is the cornerstone of any remote monitoring system for patients with AD. Wearable devices such as smartwatches and fitness trackers can monitor crucial health indicators such as gait, sleep patterns, physical activity, and falls. Environmental sensors placed in the patient's home can track temperature, motion, and other conditions to detect unusual behavior, such as wandering or falls, ensuring that immediate action can be taken [72].

Given the sensitivity of health data, robust security measures are essential. Data from wearable devices and sensors must be encrypted to prevent unauthorized access. Compliance with regulations such as the GDPR and HIPAA is necessary to protect patient privacy. Strong authentication methods and regular software updates can help maintain data integrity and security.

Ease of Use for Caregivers

The system must be user-friendly, as caregivers for individuals with ADRD may not be technologically savvy. A simple, intuitive interface is crucial, allowing for straightforward navigation and clear, actionable alerts to reduce ambiguity and stress. Customizable notifications and automated alerts ensure that caregivers are informed of critical issues without needing to constantly monitor the system while minimizing false alarms to avoid unnecessary stress. In addition, providing educational resources within the system helps caregivers understand how to best use the monitoring tools and improve their caregiving skills. This approach empowers caregivers, enhances efficiency, and improves patient safety by facilitating timely interventions [73,74].

Ethical Considerations

Ethical considerations for a potential remote monitoring framework for patients with AD include ensuring informed consent and respecting patient autonomy. Considering cognitive impairments, obtaining informed consent must involve patients as much as possible as well as legal representatives or caregivers when necessary to ensure understanding and voluntary participation. Privacy and confidentiality are paramount, requiring compliance with data protection regulations and secure data handling practices. The system should be minimally intrusive, using discreet technologies to balance safety with patient dignity and avoiding constant visible monitoring that could lead to a loss of independence. Transparency in communication about the system's operation and data use, as well as providing feedback mechanisms, builds trust and addresses concerns. Ethical design principles involving user-centered approaches and bias mitigation in AI, alongside regular ethical reviews and oversight by ethics committees, ensure that the system remains respectful and patient centered while enhancing safety [75,76].

Compatibility With Existing Systems

To be effective, the remote monitoring system for patients with AD must integrate seamlessly with existing health care infrastructure, such as electronic health records (EHRs) [77]. This integration ensures that all relevant health data from the monitoring system are accurately and efficiently captured within the broader health care framework. Using standardized protocols

XSL•FO
RenderX

and application programming interfaces is critical for facilitating data sharing and interoperability [78]. These standards, such as Health Level Seven Fast Healthcare Interoperability Resources, ensure that data from the monitoring system can be easily and securely exchanged with different EHR systems and other health IT platforms [79]. Seamless integration allows physicians, specialists, and other clinicians to access comprehensive, up-to-date information about patients, promoting coordinated care. For instance, if a remote monitoring system detects a fall or wandering incident, this information can be automatically logged in the patient's EHR, alerting HCPs in real time. This ensures that primary care physicians, specialists, and hospital staff have a unified view of the patient's health status and recent events, enabling more informed decision-making and timely interventions.

Moreover, compatibility with existing systems helps in reducing duplication of efforts and minimizes the risk of errors. HCPs can avoid manually entering data, which not only saves time but also reduces the likelihood of transcription errors. By ensuring that the remote monitoring data are automatically integrated into EHRs, the system enhances the accuracy and reliability of patient records. In addition to technical interoperability, organizational processes and workflows must be considered to ensure smooth integration. Training for physicians, nurses, and other HCPs on how to use the new system and interpret its data within the context of existing EHRs is essential. Developing clear protocols for how and when data from the monitoring system should be used in patient care can help ensure that the system is used effectively. By enabling seamless data sharing and integration, the system supports a more coordinated and comprehensive approach to health care, ultimately improving outcomes for patients with AD and reducing the burden on caregivers and medical professionals.

Scalability and Flexibility

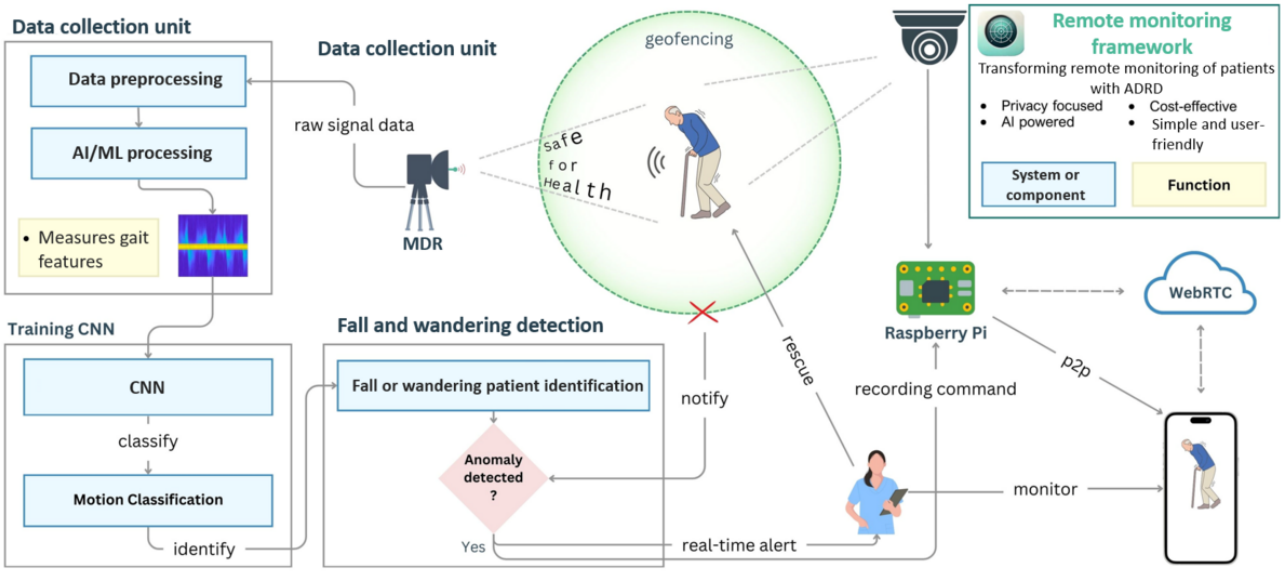
A scalable system is essential for accommodating the increasing number of patients with AD who require care. As demand for remote monitoring solutions grows, the system must expand without compromising performance or reliability. This need involves designing the system architecture to support a larger user base and additional data processing and storage capabilities. Scalable infrastructure ensures that the system can handle a surge in the number of patients and caregivers, allowing health care providers to maintain high standards of care even as the user population increases. Moreover, incorporating standardized interfaces and protocols such as application programming interfaces and interoperability standards ensures that the system can easily connect with new devices and technologies, facilitating continuous improvement and innovation [80].

Flexibility in the remote monitoring system is equally important. The system should have a modular architecture that allows for the easy integration of new sensors and technologies as they become available. This modular approach ensures that the system can adapt to technological advancements and incorporate innovative solutions without requiring a complete redesign. It should also be configurable to meet the specific requirements of various health care settings, such as in-home care, assisted living facilities, or hospitals, providing tailored solutions that address the unique challenges of each environment. The system's scalability and flexibility ensure that it adapts to evolving health care needs, enhancing patient care and supporting the growth of remote monitoring technologies [80].

Technology Components

Wearable technology is essential for health monitoring, allowing for the real-time tracking of multiple health variables such as heart rate, physical activity, sleep habits, and location [56,72]. These devices help monitor the patient's daily routines and identify emergencies such as falls. Environmental sensors also enhance the patient's living environment by monitoring door activity, motion, and room temperature to detect unusual activity. For instance, if a patient leaves the house at an unusual time, an alert can be issued to the caregiver. Smartphone apps enable caregivers to easily monitor and receive notifications, enter observations, create personalized alerts, and access learning materials. Continuous connectivity ensures that caregivers are always informed about the patient's status.

Implementing AI and machine learning algorithms to analyze data collected from wearables and other devices allows for the identification of trends indicating potential health issues. These predictive analytics enable caregivers to anticipate problems and take preventive measures before they become critical, thus improving patient care and safety. Moreover, an IoT infrastructure is essential for ensuring seamless data transfer between all connected devices, with cloud computing offering scalable processing and storage capacity and edge computing minimizing delays by processing data locally. Effective data management is crucial for making sense of the vast amounts of data generated by the system, allowing for trend analysis and informed clinical decisions. Advanced analytics techniques can also provide personalized patient care. In addition, robust security technologies such as intrusion detection systems, firewalls, and encryption methods are vital to protect the system from threats, with frequent maintenance and updates ensuring ongoing security



Comprehensive Framework

Overview

On the basis of the discussions in the previous subsections and the findings of previous studies, we propose a comprehensive remote monitoring framework, as shown in Figure 4, by incorporating the use of wearable technologies, sensors, AI-powered analytics, and a safe IoT infrastructure. The elements in the schematic framework are intricately connected and together create a comprehensive system for the remote monitoring of patients with AD. The framework is designed with a strong focus on health and safety. The use of microradar technology ensures that monitoring is nonintrusive and safe for patients, reducing the stress associated with traditional monitoring systems. This framework not only enhances patient safety but also alleviates the burden on caregivers by providing reliable, real-time support and intervention tools. The following is a detailed discussion of how each point contributes to the overall monitoring framework.

XSL•FO
RenderX

Figure 4. Schematic framework for remote monitoring of patients with Alzheimer disease. ADRD: Alzheimer disease and related dementias; AI: artificial intelligence; CNN: convolutional neural network; MDR: micro-Doppler radar; ML: machine learning; P2P: peer to peer; WebRTC: Web Real-Time Communication.

Data Collection

The data collection unit is the central component of the monitoring system and is responsible for gathering and processing the data required to track the patient's movements and health status effectively. At its core, the unit uses micro-Doppler radar technology to capture raw signal data by continuously monitoring the patient's movements in a nonintrusive manner [81]. This technology is crucial as it does not require the patient to wear any devices or interact with the system, thereby preserving the patient's privacy and minimizing any stress or discomfort that might arise from traditional monitoring systems. The raw data collected by the micro-Doppler radar undergoes a critical preprocessing stage in which essential gait features are extracted. This step is vital in filtering out noise and isolating the most relevant aspects of the patient's movements that could signal potential risks. Once preprocessed, the data are fed into advanced AI and machine learning algorithms, which analyze the extracted features to identify patterns in the patient's movements. This sophisticated processing enables the system to distinguish between normal daily activities and potentially hazardous situations such as falls or wandering, thereby enhancing the system's ability to ensure the patient's safety while maintaining their dignity and comfort.

Data Processing

The data processing component plays a critical role in enhancing the system's ability to accurately classify various patient movements, which is fundamental to ensuring effective monitoring and maintaining the safety of individuals with ADRD. The process begins with preprocessed data being fed into a convolutional neural network [82], a powerful AI model specifically designed to recognize and analyze patterns within the input data. This network is trained to classify different types of motions, enabling it to distinguish between normal daily activities such as walking or sitting and potentially hazardous incidents that may require immediate intervention, such as falls or wandering outside a designated safe zone. The convolutional neural network's ability to make these distinctions is vital to the system's overall accuracy and reliability as it allows for the early detection of unusual or dangerous behaviors. This, in turn, facilitates timely alerts and responses, ensuring that caregivers can intervene quickly and appropriately to protect the patient's well-being. Through this advanced data processing approach, the system not only enhances patient safety but also provides peace of mind to caregivers through the knowledge that the system is capable of accurately monitoring and responding to the specific needs of patients with ADRD.

Fall and Wandering Detection

The fall and wandering detection component is a critical part of the monitoring system, designed to ensure the continuous safety of patients by closely tracking their movements and identifying any signs of falling or wandering outside a predefined safe area. The system uses a geofencing approach in which a *defined* boundary or safe zone is established around the patient's environment. This safe zone is carefully configured based on the patient's needs and typical movement patterns. The system continuously monitors the patient's movements within this boundary using sophisticated pattern identification techniques. By analyzing these movement patterns in real time, the system can quickly detect any deviations from the norm. For example, if the patient crosses this virtual boundary or exhibits movements that suggest a fall, such as a sudden loss of balance or an abrupt change in posture, the system immediately flags this behavior as an anomaly. This continuous, vigilant monitoring is essential for identifying potential risks before they can lead to serious harm.

Once an anomaly is detected, the system's response should be both swift and automated. The anomaly detection process should be finely tuned to recognize specific triggers, such as the patient moving outside the safe zone or experiencing a fall. When such an event is identified, the system automatically triggers an alert, ensuring that caregivers are notified in real time. These alerts should be designed to reach caregivers through various channels,

XSL•FO
RenderX

such as mobile notifications or direct messages, providing them with immediate information about the patient's situation. This real-time notification system is crucial for enabling caregivers to respond promptly and appropriately to any incidents, whether it involves assisting the patient after a fall or guiding them back to safety after wandering. The combination of continuous monitoring and instantaneous alerting forms a robust safety net, significantly reducing the risks associated with falls and wandering in patients with ADRD.

Caregiver Notification and Support

The caregiver notification and support component is designed to empower caregivers with the tools and information they need to effectively monitor and respond to the needs of patients in real time. Central to this component are real-time alerts, which are instantly sent to caregivers' devices, ensuring that they are always aware of the patient's status. These immediate notifications are particularly crucial in emergency situations, such as when a fall or wandering event occurs. By receiving alerts the moment an anomaly is detected, caregivers can intervene promptly, providing necessary assistance or preventing further harm to the patient. This real-time communication is key to maintaining the safety and well-being of patients with ADRD.

In addition, the system is equipped with a recording command and rescue feature facilitated by a Raspberry Pi module. This module plays a vital role by capturing and recording the event as soon as an anomaly is detected. The recorded data are automatically sent to caregivers, offering them detailed insights into the incident. This documentation not only aids in immediate rescue actions but also serves as a valuable resource for later analysis. By reviewing recorded incidents, caregivers and medical professionals can better understand the circumstances leading up to the event, which is essential for medical evaluations and refining future care strategies. The ability to document and analyze these events ensures that care can be continuously improved, ultimately enhancing the quality of life of both patients and caregivers.

WebRTC and P2P Communication

The framework integrates advanced communication technologies to ensure seamless monitoring and interaction between caregivers and the system, providing a reliable and immediate connection regardless of location. A key component of this system is the use of WebRTC technology, which facilitates real-time P2P communication [83,84]. This technology allows caregivers to monitor the patient from their smartphones or other devices with ease and without delay, ensuring that they remain connected to the patient's status at all times. The use of WebRTC ensures that the communication is not only immediate but also direct, reducing latency and enhancing the responsiveness of the system.

This capability significantly enhances patient safety as it allows caregivers to maintain a continuous, real-time connection with the system, enabling them to respond quickly to any situation that may arise. Whether it is monitoring routine activities or responding to alerts triggered by the system, WebRTC ensures that caregivers can provide timely and effective interventions. The seamless monitoring facilitated by this technology is crucial for reinforcing the safety net around patients with ADRD, giving caregivers the confidence and tools they need to manage their loved ones' care effectively, no matter where they are.

Conclusions

This study highlights the revolutionary potential of remote monitoring technologies in AD care, emphasizing the critical balance among innovation, practicality, and empathy. The comprehensive analysis revealed that, while wearable devices and ambient sensors significantly enhance the ability to track and support patients with AD, they also introduce challenges related to privacy, data security, and user acceptance. The findings stress the necessity of involving patients and caregivers in the design process to ensure that these technologies meet their specific needs and regulatory requirements, which is crucial to the successful implementation of these technologies.

The proposed remote monitoring framework integrates cutting-edge microradar technology with AI-powered processing to create a nonintrusive, privacy-conscious solution for monitoring patients with AD and dementia. By focusing on real-time data processing, caregiver notification, and seamless communication, the system not only enhances patient safety but also provides critical support to caregivers, ultimately improving the quality of care for individuals with ADRD. Future research can focus on refining these systems to enhance their usability, accessibility, and security, thereby improving the overall caregiving experience and patient well-being. By advancing remote monitoring practices, we can create a supportive environment that alleviates caregiver burdens and promotes a higher quality of life for individuals living with AD.

Abstract

Background: With the rapid expansion of wearable technologies, there is increased interest in their utility for passive data collection applications in research on aging. Wearables can be beneficial for research with people with dementia and their families, who have burdens that can make both study participation and reliable data collection more difficult, especially as dementia progresses, but their use also has challenges. Population-specific issues affecting the success of wearables for data collection can include remembering to wear a device, fluctuating acceptance of the device or study participation, and reliance on already strained caregivers.

Objective: This study aimed to systematically evaluate contemporary wearables research to describe persons with dementia's experiences with wearables, their desired qualities, and protocol needs to enhance participant buy-in and sustained wearing for better quality dementia research.

Methods: We used the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 checklist for systematic reviews and searched 3 scholarly databases using Medical Subject Headings (MeSH) terms for papers published since 2018 featuring the use or discussion of wearable devices for persons with dementia. We screened 1757 abstracts and retained 58 for full-text review.

Results: We present synthesized preferences, barriers, and facilitators to buy-in and adherence to wearables in dementia research. A total of 29 factors were categorized into 4 overarching categories aligned with study development: device selection, protocol considerations, enhancing recruitment, and promoting adherence.

Conclusions: These findings inform researcher guidelines for wearable device selection and protocol design to enhance the utility of wearables in future longitudinal research featuring persons with dementia and their caregivers.

Introduction

Background

The growing prevalence of dementia and its substantial economic and social impacts have led to increased attention and funding allocations for research supporting persons living with dementia and their caregivers as well as dementia prevention research [1]. Obtaining the perspective of persons living with dementia and their caregivers is critical to advancing our understanding of dementia to not only find effective treatments but also to address burdens often associated with providing care to this population [2,3]. Engaging persons living with dementia and their caregivers in research studies can be challenging for many reasons, including the fluctuating cognitive capacities of individuals with dementia, the logistical and emotional demands placed on caregivers, and the need for research protocols that accommodate the specific needs and

XSL•FO
RenderX

limitations of this population [3]. Innovative methods to increase meaningful engagement in research studies involving persons living with dementia and their caregivers are warranted.

Meeting Researcher Needs

Wearable technology is a noninvasive, passive way to collect a variety of data over long periods and offers the potential benefit of enhancing care and prevention efforts [4-6]. Remote data collection, such as that offered by wearable technology, has many potential benefits, including reducing recall bias and decreasing the burden placed on participants owing to frequent contact for research purposes. Identifying wearables and research protocols that meet both researcher and participant needs will help wearable technology be more effectively used in longitudinal dementia studies [7]. As the wearable technology market is expected to continue growing substantially [8], guidance for researchers to optimize the selection of devices to enhance buy-in and adherence in their studies is necessary. Wearable devices and research strategies tailored to persons living with dementia and their care providers are crucial for optimizing long-term research with this population [9].

Currently, longitudinal dementia research with wearables faces 3 overarching challenges. First, the challenges particular to persons with dementia and their caregivers and health care professionals must be considered to gain long-term buy-in and use, especially as dementia progresses and caregiving burdens increase [10,11]. Population-specific issues include remembering to wear or charge the device, ethical informed consent [12], and privacy concerns [13,14] that may differ from cognitively intact older adults [15,16]. Second, there is a multitude of wearables on the market with a variety of features and hardware forms at various costs that have not been evaluated in terms of this population's usability and adherence factors. Third, wearables must also provide consistent, accurate, and useful data that meet researcher needs (eg, activity monitors, GPS, and location information) and have limited or easily resolvable technical problems, user-related issues, or data access factors [17].

To date, there has not been a systematic evaluation of wearables for research that holistically examines whether wearables meet the needs of persons with dementia, their caregivers, and researchers to enhance participant buy-in and research utility. Moreover, with the rapid expansion and advancement of wearable technology in the last few years, new research on participant experiences and desires for wearables is necessary. Recent wearables research with this population has featured focus group discussions with limited representation of persons with dementia and their caregivers [10,18], as compared to the experiences of older adults without dementia [19]. Observational research that could inform wearable acceptance and adherence strategies has often been limited to very short-term evaluation periods (typically up to 7 days) with a handful of activity monitoring devices [20-22]. Identifying factors related to wearables that are acceptable to persons living with dementia and their care providers, as well as population-specific support systems, is necessary to strengthen the quality of research requiring long-term adherence [7].

Objectives

This study aimed to conduct a systematic review of dementia-related preferences, barriers, and facilitators to using wearables in research studies to inform future study development, including device selection and participant support protocols.

Methods

Data Sources

This systematic review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 checklist (Multimedia Appendix 1) [23]. Original research studies were identified from the PubMed, MEDLINE, Scopus, and CINAHL databases (all last consulted in January 2023) and Google Scholar. In March 2024, approximately 500 results were reviewed to capture additional references since the 2023 search. The search strategy included a combination of Medical Subject Headings (MeSH) terms and keywords. Categorized according to the PICO (population, intervention, comparison, and outcomes) framework, search terms were used in OR statements in combination for the population ("dementia," "Alzheimer* Disease," "memory loss," and "cognitive impairment") and the intervention or indicator ("wearable*," "wearable sensor*," "tracker*," "biosensor*," "Fitbit," "wearable electronic*," "remote monitoring," and "pedometer"). Regarding comparison, the inclusion criteria did not require intervention trials, whereas for outcomes, the inclusion criteria did not specify the outcomes of the studies.

The full text of the relevant articles was retrieved from the Web of Science, Google Scholar, and library access at the University of Michigan. The articles were reviewed for additional related references.

Study Selection

The selection criteria for the literature search included (1) full-text data from primary peer-reviewed journal articles, commentaries, and conference proceedings; (2) use of remote monitoring via electronic devices that captured data of persons; (3) enrollment of, or reference to, populations living with Alzheimer disease, dementias, or chronic memory impairment or loss impairment; (4) publication in English from January 2018 to March 2024; and (5) documentation of any preferences, barriers, or facilitators to wearables device use. Notably, research featuring Huntington or Parkinson disease was included if participants were experiencing dementia-type impairment and otherwise met the inclusion criteria. Studies were excluded if they (1) did not meet the inclusion criteria, (2) used an implantable wearable or a device not intended for data collection (eg, hearing aids), (3) reported only a study protocol, or (4) included no person interaction (eg, device development without consulting with the population considered affected). Dissertations, books, book chapters, other reviews, and single-case studies were excluded.

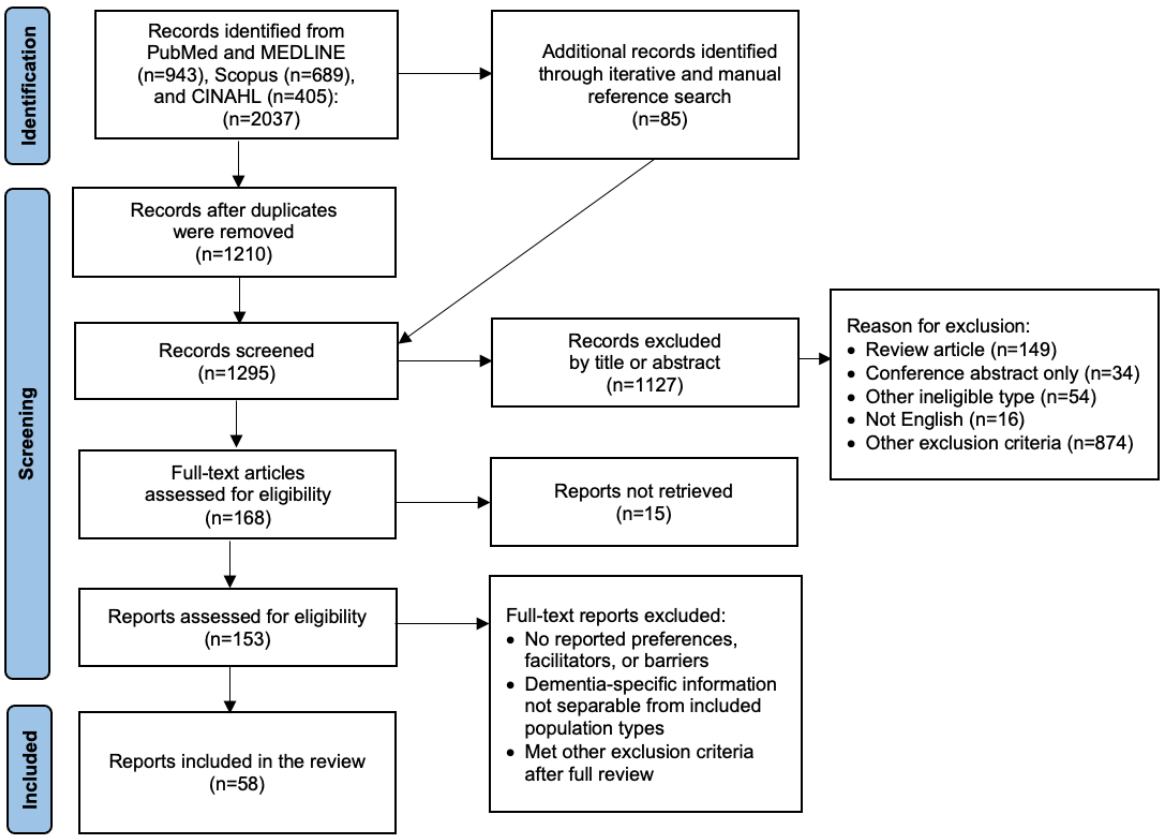
CMP searched independently, and CMP and CF reviewed titles and abstracts for relevance and subsequently conducted the full review. CMP manually searched the reference sections of these full-text articles and key reviews for additional citations. RMSL

XSL•FO
RenderX

independently reviewed the search criteria and list of full-text articles to meet the eligibility criteria. The authors used EndNote (Clarivate), a bibliographic tool that allowed them to organize PDFs of articles by topic, along with other data about each article.

Data Extraction and Analysis

Data extracted (by CMP) from the full text of the eligible studies included, when available, publication details, study location, study design, study population, device type and location worn, and device-wearing duration. For the focus of this study, we extracted information related to the preferences, barriers, and facilitators of the use, adoption, maintenance, and adherence of wearable electronic devices by persons with dementia, including ideal device qualities and protocol needs for persons living with dementia and their caregivers. This information could come from the researchers (eg, procedures and processes attempted), persons with dementia (eg, reported preferences and difficulties inhibiting ongoing use), or persons caring for those living with dementia, whether health professionals or informal family caregivers (eg, encouraging persons to wear the device).



The extracted qualitative data on preferences, barriers, and facilitators were reviewed and initially synthesized for each study by CMP into a common factor coding structure using a grounded theory qualitative research approach [24]. This approach does not presuppose findings but relies on iterative "constant" comparison of collected data to develop codes and overarching themes. RMSL reviewed the summaries and factor synthesis, which CMP and RMSL then independently assigned to each study. The factor assignments were reviewed, and discrepancies were adjudicated together. We report the descriptive frequencies of the factors identified and noted in at least 5 studies and provide a qualitative synthesis of their implications for optimizing long-term dementia research.

Results

Overview

This systematic review identified 1757 studies through the databases as well as iterative and manual reference searches. After the eligibility criteria were applied, 3.3% (58/1757) of the studies were retained for data extraction analysis (Figure 1 [23]). Most studies (1127/1295, 87.03%) were excluded based on the abstract review because the device evaluated was not a wearable or the population had some cognitive impairment but did not specifically include dementia. The studies were primarily observational (eg, feasibility studies) and qualitative (eg, using interviews or focus groups), with only 19% (11/58) featuring some type of trial. Participants were most often persons living with dementia in the community (as opposed to residential care), their informal family care partners, and paid dementia care health professionals. The duration for which persons living with dementia were asked to wear the study device ranged from a few hours over several days to 12 months, though 7 days was a common wear period. Information pertaining to the individual studies, including the type of wearable, is summarized in Multimedia Appendix 2 [9,10,18,20,22,25-60].

Figure 1. PRISMA 2020 flow diagram for the systematic review of wearables in dementia research.

XSL•FO
RenderX

Barriers, facilitators, and preferences from the 58 studies were qualitatively synthesized into a total of 29 factors that fit into 4 overarching themes. These themes are categorized by issues dementia researchers should consider from study development to deployment: device selection, protocol considerations, enhancing recruitment, and promoting adherence. Although we categorized these factors by greatest relevance to a particular study section, it should be recognized that many of the factors are interconnected and related. The frequency and proportion of studies featuring each factor are detailed in Table 1. The factors present in each study and their cross-reference numbers are available in Multimedia Appendix 3 [9,10,18,20,22,25-77]. As we describe the factors in the results, we use the term caregivers inclusively to mean both informal (ie, unpaid, often family members) and paid caregivers (eg, health professionals and residential care staff) and provide relevant quotes that capture participant experiences. In the Discussion section, we offer a synthesis of recommendations for researchers planning to conduct longitudinal research with populations with dementia.

Table 1. Presence of synthesized factors across the studies (N=58).

Device Selection

Easy to Use

Given the care burden of family members or paid caregivers in residential settings, a wearable's ease of use was paramount when asking caregivers to be involved in a study. It was the most frequently identified factor in studies, with 36% (21/58) of studies mentioning it. The wearable device must be easy to use [25-27,61-65] with an intuitive interface and features [28-31]. The device should require little maintenance or technical support for everyday use, and any interaction with the device required by the study should be simple [10,28,32-35,66]. Some studies explicitly noted that perceived ease of use was associated with more positive attitudes toward wearing the device and less effort or sense of inconvenience in participation [27,36-39]. As a person living with dementia exclaimed in the study by Gris et al [38], "Older people need to use simple things!"

Smaller Size and Weight

Almost without exception, participants desired smaller and lighter wearables or expressed discontent about the size and weight of the device they were asked to wear in the study [34,35,40-42,63,64,66-68]. The influence of a wearable's size and weight was the most frequent physical form factor, with 31% (18/58) of the studies including comments about it, and it was the fourth most common factor identified overall. While rare, there were some exceptions to participants desiring smaller devices overall. Some suggested enlarging certain facets of a device, such as having a larger face or font to read [43] or larger buttons to interact with [27].

Comfort

The physical ease of wearing the device was important [28,31-33,38,41,44,67,69], with discomfort specifically cited as a reason why participants removed the device in several studies [34,45,66]. *Comfort* was sometimes explicitly linked with *unobtrusive*, as complementary qualities [20,29,61]. Nevertheless, prototype devices that were bulky or wearables with a more invasive application (eg, required taping to limbs or backs) were mostly tolerated in the short term. However, simply put, "If residents would show discomfort related to the wearable, the wearable would not be used" [61].

Fits Into Routine

Studies found that if a device type was already familiar or similar to what caregivers and persons living with dementia already used regularly, the wearable could be seen as convenient and more easily fit into a participant's lifestyle [10,30,32,33,46,67,70]. Wristwatches were the most frequently cited as meeting these criteria [20,29,35,38,41,47]. At the same time, devices might also be removed if accessory removal is also part of a participant's routine [20,32,41]: "To tackle such barriers [to using mHealth devices] will likewise require (informal) caregivers to change their attitudes towards using digital technologies and the integration of these technologies into routine care" [30].

Unobtrusive

A wearable that is not obvious or can be hidden was considered a distinct positive [25,29,35,38,70,71]. Having the ability to conceal a wearable alleviated some worry about a person living with dementia being resistant to wearing the device or removing it (refer to the Self-Removal subsection), which could be especially pertinent in studies involving individuals with more advanced stages of dementia [61,66,68]. Unobtrusive devices were also seen as reducing the potential of drawing attention to themselves or experiencing stigma associated with wearing a device [10,42,61] (refer to the Stigma subsection). Like the *fits into routine* factor, wristwatches were commonly cited as an unobtrusive solution [10,20], but something that could be slipped onto a belt or into a shoe was also noted as a viable option [10,29].

Tailorable

Having the option to use a wearable in a way that fits a person's particular style preferences was desired, from format (eg, neck pendant or watch) to style (eg, colors and design) [10,29,34,35,38,61,62,71], as some had concerns with the particular format that was provided in the study and desired a different way to wear the device [26,31,68]. Alternative device forms can include a spectrum of participants and their day-to-day presentations (eg, gender and culture) [10,18]. Offering a wearable in several different forms could help a device suit the *fits into routine* factor, but the *tailorable* factor highlights that singular forms may not fit into everyone's routine equally: "Several members in all four groups expressed a desire for more options in device styles...all groups asked if alternative styles could include a broach, belt clip, small bracelet, or ankle bracelet" [31].

Materials

Nonspecific material concerns or durability were cited as important considerations for wearables to be satisfactory to participants and researchers alike [29,41,63]. Specific material issues such as softness [34,63,66] and the need to make wearables safe for those with skin sensitivities or allergies were also mentioned [10,28,34,61]. Some participants stopped wearing the device altogether because it caused irritation [22] or even skin abrasions [48].

Aesthetics

The general appearance of the device design in its look and feel could be a barrier to everyday use and, thus, adherence [41,43,47,63,64]. Size, form, color, and device material all play a role in the aesthetic attractiveness of a wearable [31,34,35]. For example, participants in the study conducted by Jacklin et al [31] were dissatisfied with the prototype wearable they were testing, describing it as "big and clumsy looking" and "rubbery."

Easy to Wear

Diminishing fine motor skills in persons living with dementia made *easy to wear*, or how simply one can put on or take off the wearable, an issue for day-to-day use [10,62,65]. Wearables that were difficult for the wearer to put on or take off by themselves required caregiver support that could add stress to both the person living with dementia and their caregiver,

XSL•FO
RenderX

creating participation burden and a sense of lack of independence [34,48]. Some wearables were slightly more complicated and required specific sensor placement, which was either difficult to apply correctly or failed to remain securely attached [34,49,50].

The factor *easy to wear* is distinct from *easy to use* and may not play a role if a wearable is designed to be worn continuously. For example, a family caregiver reported that an accelerometer was "a little bit difficult to put on, so [the persons living with dementia] did do it but...it's not easy." The researchers echoed that "the wristband of the accelerometers could be difficult to fasten" but reported that afterward, "the accelerometers were not burdensome to wear" [65].

Water Resistant

Water-resistant or waterproof wearables were recommended [28,61,64] to minimize potential disruptions to data collection. Along with charging the device, a common point of noncompliance occurred when participants forgot to put the wearable back on after removing it for bathing (refer to the Remembering the Device subsection) [29,34]. By selecting a waterproof device and asking participants not to remove it, study protocols do not have to rely on persons living with dementia or their caregivers remembering to take off the device during bathing and, therefore, can reduce the number of study *task requirements* and related *burden impact* [44,63]. Cruz-Sandoval et al [29] suggested that minimizing the need to remove a device can reduce instances of "resistance" from persons living with dementia, and therefore, waterproof devices "can ease some of the burden on caregivers" as well.

Protocol Considerations

Privacy Concerns

Many studies noted that privacy was an issue, with participants voicing concerns about data security and who had access to the wearable's data [10,18,26,31,38,63,68,71]. For example, a caregiver's spouse worried about third-party breaches of her wearable data, explaining that "privacy and security are important to his wife because '...she understands just how easily those systems can be hacked'" [71].

At the same time, some persons living with dementia and their caregivers stated explicitly that privacy concerns were outweighed by the personal or societal benefits of their study participation [25,33], or they reported no privacy concerns [27]. Participants understood that data sharing was often necessary to meet the goals of the study, and privacy concerns were ameliorated when researchers established trust around data management: "Both informal caregivers and the nursing staff were not concerned about privacy issues regarding the wearable, as they consider biomedical variables as de-individualized values. The participants trusted the researchers and nursing home regarding good data handling, as they felt well-informed" [61].

Researchers were able to build trust and attenuate privacy concerns through transparency about data access and security measures during the informed consent processes and throughout the study [61,72]. Empowering participants to have control over privacy options (eg, allowing the collection of some but not all data) and offering the ability to turn off or select what data to monitor also helped [51,73].

Consent Capacity

The ability of persons living with dementia to understand and actively affirm their study participation is an ethical imperative but was specifically mentioned as a potential difficulty by several studies [38,71]. Especially in longer-term studies, seeking ongoing consent to participate was highlighted as necessary, with suggestions to check in regularly to assess the cognitive capacity of the persons living with dementia and their willingness to participate [20,51,74]: "Fluctuating cognition can be a significant barrier to the remote monitoring of isolated patients as forgetting about one's motivations to be monitored can lead to anxiety and agitation for being watched and, consequently, the disablement or destruction of equipment" [74].

At odds with fully informed consent was the general awareness of persons living with dementia regarding their participation or the device [32,43]. At this level of impairment, consent from a caregiver or another proxy for the persons living with dementia was sometimes sought instead, which could be an appropriate barrier to inclusion [22,69,70]. Another major challenge is reconciling what to do when a person living with dementia desires conflict with the caregiver's desire for them to engage in the study and wear the device [10,68]. Under consideration is the issue of dignity, respect for autonomy, and how ignoring these or not obtaining assent could lead to agitation: "In one case, [the study staff] visited the participant after he had refused to wear it on his wrist, saying his wife was tagging him 'like a dog'" [68]. In another study [10], a caregiver reported "[My husband] would have never given his consent even at the beginning—he liked the independence of making his own decisions and doing what he wanted. And I would have had to do it without his consent."

It was recommended that, when possible, researchers, caregivers of persons living with dementia, and their proxies should attend to their care recipient's wishes, whether from an explicit advanced directive [73] or knowledge of their comfort with similar technology [30].

Battery

The longevity of battery life and the ease of charging were noted as concerns for both researchers and participants [9,28,38,63,64,75]. Wearables with a battery life of at least several days were ideal [28,29,52,63], decreasing the need for participants to remember to charge the device [9,10,72] (ie, simplifying *task requirements*), which also minimized data collection interruptions for researchers. Low battery warnings from the device or study staff were seen as a useful tool to ensure an adequate charge of the battery [10,32,68]. Necessarily, the burden of charging was exacerbated when a caregiver was not on site to physically assist or when the charging mechanism was difficult to implement [35].

XSL•FO
RenderX

Adjustment Period

Participants may need time to acclimate to wearing the device (eg, establish wearing routines) and to resolve technical issues before consistent adherence and, therefore, consistent data quality, as adherence tended to improve after an initial period [9,29,32,33,41,53,61]. On the other hand, some studies found better compliance earlier in a study period [42,54,65], perhaps because of novelty. Adjustment periods featuring cognitive aids such as instructional pamphlets and study staff check-ins provided early troubleshooting and time to build new routines [9,29,33].

Task Requirements

Cognitive impairment and caregiving burden were barriers to protocol adherence when participants were asked to do more than simply wear the device [55,56,74,75]. When a study protocol required additional activity from either the persons living with dementia or a caregiver, such as completing bedtime and wake-up event markers, they were less likely to remember or be able to comply [9,50,57,72].

Enhancing Recruitment

Technical Anxiety

Although many interacted with the study wearables and related technology platforms successfully, participants' sense of a lack of technical proficiency and negative attitudes about technology were reported as a perceived barrier to enrollment [10,18,27,37,38,41,71] and adherence during the study [29,53,62]. Caregivers and persons living with dementia alike expressed concern about the complexity or technical know-how needed to operate the wearables [29,36,53,63,74]. Technical anxiety could present as worrying about damaging or losing the device [20,29,34]. The level of technical anxiety and attitudes toward the technology were related to age qualitatively and statistically [10,27,38,53,62] and previous experience with devices [36,46,76]. Participants in a study actually rated themselves as less technologically proficient at the end of the study because of difficulty with the wearable [42].

Multifunctional

Participants saw the potential for the device and platform to offer more information or other uses to the wearer as a benefit of being involved in the research [27,71]. Being able to track their health and activity, signal health events or emergencies (eg, wandering or fall alerts), provide directions, or offer location services, among others, were cited as desirable features [10,25,27,29-31,34,63,64,67,74]. Simpler functions such as information about time, date, and alarm capacity were also ideal wearable facets [10,32,35,41,52,63]: "Participants with dementia indicated that multiple purposes for the locator device, such as being able to measure heart rate, blood pressure and activity level, is advantageous as it would streamline the number of devices that they and their caregivers must contend with" [10]. Stavropoulos et al [63] reported, "Feedback suggested that some people with dementia may be more willing to accept technology that supports them in their daily functioning, in addition to assessing it."

Burden Impact

Caregivers especially liked the potential the wearables offered in terms of supporting their caregiving role and tasks, which, in turn, reduced related burden and stress [27,32,39,64,69]. Factors such as a wearable's capacity for *remote monitoring* and *providing health insights* could improve quality of life or provide peace of mind [33,39,63,67,72]. However, when the wearable was technically difficult to use (*easy to use)* or researchers required additional time or study activity (refer to the Task Requirements subsection), being involved in the study was perceived as a cause of additional burden and a deterrent to both enrollment and continued participation [29,32,33,58,59,61,70,74]. Notably, participants in several studies reported experiencing a mix of both reduced and heightened burden, which varied according to specific facets of the research or from using the wearable [32,33,65,69]: "The nursing staff indicated that they did not want to spend valuable care-time if the foreseen benefit of the wearable for the specific resident was not evident to them. Likewise, also informal caregivers found it important to know the potential individual benefits, before deciding whether to bother the resident with the wearable, as they anticipated some level of resistance to wearing the wristband by the residents" [61].

Stigma

Caregivers and persons living with dementia expressed concerns about the stigma associated with the wearable and the wearable identifying their care recipient (or themselves) as affected by the hidden disability [10,18,30,64]. There was concern about social acceptance and the visibility of the device, as well as the perceptions or comments that it might engender (eg, that they are under surveillance or need to be monitored) [33,34,61,72]. On the other hand, "social influence" was often a positive, with care providers or fellow persons living with dementia offering positive comments or encouraging the use of the wearable [29,37,39,76].

Families and professional care providers alike were sensitive to the negative connotation that some wearables might cause. An Alzheimer Society staff member reported that some families might avoid incorporating a MedicAlert bracelet in their care management plans because "It's a signifier or something that's perceived to bring stigma—[the persons living with dementia] don't want to be out there clearly marked in some way, that there's something wrong with them. Nor does the family" [18].

Caregiver Buy-In

Caregiver buy-in underlies many facets of wearable studies featuring persons living with dementia, as many studies relied on caregiver commitment and coordination with the researchers to do study activities (refer to the Caregiver Support subsection) [20,36,57,61,70]. Moreover, they played significant roles in facilitating understanding of the study by persons living with dementia [29,47] and in encouraging them to wear the device [39,41]. Some studies specifically cited the need for caregivers to have perceived usefulness or reasons to commit to reducing perceived potential burden or risks to enroll themselves and their care recipient in the study [61,72,76]. Gaining caregiver buy-in could be enhanced by reducing participation burdens

XSL•FO
RenderX

(eg, fewer *task requirements*, *easy-to-use* devices, and offering ongoing *technical support*) and experiencing personal benefit from the study (eg, *remote monitoring* and *providing health insights*).

Connectivity

Passive, remote monitoring is the defining advantage of wearable device studies. However, technical connectivity requirements can be a barrier to enrollment [10,31,61,69,74] and may create logistical problems for data transmission [18,31,56,77]. For example, requiring faster Wi-Fi or consistent Bluetooth linkage with a smartphone for more frequent data uploads [67,75,77] may introduce recruitment bias to individuals of higher socioeconomic status and those who are already technically inclined: "The lack of internet connection in patient homes and of funding for caregivers and family member to purchase assistive or communication devices are frequently coupled with skepticism or low abilities to engage with digital products" [74].

Promoting Adherence

Remote Monitoring

Remote monitoring was the most frequently cited desirable and useful feature (mentioned in 19/58, 33% of studies) when engaging in a wearable study among populations with dementia [10,25,27,34,59,61,69,76]. Geolocation-based remote monitoring enabled caregivers to track the movements of persons living with dementia when they were not present, including movement outside the home. Remote monitoring was also seen as a way to know about the well-being of persons living with dementia, for example, by the identification of agitated movement or interrupted sleep [32,40,77]. Remote monitoring enhanced the *independence* of the person living with dementia [27,38,63] while providing informal caregivers with peace of mind regarding the safety of persons living with dementia (eg, reduces *burden impact*) [46,63,64,67,72].

For some participants, the utility of the benefits of geolocation services conclusively outweighed potential *privacy concerns* [25,42]. However, for some, introducing the idea of being monitored could be seen as an infringement on autonomy and privacy [25,31], such as when "some participants feared that proud Anishinaabe older adults would be offended by the idea that their movements would be tracked" [31].

Provide Health Insight

Providing health insight to the participants was one of the top factors mentioned as a benefit to ongoing participation and use of a study's wearable. Paralleling the *multifunctional* factor as an aid to enrollment incentives, health insights included, for example, information on blood pressure, heart rate, sleep quality, and steps. Having ongoing access to this health data motivated participants' personal activity, helped caregivers monitor for health crises, and provided more general insight into the well-being of persons living with dementia [10,25,27,29,32,33,38,53,54,58,61,63,69,74,77]. In addition, they appreciated that this health information could be useful to residential staff and physicians in informing care decisions [25,27,32,34,61,64,69]. A caregiver in the study by Lazarou et al [25] said that with the information from the wearable, "we could monitor her daily activity and communicate any problems to the doctors. It helped us a lot to understand what is going on."

Technical Support

As *technical anxiety* was a barrier, providing initial technical training and ongoing technical support was identified as a complementary facilitator [20,26,37-39,50,74]. Staff availability to provide training at enrollment, support during an adjustment period, and assistance as needed throughout the study helped improve adherence [29,33,77]. Stand-alone instructional materials and cognitive aids were useful to participants who sought to troubleshoot issues on their own [9,10,47,66]. Along with data monitoring, regular proactive check-ins with participants made (or would have made) staff aware of technical problems and helped maintain better compliance [29,45,53,68,77].

For example, Gelonch et al [33] provided caregivers with initial training and ongoing technical assistance, and consequently, they supported their care recipient's use of a lifelogging camera: "The [persons living with dementia] said that the support and supervision provided by their caregiver in certain tasks or actions, such as connecting and loading the camera, were also key for them continuing with the experiment."

Even when apprehensive about using the technology (refer to the Technical Anxiety subsection), participants commonly showed a readiness to learn how to operate the wearable devices and follow study protocol. As recounted by Anderson et al [36], "Many were not necessarily technologically proficient caregivers, but they wanted to be useful. None of the caregivers implied that the research should not continue to be refined."

Caregiver Support

While the importance of *caregiver buy-in* was highlighted in recruitment, in this section, we underscore the importance of caregivers and their investment in the study for continued wearables adherence [36,39,71,77]. Many research protocols required caregiver activity to accomplish their goals by having them be the primary study participant or helping persons living with dementia complete study tasks [29,44] and, importantly, charging the wearable [35,77]. Many factors depend on the caregiver, such as helping persons living with dementia *remember the device* [20,41], assisting with putting it on (refer to the Easy to Wear subsection) [34,48], or understanding how to operate the wearable [33]. In addition, caregivers could be instrumental in explaining facets of the study and, in other ways, facilitating communication of research needs to their care recipient throughout the study [29,68].

Notably, relying on caregiver support can be a major ask (ie, increase *burden impact*): "The caregivers were able to be present almost all the time. They demonstrated personal investment in the care that the person living with dementia received. Their willingness to participate in, work with researchers, and use technology 24 hours a day for 30-60 days was a significant commitment" [36].

XSL•FO
RenderX

Safety

Broadly speaking, wearable technologies were seen as an instrument for enhancing the safety of persons living with dementia [45,46,71,72]. This potential positive was specifically identified as an ongoing benefit, often in tandem with or implied within *remote monitoring* and *providing health insight*. Wearables offer a sense of security to persons living with dementia and their care providers, aiding aging in place by alerting caregivers to life events or potential crises (eg, elopement or fall monitor) and detecting changes in health or behavioral patterns [28,31,34,59].

On rare occasions, the device itself was harmful, such as when an over-ear device caused skin abrasions [48] or when participants desired a different product or sensor design for safety reasons [69]. In contrast to other participants in their study, a caregiver in the study by Snyder et al [71] explained that they felt the wearable, an emergency response pendant, gave a false sense of security, saying, "My reluctance is that it doesn't seem...It can't stop something from happening to her. It just alerts you maybe if something does."

Remembering the Device

Adherence in wearable studies was affected by persons living with dementia's ongoing ability to remember what the device was for [22,29,42]. Not remembering the purpose of the device could also result in "confusion and agitation" [43]. More commonly, persons living with dementia simply forgot to wear the device [10,20,63,75], especially after removing it for bathing (if not *water resistant*) or sleep, often resulting in failure to put it back on [34,65]. Better adherence was reported earlier in the day [53,77], potentially because of sundowning: "Due to memory impairment participants had to be constantly reminded to wear the device and they could change their opinion from one day to the other. Activities that made wearing the device more salient, such as the need to take it off to charge it or bathing, proved challenging with some participants" [20].

Independence

Whether the device provided geolocating, physical activity monitoring, or health alerts, participants, especially caregivers, saw these devices and platform features as enhancing the independence and autonomy of persons living with dementia [10,27,39,63,67,71]. Participants' ongoing access to the data and ability to turn off data collection at their discretion contributed to a sense of agency within the study itself [33,38]. Similar to the potential harms of *remote monitoring*, Synder et al [71] framed this positive as part of the "conundrum between the benefits of having peace of mind, a sense of self-efficacy, and greater independence versus perceiving (remote monitoring technologies) as an invasion of privacy, a security risk, a false sense of security, and a distraction."

Self-Removal

Taking off the device when not instructed was an issue in several studies [44,60]. This could be temporary, such as during bathing, or routine, such as removing accessories before sleep [32,72]. In some cases, removal was longer term, often due to agitation (possibly related to sundowning) or discomfort [22,32,66]. Some researchers and care providers suggested or chose to put the wearable out of reach (eg, on their back) to prevent self-removal by persons living with dementia [60,61].

Discussion

Principal Findings

Overview

This review identified barriers, facilitators, and preferences that could improve the quality of research studies featuring wearable devices and persons living with dementia. The review included studies encompassing a variety of study designs and perspectives from researchers, persons living with dementia, and their caregivers (both unpaid family members and paid professionals), ensuring broad inclusion of research experiences. We offer a qualitative synthesis of these findings to enhance enrollment and adherence in long-term wearable research featuring persons living with dementia. Recommendations for future research fall within 3 main categories: device selection, ethical study design, and technical and data management plans.

Device Selection

Dementia Impairment Level Requires Different Devices

We identified the importance of selecting multifunctional devices with the capacity for participants to monitor their own or their care recipient's data, whether on the device itself or via a dedicated platform. However, what persons living with dementia and their caregivers preferred in terms of devices was sometimes different depending on the advancement of dementia in their target population. In earlier stages, persons living with dementia themselves were more engaged and desired more interactive, multifunctional devices that provided personal benefit to them. However, persons living with more severe dementia, from their perspective and their caregivers' perspectives, desired or interacted with only simpler wearable form factor and features (eg, just used the clock feature) [77]. Even less obtrusive devices or ones out of reach may also be warranted if they are more likely to remove the device themselves as dementia progresses.

The growing ubiquity of remote monitoring and wearable devices for everyday use likely makes stigma less of a concern as we move into the future because an older adult will not stand out when wearing something such as that, especially if it is unobtrusive or looks like an everyday wristwatch. The availability of the devices likely also drives expectations of what participants will personally gain from being in a research study, as people are more familiar with what type of information gathering is theoretically possible, and participants may expect to have access to that information too.

Wristwatches Fits Into Routine but Could Also Be Problematic

Wristwatch wearables were highly recommended as they are part of normal wear for many and offer different levels of multifunctionality. In addition, their unobtrusiveness can reduce stigma [10]. However, habitual device removal during sleep and bathing often conflicted with the research protocols requiring participants to wear the devices all the time [32,41]. Waterproof forms, along with clear instructions for the caregiver

XSL•FO
RenderX

and persons living with dementia to avoid removal in these situations, are useful. Researchers should understand that adjustment periods may be warranted with proactive reminders as participants acclimate to the newer routine and have fewer persistent issues [41].

Ethical Study Design

Attend to Fluctuating Consent Capacity in Persons Living With Dementia

Persons living with dementia feel actively engaged in the research and empowered over their health status when they can see their health data and decide when to engage in the study. However, progressive impairment can mean a person living with dementia may experience fluctuating ability to consent and understand the protocol for a long-term study. Researchers in longer-term studies should establish ongoing communication to monitor possible changes in device preferences or needs. Advanced cognitive decline from dementia can mean decision-making and consent ability are totally compromised for the person living with dementia. Reliance on a caregiver or another surrogate for consent is common, but studies emphasized that if the person living with dementia has given their thoughts on similar situations before, those preferences should be prioritized. Respecting participants' agency is paramount; recognizing and responding to the issues of ongoing consent in this population is key to conducting an ethical study. Actively checking in with participants on a regular basis in long-term studies to gain assent or consent for continued data collection is ethical and may also be required by institutional review boards, given expected cognitive changes.

Promote Inclusivity With Wearable and Protocol Choices

Researchers should be aware of how their study protocol and wearable device requirements may impact who can or would enroll in their study. Some studies, such as that by Cohen et al [53], suggested screening participants for technical knowledge and ability as a way of ensuring compliant participants are enrolled. However, this is not inclusive and could result in bias in recruitment. Instead, preexisting technology and connectivity needs (eg, stable Wi-Fi) should be minimized or eliminated to enhance distributive justice [73,78] and increase the representativeness of the study results. Researchers can reduce the burden and increase equity by not requiring constant wireless connectivity or by supplying the technology to participants. However, intermittent data collection may be at odds with proactive data monitoring for troubleshooting purposes. Staff phone calls or other lower-technology check-ins are recommended in this case.

If possible, different formats and styles (eg, watch vs pendant and watchband options) that are familiar and fit a participant's personal, cultural, and gender preferences should be offered [79]. However, it is important to balance these preferences with the type and quality of data that each format can reliably collect [34]. As evidenced by this review and other research efforts, user-centered codevelopment of wearables with persons living with dementia for research purposes is feasible [38,80] and should continue to be explored to enhance recruitment and adherence in longitudinal studies featuring persons living with dementia.

Data Management

Implement Data Management Plans

We categorized a total of 29 factors into 4 categories that aligned with study development (device selection, protocol considerations, enhancing recruitment, and promoting adherence). However, a fifth category—data management—was largely left uncommented on, as studies were primarily focused on the needs and preferences of the participants rather than the researchers. Participants may report ongoing adherence, but making sure a wearable is not only worn but also collecting data is paramount to conducting quality longitudinal research.

Researchers' data management plans should comprise data collection, storage, and processing for analysis [29,73]. For example, researchers conducting long-term studies should know how long their device batteries will last under their protocol and have procedures in place to limit both data loss and participant burden (eg, reminders to participants to charge their devices). By regularly checking data for completeness, researchers can identify technical problems and offer troubleshooting to resolve missing data issues. Researchers should also have a loss prevention plan for the wearable to reduce missing or inactive devices and the resulting data loss.

For example, Cruz-Sandoval et al [29] had a comprehensive data management plan for a wearable study in an assisted living setting. They combined weekly program visits with battery charging, data collection (ie, upload and synchronization with the study server), and addressed technical troubleshooting needs. They also reviewed the uploaded data for abnormal data patterns and double-checked with caregivers "as soon as possible" to understand if the abnormal data were valid or if they should flag it for deletion. As a loss prevention plan, the researchers also asked the staff to report on the location of the device at the end of each work shift. Particular data management plans could also influence device options; Muurling et al [81] recommended that real-time participant access to device data could both increase adherence and help alert researchers to data issues in close to real time.

Collective Data Management Efforts Could Enhance Support for Wearables Research

To reduce researcher data burden in individual studies, research groups could build infrastructure and codebases to share collectively in an open-access format (eg, on GitHub). Although researcher perspectives on the use of the devices and subsequent data management were generally missing in the studies, 1 study reported that their experience organizing, cleaning, and analyzing Fitbit data were "onerous and time consuming" and recommended that others use automated data management software [77]. Researchers should be aware that many commercial, proprietary wearables may not offer researchers access to the raw data, which may limit secondary utility and increase reliance on the original developers for measure validation. Other collective data enhancements include setting standard definitions or ideal compliance goals, which varied across studies or were not reported at all. Clear, agreed-upon

XSL•FO
RenderX

definitions for adherence and reporting standards are critical for improving long-term dementia research with wearable devices [9,47]. Indeed, a lack of specific, consistent adherence and attrition data from many studies made quantitative comparisons related to the factors impossible. When combined with real-time data monitoring, shared data expertise can help researchers determine whether seemingly incoherent data result from technical issues, allowing for timely resolution [81], or from changes in cognitive function and life circumstances as dementia progresses [82].

Informing Wearable Technology Adoption and Use Models

This systematic review evaluated preferences, barriers, and facilitators to wearables in a study setting, so everyday technology adoption measures may not be entirely applicable. Indeed, caregivers and persons living with dementia may endure adjustment periods, committing themselves to using difficult technologies if the knowledge gained will advance dementia prevention efforts or benefit other caregivers [82]. However, because of the lack of consistent quantitative data, we could not assess factor relationships quantitatively with wearable technology adoption and use models such as the unified theory of acceptance and use of technology model [83], its extended version—the unified theory of acceptance and use of technology 2 model [37], the wearable acceptance in health care model [84], or the technology acceptance model 3 [85]. These measures may also need to be updated as overall perceptions of technology change and its use becomes more ubiquitous, even among older adults. Surveys and other marketing research indicate that although fewer older adults use wearables compared to other age demographics, approximately 25% of US adults aged ≥65 were using wearables in 2023 [86], a rapid increase even in just the last few years [87]. Moreover, these measures relate to technology acceptance in general, while motivations underlying intentions and actual use of wearables may be different, especially as noted within research contexts. A research-specific technology acceptance questionnaire could help researchers understand perceptions directly related to their needs and identify additional barriers to recruitment and adherence.

There is also utility in a more systematic assessment of wearable device qualities themselves and how they relate to adherence. The use of measures such as the Quebec User Evaluation of Satisfaction With Assistive Technology (QUEST; version 2.0) can simplify device comparisons and inform future wearable choices or commercial development. Future reviews could also benefit from standard reporting of why particular devices were chosen in original studies.

Clinical Implications

We have reviewed and identified factors related to the use of wearables in long-term dementia research. However, wearables are also a potentially viable way to gather data for clinical decision-making because they can offer a way for clinicians to proactively monitor health data and circumvent some of the challenges around gathering a patient history from someone with dementia [64,88]. Supporting this potential, a large cohort study of cognitively healthy participants showed that changes in long-term 24-hour activity patterns were associated with elevated risk for the onset of Alzheimer disease, Parkinson disease, and cognitive decline [89]. Moreover, as wearable devices are being used more by the general population, clinicians are experiencing patients coming in with questions about what they have learned from their own wearable devices. Improving research in this area can help clinicians think about how they can interpret and use wearable data in a meaningful way (eg, personalized medicine). Clinicians could use the results of this paper to guide a conversation with their patients about selecting a wearable that is beneficial for meeting the needs of both the patient and their health care team, which could also enhance adherence.

Limitations and Strengths

Our findings are generally agnostic of cognitive impairment status or degree of dementia, reflecting the participant mix seen in the studies, which also often did not disambiguate by the severity or type of dementia (eg, Alzheimer disease and Lewy body disease), which may influence findings as well as the generalizability of findings. Because our analysis was not limited to specific device types or study goals (eg, physical activity or dementia prevention), not all factors may be applicable to all future research applications. We did not perform a formal risk of bias assessment because of the heterogeneity of the study types included, and we note that many studies may be considered at high risk of bias because of smaller sample sizes. However, considering the outcomes of interest for this study were qualitative in nature, the samples were considered sufficient.

Because our extraction captured all reported barriers and facilitators regardless of their origin, we identified the holistic perspective of researchers, persons living with dementia, and their care providers, including unpaid family members or paid health professionals. We systematically coded barriers, facilitators, and perspectives using a grounded, qualitative approach, which did not presuppose expected outcomes, allowing for new or unexpected insights. We offer a comprehensive synthesis of multiple types of studies featuring many wearables and outcomes of interest, identifying overarching themes core to long-term wearable research featuring populations with dementia.

Conclusions

We described factors critical to enhancing dementia study recruitment and wearable adherence, emphasizing how those factors should be considered collectively in an ethical context to meet both researcher needs and participant desires. Organized by study design order and literature prevalence, dementia researchers can use the findings of this systematic review to thoughtfully design quality, long-term wearable studies. The incorporation of wearable technology in dementia research presents a promising pathway to surmount traditional challenges associated with studying persons living with dementia and their caregivers. By leveraging these noninvasive tools, researchers can obtain continuous, objective data for use in advancing treatment, care, and prevention efforts. The results of this evaluation will facilitate quality improvement in ongoing research efforts and contribute to a more person-centered approach to developing effective interventions and prevention strategies.

Abstract

Background: Older adults with chronic diseases are key beneficiaries of digital health technologies, yet adoption remains inconsistent, particularly in rural areas and among certain demographic groups, such as older women.

Objective: This systematic review aimed to identify barriers to and facilitators of digital health adoption among older adults with chronic diseases, with particular attention to rural-urban differences, co-design, and equity-relevant factors.

Methods: This updated review built on a previously published review by extending the search to include PsycArticles, Scopus, Web of Science, and PubMed databases for studies published between April 2022 and September 2024. Gray literature from August 2021 onward was also included. Studies were eligible if they reported barriers to or facilitators of digital health adoption among adults aged ≥60 years with chronic diseases. Findings were mapped to the capability, opportunity, and motivation–behavior model and analyzed using the PROGRESS-Plus (place of residence; race, ethnicity, culture, and language; occupation; gender and sex; religion; education; socioeconomic status; and social capital–plus) equity framework. Quality was assessed using the Mixed Methods Appraisal Tool, and all results are reported in line with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines.
